JULY to OCTOBER, 1910

" *To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH

London
MACMILLAN AND CO., LIMITED
NEW YORK: THE MACMILLAN COMPANY

Richard Clay and Sons, Limited,
bread street hill, e.c., and
bungay, suffolk.

INDEX.

Abbott (W. J. Lewis), Classification of the British Stone Age and some New and Little-known Horizons and Cultures, 30
Absorption, Radiation and, Prof. Humphreys, 52
Ach (Prof. Narziss), Ueber den Willensakt und das Temperament, 199
Acoustics: the Propagation of Sound in a Fog, C. J. T. Sewell, 62
Adamović (Prof. Lujo), die Vegetationsverhältnisse der Balkanländer (Mosische Länder), 135; aus Bosnien und der Herzegovinia, 395
Adams (Franklin), Prevention of Dew Deposit upon Lens Surfaces, 52
Adhikary (Birendra Bhusan), Preparation of Phenyl-nitromethane by the Interaction of Mercurous Nitrite and Benzyl Chloride, 292
Aëronautics: Experiments on Air Resistance, Dr. T. E. Stanton, 13; Relation of the Wind to Aërial Navigation, Prof. A. L. Rotch, 151; IV. Congrès international d'Aéronautique, 1909, Procès verbaux, Rapports et Mémoires, Prof. G. H. Bryan, F.R.S., 229; Bibliography of Aëronautics, Paul Brockett, Prof. G. H. Bryan, F.R.S., 229; Petite Encyclopédie aéronautique, L. Ventou-Duclaux, Prof. G. H. Bryan, F.R.S., 229; the Encyclopædia of Sports and Games, Prof. G. H. Bryan, F.R.S., 229; Results of the Italian Aëronautical Experiments near Zanzibar during the Last Week of July, 1908, 506
Africa: the Journal of the East Africa and Uganda Natural History Society, Sir H. H. Johnston, G.C.M.G., K.C.B., 80; the Ethnology, Botany, Geology, and Meteorology of German East Africa, Sir H. H. Johnston, G.C.M.G., K.C.B., 106; Science in South Africa, 158; the Ore Deposits of South Africa, J. P. Johnson, 293; Veterinary Research in the Transvaal, 321
Agaric with Sterile Gills, an, W. B. Grove, 531
Agassiz (Col. Georges), Death of, 81
Agriculture: a Manual of Practical Farming, John McLennan, 38; How to Use Nitrate of Soda, 50; Report of the Agricultural Experimental Station, Lafayette, Indiana, 83; Death and Obituary Notice of John B. Carruthers, 114; Life-history and the Means of Controlling the Hop Flea-beetle, W. B. Parker, 117; Fertilising Value of Seaweed, 151; Tobacco produced in India, Mr. and Mrs. Howard, 151; Physiological Effect on the Cow of the Milking Machine, 181; Relation between the Reduction in Area of Wheat in England and the Increased Yield, Mr. Vigor, 182; the Year-book of the Khedivial Agricultural Society, Cairo, 1909, 184; Studies of Egyptian Cotton, Lawrence Ball, 184; the Manufacture of Cane Sugar, Llewellyn Jones and F. I. Scard, 190; Lead Chromate as Insecticides, 212; Recent Agricultural Publications in Great Britain, 219; the Sclerotinia Disease of the Gooseberry, Mr. Salmon, 219; Effect of Overhead Electrical Discharges on Plant Growth, Mr. Priestley, 219; Secondary Effects of Manures on the Soil, Mr. Hall, 219; Physiological Problems of the Stock-breeder, F. H. A. Marshall, 219; Legislation in the West Indies for the Control of Pests and Diseases of Imported Plants, Mr. Ballou, 247; Bacterial Blight in Cotton caused by *Bact. Malvacearum*, Mr. McCall, 247; Outbreak of Blister-blight on Tea in the Darjeeling District in 1908 and 1909, 247; Cause of the Colour of Black Cotton Soil, Mr. Annett, 247; Fruit Experiments, Mr. Howard, 247; the Journal of the South-eastern Agricultural College, Wye, Kent, 253; Beet Sugar Making and its Chemical Control, Y. Nikaido, 424; Recent Investigations on the Cultivation of Rubber, 510; Effect of Heat on Soils, C. Harold Wright, 530; Possibility of Raising Ostriches in the Transvaal, 543; *see also* British Association
Agrogeology: the First International Agrogeological Conference, Dr. E. J. Russell, 157; Russian Soils, Prof. Glinka, 157
Ainslie (Mr.), the Large Corn-stalk-borer, 18
Air, Models of Meteorological Conditions in the Free, 59
Air Resistance, Experiments on, Dr. T. E. Stanton, 13
Airship Flights, 512
Aitken (Dr. John), Did the Tail of Halley's Comet affect the Earth's Atmosphere? 228
Aitken (Mr.), Rediscovery of Brooks's Periodical Comet (1889 V.), 438
Akikũyu, the, of British East Africa, With a Prehistoric People, W. Scoresby Routledge and Katherine Routledge, Sir H. H. Johnston, G.C.M.G., K.C.B., 41
Albrecht (Prof.), the Variation of Latitude, 20
Alcock (Lt.-Col. A., F.R.S.), Catalogue of the Indian Decapod Crustacea in the Collection of the Indian Museum, 524
Algol's Satellite, Irregularities in the Motion of, Enzo Mora, 472
Allen (Glover M.), Insectivorous Mammal, *Solenodon paradoxus*, of San Domingo, 315
Allen (Mr.), Synthetic Study of Diopside and its Relations to Calcium and Magnesium Metasilicates, 375
Alpine Flowers and Gardens, Painted and Described, G. Flemwell, 37
Alps, Summer Flowers of the High, Somerville Hastings, 37
Alternate-current Theory, the Foundations of, Dr. C. V. Drysdale, Prof. Gisbert Kapp, 6
Ambrecht (Mr.), Change of Colour of Sapphires and other Precious Stones by the Action of Radium, 179
Ameghino (Dr. F.), Human Skulls and Skeletons and Supposed Evidence of Human Work, 402
America: Fossil Vertebrates in the American Museum of Natural History, 12; Glaciers, Goldfields, and Landslides in North America, 76; Recent Work of Geological Surveys, iv., the United States, 121; List of Documents in Spanish Archives relating to the History of the United States which have been Printed or of which Transcripts are Preserved in American Libraries, J. A. Robertson, 238; Selections from American Zoological Work, 547
Ammonia, Coal Tar and, Prof. George Lunge, 166
Amory (Dr. Robert), Death of, 340
Anatomy: the Anatomy and Relationship of the Negro and

Negroid Races, Hunterian Lectures at Royal College of Surgeons, Prof. Arthur Keith, 54; International Congress of Anatomists at Brussels, 252
Anderson (Prof. R. J.), the Temporal Bone in Primates, 550
Animal Romances, Graham Renshaw, 100
Annam, On and Off Duty in, Gabrielle M. Vassal, J. Thomson, 243
Annett (Mr.), Cause of the Colour of Black Cotton Soil, 247
Antarctica: Antarctic Pycnogons, Dr. W. T. Calman, 104; Deutsche Südpolar-Expedition, 1901–3, die Grundproben der Deutschen Südpolar-Expedition, 1901–3, E. Philippi, 167; National Antarctic Expedition, 1901–4, Natural History, vol. v., Zoology and Botany, 205; British Antarctic Expedition, 1907–9, under the Command of Sir E. H. Shackleton, C.V.O., Reports on Scientific Investigations, vol. i., Biology, 205; Expédition Antarctique Belge, Résultats du Voyage du S.Y. *Belgica* en 1897–8–9, Sous le Commandement de A. de Gerlache de Gomery, Rapports scientifiques, Botanique-Diatomées, H. Van Heurck, Geologie-Petrographische Untersuchung der Gesteinproben, A. Pelikan, Quelques Plantes Fossiles des Terres Magellaniques, Prof. A. Gilkinet, Oceanographie-les Glaces-Glace de Mer et Banquises, H. Arctowski, Zoologie-Schizopoda and Cumacea, H. J. Hansen, 205; Date of Lieut. Filchner's Antarctic Expedition, 400
Anthropogeography of the Polar Eskimos, Contributions to the Ethnology and, Dr. H. P. Steensby, 443
Anthropology: Collection of Human Bones found on the Site of an Augustinian Friary near the Corn Market, Cambridge, Dr. W. L. Duckworth and W. J. Pocock, 16; Royal Anthropological Institute, 30; Totemism and Exogamy, a Treatise on certain Early Forms of Superstition and Society, Prof. J. G. Frazer, A. E. Crawley, 31; Prehistoric Man, Joseph McCabe, 39; the Position of the Father's Sister in Oceania, Dr. W. H. R. Rivers, 48; the Anatomy and Relationship of the Negro and Negroid Races, Hunterian Lectures at Royal College of Surgeons, Prof. Arthur Keith, 54; Origin of the Fulah or Filani Race, Capt. A. J. N. Tremearne, 82; Antiquities of the Ouachita Valley, Clarence B. Moore, Dr. A. C. Haddon, F.R.S., 129; Colonial Empire of the Phœnicians, Louis Seret, 211; Anthropological Society of Paris, 2[illegible]; the Jesup North Pacific Expedition, the Kwakiutl of Vaucouver Island, Frank Boas, Chukchee Mythology, Waldemar Bogoras, the Yukaghir and the Yukaghirized Tungus, Waldemar Jockelson, Dr. A. C. Haddon, F.R.S., 250; Skull Discovered at Galley Hill, Kent, 270; Filipino Racial Types at Taytay, R. B. Bean and F. S. Planta, 340; Chimariko Tribe of Indians Inhabiting Trinity County, in North California, 370; Discovery in the Neighbourhood of the Pyramid of Sneferu (B.C. 4600) of a Stone Tomb Dating from a Time before the Construction of the Pyramid, Prof. Flinders Petrie, 401; System of "Wireless Telegraphy" in use among the Indian Tribes of the Putumayo River, W. E. Hardenburg, 436; *see also* British Association
Antike Tierwelt, die, Otto Keller, 357
Antoniadi (M.), Subjective Phenomena on Mars, 120; Occultation of η Gemini by the Planet Venus, 196; the Recent Occultation of η Geminorum by Venus, 317; Halley's Comet, 322
Ants, the Prince and his, (Ciondolino), Luigi Bertelli, 138
Arabian Astronomical Instruments, Prof. E. Wiedemann, 472
Archæology: Arthur's Round Table in Glamorgan, Rev. John Griffith, 8; Pit-dwellings in the District of Holderness, Canon Greenwell and R. A. Gatty, 16; Prehistoric Rhodesia, Richard N. Hall, 32; Excavations at the Glastonbury Lake-village, Arthur Bulleid and H. St. George Gray, 82; Processes of Prehistoric Pottery-making, N. W. Thomas and Capt. A. J. N. Tremearne, 116; Date of Narrow Cultivation Terraces, Lynchets, 116; Antiquities of the Ouachita Valley, Clarence B. Moore, Dr. A. C. Haddon, F.R.S., 129; Discovery of the Site of the Famous Cyprian Temple of Aphrodite-Astarte, Dr. Max O. Richter and Dr. K. Koritsky, 149; Death of Prof. A. Michaelis, 210; Neolithic Implements from Bridlington, Mr. Sheppard, 246; Recent Finds made in Rock Shelters once Occupied by Strand Loopers, Dr. L. Péringuey, 262; Classification of the British Stone Age and Some New and Little-known Horizons and Cultures, W. J. Lewis Abbott, 30; Stone-headed Axe from Rennell Island, C. M. Woodford, 314; Model of the Fine Dolmen Situated at Coldrum, in Maidstone Museum, 401; "Tomb of the Double Axes," Dr. A. J. Evans, 401; the Royal Commission on Welsh Monuments, Rev. John Griffith, 404; the Archæological Survey of Nubia, Prof. G. Eliot Smith and Dr. D. E. Derry, 406; Customs at Holy Wells, Zorah Godden, 429; Geological and Archæological Notes on Orangia, J. P. Johnson, 465; Archæological Expedition in Sardis, Prof. Howard C. Butler, 503; Prehistoric Boat Discovered at Brigg in 1886, T. Shepherd, 542
Archbutt (Mr.), Provident Use of Coal, 519
Architecture: Condition of the Leaning Tower of Pisa, 48; the Leaning Tower of Pisa, Prof. A. Batelli, 146; Edward G. Brown, 297; Arthur T. Bolton, 297; Report of Pisa Commission on the Leaning Tower, Prof. William H. Goodyear, 471; Town-planning, A. E. Crawley, 498
Arctica: die Polarwelt und ihre Nachbarländer, O. Nordenskjöld, 236; North Polar Exploration, 245; Expedition Ship *Alabama*, 245
Arctowski (H.), Expédition Antarctique Belge, Résultats du Voyage du S.Y. *Belgica* en 1897–8–9 sous le Commandement de A. de Gerlache de Gomery, Rapports scientifiques, Oceanographie—Les Glaces—Glace de Mer et Banquises, 205
Ardigo (Prof. Robert), an Inconsistent Preliminary Objection against Positivism, 461
Argentina, Catalogo Sistematico y Descriptivo de las Aves de la Republica, Roberto Dabbene, 427
Argentine Biology, Australian and, 186
Arkansas and Louisiana, Archæological and Anthropological Investigations in, Dr. A. C. Haddon, F.R.S., 129
Armstrong (Dr. E. F.), Existing Knowledge with Regard to the Oxydases, 518
Armstrong (Prof.), Crystallographic Examinations of Twenty-nine Derivatives of the *p*-Dihalogenbenzene-sulphonic Acids, 403
Armstrong (Prof.), Impossibility of any Interaction taking Place between Two Substances if Neither was an Electrolyte, 517
Armstrong (Prof. H. E.), Provident Use of Coal, 518
Arnold (Prof. J. O.), Theory of Hardening Carbon Steels, 440; a Fourth Recalescence in Steel, 518
Arnold-Bemrose (H. H.), Derbyshire, 426
d'Arrest's Comet (1910c), Rediscovery of, M. Gonnessiat, 317; Observations of d'Arrest's Comet at the Observatory of Algiers, M. Gonnessiat, 324; M. Baillaud, 324
Arthur's Round Table in Glamorgan, Rev. John Griffith, 8
Ascoli (F. D.), Rivers of Dacca District, 30
Ashworth (Dr. J. H.), Zoology at the British Association, 548
Ashworth (Dr. J. R.), the Temperature Coefficients of the Ferromagnetic Metals, 238
Asia, a Systematic Geography of, G. W. Webb, 426
Asiatic Society of Bengal, 30, 292, 422
Association of Economic Biologists, 156
Association of Technical Institutions, the, 90
Assyriology: Death of Hormuzd Rassam, 400
Astronomy: Halley's Comet, Dr. James Moir, 9; Dr. Wolf, 19; Prof. Seeliger, 19; M. Eginitis, 19, 52; Comas Sola, 19; M. Nordmann, 19; Mr. Leach, 19; Dr. Ebell, 52; Prof. Fowler, 52; Father Iniguez, 52; Herr v. d. Pahlen, 86; Dr. Ristenpart, 86; G. Millochau and H. Godard, 120; Prof. Frost, 152; Mr. Motherwell, 183; Prof. Barnard, 183, 322; Mr. Helmcken, 184; Father Stein, 184; Herr Sykora, 322; Dr. Hartmann, 322; M. Antoniadi, 322; K. Saotome, 322; Drs. Cowell and Crommelin, 322; M. Iwanow, 322; Mr. Merfield, 322; Messrs. Crawford and Meyer, 322; Mr. Slocum, 323; Earth-current Observations in Stockholm during the Transit of Halley's Comet on May 19, D. Stenquist and E. Petri, 9; Some Phenomena shown by Halley's Comet after its Passage across the Sun, D. Eginitis, 64; Phenomena presented by the Tail of Halley's Comet during the Passage of May 19 last, H. Deslandres and J. Bosler, 163; Did the Tail of Halley's Comet affect the Earth's Atmosphere? Dr.

John Aitken, 228; Further Observations of Halley's Comet, Michie Smith and John Evershed, 374; C. D. Perrine, 374; Velocities and Accelerations of the Ejecta from Halley's Comet, Profs. Barnard and Lowell, 404; J. Comas Sola, 404; Time of the Solar Transit of Halley's Comet, 472; Death of Prof. G. V. Schiaparelli, 14; Obituary Notice of, 44; Our Astronomical Column, 19, 52, 86, 120, 152, 183, 213, 248, 272, 317, 344, 374, 404, 438, 472, 507, 544; Astronomical Occurrences in July, 19; in August, 120; in September, 272; in October, 438; Ephemeris for Comet 1910a, Prof. Kobold, 19; Prof. Barnard, 19; Observations of Comet 1910a, Dr. Karl Bohlin, 272; Prof. Ricco, 472; Photographs of Morehouse's Comet, Messrs. Hirayama and Toda, 19; the Determination of Position near the Poles, Mr. Hinks, 19; the Variation of Latitude, Prof. Albrecht, 20; New Canals and Lakes on Mars, M. Jonckheere, 20; Subjective Phenomena on Mars, M. Antoniadi, 120; Mars in 1909 as seen at the Lowell Observatory, Prof. Percival Lowell, 172; Water Vapour on Mars, Prof. Campbell, 317; Prof. Frank W. Very, 405; a Suggested Volcanic Origin of Martian Features, Dr. Wilhelm Krebs, 344; International Union for Cooperation in Solar Research, 22; Prof. Arthur Schuster, F.R.S., 463, Death and Obituary Notice of Prof. J. G. Galle, 45; Death of Prof. T. Zona, 46; Death of Dr. Wilhelm Winkler, 47; Prevention of Dew Deposits upon Lens Surfaces, Franklin Adams, 52; a Variable Star as a Time Constant, Prof. Barnard, 52; Radiation and Absorption, Prof. Humphreys, 52; an Interesting Occultation, Arthur Burnett, 73; the Next Total Eclipse of the Sun, Dr. William J. S. Lockyer, 75; the Total Solar Eclipse, May 9, 1910, Dr. William J. S. Lockyer, 113; the Total Solar Eclipse of April 28, 1911, Dr. Pio Emanuelli, 172; Harvard College Observatory, Prof. E. C. Pickering, 86; Photographs of Auroræ, Carl Störmer, 86; Displacement of Spectral Lines at the Sun's Limb, A Perot, 86; the Pressure of Light on Gases, Dr. Lebedew, 86; the Determination of Stellar Radial Velocities, Prof. Frost, 86; Prof. R. W. Wood, 86; the Evolution of Worlds, Prof. Percival Lowell, William E. Rolston, 99; Present Meteoric Displays, W. F. Denning, 105; Death of J. Ellard Gore, 116; the Genesis of Various Lunar Features, M. Puiseux, 120; the Gnomon in Ancient Astronomy, Jules Sagaret, 120; the Leeds Astronomical Society, 120; a Central Bureau for Meteor Observations, 152; the Rotation of Sun-spots, P. Kempf, 152; Large Meteorites, Edmund O. Hovey, 152; the United States Naval Observatory, 152; Measures of Double Stars, Prof. Burnham, 152; Dr. Lau, 317; Mr. Sellors, 507; the Study of Double Stars for Amateurs, G. F. Chambers, 273; Popular Astronomy, Prof. Simon Newcomb, 171; Photographs of Nebulæ, Dr. Ritchey, 183; the Accurate Measurement of Photographs, Prof. E. C. Pickering, 184; Observations of Perseids in 1909, S. Beljawsky, 184; Results from Micrometric Observations of Eros, 1900, Mr. Hinks, 184; Occultation of η Gemini by the Planet Venus, M. Antoniadi, F. Baldet, and F. Quénisset, 196; the Recent Occultation of η Geminorum by Venus, MM. Baldet, Quénisset, and Antoniadi, 317; Occultation of η Geminorum by Venus, July 26, observed at Lyons, J. Guillaume and J. Merlin, 390; Discovery of a Small Planet, presumably New, José Comas Sola, 196; Perseid Meteoric Shower, 1910, W. F. Denning, 204, 248; C. L. Brook, 248; W. H. Steavenson, 248; Miss Warner, 248; D. E. Packer, 248; W. Johnson, 248; E. F. Sawyer, 439; Brilliant Meteor of July 31, Father A. L. Cortie, 204; a New Comet, Rev. J. H. Metcalf, 213; Mr. Burton, 213; Metcalf's Comet, 1910b, 249, 273; M. Guillaume, 249; Dr. Kobold, 249, 344, 507; Prof. Pickering, 344; M. Quénisset, 507; Observations of Metcalf's Comet, J. Guillaume, 261; Observations of the Comet 1910b (Metcalf), August 9, 1910, M. Coggia, 261; Observations of Metcalf's Comet, 1910b, M. Borrelly, 261; M. Schaumasse, 292; Observations of Metcalf's Comet made at the Paris Observatory, J. Chatelu, 261; Properties of the Polar Filaments of the Sun, H. Deslandres, 228; Photographs of Daniel's Comet, 1907d, Prof. Barnard, 249; Precession and the Solar Motion, Prof. Boss, 249; Calcium Vapour in the Sun, C. E. St. John, 249; Observations of Comets, Dr. Max Wolf, 213; Observations of Mercury, G. and V. Fournier, 213; M. Jarry-Desloges, 213; Dispersion of Light in Interstellar Space, Herr Beljawsky, 213; Anomalous Scattering of Light, Dr. Julius, 214; the Spiral Nebula M51 (Canum Venaticorum), Madame Dorothea Isaac Roberts, 214; Supplement to the "Astronomische Nachrichten," 214; the Paris Observatory, M. Baillaud, 272; the Sun's Velocity through Space, Profs. Frost and Kapteyn, 272; Parallax of Fourth-type Stars, Prof. Kapteyn, 273; the Maximum of Mira in 1909, Prof. Nijland, 273; Mr. Ichinohe, 273; Rediscovery of d'Arrest's Comet (1910c), M. Gonnessiat, 317; Observation of the d'Arrest Comet at the Observatory of Algiers, M. Gonnessiat, 324; M. Baillaud, 324; Search-ephemerides for Comets 1889 V. (Brooks) and 1890 VII. (Spitaler), Dr. Bauschinger, 317; F. Hopfner, 317; the Sun-spots of 1909, Dr. E. Guerrieri, 317; the Permanent International Committee for the "Carte du Ciel," 317; Meteors and Bolides, Prof. Guido Cora, 317; History of Navigation, Prof. Marguet, 317; Meteoric Fireballs, Rev. W. F. A. Ellison, 318; Rev. J. C. W. Herschel, 318; a Suspected New Planet, Prof. J. Comas Sola, 344; Definitive Elements for Comet 1852 IV., Adolf Hnatek, 344; the Passage of the Earth through the Tail of the 1861 Comet, R. Baer, 344; the Spectrum of Cyanogen, Comte de Gramont and M. Drecq, 344; Researches on the Colours of Stars, Osten Bergstrand, 344; "Mock Suns," James F. Ronca, 345; "Mock Suns" at Eastbourne, Mrs. A. M. Butler, 374; Astronomy in India, 374; an Oblique Belt on Jupiter, Scriven Bolton, 362; the Distances of Red Stars, Dr. H. Norris Russell, 374; Astronomy: a Handy Manual for Students and Others, Prof. F. W. Dyson, F.R.S., 393; Chats about Astronomy, H. P. Hollis, 393; Observations of Comets, M. Gonnessiat, 404; Mr. Innes, 404; the Solar Physics Observatory, South Kensington, 404; the Determination of Longitude, Dr. Jean Mascart, 404; Transactions of the Astronomical Observatory of Yale University, Parallax Investigations on Thirty-five Selected Stars by Frederick L. Chase, Mason F. Smith, and William L. Elkin, 433; a Bright Meteor, 438; Rediscovery of Brooks's Periodical Comet (1889 V.), 1910d, Messrs. Aitken and Wilson, 438; the Luminosity of Comets, W. L. Dudley, 439; Coloured Stars between the Pole and 60° N. Declination, Herr Krüger, 439; Observations of the Companion of Sirius, Prof. Barnard, 439; a Modified Method for Nadir Observations, R. M. Stewart, 439; a New Micrometer, Dr. Doberck, 439; the Mean Parallax of Tenth-magnitude Stars, Dr. H. E. Lau, 439; Halley Meteors, Prof. David Todd, 439; Announcement of a Nova, Mrs. Fleming, 472; Arabian Astronomical Instruments, Prof. E. Wiedemann, 472; New Ephemerides for Saturn, Uranus, and Neptune, Dr Downing, 472; a Bright Projection on Saturn, M. Maggini, 507; Origin of Cometary Bodies and Saturn's Rings, Dr. Henry Wile, 522; Irregularities in the Motion of Algol's Satellite, Enzo Mora, 472; the Cambridge Observatory, Sir Robert Ball, 472; Prof. Newall, 472; Observations of Neptune's Satellite, Prof. Barnard, 472; Spectrum and Radial Velocity of ϕ Persei, Dr. Ludendorff, 507; Death and Obituary Notice of Thorvald Nicolai Thiele, 503; Comets and Electrons, Prof. Righi, 507; Recent Results in Solar Physics, Prof. Riccò, 507; the Amateur Astronomer, Gideon Riegler, W. E. Rolston, 526; a Brilliant Meteor on October 23, W. F. Denning, 544; J. E. Clark, 544; Simultaneous Photographic Observations of a Remarkable Meteor, Herr Sykora, 544; Two Remarkable Prominences, Dr. F Slocum, 544; the Relations between Solar and Terrestrial Phenomena, Abbé Th. Moreux, 545; Search-ephemerides for Westphal's Comet, 1852 IV., A. Hnatek, 545

Astrophysics: the Pressure of Light on Gases, Dr. Lebedew, 86

Atkins (W. R. G.), Cryoscopic Determination of the Osmotic Pressure in Some Plant Organs, 211

Atlas, an Economic, J. G. Bartholomew, 426

Atlases, a List of Geographical, in the Library of Congress, with Bibliographical Notes, 325

Atmosphäre, Die Temperatur Verhältnisse in der freien, [Ergebnisse der internationalen unbemannter Ballonaufstiege], Dr. Arthur Wagner, E. Gold, 42
Atomic Weights, 207
Atwood (W. W.), Glacial History of the Uinta and Wasatch Mountains, 122
Auerbach (Prof. Felix), Geschichtstafeln der Physik, 457
Auger (V.), Manganate of Sodium and its Hydrates, 64
Augustin (E.), Ueber japanische Seewalzen, 34
Aurorae, Photographs of, Carl Störmer, 86
Australia, Rainfall of Rhodesia and, 187
Australian and Argentine Biology, 186
Austria, Mathematics in, 399
Aviation: Death and Obituary Notice of the Hon. Charles Stewart Rolls, Dr. William J. S. Lockyer, 46; the Art of Aviation, R. W. A. Brewer, Prof. G. H. Bryan, F.R.S., 229; How to Build an Aëroplane, R. Petit, Prof. G. H. Bryan, F.R.S., 229; How to Build a 20-foot Biplane Glider, A. P. Morgan, Prof. G. H. Bryan, F.R.S., 229; Les Aéroplanes, considérations théoriques, P. Raybaud, Prof. G. H. Bryan, F.R.S., 229; Ballons et Aéroplanes, G. Besançon, Prof. G. H. Bryan, F.R.S., 229; L'Aviation, Prof. Paul Painlevé and Prof. Emile Borel, Prof. G. H. Bryan, F.R.S., 229; Navigation in der Luft, Prof. A. Marcuse, Prof. G. H. Bryan, F.R.S., 229; Stabilitié des Aéroplanes, Surface Métacentrique, Prof. M. Brillouin, Prof. G. H. Bryan, F.R.S., 229; Die Seitensteuer der Flugmaschinen, Prof. H. Reissner, Prof. G. H. Bryan, F.R.S., 229; National Fund Airship Flight, 369; Progress of Aviation during the Past Year, 373; Erasmus Darwin Prophesied Advent of Aërial Navigation, 370, Arthur Platt, 397; Death of M. G. Chavez, Flight Across the Alps from Brigue to Domo d'Ossola, 400; Airship Flights, 512

Backe (A.), Researches on *Iso*-Maltol, 64

Oxley, 515; Principles of Mechanical Flight, Prof. G. H. Bryan, 515; Dugald Clerk, 515; Atmospheric Electricity, Dr. Charles Chree, 515; Existence of a Positive Gradient of Potential during Fine Weather and a Negative Gradient during Wet Weather, Sir Oliver Lodge, 515; Dr. Shaw, 515; Sir J. J. Thomson, 515; a New Instrument, the Variograph, for Measuring Short Waves in Atmospheric Pressure, Dr. W. Schmidt, 516; Records from the Upper Atmosphere Obtained during Passage of the Earth through the Tail of Halley's Comet, Mr. Dines, 516; Vertical Temperature Gradients in Canada in the Winter Months, Mr. Stupart, 516; Results of an Investigation into the Effect of Radiation on H, the Height, and *Te*, the Temperature, of the Advective Region, Mr. Gold, 516; Sensitive Bifilar Seismograph for Recording Undulatory Movements of the Earth's Surface of Short Period, Prof. F. G. Bailey, 516; a Successful Attempt to Simplify the Long-range Spectrograph to Make it Suitable for Industrial Investigations concerning Metals, Alloys, &c., Prof. C. Féry, 516; Magnetic Field Produced by the Motion of a Charged Condenser through Space, W. F. G. Swann, 516; Results of Experiments on the Secondary Radiation from Carbon at Low Temperatures when Bombarded by the α Rays from Polonium, V. E. Pound, 516; Resolution of the Spectral Lines of Mercury by a High-grade Echelon Spectroscope, Prof. McLennan and N. Macallum, 516; Active Deposit Obtained when the Emanation from Actinium is Allowed to Diffuse Freely between Two Parallel Plates Placed about 2 Millimetres apart over the Actinium Salt, the Plates being Maintained at a Difference of Potential of 250 volts, W. T. Kennedy, 516; Recoil of Radium B from Radium A, Drs. W. Makower and S. Russ and E. J. Evans, 516; Stars and their Temperatures, Sir Norman Lockyer, 516; So-called "Sudden Commencements" of Magnetic Storms, Dr. Bauer, 516; Dr. Chree, 516

Section B (*Chemistry*).—Opening Address by J. E. Stead, F.R.S., F.I.C. F.C.S., President of the Section, 302; Researches upon the Chemical Aspects of Gaseous Combustion during the Past Thirty Years, Prof. Bone, 517; Combustion, Sir J. J. Thomson, 517; Velocity of Sound not a Constant Quantity, Sir Oliver Lodge, 517; Explosion of Hydrogen and Chlorine by Light, Prof. H. B. Dixon, 517; Impossibility of any Interaction Taking Place between Two Substances if Neither was an Electrolyte, Prof. Armstrong, 517; Molecular Weight of Radium Emanation, Sir Wm. Ramsay and Dr. R. W. Gray, 517; Biochemistry of Respiration, F. F. Blackman, 517; Existing Knowledge with Regard to the Oxydases, Dr. E. F. Armstrong, 518; a Fourth Recalescence in Steel, Prof. J. O. Arnold, 518; Dr. C. H. Carpenter, 518; Mr. Stead, 518; Allotropy or Transmutation, Prof. H. M. Howe, 518; Closing and Welding of Blow-holes in Steel Ingots, Prof. H. M. Howe, 518; Mr. Stead, 518; Provident Use of Coal, Prof. H. E. Armstrong, 518; Prof. A. Smithells, 519; Dr. Beilby, 519; Mr. Archbutt, 519; Properties of a Series of Steels with Varying Carbon Contents, Prof. McWilliam, 519; Crystalline Structure of Iron at High Temperatures, Dr. Rosenhain, 519; Ferro-silicon, Dr. S. M. Copeman, 519; Dr. Wilson Hake, 519; S. R. Bennett, 519; Corrosion of Iron and Steel, Dr. J. N. Friend, 519; Influence of Heat Treatment on the Corrosion, Solubility, and Solution Pressures of Steel, C. Chappell and F. Hodson, 519; Relative Instability of the Trimethylene Ring, Dr. J. F. Thorpe, 519; Elimination of a Carbethoxyl Group during the Closing of the Five-membered Ring, A. D. Mitchell and Dr. J. F. Thorpe, 519; Molecular Association in Water, W. E. S. Turner and C. J. Peddle, 519; Affinities of the Halogen Elements, W. E. S. Turner, 519; Molecular Complexity of Nitrosoamines, W. E. S. Turner and E. W. Merry, 520; Action of Metals upon Alcohols, Dr. F. M. Perkin, 520

Sub-Section of B (*Agricultural Sub-Section*).—Opening Address by A. D. Hall, M.A., F.R.S., Chairman of the Sub-section, 309

Section C (*Geology*).—Opening Address by Prof. A. P. Coleman, M.A., Ph.D., F.R.S., President of the Section, the History of the "Canadian Shield," 333; Graptolitic Zones from the Salopian Beds of the Cautly District, Sedburgh, Miss G. R. Whatney and Miss E. G. Welch, 520; the Concealed Coalfield of Notts, Derby, and Yorkshire, Prof. P. F. Kendall, 520; the Shelly Moraine of the Sefström Glacier, Spitsbergen, G. W. Lamplugh, 520

Section D (*Zoology*).—Opening Address by Prof. G. C. Bourne, M.A., D.Sc., F.R.S., President of the Section, 378; Hormones in Relation to Inheritance, Gilbert C. Bourne, 462; Zoology at the British Association, Dr. J. H. Ashworth, 548; Coral Snakes and Peacocks, Dr. H. F. Gadow, F.R.S., 548; Coccidia and Coccidiosis in Birds, Dr. H. B. Fantham, 548; the Formation and Arrangement of the Opercular Chætae of Sabellaria, Arnold T. Watson, 549; the Anatomy and Physiology of *Calma glaucoides*, T. J. Evans, 549; Sex and Immunity, Geoffrey Smith, 549; Prof. Bateson, F.R.S., 549; Prof. Hartog, 549; the Colours of Insect Larvæ, Prof. Walter Garstang, 549; Mr. Doncaster, 550; Insect Coloration, Mark L. Sykes, 550; G. Story, 550; the Biology of Teleost and Elasmobranch Eggs, Dr. W. J. Dakin, 550; Semination in the Sanderling, Prof. C. J. Patten, 550; Anatomical Adaptations in Seals to Aquatic Life, Dr. H. W. Marett Tims, 550; the Temporal Bone in Primates, Prof. R. J. Anderson, 550; the Oxford Anthropometrical Laboratory, Dr. E. Schuster, 550; the Relation of Regeneration and Developmental Processes, Dr. J. W. Jenkinson, 550

Section E (*Geography*).—Opening Address by A. J. Herbertson, M.A., Ph.D., Professor of Geography in the University of Oxford, President of the Section, Geography and Some of its Present Needs, 383; Origin of Some of the More Characteristic Features of the Topography of Northern Nigeria, Dr. J. D. Falconer, 551; Prince Charles Foreland, Spitsbergen, Dr. W. S. Bruce, 551; Plans for a Second Scottish National Antarctic Expedition, Dr. W. S. Bruce, 551; Voyage of the *Nimrod* from Sydney to Monte Video, Captain J. K. Davis, 551; Metallurgical Industries in Relation to the Rocks of the District, Prof. A. McWilliam, 552; Importance to Sheffield of the Unoxidised Iron Ores of Leicestershire and Lincolnshire, Prof. Kendall, 552; the Humber during the Human Period, T. Sheppard, 552; Journey Across South America from Bogotá to Manáos, Dr. Hamilton Rice, 552; Geography of British Cotton-growing, J. Howard Reed, 552; Journey from India through Gilgit, Hanza, across the Pamirs, and thence by Chinese Turkestan, Mongolia, and Siberia to the Trans-Siberian Railway, Lieutenant P. T. Etherton, 552; New Globe-map of the World, William Wilson, 552; Midlothian District, James Cossar, 552; Underground Waters of the Castleton District of Derbyshire, H. Brodrick, 552

Section G (*Engineering*).—Opening Address by Prof. W. E. Dalby, M.A., M.Inst.C.E., President of the Section, British Railways, Some Facts and a Few Problems, 407; the Testing of Lathe Tool Steels, Prof. Ripper, 553; Third Report of the Committee on Gaseous Explosions, 553; Radiation from Open Flames in the Laboratory, Prof. Callendar, 553; Radiation from Gases in a Closed Combustion Chamber, Prof. Hopkinson, 553; the Ignition of Gases by Adiabatic Compression, Prof. Dixon, 553; Captain Sankey, 553; New Method of Testing the Cutting Quality of Files, Prof. Ripper, 553; Electrification of the London, Brighton, and South Coast Railway between Victoria and London Bridge, P. Dawson, 553; Use of an Accelerometer in the Measurement of Road Resistance and Horse-power, H. E. Wimperis, 553; Cyclical Changes of Temperature in a Gas-engine Cylinder near the Walls, Prof. Coker, 553; Principles of Mechanical Flight, Prof. Bryan, 554; Optical Determination of Stress, Prof. Coker, 554; Measurement of the Air Supply to a Gas-engine Cylinder, Prof. Dalby, 554; Heat Insulation, F. Bacon, 554; a New Method of Producing High-tension Electrical Discharges, Prof. E. Wilson and W. H. Wilson, 554; Machine for Testing Rubber by Means of its Mechanical Hysteresis, Prof. Schwartz, 554; Utilisation of Solar Radiation, Wind Power, and other Intermittent Natural Sources of Energy, Prof. Fessenden, 554; Experimental Investigation of the Strength of Thick Cylinders, Mr. Cook, 554

Section H (*Anthropology*).—Opening Address by W. Crooke, B.A., President of the Section, 414

Section I (*Physiology*).—Opening Address by Prof. A. B. Macallum, M.A., M.B., Ph.D., Sc.D., LL.D., F.R.S., President of the Section, 444

Section K (*Botany*).—Opening Address by Prof. James W. H. Trail, M.A., M.D., F.R.S., President of the Section, 452

Section L (*Educational Science*).—Opening Address by Principal H. A. Miers, M.A., D.Sc., F.R.S., President of the Section, 480; the Relation of Science to Industry and Commerce, R. Blair, 345

British Fossils 101

British Isles, the Gulf Stream Drift and the Weather of the, Dr. H. Bassett, 44

British Isles in Pictures, the, H. Clive Barnard, 238

British Mammals, a History of, G. E. H. Barrett-Hamilton, 493

British Marine Zoology, Prof. E. W. MacBride, F.R.S., 252, 330, 396, 462; Prof. W. A. Herdman, F.R.S., 329, 396, 462; Dr. Wm. J. Dakin, 396

British Medical Association in London, the, 153

British Museum: Catalogue of the Fossil Bryozoa in the Department of Geology, British Museum (Natural History), Prof. J. W. Gregory, F.R.S., 8; Catalogue of the Books, Manuscripts, Maps, and Drawings in the British Museum (Natural History), 266; Guide to Mr.

Worthington Smith's Drawings of Field and Cultivated Mushrooms and Poisonous or Worthless Fungi often Mistaken for Mushrooms, Exhibited in the Department of Botany, British Museum (Natural History), 361; Mineral Specimens Acquired by British Museum, 467; Handbook to the Ethnographical Collection, 536

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, JULY 7, 1910.

THE LAWS OF HEREDITY.

The Laws of Heredity. By G. Archdall Reid. With a diagrammatic representation by Prof. H. H. Turner. Pp. xi+548. (London: Methuen and Co., Ltd., 1910.) Price 21s. net.

DR. ARCHDALL REID confesses that he is an "extreme Darwinian." It is interesting that he has reached this position from the study of the human species. He finds that this "vast field of research has been left practically untilled by students of heredity." He is not, properly speaking, a naturalist; in fact, he has rather a poor opinion of naturalistic work, and especially, I am sorry to say, of botanical. This is the more remarkable as Darwin himself loved "to exalt plants," and largely drew upon their study for his theory. The author is, however, a physician who, unlike most of his calling, is not satisfied with being empirical. He finds himself "able to watch, under conditions ensuring great accuracy, the tremendous and crucial experiments made by nature." With many of his results we are already familiar from his previous writings. They are beginning to obtain general acceptance; in proportion as they do so, they must profoundly change our mode of dealing with social problems of the utmost importance.

The object of the present work is apparently to set out the results of his investigations in a systematic form, and to show that they can be exhibited as deductions from widely accepted principles. The method has undoubtedly the advantage that it has enabled him to look at the whole subject from a new point of view, and to bring a very acute criticism to bear upon a good many questions on which opinion at the moment is much divided.

As Mill long ago pointed out, all science tends to become deductive, and biology cannot be excluded. But the progress which any particular science can make in this direction altogether depends on the certainty which attaches to the assumptions or propositions with which we start. And where the phenomena, as in the case of biology, are complicated and obscure, the difficulty must always arise as to whether the proposition we start from is really exhaustive of the fact. The validity of the conclusion cannot exceed that of the premises. Lord Kelvin's attempt to determine the age of the earth is an example. The conditions of the problem have proved to be insufficient, and I suppose no physicist would now refuse an evolutionist a blank cheque as to time.

Darwin himself linked together a number of separate inductions into a more comprehensive one from which he then argued deductively. Dr. Archdall Reid has continued the process, and in the first ten chapters of his book has attempted a synthesis of existing evolutionary theory. It is to be noted that when this is done the order of exposition is rarely that in which discovery was made. This is well known, for example, to be the case with the text-book treatment of the Newtonian theory. The process is, however, valuable, as it not merely brings to light a clear chain of causation, but by vigorously testing the strength of each link, often reveals unsuspected weakness, and may even suggest new discovery.

The author accepts and starts from Weismann's theory of the continuity of the germ-plasm. From this he makes the fundamental deduction that "individuals, for example, men, are nothing more than dwellings which the germ-plasm builds about its germinal descendants." Thence it follows "that the child inherits nothing from his parent." What it does inherit is nothing more than what was "inborn" in the germ-plasm from which it started. The germ-plasm, under the stimulus of nutrition, reproduces itself, and also produces the enveloping soma. But the latter also requires the stimulus of use ("injury" may be regarded as use with a minus sign), as well as that of nutrition: a limb will not reach full development unless used, and mental powers will remain dormant unless exercised. But the characters so developed are "rooted, as it were, in the germ-plasm." They flow from it: the question which has long divided biologists is whether modification of those characters produced by the stimulus of use can flow back and be transmitted to a succeeding generation. Darwin latterly apparently thought they could.

Herbert Spencer built upon their doing so his ethical system. "Most biologists reject the Lamarckian doctrine," on the ground that it is against the weight of evidence. That is my own position. But the author himself admits that there is some evidence in its favour, yet unhesitatingly also rejects it on deductive grounds. The argument is rather subtle; but it amounts to this: a character which develops under the stimulus of use cannot develop under the stimulus of nutriment alone. If it did so it would be "a miracle." But I am not sure that this is not an assumption. In a unicellular organism the soma and germ-plasm are identical, and as we rise in the scale of plants the separation of the germ-plasm is far from being as complete as it is in animals. In many plants, as in the well-known case of Begonia, a somatic cell will reproduce the whole individual, germ-plasm and all. I am not prepared to assert that the new germ-plasm is free from derived somatic influence. On the other hand, I know of no reason to think that it is not.

The Lamarckian doctrine being dismissed, natural selection is examined. Like Prof. Karl Pearson, Dr. Archdall Reid infers this immediately from "selective mortality" in mankind. He points out that this cannot be proved in the case of "wild plants and animals," but "presumably" it occurs. I doubt if disease is a dominant selective factor in nature, though no doubt it has been occasionally operative, and on a large scale. He puts the theory on too narrow a basis, and ignores the struggle for existence. What plants have to fight for is room to perfect their seeds and space for them to germinate.

This is not the only short cut to the root of the matter. "The plain fact that living beings are able to exist is a proof of adaptation." It does not appear to me to be self-evident, though Paley would probably have agreed. Anyhow, it is rather like trying to enter Darwinism by the back-door instead of toiling up the steps. I collect a somewhat better argument. Man is "manifestly a bundle of adaptations." "The growth of modern physiology implies merely an increased power of interpreting human traits in terms of their utilities." "Presumably adaptation is not less perfect in plants and lower animals than in man." Yet, as Rolleston used to tell us at Oxford, that sort of statement would not convict a poacher. Fortunately, evolutionists have a better case for the court.

Next we come to variation, which affords the material for natural selection to work upon, and some important conclusions are arrived at. Excluding any possible influence of the soma, and I agree, variation must be resident in the germ-plasm. "Reasoning by analogy," it is inferred that this is itself "established and maintained by natural selection." This involves the paradox that it preceded that which produced it. "Its origins are lost in obscurity." No doubt; but if I may try my own hand at deduction, I would suggest that primitive variation was a necessary consequence of molecular instability, and as I regard natural selection as a sort of physical principle like "least action" or gravitation, it would begin to operate at once.

The most fundamental point in the whole argument is the relation of the germ-plasm to the environment. Here two classes of facts have to be faced; first, the undoubted one, on which I have often insisted, that a few years' cultivation of a wild species breaks down its stability; and, secondly, such cases as the supposed degeneration of European dogs in India. I can only accept variation at present as an unresolved phenomenon. I have never contended that the environment could act as more than a stimulus to it, and I have no doubt that it does. Someone has used a better expression in saying that it pulls the trigger. To suppose that it has any directive action lands one at once in Lamarckism. The degeneration question is much more serious. To attempt to get over it by saying that "evolution is never perfect" and that "exceptions occur" is not "facing the music." Now this story of the degeneration of domestic animals and plants is an obsession in India. I have had occasion to test it in the case of the latter, and satisfied myself that it was due to mongrelising; and, as to Clayton's beans, I completely exploded a similar case in Arabis some years ago in these pages. My own conclusion is that variation is inherent and spontaneous in the germ-plasm; and the "germinal power of resisting enforced change" is an undoubted fact which manifests itself in "specific stability."

The varying germ-plasm inherits and transmits variations. Thus we are led to the thorny question of recapitulation. Sedgwick agrees that it is "a deduction from the theory of evolution," but that it "is still without satisfactory proof." On the other hand, in the same volume, W. B. Scott finds that in brachiopods, "in the more advanced genera, the developmental stages clearly indicate the ancestral genera of the series." The botanist is constantly running up against recapitulative structures. When he finds a trace of a prothallus in a flowering plant and a spermatozoid in the pollen-tube of Salisburia, it is difficult to avoid the conclusion of Bower that land-plants had aquatic ancestors. We must, however, agree with Prof. Sollas that "nature no doubt is a strict adherent to logic, but she betrays a singular want of method in recording the steps of her argument."

Dr. Archdall Reid thinks, and no doubt rightly, that "the main reason against a full acceptance of the Darwinian doctrine" is "the retrogression of useless parts and organs." His solution of this difficult problem is one of the most novel and interesting things in his book, and will probably be subjected to most criticism. Thirty-two yearlings, costing 51,520 guineas, only produced two winners. From this and similar cases he draws the inference that retrogression preponderates over progression. He accounts for it by supposing that there has been a selection of germ-plasms which "tended on the whole to vary retrogressively." But retrogression in turn "is checked only by selection." The difficulty at once arises to reconcile this view with the biometric result which he admits, that "variation tends to occur about equally about the specific mean." Incidentally it may be noted that he identifies retrogression with reversion.

The various solutions of the problem which have been attempted are discussed. There is a risk that the terminology used may cover a *petitio principii*. Given an organism, how is it to be adapted to a different environment? The adjustment may be effected by further complication or by simplification. It may be noted that in regard to the latter there is a close parallel in the evolution of machinery. Whole trains of mechanism are continually being swept away with an increase of efficiency. Compare, for example, a turbine with a marine engine. Here structural retrogression has made for functional progression. We owe it to Lankester for pointing out that "degeneration" is really simplification leading to closer adaptation. Progress in biology is not ethical, but position in the phyletic scale. The last of the Plantagenets is said to have kept a turnpike; but he may have been not the less authentic.

The instability of prize-bred domesticated races requires careful scrutiny. The late Duke of Devonshire pointed out to Lankester that racehorses are bred for speed and not for "points." The conclusion that I draw from Sir Walter Gilbey's facts is that breeders have not yet succeeded in fixing this particular quality. But short-horns, which are bred for points, have reached a high degree of stability; if they had not no one would give a thousand guineas for a bull. The purchase of a possible racehorse is confessedly a gamble. For my own part, I am content with Lankester's view that nature "with remorseless thoroughness" can throw overboard hereditary tendencies, if it is advantageous to do so; and this is really the same thing as Dr. Archdall Reid's selection of retrogressive germ-plasms, except that he throws on natural selection the burden of defeating its own aim.

Apart from speculation, we have in Galton's law of regression to mediocrity an empirical result which is perfectly general inasmuch as it deals impartially with excess and defect. It produces "a sensible stability of type and variation from generation to generation." It has always appeared to me the most important positive addition to the Darwinian theory, and it has seemed possible that it would open the door to a mechanical explanation of retrogression, or, as I prefer to say, of simplification; and this is apparently in Archdall Reid's mind, as he remarks that "regression is but the first phase of retrogression," though he has not followed it out further. Regression is independent, apparently, of natural selection, while retrogression is not.

This leads to another point which is often overlooked. The mere "maintenance of a structure" is dependent on the continued action of natural selection. As Poulton insists, it is by its operation that "all functional parts of an organism are kept up to a high standard." It may be a private heresy of my own, but I can attach no more meaning to the "cessation" and "reversal" of selection than if those terms were applied to gravitation.

The chapter on Mendel's laws is altogether admirable. It is probably the most luminous account of them which has been published. "There can be no doubt of the actual occurrence of the Mendelian phenomena. We must, endeavour, therefore, to estimate the part played by them in nature." Now where species or stable varieties are crossed we get simple blending, as in the Mulatto. "Mendelian reproduction is one of the rarest things in nature." "Mendelian traits . . . are common only when artificial varieties . . . are crossed by man." It would be impossible with any justice to attempt to summarise the argument. The majority of Mendelian traits "are concerned with reproduction." The illuminating conclusion, in which, however, the author finds himself anticipated by T. H. Morgan, is reached that they are analogous to sexual characters which are alternative, *i.e.* are latent or patent in the opposite sex. If this explanation holds good, and it has the obvious merit of including phenomena not obviously connected at first sight, it effectually disposes of "segregation"; and "unit-characters" necessarily follow. But their existence had already become precarious, for Prof. Karl Pearson kindly informs me that he has entirely failed to discover any which, to put it briefly, can be described as having unitary properties. It is pointed out that the inheritance of mutations is alternative, and the inference is drawn that characters which blend in crossing cannot have arisen as mutations.

Lastly, we come to the "Function of Sex." This is found to be an adaptation "to blend parental characters." Further, it is concluded that "blending, with its swamping effects . . . eliminates useless characters and variations." This at once explains retrogression, and at bottom on this head there is probably not much difference between Lankester and the author. Mutations are alternative and Mendelian; fluctuations are blended; whence Galton's law of regression and stability at once follows. "The average experience of the whole race . . . becomes the determining factor in evolution."

Two incidental points deserve notice. Parthenogenesis "occurs as a rule amongst simple forms." But it is found to occur much more frequently than was supposed amongst flowering plants; the dandelion is an example. Still, it may be presumed that sexual reproduction and cross-fertilisation occasionally occur. Fertility, both on biometric and general grounds, is thought to be a transmissible adaptation. Karl Pearson has, however, arrived at the important conclusion that there is "little or no demonstrable inheritance of fertility." Further, he is "forced to the conclusion that the smallness of the hereditary factor in fertility is an essential feature of Darwinian evolution." It is interesting to note that in this case deductive reasoning has led to diametrically opposite conclusions.

This disposes of the first part of the book. I do not know that I have come across anything more suggestive on the subject since the "Origin" itself. It may be added that Prof. Turner has thrown the main argument into a quasi-mathematical shape in the appendix. The latter and larger portion of the book is difficult to review in any reasonable space. It is a striking commentary on the contention of de Vries that organic evolution has nothing to say on social problems. It ranges over a wide field, including even a short system of philosophy, and will probably be found the more interesting because the least technical, and might well have been published separately.

Disease and immunity are admirably discussed. Races become tolerant through selection working on germinal variation. Protoplasm learns to neutralise toxins. Twenty years ago I ventured with bated breath to hint the possibility of its education. The result is that the microbe and not the sword is the ultimate "empire-builder"; and subject-races will either absorb or expel their conquerers. The argument is extended to alcohol and narcotics. All races who win their freedom from vicious indulgence must first be slaves to it. Insusceptibility to its charm, though not precisely parallel to disease-immunity, is, like it, a product of germinal variation. Meanwhile, selection slowly eliminates those who do not possess it. If it is true that the English are the most drunken of existing races, and that "about one death in seven" amongst them is due to alcohol, it has its work cut out for it. Still, it is at work; and any attempt to interfere with it by the total suppression of alcohol would simply result in the production of a more susceptible race.

Fortunately, though susceptibility is germinal, indulgence is an acquired habit. It follows that the children of drunkards will not necessarily follow in their parents' steps, and Karl Pearson confirms this from biometric data. The same reasoning applies to slum-dwellers. Here also the injury is somatic and not germinal, and would disappear if the conditions were improved; it is not transmitted, but reproduced in the offspring, which the experience of Dr. Barnardo's Homes shows is still capable of healthy development. Slums are continually recruited from outside; it is probable, therefore, that little, if any, germinal mischief has been produced. But it can be shown on Dr. Archdall Reid's own principles that, given time, an adapted and degenerate race would develop, which would be parasitic on the community, and probably prolific.

The chapters on mind I must leave to the psychologist. Lankester is followed in seeing in "the relatively enormous size of the brain in man and the corresponding increase in its activity and capacity," the fundamental distinction between man and other animals. "Educability is nothing more than a power of growing mentally under the stimulus of experience." This is inherited, while the resulting mental acquirements are not. The real test of education is the *quality* of thinking produced. I cannot, however, follow the author in his condemnation of Karl Pearson's Huxley lecture, the conclusions of which I believe to be, not merely perfectly sound, but of the deepest importance. Dr. Archdall Reid tells us that "ability is inborn"; Karl Pearson says it is "bred." I fail to see the distinction. Feeble-mindedness is found to consist in "incapacity to learn" and to be a "reversion to a pre-human mental state." Being germinal, it is inherited, and the community is justified in restraining its marked fertility.

Here I must conclude my review of a very remarkable book; the more remarkable as it is the work of a man somewhat aloof from the scientific world, and written as the recreation of a strenuous professional life. The author invites criticism, and I have not stinted it. He will doubtless get plenty more.

Perhaps Dr. Archdall Reid's more vulnerable point is the superior certitude which he (and Dr. Donkin) claim for deduction over observation and experiment (which is only observation of facts not immediately patent). It is true that when we come across an apparently irreconcilable fact, its improbability depends on the certitude of the law with which it conflicts. It may be due to experimental error in its widest sense; but it may be the germ of a new discovery. Newton laid aside his theory for a time because he could not reconcile it with the moon's motion. But Greenwich did not abandon it when it was found that the path of Halley's comet was not an ellipse. Certitude is built up by accumulated verification. Even mathematics, which are purely deductive, cannot wholly dispense with it. It was long thought that the conversion of linear into circular motion was impossible until Peaucellier effected it. And even so distinguished a mathematician as Sylvester once told me that he had published a number of theorems which, when tested arithmetically, proved to be untrue. Experiment cannot always wait on deduction. Röntgen's great discovery was an accident. A discrepancy in the weight of nitrogen revealed argon. It would possibly have been a long time before physicists found out for themselves Brownian motion and osmotic pressure unless botanists had done it for them. Darwin found by experiment that cross-fertilisation was advantageous to plants, and it is difficult to see how the fact could have been arrived at in any other way.

Huxley must have projected a prophetic eye into the future when he wrote:—

"The great danger which besets all men of large speculative faculty, is the temptation to deal with the accepted facts in natural science, as if they were not only correct but exhaustive; as if they might be dealt with deductively, in the same way as propositions in Euclid may be dealt with. In reality every such statement, however true it may be, is true only relatively to the means of observation and the point of view of those who have examined it. So far it may be depended upon. But whether it will bear every speculative conclusion that may be logically deduced from it, is quite another question."

The warning is not unneeded in many directions. It is, I think, particularly needed in regard to Dr. Archdall Reid's impatience with biometry and taxonomy, or rather, I should say, imperfect acquaintance with their aim and methods. He appears to think that biometric method begins and ends with mere enumeration. But such a research as that of Karl Pearson on the distribution of stars in space would show him that it goes a good deal farther. As Karl Pearson tells us, biology "has now developed theories of such complexity, that without the aid of the highest mathematical analysis it is wholly unable to state whether its theories are accurate or not." For my part, when a distinguished mathematician is willing to devote his splendid gifts to the task, my attitude is not querulous, but one of profound gratitude.

And taxonomy is even less a ground for impatience. For, as Linnæus saw, its real aim is to embrace all organisms in a natural classification. The principle of descent is implicit in this, and it was therefore towards it that all taxonomists were unconsciously working. Far from being hostile, it was amongst the systematists—Hooker, Asa Gray, Bentham, Bates, and Wallace—that Darwin found his most ardent champions.

W. T. THISELTON-DYER.

THE METABOLISM OF MARINE ANIMALS.

Die Ernährung der Wassertiere und der Stoffhaushalt der Gewässer. By Prof. August Pütter. Pp. iv+168. (Jena: Gustav Fischer, 1909.) Price 5 marks (unbound).

TWO years ago Prof. Pütter published three papers dealing with the metabolism of marine animals. The thesis advanced as the result of these investigations may be briefly summarised as follows:—the nutrition of a very great number of marine animals belonging to all phyla is not effected in the manner characteristic of the mammal, that is, by the ingestion of solid organised food, and by the subsequent digestion and absorption of this matter by special organs, but by the direct absorption of carbon and nitrogen compounds which are contained in solution in the sea. The notion that many animals were really saprozoic in their habits was not really a new one; most internal parasites, whether provided or not with an alimentary canal, obviously exhibit such a mode of nutrition; but the hypothesis that animals living in the open feed otherwise than by the ingestion of solid organised food, or by the utilisation of photosynthetic products elaborated by the activity of commensal algæ, was a new one, and has provoked much discussion. Pütter's methods have been criticised by Henze and Lohmann, and the paper now under review amplifies the author's former work, and to some extent meets the criticisms advanced.

The proof of the thesis is developed along three main lines. The author has studied the intensity of metabolism in a number of forms, and has found that this is proportional to the unit of surface, and not to the unit of mass. Therefore the relatively minute organisms which are found among the plankton, or even those larger animals which are provided with a large absorptive surface in the shape of gills, ctenidia, respiratory plumes, &c., and internal diverticula, are able to utilise the exceedingly dilute solution of organic carbon and nitrogen compounds contained in sea water. The intensity of metabolism is measured by the oxygen consumption and the carbonic acid output, and, generally speaking, the rate of exchange is, roughly, constant in animals of the same general type of organisation, when it is regarded as a function of the unit of surface. The divergencies from this approximately constant rate are to be regarded as dependent on the deviations from the usual mode of metabolism characteristic of the animal group considered.

The second line of proof depends on the existence of compounds of carbon other than carbonates, and compounds of nitrogen other than ammonia, nitrates, and nitrites, in solution in sea water. From the author's point of view the sea is an immense storehouse of dissolved food-stuff, which is utilised by most marine animals. In his first papers, Pütter estimated that the water of Naples Bay contained some 65 milligrams of organic carbon (volatile and higher fatty acids, and carbohydrates) per litre. Shortly afterwards Henze showed that the amount was greatly over-estimated, and that the proportion of such substances present was so small that it lay within the limits of error of the experimental methods employed by Pütter. Raben, however, showed that the water from the North Sea and Baltic did actually contain measurable quantities of organic carbon varying from about 3 to 37 milligrams per litre. If these results should be confirmed, they would back up Pütter's hypothesis, since the solution would then be sufficiently concentrated to act as a food medium.

The third line of proof is much stronger, but it depends on the author's estimates of the rate of exchange of oxygen and carbonic acid in the animals studied. Taking the case of plankton-feeding creatures, he shows that it is, in most cases, impossible that a sufficient amount of food can be obtained from the plankton to account for the rate of metabolic exchange. A sponge (Suberites), for instance, of some 60 grams weight required about 0·92 mgrm. of carbon per hour. Now taking a certain density of the plankton, this postulated that the sponge would have to pass some 242 litres of water through its canal system in order to get the necessary food-stuff from the plankton. It is quite impossible, of course, that the animal can filter this volume of fluid in the time. It has been shown by Lohmann that Pütter underestimated the density of the plankton, and by Henze that he over-estimated the concentration of the sea water in carbon compounds. But when the revised values are substituted, the argument is not materially affected. A further instance of the same nature is that of the copepod Calanus. If this animal feeds exclusively on plankton diatoms it must ingest some 16,000 medium-sized Coscinodisci, or about ten millions of Thalassiosiræ, in order to account for its metabolic exchange. Such figures appear to preclude the possibility of an exclusive feeding on diatoms.

It is, of course, quite probable that marine animals may feed in the same way as internal parasites, by absorption of dissolved food-stuff, and that this mode of nutrition may proceed simultaneously with that depending on the existence of an alimentary canal. If the metabolism of the lower invertebrates had been studied as carefully as that of the warm-blooded animal, this contention might have been accepted long ago. It is mainly by analogy with the latter that we ascribe respiratory functions to the structures called gills; they might just as reasonably be regarded as organs for absorption of food-stuff. However this may be, it appears from the work now noticed that the conclusions are only very probable ones until the data representing the rate of exchange of oxygen and carbonic acid have been critically revised. The proof or disproof of the author's thesis will be effected by such revision.

J. J.

SMALLPOX AND VACCINATION IN BRITISH INDIA.

Smallpox and Vaccination in British India. By Major S. P. James. Pp. xi+106. (Calcutta: Thacker, Spink and Co., 1909.) Price 7*s.* 6*d.*

AT a time when the study of tropical diseases is setting its indelible mark on the history of the progress of medicine, it is well to be reminded that in the tropics we have diseases that can by no means be considered exclusively tropical.

Major James's work deals with smallpox in India, that is, in a country, as the author bids us bear in mind, where the people

"live amid surroundings which could not be more favourable to the spread of epidemic disease if they had been especially devised to that end."

In a country "where sanitation is still in its infancy," where a continually growing proportion of the population lives in the towns and cities, where there is an enormous and continued extension of movement among the population and of communication within the country generally, where that typical "insanitary" disease, cholera, has on the whole increased, and where, in spite of all this, smallpox has decreased. Those who have studied the decline or disappearance of smallpox in other countries know that there is one, and only one, factor which could explain such a phenomenon, viz. vaccination; and that vaccination is the cause of the decline in India the author shows in plain and easily understood language, and with the aid of simple statistics that require no alleged "jugglery" for their setting forth.

Although there is a general belief that inoculation, the precursor of vaccination, was in use in India from time immemorial, yet the author adduces evidence that in modern times, where we have trustworthy information, it was entirely unknown in certain provinces, but he does not suggest any explanation of this curious discrepancy. Where inoculation was practised it was apparently done with marked success, but the regulations attending it were strict. At a later period, when irregularities in the practice arose, it became one of considerable danger, and was gradually superseded by the introduction of vaccination.

In chapter iii. is given a short account of the origin of vaccination from the first introduction of human vaccine threads into India in 1902 down to the use of calf lymph at the present day. It is interesting to note the opposition to vaccination in Bengal, as a few years ago the writer experienced there perfectly irrational opposition to the making of finger-pricks for simple blood examinations.

The following simple tables will suffice to give an idea of how smallpox had decreased from periods in which there was "less" vaccination to those in which there was "more," but to be fully appreciated the original data in Major James's book should be consulted.

	1868–1887 Smallpox death-rate per million of population	1888–1907 Smallpox death-rate per million of population
Bombay	537·2	240·5
Central Provinces	1020·1	502·7
Punjab	1099·3	520·7
Madras	1163·9	673·0
Berar	1083·1	183·0
British India as a whole	1032·3	466·0

If these latter figures are compared with the chart of the total number of vaccinations performed in British India, it will be seen at once that the fall in smallpox mortality coincides with the rise of vaccination.

Another method which is independent of statistics of population is to consider the proportion which smallpox deaths bear to the total deaths from all causes in two periods, one with "less" and the other with "more" vaccination. If an "epidemic" is now arbitrarily defined as one in which the deaths from smallpox form 5 or more per cent. of the deaths from all causes, we get the following data here put in tabular form:—

	1868–1887 No. of epidemics	1888–1907 No. of epidemics
Central Provinces	5	0
Punjab	7	0
British India as a whole	9	0

Another interesting observation is that prior to 1886 the attack rate among natives was always greater than among the European troops, but that after this date the position was reversed. The explanation given by the author is that since 1885 vaccination and successful re-vaccination have been less carefully attended to among Europeans than among native troops, and figures are given showing that among Europeans in 1906 there were more than 20,000 individuals without any marks or record of vaccination—a sufficiently lax condition of affairs—but the proof to be complete should have given the corresponding figures for the native troops. Another very interesting table is that showing the constantly greater incidence of smallpox among the wives of European soldiers than among the men, while as regards cholera and enteric fever the reverse is the case. The difference is due, no doubt, as the author points out, to the almost total absence of successful re-vaccination among the women. To the table there should, we think, have been added the "strength" of the women.

Other equally convincing tables are given, invariably pointing to some factor (vaccination) influencing the figures in the same direction; the tables, moreover, have the merit of being simple, though, as the author points out, if subjected to analysis they would be even more convincing, if that were necessary.

The laborious task the author set himself has been well done. We are not aware what steps are taken in India to explain the merits of vaccination to the people, but nothing could do so better than this book, or a short digest of it if that be possible.

THE ALTERNATE-CURRENT THEORY.

The Foundations of Alternate Current Theory. By Dr. C. V. Drysdale. Pp. xi+300. (London: Edward Arnold, 1910.) Price 8s. 6d. net.

IN English text-books on electrical engineering one finds occasionally an attempt to elucidate some property of an electric circuit by a mechanical model. A favourite analogy is a water-tank with pipe and stop-cock. The head of water represents E.M.F., the pipe takes the place of the conductor, the stop-cock that of the switch, and the flow of water represents the current. Also, a railway waggon with buffer-springs is often used to explain inductance and capacity. These analogies are, however, only used as additional explanations of a theory built up independently of them. In the present book they are the theory itself, or rather the foundation on which the author builds up the theory of alternating-current working. Hence it becomes a matter of the greatest importance that the mechanical properties of the particular model chosen should not merely approximately, but with mathematical precision, represent the corresponding electrical properties of the circuit it is intended to represent.

It becomes thus necessary to idealise the mechanical model by attributing to it properties which differ more or less from those it actually has in its natural condition. Take as an example the conceptions of electric current and ohmic resistance. According to the author's "foundations," these are respectively represented by speed (linear or angular) and friction. But what kind of friction? The coefficient of friction as applicable to solid bodies will not do, for this implies the existence of pressure between the surfaces in contact, and there is nothing analogous to pressure in the electrical case.

Thus one is driven to assume that ohmic resistance can only be represented by liquid friction of a particular kind, namely, of a kind which will cause the frictional resisting force to increase exactly in proportion to the speed with which a body is moved through the liquid. The author takes a boat which is towed through the water, and assumes that the pull in the tow-rope is exactly proportional to the speed. As an alternative to the tow-rope he assumes that the boat is fitted with a propeller which exerts the same thrust at all speeds, and he uses this model to illustrate the case of an inductive circuit. The mass of the boat corresponds to the inductance; the frictional coefficient, that is, the resisting force per unit speed, corresponds to the ohmic resistance, and the speed to the electric current. The E.M.F. is represented by the thrust of the propeller. Under these conditions the speed of the boat will increase by a logarithmic curve, and approach asymptotically the final value where the thrust of the propeller is exactly balanced by the frictional resistance. Thus, having discarded our conception of the real nature of ships' resistance and propeller thrust and substituted an idealised model, the performance of this model is an exact representation of what goes on in an electric circuit, and the equation of the speed of the boat is identical with the equation of the current in the electric circuit.

The author has not contented himself by merely imagining mechanical models, but has actually constructed one so as to be able to demonstrate the properties of an electric circuit. The model consists of a square frame, one side being provided with rails for a car to travel along. To represent ohmic resistance, the car can be fitted with a paddle moving in a liquid. The mass of the car represents inductance, the force with which it is pulled along stands for E.M.F., the speed for current, the displacement for quantity of electricity (coulombs), and if a capacity effect is to be shown an elastic string is attached to the car. In addition to this model, the author has others to show various electrical phenomena, all of them very ingenious and instructive, especially when he shows side by side curves of harmonic motions obtained by oscillograph attached to the electric circuit, on the one hand, and, on the other, curves obtained by mechanical means from the corresponding models.

The book is divided into four parts. In the first the fundamental principles are established by mechanical analogies; then comes an exposition of harmonic motions; whilst in the third part the properties of alternating-current circuits are studied in detail, including a chapter on the symbolic method. In the fourth part we find practical applications to transformers, motors, polyphase circuits, and high-frequency oscillations. At the end we find a number of problems given as exercises for students. These are well selected.

GISBERT KAPP.

OUR BOOK SHELF.

The New School of Japan, Founded for the Purpose of Making the Use of the Newly Invented Letters. Pp. x+58. (Tokyo: Dokuritsu Bungakki.)

THIS singular production is an attempt, by means of a quaintly conceived dialogue between two Japanese script reformers, to enlist home and foreign support, especially financial support, towards the promulgation of yet another script for the purposes of the Japanese written language, by modifications of and additions to the roman alphabet of the West. But European scholars have already accomplished this, and the existing system of romanisation is sufficiently perfect for all practical purposes. That system uses the roman letters, as we use them, to transcribe the characters of the Japanese syllabary, each of which represents a vowel or an open syllable; thus *ka, ki, ku, ko, ke* represent simply and adequately corresponding simple *kana* (syllabic) characters. But the proposed system would use single alphabetic letters to represent the *kana*. Thus *ka, ki*, &c., are written *n, v, u, k*; for *ke* a sort of reversed *k* is used. The modifications of sound, voicing, doubling, and lengthening are denoted by ordinary devices and combinations of these, and a few new letters are invented. Thus *Kono hon wa, Okuma Shigeru to Yamada Eizo* . . . (this book contains a talk between Okuma Sh. and Yamada Ei.) is printed, according to the new system, *Pk cx g Ttuf-Cat m Ofr-Tict* (two or three new letters are represented here by their nearest usual ones). Eizo Yamada is the "originator" of the new system; the preface, dated November, 1909, is signed by him and Muneyasu Oki, who is "business associate," and photographs of inventor and associate follow the preface.

For our part we fail to see any advantage whatever in this proposal. Why the Japanese continue to put their thought on paper under a variety of forms that render mere decipherment an impossibility to all foreigners save a very few who have time and patience, or are under some necessity to undertake a most repulsive study of several years' duration at least, the people of Japan alone can tell. Written Japanese, mainly on this account, is more difficult to acquire, even to read merely, than Chinese, yet with a very few changes the difficulty might be very greatly lessened without change of character, and with romanisation would largely disappear. In no long course of time, probably, the unintelligent use of the Chinese ideograph would diminish, the assimilation of written to colloquial speech would develop, and Japanese would present only the ordinary difficulties incident to a strange vocabulary, a syntax based upon impersonality and lack of inflections, and a mass of idioms necessarily differing widely in allusion and reference from those of Aryan languages.

F. VICTOR DICKINS.

Catalogue of the Fossil Bryozoa in the Department of Geology, British Museum (Natural History). Vol. ii., the Cretaceous Bryozoa. By Prof. J. W. Gregory, F.R.S. Pp. xlviii+346; 9 plates. (London: Printed by order of the Trustees, 1909.)

OWING to the author's absence from England and his retirement from the staff of the Museum, a period of ten years has elapsed between the date of publication of the present volume and its predecessor. This unusual delay has, however, been by no means an unmixed disadvantage, since it has enabled Prof. Gregory to incorporate information and to take advantage of theories of classification which would not have been available had this volume appeared several years earlier. It was originally intended to complete the subject in two volumes, but the wealth of material has rendered it necessary to allot a third volume—now in preparation by Prof. Gregory's successor in the Museum, Mr. W. D. Lang—to the Chilostomata.

In concluding his share of the work, Prof. Gregory gives a valuable general account of the Cretaceous bryozoan fauna and its relationships. The Cretaceous is the era in which the modern types of Bryozoa first attained to importance and replaced the older forms. The most characteristic group of the epoch is the Cyclostomata, which is now a waning type, and dates from the Jurassic. A second ordinal group, the Trepostomata, represents a Palæozoic type, which became decadent in the Upper Cretaceous, and finally disappeared in the Cænozoic. On the other hand, the Chilostomata, of which but two Jurassic species are known, attained an enormous development in the Upper Cretaceous, and forms the dominant type in the seas of to-day.

After a long review of the classification of the Cyclostomata, Prof. Gregory points out the value of the Bryozoa for zonal classification of the Chalk, remarking that recent investigations have shown—in contradistinction to older views—many of the species to have a very restricted vertical distribution.

The work is a most valuable and trustworthy contribution to the natural history of the Cretaceous Bryozoa, which, in Great Britain, at any rate, have previously received comparatively little attention at the hands of palæontologists.

Problèmes et Exercices de Mathématiques générales. By Prof. E. Fabry. Pp. 420. (Paris: A. Hermann et Fils, 1910.) Price 10 francs.

THIS useful collection reminds us that mathematical examinations are not peculiar to Great Britain, and provides an interesting specimen of the kind of questions set in France to candidates of about the same standing as English candidates for an ordinary science degree. It contains the enunciations of 739 problems, ranging from elementary algebra and calculus to solid geometry and differential equations, and also including about a hundred questions in statics and dynamics. Pages 81–420 contain the solutions, which, as might be expected, are clear and elegant. No book of this kind can supply the place of a competent teacher, but a student who has to work by himself will find Prof. Fabry's work very helpful, and a good model in point of style. M.

LETTERS TO THE EDITOR.

Arthur's Round Table in Glamorgan.

THE history of the Gorsedd of the Bards is closely bound up with the history of Glamorgan. Early in the history of the winning of the district by the Anglo-Normans, one of the earls of Gloucester, as lord of Glamorgan, took the institution under his protection and patronage, and it became known as Gorsedd Tir Iarll, "Gorsedd of the Earl's Land," and the district, comprising the parishes of Llangynwyd, Bettws, and Margam, is still called after the title of the noble patron of the bards. From about the middle of the twelfth century, the history of the institution, as well as the succession of presiding bards, is as clear as one might expect to find the history of a largely secret society to be. What history is recorded in bardic writings of the institution before that date represents it as Arthur's Round Table, moved from place to place with

The Maesteg Circle-avenue and its Builders.

the seat of government, from Caerleon-upon-Usk to Loughor, back to Cardiff, its wanderings having been confined within the boundaries of the diocese of Llandaff, until finally it found a resting-place in the Earl's Land. There is little reason to doubt the substantial truth of such records, and it is something to note that Arthur's Round Table, by name, has been all along regarded as the living institution known as Gorsedd of the Bards of the Isle of Britain.

There are bards still living who were received as members of the Gorsedd by bards who represented an unbroken tradition and succession in the Earl's Land at least from the twelfth century. One of these bards, "Morien," known also as "Gwyddon Tir Iarll," was present at the "re-awakening," in bardic parlance, of Arthur's Round Table on June 22, 1910, when a temple-observatory, which I had the honour of erecting at Maesteg, in the parish of Llangynwyd, the centre of the Earl's Land, was duly opened by the Archdruid of Wales, assisted by officers and members of the National Gorsedd, and other bards and friends of the bardic cause.

In designing the work, I endeavoured to combine the essential requirements of bardic tradition with all the ascertained principles of primitive architecture as shown in monuments of which the bardic Gorsedd is a representative. Every detail was based either on tradition or actual practice as observed in monuments. As at Avebury and Stonehenge, the avenue was added to the circle. Each stone selected has a fairly straight side, which has been utilised as an independent alignment. The avenue, as well as the tallest stone, are approximately oriented to the sun's place on St. David's Day, March 1. Three divisions of the year, and alignments to sunrise or sunset for every three weeks, are provided by the stones. The use of each stone will be found by keeping its straight side to the right. The diameter of the circle is 27 feet; the length of the avenue 54 feet; the total length of the work is 81 feet. In all such measurements, the Gorsedd rule that all extensions should be in threes, or multiples of three, was observed. The width of the avenue represents the distance, as measured on the horizon and viewed from the centre stone, between Candlemas and the equinox. True to ancient practice, the westward view of the avenue is "blocked" by a stone, which otherwise represents the fashion in Aberdeenshire circles, noticed by Sir Norman Lockyer, of placing a stone at right angles to the direction required.

JOHN GRIFFITH.

Llangynwyd, Glam.

Halley's Comet.

I DO not know if the enclosed is of any general interest or not; it is an attempt to photograph Halley's comet (as seen here) without any special apparatus. The tail was about 90° long on May 17, and probably 115° on May 18,

Halley's Comet in Pisces as seen at 5.30 a.m. on May 17 with 15′ exposure.

taking the calculated position of the nucleus, which had not risen when dawn came. On May 20 (on the other side) the tail was only 15° or 20° long, but both twilight and moon interfered. It was 35° long on May 23.

JAMES MOIR.

Mines Department, Johannesburg, June 10.

Earth-current Observations in Stockholm during the Transit of Halley's Comet on May 19.

WHEN Halley's comet was passing across the sun on May 19 we took, at the central telegraph station at Stockholm, some observations of earth-currents, which were measured on two lines, Stockholm-Göteborg and Sundsvall-Stockholm. The measurements were performed from minute to minute from 0h. 40m. to 3h. 45m. a.m. (mid-European time). The geographical coordinates for the three places mentioned are the following:—

Sundsvall ...	$\phi = 62°\ 23'$ N.	...	$\lambda = 17°\ 19'$ E. from Greenwich
Stockholm ..	59 21	...	18 3
Göteborg .	57 42	...	11 58

The resistance of the line Stockholm-Göteborg was 2940 ohms, and that of the line Sundsvall-Stockholm 2336 ohms. From the current-strengths measured in milliamperes we obtain the potential differences expressed in millivolts per km. by multiplication with r/l, r indicating the ohm-resistance of the line and l the distance in km. from end to end. For calculating the components of the potential difference E.-W. (V) and N.-S. (V′) we have the formulæ

$$V = 7{\cdot}73i - 3{\cdot}32i'$$
$$V' = 0{\cdot}871i + 6{\cdot}60i',$$

i and i' indicating the observed current-strengths on the Stockholm-Göteborg and the Sundsvall-Stockholm lines. The measured current-strengths proved considerably above the normal at this time of day, though by no means reaching to that of a magnetic storm. The two components, expressed in millivolts per km. (every fifteenth minute), are as follows. The potential differences are considered positive in the directions E.-W. and N.-S.:—

h. m.	V	V′	h. m.	V	V′
0 45 ...	−55·6 ...	− 6·3 ...	2 15 ...	−16·5 ...	+24·6
1 0 ...	− 6·8 ...	+ 2·0 ...	0 30 ...	−23·5 ...	+12·7
0 15 ...	+ 3·9 ...	+ 0·4 ...	0 45 ...	−25·5 ...	+16·7
0 30 ...	− 3·4 ...	− 9·5 ...	3 0 ...	− 7·2 ..	+ 1·3
0 45 ...	− 6·2 ...	+ 4·2 ...	0 16 ...	− 0·4 ...	− 5·6
2 0 ...	− 8·0 ...	+15·8 ...	0 30 ...	− 8·8 ...	−10·2
			0 45 ..	−16·9 ...	+ 2·9

The greatest disturbances occurred shortly before and after 2h. a.m.: V max. = +68·1, V′ max. = +56·6 millivolts per km.

Leptocephalus hyoproroides and L. thorianus.

IN my paper "On the Occurrence of Leptocephali (Larval Muraenoids) in the Atlantic West of Europe" (*Meddelelser fra Kommissionen for Havundersøgelser*, Serie Fiskeri, Bind iii., No. 6, 1909, p. 12, Pl. i., Fig. 8, Pl. ii., Figs. 1–7), I have described and figured a hitherto unknown Leptocephalus species under the name of *Leptocephalus hyoproroides*, n.sp. It had escaped my attention, however, that this name had already been employed by P. Strömman in "Leptocephalids in the University Zoological Museum at Upsala," Upsala, 1896, p. 30, Pl. iv., Figs. 5–6, for another form similar in habit, but differing quite definitely in several characters, *e.g.* the pigmentation and position of the anus, from the form described by me. I would therefore propose that the name of the latter should be changed to *Leptocephalus thorianus*, n.sp. (after the Danish research steamer *Thor*, on the cruises of which the species in question was discovered).

JOHS. SCHMIDT.

Static Charge in Bicycle Frame

WHILE riding a bicycle recently I was overtaken by a thunderstorm, and took shelter beneath a convenient tree after propping the machine against a wall. When the rain had ceased, in the course of about fifteen minutes, I re-mounted, with my hands upon the handles in the usual manner. The handles are of composition, resembling vulcanite or a similar non-conducting material, the pedals are shod with rubber, and the leather saddle completes the insulation of the rider from the frame. Upon exchanging my grip of one of the handles for the bar, I felt the effects of a static charge which was sufficiently startling to endanger equilibrium for the moment. I do not suggest that the pneumatic tyre, which successfully insulates a vehicle from the earth, adds a new terror to locomotion, for even a timid rider in traffic would hardly be endangered, but it would be interesting to know if this phenomenon has been observed before, either on cycles or motor-cars.

MARINE BIOLOGICAL PHOTOGRAPHY.

THOUGH year by year photography plays a greater part in the illustration of works on natural history, marine biology does not appear to have received its full share of attention from the scientific photographer.

It can be claimed for photography that it is an accurate and rapid method of making marine biological records. The rapidity admits of the recording of delicate structures during life, thus avoiding the opacity and distortion that so soon follow death; but the main advantage lies in the fact that by means of photography the number of workers making records can be greatly increased. Expert biologists who have the time to make drawings of minute structures are distinctly limited in number, whereas the photographer with but a general biological knowledge is able to make accurate and useful records of structures, possibly quite new to him, and many points of which he might miss were he to draw them.

FIG 1.—Young Thornback Ray.

In order to derive the full advantages offered by photography, the worker must be prepared, in addition to illustrating minute structures, to deal with the habits, movements, characteristic postures, and general external appearance of any particular marine animal. Such records should preferably be made in natural environments, but, failing this, in special tanks.

Prof. Reighard, in his contribution "Photography of Aquatic Animals in their Natural Environments," describes very fully subaquatic photography and photography with the camera above water. Subaquatic photography, however, has a very limited application, mainly in consequence of the want of light, and for obtaining details of external structure is not nearly so satisfactory as photography in special tanks.

With the camera above water the main difficulty to be overcome is due to the photograph having to be taken through two media, air and water, for the light reflected from the surface of the water, being greater than that reflected from the object to be photographed, the desired image is obscured in the general fogging of the photographic plate. When photographing a submerged object with the camera directed at an angle to the surface of the water, this reflection from the water can be avoided by holding a screen at a suitable angle immediately above the object.

When taking a photograph directly above the object, the light must be cut off above the camera. The illustration of a young thornback ray was taken in 8 inches of water, with a golf umbrella held over the head of the operator.

For tank work the most useful arrangement is a tank about 3 feet long, 2 feet high, and 6 to 8 inches from front to back, the bottom and sides being of wood, the front and back of $\frac{1}{4}$-inch plate-glass. Inlet and outlet pipes pierce the sides, and there must be arrangements for a constant supply of salt or fresh water which can be sent through the tank at will. The specimen placed in the tank usually sulks at the bottom; if, after a time, the water is suddenly turned on, the fish or other creature heads up to the stream, and a snapshot can be taken in a natural position. For the above work it is desirable to use a reflex camera with a rapid lens of not less than 8-inch focal length.

For the photography of comparatively small and microscopic marine objects a special apparatus is necessary. I use a portable apparatus with which it is possible to take a photograph of a specimen in a horizontal or vertical position, by transmitted or reflected light, and by means of a mirror to see the object up to the last moment before exposure, so as to ensure a living specimen being photographed in a suitable position. There is also a fixed stage upon which a specimen can be placed in a tank or cell, and a photograph taken of any desired magnification without moving the specimen.

When photographing from life-size up to 25 magnifications I use lenses of 6-inch, $3\frac{1}{2}$-inch, and 35-mm. focal lengths, on a camera having an extension of 36 inches without a microscope. For higher magnifications I drop a microscope into the apparatus, and get any desired magnification up to 2600 with a 1/12-inch oil immersion.

FIG. 2.—Whelk feeding on Crayfish.

The exceptional length of bellows extension is necessary in order to obtain a high degree of magnification from a lens of comparatively long focus, thus ensuring all parts of the specimen being in focus at the same time.

The advantages of such an apparatus at a biological station or on a research boat are obvious, for specimens taken from the trawl or tow-net can be placed in suitable tanks or cells by the biologist, and

FIG. 3.—Pecten turning over.

photographed, living, anæsthetised, or dead, by an assistant. Any number of useful records could thus be made from fresh specimens of any particular catch. For photographic purposes it is desirable to obtain perfect living specimens; but the photography of

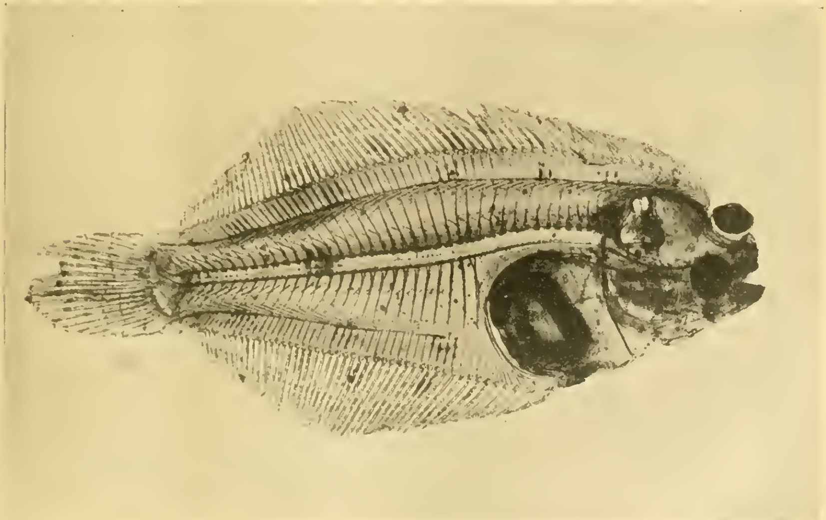

FIG. 4.—Plaice Larva.

numerous imperfect specimens is also very valuable, for at any time a perfect drawing can be made from the material so collected.

As an additional use, this apparatus can with advantage be employed when counting specimens in the analysis of a plankton catch, for the area under the field of the microscope can be thrown on to a sheet of paper and the specimens ticked off.

When working with artificial light, the illuminant should be of sufficient power to ensure against the want of light being a hindering factor. I use a very useful little arc lamp made by Messrs. Leitz, when electric power is available; failing this, an oxyhydrogen light, though good results can be obtained with an acetylene lamp. When using arc or limelight it is necessary to have a cooling tank between the light and the specimen.

With either arc or limelight, working with a Zeiss microplanar lens at F. 4·5 on a medium rapid plate, a full exposure can be obtained in one-tenth of a second up to twenty-five magnifications.

Reference has been made already to photographs taken in natural environments. As an illustration of the recording of the habits of marine animals is shown the photograph of the common dog-whelk (Buccinum) holding with its foot the abdomen of a dead crayfish. On removing the crayfish it was found that the whelk had partially sawn through the shell by means of its radula.

A characteristic movement is shown in the photograph of a pecten turning itself over.

Recently I had the opportunity of taking numerous pecten photographs under the direction of Mr. W. J. Dakin, and by his kind permission I am able to show an instantaneous photograph of this mollusc, in the act of turning itself over, after having been placed on the left valve. The other photographs taken showed the gradual opening of the pecten, until the valves were separated as much again as in the photograph shown. The present illustration shows the sudden act of closure, by which the turning movement is brought about, almost completed.

Of photographs taken with the special apparatus described, two illustrations are given; the first that of a plaice larva 13 mm. in length, and magnified five times; the second that of a crustacean, one of the Mysidacea, 2 mm. in length, magnified fifteen times. This photograph shows very distinctly the two statocysts on the uropods or appendages of the sixth abdominal segment, and gives a good general view of the animal.

FIG. 5.—A Mysidacea.

Higher magnifications of any particular part are obtained as described by slipping the microscope into the apparatus.

In addition to the above methods, the natural colours of marine animals may be recorded on the autochrome plate. The autochrome plate is particularly useful when it is desired to make a permanent record of a stained specimen where the staining is of a fugitive character.

FRANCIS WARD.

SOME EXTINCT VERTEBRATE ANIMALS FROM NORTH AMERICA.[1]

A NEW volume of collected papers, published by the American Museum of Natural History, New York, enables us to realise how important and numerous are the additions to our knowledge of extinct vertebrate animals still made by systematic explorations in North America. The contributions now received deal with the work of only four years, 1904–8, accomplished by one institution; but they make great advances in nearly all parts of the subject to which they relate, and their value is increased by the excellent text-figures and plates with which they are illustrated. The pioneer discoveries of Leidy, Marsh, and Cope furnished for many years a continual series of surprises for the student of extinct vertebrates; their successors during the past decade and a half have not only filled in many details in the preliminary view thus obtained, but have also been scarcely less successful in recovering unexpected groups and missing links. Present explorers have, indeed, the advantage of being able to pursue their work in the remote west in peaceful leisure, without any armed escort, and so have facilities for determining the relative positions of the strata from which they excavate the various fossils. In the early days, with hurried traverses, there was a tendency to decide the relative ages of the fossils solely by their own peculiar features, without any exact observations in the field. The result was sometimes an argument in a vicious circle. As shown by the volume now before us, that is all changed. We find detailed descriptions of specimens from the Permian of Texas, the Upper Cretaceous of Montana, the Eocene of Wyoming, and the Miocene of South Dakota. Accompanying them are well-illustrated exact accounts of all these formations and localities, determining the relative ages of the genera and species which were obtained from them.

The scientific work of the palæontologists in the American Museum is of two kinds. Part is devoted to the reconstruction and mounting of skeletons of general interest; part is concerned with the most detailed and special research, for which it often happens that not more than mere fragments are available. The publications record the results in both directions, and thus provide ample material, not only for the specialist, but for anyone interested in the broader features of natural history. It must also be added that the reconstructed skeletons are prepared with the greatest scientific care. The fine example of the Columbian mammoth now described, for example, was mounted after an elaborate study of the arrangement of the footprints of a living elephant and the attitude of its limbs when walking. The skeletons of Equidæ were similarly mounted after studies of the living horse—especially after a study of the Arab, to which one article in the new volume is devoted. Among startling mounts for which existing animals give little help may be specially mentioned the reconstructed skeleton of Naosaurus, which is one of the primitive reptiles from the Permian of Texas not hitherto found in a complete state. It is a long-bodied, squat reptile, with a formidable array of sabre-like teeth, and a high, thorny frill along the back, which is supported by the much-elongated neural spines of the vertebræ (Fig. 1). Prof. Osborn, who describes this specimen, is careful to explain exactly on what material the various parts of the recon-

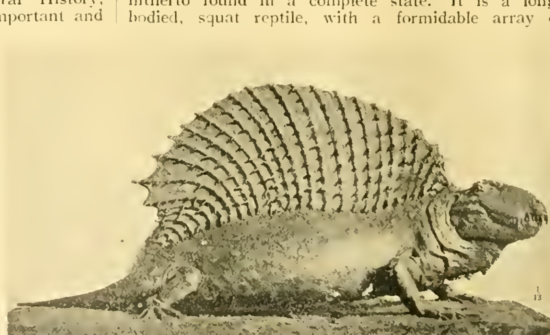

FIG. 1.—Model of *Naosaurus claviger*, by Mr. C. R. Knight.

[1] "Fossil Vertebrates in the American Museum of Natural History." Department of Vertebrate Palæontology. Vol. iii., Articles collected from the American Museum Bulletin for the years 1904–8, by H. Fairfield Osborn, &c. (New York, 1909.)

struction are based, so that each may judge of the extent to which it is trustworthy.

Perhaps the most interesting real novelty is a small skeleton from the Middle Eocene of Wyoming, determined by Prof. Osborn to belong to a primitive armadillo. Fragments of this animal were obtained some years ago by Dr. J. L. Wortman, and ascribed by him to a Lemuroid under the name of Metacheiromys. Four good specimens now seem to show that it is truly an armadillo, differing chiefly from the typical existing armadillos in "the probable presence of a leathery instead of a bony shield, of an enamel covering on the single large caniniform teeth in the upper and lower jaws and the degeneration of other teeth." This discovery confirms the suppositions of Marsh, Wortman, and Schlosser as to the existence of Edentata in North America in the Eocene period; and it adds to the difficulties of understanding the early Tertiary mammal faunas of South America.

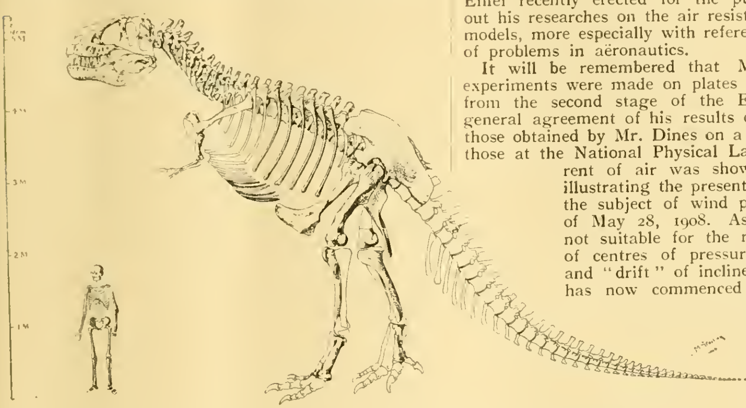

Fig. 2.—Restoration of *Tyrannosaurus rex*. From the type skeleton, American Museum of Natural History.

Another astonishing discovery is that of a colossal carnivorous Dinosaur, Tyrannosaurus (Fig. 2), from the Upper Cretaceous (Laramie formation) of Wyoming and Montana. It has hitherto been supposed that the flesh-eaters were all much smaller than the largest vegetable-feeders among Dinosaurs; but here is a reptile like Megalosaurus, with a skull from 4 to 5 feet in length, and when standing on its heavy hindquarters reaching a height of from 16 to 17 feet. Another new herbivorous Dinosaur, Ankylosaurus, from the same geological formation, measures 14 feet in length, and is armoured like the South American Glyptodons.

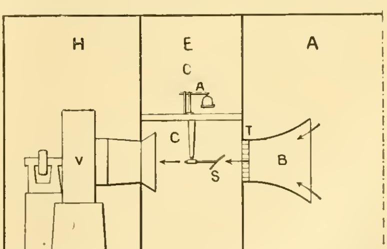
The technical papers on remains of horses and rhinoceroses, by Prof. Osborn and others, and on camels and deer, by Dr. Matthew, are of extreme scientific value. The discussion of the extinct horses is especially exhaustive, and the result is that it becomes impossible at present to recognise any exact genetic series. Mr. Gidley even remarks that "there is a considerable phyletic hiatus between the groups of the Equidæ, which are as yet not bridged over by intermediate forms"; and he adds that this hiatus is particularly marked between the Anchitherium-group and the Protohippus-group, which "greatly overlap each other in time." Dr. Matthew's explanation of most of our difficulties in understanding the evolution of the European and North American Tertiary mammalia is that northern Asia was their actual place of origin. He thinks that "in Europe, on one side of this centre, in America, on the other side, we have parallel series of approximate phylogenies; sometimes closer in the one country, sometimes in the other." Until the early Tertiary mammalia of northern Asia are discovered, we cannot advance much further towards real origins.

Prof. Osborn and his associates are indeed to be congratulated on the wide import of the work they have done, and the excellent manner in which it is published. We would commend it to the notice of all students of biology. A. S. W.

EXPERIMENTS ON AIR RESISTANCE.

In *La Nature* (February 26) there is a description by M. Fournier of the new laboratory which M. Eiffel recently erected for the purpose of carrying out his researches on the air resistance of plates and models, more especially with reference to the solution of problems in aëronautics.

It will be remembered that M. Eiffel's earlier experiments were made on plates and models let fall from the second stage of the Eiffel Tower. The general agreement of his results on flat plates with those obtained by Mr. Dines on a whirling table and those at the National Physical Laboratory in a current of air was shown in the curves illustrating the present writer's article on the subject of wind pressure in Nature of May 28, 1908. As this method was not suitable for the rapid determination of centres of pressure, and the "lift" and "drift" of inclined plates, M. Eiffel has now commenced experiments in a current of air, and the manner in which this current is maintained presents some novel and interesting features. Hitherto, experiments by this method have been carried out by suspending the models in a long channel with parallel sides through which air was drawn by means of a fan. This arrangement is open to two objections—(1) the difficulty of maintaining the velocity of the current uniform across the channel, and (2) the limited size of the models which could be used without an appreciable effect on the resistance due to the walls of the channel. The first difficulty is overcome by introducing resistances to the flow where necessary, which is a long and tedious process, and the second by limiting the size of the models to within two or three per cent. of the area of the channel. The novelty of M. Eiffel's method consists in his using a comparatively short channel, and in suspending his models in a closed



chamber which constitutes an enlargement of the channel.

The general arrangements will be clear from the diagrammatic sketch in the figure. C is the observation chamber, which is air-tight, and provided with a platform for carrying the observer and the necessary measuring appliances. B is the bell-mouthed air inlet, which is provided with a series of guide plates of honeycomb section on the delivery side to ensure that the air enters the chamber in parallel filaments. V is the outlet and suction fan. S is the model under test, connected to the weighing beam at A.

The advantages of this method as regards simplicity, comparative cheapness of construction, and convenience in making the observations are obvious, and in respect of its accuracy it is claimed that, using the results of M. Eiffel's earlier experiments on falling plates as data, a complete check has been afforded by the results obtained in the new apparatus. It may be doubted, however, if the accuracy of this method is so great as that obtained in a carefully designed parallel channel, for there can hardly fail to be a disturbance of the stream lines due to the sudden enlargement at the inlet similar to that observed in the flow of water. From a curve published in the article, it appears that plates as large as 90 cm. by 15 cm. have been used in a current drawn from an inlet 150 cm. in diameter. According to the writer's experience with this method, the apparent pressure for normal impingement of the current on a plate the area of which is the same fraction of that of the inlet as in the examples cited would be about 10 per cent. in excess of its true value, but in the case of small inclinations, which is, of course, relatively more important in aëronautical work, the error would be much smaller, and possibly of the same order of magnitude as those incurred in the estimations of the velocity of the current. In this branch of aëronautics valuable results may be expected from M. Eiffel's researches.

T. E. Stanton.

C. H. GREVILLE WILLIAMS, F.R.S.

Charles Hanson Greville Williams was born at Cheltenham, September 22, 1829, the son of S. Hanson Williams, a solicitor; his death occurred on June 15, 1910. He commenced his professional career as first assistant to Prof. Anderson, of Glasgow University; after some years spent in research work he moved to Edinburgh, where he conducted a tutorial class under Dr. Lyon Playfair. From 1857 to 1859 he was lecturer on chemistry in the Normal College, Swansea. In 1859 he returned to Glasgow as chemist to the works of Messrs. Miller, chemical manufacturers. He migrated to Greenford Green in 1863, remaining with Messrs. Perkin until 1868. About that year he entered into partnership with M. Édouard Thomas, at the Star Chemical Works, Brentford, the firm being makers of coal-tar colours, and subsisting until 1877. Mr. Greville Williams about this time gave up his connection with manufacturing chemistry and became photometric supervisor to the Gas Light and Coke Company, with whom he remained until 1901, then retiring into the country, where he seldom saw his old friends and acquaintances, but was much interested in the study of the ancient Egyptian language and the translation of inscriptions. Until rheumatism disabled him he was an expert draughtsman and calligraphist, a fair game shot, and an enthusiastic angler. Although in reality a charming companion, with unusual conversational powers, and a keen appreciation of literary and artistic culture, Greville Williams possessed a very modest and retiring disposition, and became, especially of late years, an almost complete recluse. He was more nervous about his state of health than he need have been, and, in consequence, cut himself off unnecessarily from scientific and social intercourse. This isolation was also due, no doubt, in part to his straitened circumstances, which necessitated strict economy and debarred him from the continuance of his scientific researches—hard lines for a thorough enthusiast; and such he was, possessed, moreover, with the true chemical instinct and a general scientific aptitude. It is a pity that the genius for investigation which was shown in his researches on isoprene, on beryl, and on the bases from bituminous shale, from the Boghead mineral, and from the destructive distillation of cinchonine, did not develop in accordance with more modern methods in his later years. But he made many interesting discoveries, and has left a considerable record of thoroughly sound work.

Greville Williams was elected F.R.S. in June, 1862. He outlived the rest of the distinguished "fifteen" of that year. It was in 1862 also that he joined the Chemical Society. He contributed a number of papers to the publications of these societies, as well as many notes to the *Chemical News*, and also wrote articles for Ure's Dictionary and for Watts's Dictionary, as well as for the *Journal of Gas Lighting*. His chief literary work was "A Handbook of Chemical Manipulation" (Van Voorst, 1857); a supplement appeared in 1879.

On November 25, 1852, Greville Williams married Henrietta Bosher; she died on February 16, 1904. One son and three daughters survive.

The writer of this notice has lost a friend of nearly sixty years' standing—a friend of rare quality and of high Christian character.

A. H. C.

NOTES.

We announce with deep regret the death, on Monday last at Milan, at the age of seventy-five years, of Prof. G. V. Schiaparelli, Foreign Member of the Royal Society.

The death (on June 12) is announced of Dr. W. H. Seaman, professor of chemistry in Harvard University, at the age of seventy-three years.

We regret to announce the death, on July 4, of Mr. R. Russell, I.S.O., who was for thirty-six years connected with the administration of education in Natal. In 1877 he became Superintendent of Education, and retired in 1903.

At the general monthly meeting of the members of the Royal Institution, held on Monday last, it was announced that the King has consented to become Patron of the institution.

The Janssen prize of the Paris Academy of Sciences has been awarded to Prof. W. W. Campbell, director of the Lick Observatory, University of California.

Sir J. J. Thomson, F.R.S., has been elected president of the Junior Institution of Engineers, in succession to Sir H. J. Oram, K.C.B.

Dr. F. A. Bather, F.R.S., has been appointed by the trustees to represent the British Museum (Natural History) at the forthcoming International Geological Congress in Stockholm.

The Cullen Victoria Jubilee prize has been awarded by the Royal College of Physicians of Edinburgh to Dr. R. W. Philip, for his work on tuberculosis. The prize is awarded once in every four years for the "most important contribution to practical medicine."

THE Journal of the American Medical Association states that a bronze relief portrait of Prof. W. Osler, F.R.S., has been placed in Osler Hall of the Medical and Chirurgical Faculty, Baltimore. It is an enlargement of the small one now in the Johns Hopkins Medical Library.

MR. C. O. WATERHOUSE, I.S.O., who for the period of forty-four years was in the service of the trustees of the British Museum, has just retired from the position of assistant-keeper in charge of the insect section of the Zoological Department of the Natural History Museum. To mark the occasion of his retirement, he was last week presented by many colleagues and friends with an illuminated address, a Sheraton bureau-bookcase, a gold watch, and an aneroid barometer.

PROF. ANGELO MOSSO asks us to announce that the Monte Rosa laboratories, which are equipped with all necessary scientific instruments, will re-open on July 15, and that the Royal Society has at its disposal nominations for two workers in botany, bacteriology, zoology, physiology, terrestrial physics or meteorology.

THE banquet to the five past-presidents of the Chemical Society (Prof. W. Odling, F.R.S., Sir Henry E. Roscoe, F.R.S., Sir William Crookes, F.R.S., Dr. Hugo Müller, F.R.S., and Dr. A. G. Vernon Harcourt, F.R.S.) who have attained their jubilee as fellows of the society is to take place at the Savoy Hotel on Friday, November 11 next. Applications for tickets must be made to the assistant secretary of the society by, at latest, November 4. It will be remembered that the banquet was postponed from May 26 in consequence of the death of the King.

A REUTER message from Catania states that a strong shock of earthquake was felt on Sunday morning in Sicily, at Giarre, Linguaglossa, and Zafferana. A slight shock was experienced at Mimeo.

THE twenty-first annual conference of the Museums Association was opened on Tuesday at York, when the president, Dr. Tempest Anderson, delivered an address on "Volcanoes and their Museum Treatment," and papers were read by Dr. F. A. Bather, F.R.S., Dr. Scharff, Dr. E. L. Gill, and Mr. L. E. Hope on, respectively, "Palæontology Exhibits at the Japan-British Exhibition," "Cleaning Bones by a Dry Sand Process," "A Method of Exhibiting Corals," "A Simple Way of Exhibiting the Reverse of Coins and Medals," and "The Natural History Records Bureau at the Carlisle Museum."

AN exhibition of Hygiene was opened at Buenos Aires on July 3. The British section is reported to be small. It is divided into twenty-nine sub-sections, and contains specimens of surgical instruments, orthopædic appliances, and drugs. The French section is incomplete. Italy exhibits numerous health foods. Chile furnishes exhaustive bacteriological laboratories, mainly for veterinary research. The Argentine Asistencia Publica displays first-aid and life-saving appliances, preventives, &c. The promised agricultural and railway exhibitions are expected to be opened this week.

THE fifth meeting of the International Congress of Mathematicians will take place at Cambridge in 1912. In connection with one of the sections of the congress, an International Commission on Mathematical Teaching has been constituted, which includes delegates appointed by the various Governments interested in the congress, and a series of national sub-commissions has been established to assist the International Commission. The President of the Board of Education has appointed Sir George Greenhill, F.R.S., Prof. W. W. Hobson, F.R.S., and Mr. C. Godfrey to be the British delegates, and he has further appointed an advisory committee to assist the commission in the collection of reports and papers on the teaching of mathematics, and this committee, which is to act also as the British sub-commission, has been constituted as follows:—Mr. C. E. Ashford, Sir G. H. Darwin, F.R.S., Mr. C. Godfrey, Sir George Greenhill, F.R.S., Mr. G. H. Hardy, F.R.S., Prof. W. W. Hobson, F.R.S., Mr. C. S. Jackson, Sir Joseph Larmor, F.R.S., Prof. A. E. H. Love, F.R.S., and Prof. G. A. Gibson. Mr. C. S. Jackson is honorary secretary to the sub-commission.

THE programme of the joint summer meeting of the Institution of Mechanical Engineers and the American Society of Mechanical Engineers is now available. As has already been announced, the meeting will take place in Birmingham and London on July 26 to 30. The following papers are to be read and discussed:—In Birmingham: English running-shed practice, by Mr. C. W. Paget; engine-house practice, or the handling of locomotives at terminals to secure continuous operation, by Mr. F. H. Clark; handling locomotives at terminals, by Mr. F. M. Whyte; handling locomotives, by Mr. H. H. Vaughan; American locomotive terminals, by Mr. W. Forsyth; high-speed tools, and machines to fit them, by Mr. H. I. Brackenbury; tooth-gearing, by Mr. J. D. Steven; interchangeable involute gearing, a joint paper by Members of the Committee of the A.S.M.E. on standards for involute gears. In London: electrification of suburban railways, by Mr. F. W. Carter; cost of electrically-propelled suburban trains, by Mr. H. M. Hobart; economics of railway electrification, by Mr. W. B. Potter; electrification of trunk lines, by Mr. L. R. Pomeroy; electrication of railways, by Mr. G. Westinghouse.

IN connection with the summer meeting of the Association of Technical Institutions, the Mayor and Mayoress of Salford are to give a garden-party in Peel Park, Salford, and hold a reception in the Royal Museum and Art Galleries on Thursday, July 14.

THE sixty-ninth annual meeting of the Medico-psychological Association of Great Britain and Ireland will be held at the Royal College of Physicians, Edinburgh, on July 21 and 22, under the presidency of Dr. John Macpherson. Dr. C. H. Bond, 11 Chandos Street, Cavendish Square, W., is the honorary general secretary.

AN International Congress of Forensic Medicine will be held at Brussels on August 4 to 10. The programme will include psychological medicine, bacteriology, toxicology, and legislation in relation to legal medicine. Governments, academies of medicine, universities, and associations of chemists and toxicologists have been invited to send delegates. There will be an exhibition of apparatus and medical instruments in connection with the congress. The general secretary is Dr. C. Moreau, rue de la Gendarmerie, 6, Charleroi.

ACCORDING to the Journal of the Royal Society of Arts, the second International Congress on Industrial Diseases is to be held in Brussels on September 10 to 14 next. Among the questions to be discussed are:—Can industrial diseases be distinguished from accidents? What should be their distinctive characteristics? What medical equipment is provided in mines, factories, workshops, &c.? the present state of the problem of ankylostomiasis; the eye and eyesight in connection with industrial diseases; work in compressed air.

The tenth International Geographical Congress is to be held in Rome on October 15 to 22, 1911. The congress will be divided into eight sections, and communications may be made in Italian, French, German, or English. Abstracts of papers proposed for presentation to the meeting must be sent in not later than April 30, 1911, and reports on subjects brought before previous congresses or suggested by the executive subcommittee must be received not later than August 31, 1911. The president of the congress is the Marquis Raffaele Cappelli, president of the Italian Geographical Society.

According to *Science*, plans for the extension of the American Museum of Natural History are being prepared by the trustees. The present building, erected between 1874 and 1908, includes eight units, and the plans now in preparation contemplate an additional six units, completing the central hall, the east and west transepts, the east entrance pavilion, and the south-east façade.

A society called the Christopher S. Ledentzoff Society for the Development of Experimental Sciences and their Practical Applications has been formed in connection with the Moscow Imperial Technical School, the objects of which are to assist discoveries and experiments in connection with natural science; to develop technical inventions and improvements; to investigate and apply to practical use any scientific or technical discovery or improvement. The society expresses the hope that its aims will attract the notice of all similar institutions and persons working in scientific and technical spheres, and appeals for assistance to all such institutions and persons for any support which might be given by (*a*) interchange of correspondence; (*b*) a supply of lists of privileges and patents, and reports on scientific and technical subjects. Further particulars as to the aims of the society may be obtained from the secretary, care of the Imperial Technical School, Moscow.

A geographical society, called the Servian Geographical Society, has been established at Belgrade. Its first president is Prof. J. Cvijic. The society proposes to begin the publication of a quarterly journal in January next.

The Institute of Chemistry of Great Britain and Ireland gives notice of the following examinations:—in biological chemistry, bacteriology, fermentation and enzyme action, with special reference to the chemistry and bacteriology of food-stuffs, water-supply and sewage disposal, and the application of biological chemistry to industries and manufactures, beginning on Monday, October 17 next; in chemical technology in October next, the exact date to be announced later.

Speaking in the House of Commons on Wednesday of last week on the Colonial Office Vote, Colonel Seely, the Under-Secretary for the Colonies, referred to the subject of sleeping sickness, and the work that has been done or is in progress in combating it. Coincident with the coming of the white man there had been, he said, a spread of various diseases. The spread of sleeping sickness alone had been most remarkable and disastrous. How many persons had died they did not know, but that hundreds of thousands had died they did know. Tremendous efforts had been made by many countries, and he thought we might claim especially by this country, to remove this great scourge. Sir David Bruce went, with his wife, into the heart of the plague-stricken country, and spent many months there investigating this great scourge of sleeping sickness. Almost every person in the place where he lived was suffering in some degree from this sickness, and when he told the House that, out of the hundreds of thousands of cases, they did not know of a single case of recovery, he thought they would realise to how great an extent those who tried to deal with the disease took their lives in their hands when they went out to these countries. He had mentioned Sir David Bruce, but there were many others. Some had already died in this great cause, and their names were, alas! already forgotten. But when the history of brave deeds came to be written, the deeds of those men who had gone into the heart of Africa to try to combat this insidious and most fatal of all diseases would not be forgotten, and would perhaps be considered as giving more striking proof of the ability of men to overcome natural fear than almost anything else in the annals of mankind. We now knew that these diseases were caused by flies, but the difficulty of finding a remedy was immense. It was thought that the removal of the natives from the infested areas might prove a remedy. Sleeping sickness was caused by the tsetse-fly, and it was thought that if the population could be removed from the shores of the lakes where alone that fly could live, they would be cured. Unfortunately, that had not proved to be entirely the case. But still we did know a great deal more than we did before about the origin and cause of sleeping sickness, and we had checked the mortality to a most remarkable degree.

Dr. W. L. Duckworth and Mr. W. J. Pocock contribute to vol. xiv. of the Cambridge Antiquarian Society's Proceedings for the current year a paper on a collection of human bones found in the course of excavations on the site of an Augustinian Friary near the Corn Market, Cambridge. Among these appear specimens of a tall, broad-headed race which may be assigned to the British Bronze-age type, to early Danish immigrants of the Borreby class, or to later arrivals from a southerly region, perhaps Normandy or Burgundy, these last being foreign ecclesiastics who founded the Cambridge Friary. After full discussion of the question, Dr. Duckworth favours the last explanation. An excavation at Durham supplies similar relics of foreign bishops, and the proportion of these broad-headed men is too great to be provided by the local mediæval population, which, though it doubtless contained individuals of the Bronze-age type, was yet, on the whole, characterised by a very large majority of individuals with distinctly narrow heads.

Mr. W. Morfitt has been for some time engaged in the examination of a series of pit-dwellings accidentally discovered in the district of Holderness, in the East Riding of Yorkshire. Canon Greenwell and Mr. R. A. Gatty contribute an account of these discoveries to the June issue of *Man*. The people occupying this district, much of which, since their time, has been destroyed by encroachments of the sea, were evidently a very early Neolithic race, probably an early branch of that which introduced polished stone implements. Those which they possessed are almost Palæolithic in character. The fauna, however, which consisted of *Bos longifrons*, the horse, sheep or goat, hog, and red deer, is distinctly Neolithic. The only evidence of their acquaintance with the sea is the vertebra of a whale, which, on the analogy of the Guachos of the River Plate, Prof. Boyd Dawkins supposes to have been used as a seat.

The Takelma language, one of the distinct linguistic stocks of America, is now nearly extinct, being spoken by only a few survivors of the tribe in the Siletz Reservation, western Oregon. It is therefore fortunate that Mr. E. Sapir, working under the direction of the American Bureau of Ethnology, has been able to secure the record of a considerable body of their tribal mythology and folklore. This report, issued by the University of Pennsylvania, and forming part i., vol. ii., of their Anthropological Publications, is valuable from a linguistic point of view. The beliefs and mythology of the tribe exhibit curious resemblances and variances when compared with those of the neighbouring tribes, the explanation of which awaits further investigation.

To the June number of the *American Naturalist* Dr. R. L. Moodie contributes a note on the alimentary canal of a branchiosaurian salamander from the Carboniferous shales of Mazon Creek, Illinois, for which the new generic and specific name *Eumicrerpeton parvum* is proposed. The specimens, for there are two, are preserved in nodules, and were it not that soon after death the œsophagus became loosened and displaced, the viscera would recall those of a freshly dissected modern salamander. The author has compared the viscera with those of several genera of modern salamanders, and finds that they come nearest to those of an immature example of *Diemyctylus torosus* from Orcas Island, Puget Sound, the next nearest being Desmognathus, Spelerpes, and Hemidactylus. It is suggested that the adults of the three latter retain an ancestral condition of the intestine which is transient in Diemyctylus, and the author finds in the resemblance of the viscera of the fossil to the recent forms confirmation of his theory that modern salamanders are directly descended from the Branchiosauria.

In the same (June) issue of the *American Naturalist* Dr. J. Stafford gives a further account of his investigations on the early developmental history of the Canadian oyster, of which the first part was published in the journal cited for January, 1909. The author systematically employed plankton-nets in collecting the larvæ, which he claims to have been the first to recognise definitely in Canadian waters. He has also identified stages in development hitherto unobserved, including the young stages of the spat. He has defined the spatting period and the period during which the larva is free-swimming, while the developmental history has been followed up to adult stages. His results will, it is believed, be of importance in connection with commercial oyster-culture.

In a report on the giant moth-borer (*Castnia licus*), published at Georgetown, Demerara, Mr. J. J. Quelch directs attention in the strongest manner to the damage threatened to sugar-cane plantations, which form the staple industry of the colony, by the attacks of this insect. In spite of remedial measures, Enmore Plantation, where this insect inflicted so much damage in 1904 and 1905, is still suffering great loss, while Non Pareil Plantation is equally, if not more severely, affected. Some idea of the nature of the damage may be gleaned from the fact that the adult caterpillars are 3 inches in length and nearly ½ inch in thickness, and that their growth is abnormally rapid. Concerted action on the part of plantation-owners is essential if the plague is to be stayed.

A list of the grasses of Alaska, prepared by Prof. F. Lamson-Scribner and Mr. E. D. Merrill, occupies vol. xiii., part iii., of the Contributions from the United States National Herbarium. Most of the material examined comes from the coast region, as very few botanists have ventured into the practically unknown regions of the interior, so that the present list may be regarded as a working basis for future collections. It is very remarkable that not a single species of the series Panicaceæ has been collected, while all the tribes except Bambuseæ of the other series Poaceæ are represented. Poa furnishes a number of species, while Calamagrostis, Bromus, and Agropyron are well represented. The authors have provided analytical keys to the genera and species, as well as a short description for each item.

The authentic list of new garden plants of the year 1909 has been issued as Appendix iii. to the current volume of the *Kew Bulletin*. The Orchidaceæ provides, as usual, more species and varieties than any other family, amongst them being *Cirrhopetalum longissimum*, a fine plant introduced from Siam; *Dendrobium Sanderae, D. acuminatum*, both from the Philippines; and *Megaclinium purpureorachis*, from the Congo. China supplies a fair quota of plants, notably *Primula Forrestii, P. Littoniana, P. Bulleyana*, and *Rhododendron Souliei*, besides sharing with Japan in the supply of species of Juglans. The genus Salix receives additions from Asia, while Mexico furnishes several species of Mammillaria. The Kew introductions include an Encephalartos, *Baikiaea insignis*, a leguminous evergreen tree, and *Strophanthus Preussii*, a climbing shrub, all from tropical Africa; also *Euphorbia Ledienii*, from South Africa. Six new species of the fern genus Nephrolepis and *Adiantum grossum* are noteworthy.

The International Commission on Glaciers has just issued the fourteenth report upon "Les Variations périodiques des Glaciers," by Prof. E. Brückner and M. E. Muret (*Extrait des Annales de Glaciologie*, t. iv., March, 1910, pp. 161–76. Berlin: Borntraeger, 1910). This useful report, covering the year 1908, shows that the majority of glaciers under observation still continue to shrink, though the changes, as a rule, are not important. In the Swiss Alps fifty-three glaciers are probably or certainly decreasing, while fourteen are in the opposite condition. In the eastern Alps only one glacier shows some advance; in the others the general retreat continues. This it does, so far as observed, in the Italian and French Alps, but in the Pyrenees there is generally an increase, though not large. Of Norwegian glaciers thirty-five have been observed, and the table published ranges in most cases from 1904 to 1908 inclusive. In the latter year ten glaciers were growing and twenty-two shrinking. The author, Mr. P. A. Øyen, directs attention to the fact that in the central highlands the oscillation of the glaciers nearly corresponds with that of the climate, but in the western coast range it is rather retarded. In Sweden some advance is perceptible. The North American glaciers are oscillating, more especially in Alaska, and from Asia little precise information has been received. Evidently the ground which glaciers began to lose nearly half a century ago has not yet been recovered.

The June number of the Journal of the Royal Geographical Society contains papers read before the society by Dr. T. G. Longstaff on glacier exploration in the eastern Karakorum, and by Prof. J. W. Gregory on the geographical factors that control the development of Australia. Dr. Longstaff achieved four important feats: the discovery of the Saltoro Pass; the fixing of the watershed in the eastern Karakorum; the discovery of the Siachen Glacier, the greatest glacier in Asia; the discovery of the peak "Teram Kangri," with an altitude of at least 27,500 feet, and possibly the highest mountain in the world. Prof. Gregory emphasises the isolation of Australia, the contrast between the marginal and the interior zones, and discusses the problem of the water-supply, the growth of population, and the question of the possibility of white colonisation in tropical countries such as North Australia.

In one of the useful scientific papers contained in the report of the Prussian Meteorological Institute for 1909 Prof. Hellmann compares the results of the exposure of thermometers in windows and in screens, such as are now generally used in this country, with the view of a future critical discussion of temperature conditions in Germany. The first part of the inquiry, contained in the report for 1908, showed that the introduction of the window screen about the year 1880, instead of the unprotected window exposure adopted at all stations prior to that date, did not interrupt the homogeneity of the observations. In the second part of the inquiry, experiments carried out at Potsdam as regards window exposure and exposure in "Stevenson screens," now used at about two-thirds of the German stations, show that not only the readings obtained by these two methods, but those at some of the more recent stations, are not strictly comparable. The differences are relatively small in coastal cloudy and windy weather, but considerably greater in dry and sunny inland districts. For details of this interesting discussion reference must be made to the tables and curves of the mean daily range shown for each month in the original paper.

Every month sees a fresh issue of the bulletins from the Bureau of Entomology of the United States Department of Agriculture. In Circular 119 Mr. Webster describes the clover root-borer (*Hylastinus obscurus*, Marsham), which has been introduced from Europe and become established in fields of red clover in the eastern States and elsewhere, causing considerable damage. The life-history has been investigated, but no method of extermination could be discovered. Mr. Ainslie deals with the large corn-stalk-borer (*Diatraea saccharalis*, Fab.). This insect burrows in the stalks of maize close to the ground, and so weakens them that they often break off in a strong wind. It was originally a sugar-cane pest, and came from the West Indies and from Central and South America, but for some time now has devoted its attention to maize.

The presidential address delivered by Prof. M. C. Potter before the British Mycological Society has now been issued, and deals with bacteria in their relation to plant pathology. The subject has been much neglected both by bacteriologists and mycologists, in spite of the fact that at least ten plant diseases are considered to be caused by bacteria. They are pear-blight (*Bac. amylovorus*), yellow disease of hyacinth (*Pseudomonas hyacinthi*), canker of the olive (*Bac. oleae*), corn-blight (*B. zeae*), potato wet-rot (*B. solaniperda*), soft rot of hyacinth (*B. hyacinthi-septicus*), bacteriosis of the vine (*B. uvae*), cucurbit wilt (*B. tracheiphilus*), brown rot of Cruciferæ (*Pseudomonas campestris*), and potato and tomato disease (*Bac. solanacearum*). A discussion of the problem is given and a bibliography is appended.

The Chemical Society's Journal for May contains two papers by Mr. H. E. Watson on the molecular weights of helium, neon, krypton, and xenon. The neon was prepared in a state of exceptional purity by fractionating 40 litres of a mixture of helium and neon over charcoal at the temperature of liquid air, and full details are given of the methods used both in effecting the purification and in measuring the density of the gas; repeated determinations with various highly purified fractions gave values ranging from 0·8997 to 0·9006, the mean of eleven values being 0·9002. In the case of helium only two measurements were made, giving the values 0·17830 and 0·17814, mean 0·1782; as the gas which was weighed amounted only to 0·05 gram, the experimental error is placed at 1 part in 2000. Reduction of observed densities to zero pressure gave for the molecular weights of the gases of the series the values:—helium, 3·994; neon, 20·200; argon, 39·881; krypton, 82·92; xenon, 130·22.

Although the use of oil as a means of securing more rapid dissipation of the heat generated in transformers has become almost universal in the case of large transformers, very little information has been available as to the relative merits of the various oil- and air-cooling devices. This information is now supplied in a paper by Mr. R. D. Gifford, of the University of Birmingham, which will be found in the May number of the Journal of the Institution of Electrical Engineers. His measurements show that if the cooling effect of the air in the case of a transformer be taken as unity, that of the free air would be about 1·1 and that of a strong air blast about 2. With oil cooling the effect rises to about 3, and if the oil itself is cooled by the passage of cold water through a worm immersed in the oil, the cooling effect becomes 6 or 7.

Bulletin No. 40 of the Engineering Experimental Station of the University of Illinois consists of an account of measurements made by Messrs. J. K. Clement and C. M. Garland of the heat transmitted through a steel tube of 1¼-inch external diameter, with walls ⅛-inch thick, from steam outside to water inside running through the tube. The temperature of the outside surface of the tube was measured at two points by means of thermojunctions of copper-constantan placed in small holes drilled in the tube. The temperatures of the incoming and outgoing water and of the steam were determined by mercury thermometers. Curves are given showing the variation of the heat transmitted with the velocity of the stream of water and with the temperature of the steam, and the resistance to the transmission of heat is shown to be almost entirely concentrated in the films of stagnant steam and water in contact with the surfaces of the steel tube. The authors regard the present communication, not as one devoted to new facts, but as a demonstration of the utility of their method of measurement, and propose to apply the method to the investigation of problems connected with steam boilers. We should like to point out that a good deal of work has already been done in this direction both in this country and in others, and it is to be hoped that the new experiments will be directed to the solutions of problems which have not been already dealt with by Mr. Jordan or by one or other of the experimenters mentioned in Prof. Dalby's bibliography of the subject contained in the Journal of the Institution of Mechanical Engineers for last year.

We learn from *Engineering* of June 24 that Lloyd's Register of British and Foreign Shipping is about to issue rules for internal-combustion engines for marine purposes. The rules are divided into four headings. The section concerning construction strongly enforces the importance of accessibility for examination and repair, and requires that engines of more than 60 brake-horse-power, which are not reversible, and are manœuvred by clutch, must be fitted with a governor or other arrangement to prevent the racing of the engine when declutched. The cylinders are to be tested by hydraulic pressure to twice the working pressure to which they will be subjected; the water-jackets of the cylinders to 50 lb. per square inch, and the exhaust-pipes and silencers to 100 lb. per square inch. The tables are comprehensive, embracing smooth-water and open-sea service boats, and engines of 4-stroke cycle and 2-stroke cycle. Separate fuel-tanks are to be tested, with all fittings, to a head of at least 15 feet of water. Oil-fuel pipes are to be of annealed seamless copper, with flexible bends, conical joints metal to metal, with a cock or valve at each end of the pipe conveying the fuel from the tank to the carburettor or vaporiser. The machinery is to be submitted for survey annually, and practically all parts are to be examined, the fuel-tanks and all connections being, if deemed necessary by the surveyor, tested to the same pressure as when new. The screw-shaft is to be drawn at intervals of not more than two years.

In directing attention to the diversity of published results of compressive tests on cubes of concrete, the *Builder* for June 18 suggests that the explanation is to be found in the different methods and different pressures used in ramming the concrete into the test moulds. We may add to this explanation the fact that variation in the water used in mixing the concrete under test is a most important factor, influencing both the ramming pressure required and also the strength of the resulting specimen. Our contemporary suggests that an appliance such as is used in the Charlottenburg laboratory might be adopted in this country. In this appliance a ram is lifted by gearing and released by a cam, the arrangement being such that the ram always falls from the same height. After each blow the ram is automatically moved for a short distance in a direction parallel to the axis of the actuating wheel, while the mould is moved perpendicularly to the same axis. The effect is to ensure uniform ramming of the whole. It is stated that the experience at Charlottenburg shows the resistance of test blocks so prepared to be very uniform for concrete of given composition.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JULY:—

July 12. 14h. 11m. Jupiter in conjunction with the Moon (Jupiter 2° 58′ S.).
15. Mercury. Illuminated portion of disc = 0·978, Venus = 0·813.
16. 10h. 39m. Minimum of Algol (β Persei).
19. Saturn. Major axis of outer ring = 39·96″, minor axis = 12·35″.
21. 9h. 6m. Uranus in conjunction with Moon (Uranus 3° 44′ N.).
27. 6h. 29m. to 9h. 9m. Transit of Jupiter's Sat. III. (Ganymede).
27–31. Meteors abundant from Perseus and Aquarius.

HALLEY'S COMET.—A number of observations, generally confirmatory of those already noted in these columns, are recorded in No. 4421 of the *Astronomische Nachrichten*. Dr. Wolf gives a sketch of the tail showing its position, with regard to the surrounding stars, and its form as shown on a photograph taken on May 12 at 14h. 15m., Königstuhl M.T. This shows that a straight, narrow tail extended from the head to just south of 70 Pegasi, and from there to the end was bounded by two faint clouds of cometary matter, too faint to be seen visually. The outline of the northern cloud was very irregular, and departed considerably from that of the visual tail, and in any discussion as to whether the earth passed through any mass of cometary material these abnormal extensions must be taken into consideration.

Prof. Seeliger reports that, at Munich, careful observations failed to reveal any trace of the comet's head or nucleus during its passage across the solar disc, nor were any magnetic or electrical phenomena recorded which could be, with certainty, attributed to the comet. So many observers report the non-detection of the nucleus that it must now be taken as fairly certain that the material of which the head and nucleus are composed is too tenuous to interfere, effectively, with the passage of light.

M. Eginitis gives further details as to observations at Athens Observatory, and directs special attention to the peculiar shape presented by the comet on the evening of May 20. The appearance was very similar to that of a crescent moon, with a very bright condensation at the centre of the convex arc, and no extended tail was seen; such a form might be explained by assuming that the axis of the tail was nearly in the line of sight. This would also explain the apparent anomaly of the slight tail being turned towards the sun if one supposes that the curvature was sufficiently great; in this case, the passage of the earth through that part of the tail extending to its orbit would have been delayed some forty to sixty hours, and it appears to be probable, if these observations of May 20 are verified, that a passage did actually take place.

M. Comas Sola gives drawings showing the definite duplication of the nucleus on June 2, and the appearance of four or five separate condensations, *globes*, on June 4.

In an interesting communication to the *Comptes rendus* (No. 26, June 27, p. 1732), M. Nordmann discusses the amount and the nature of the light emitted by the comet, as observed with his colour-screen photometer. He finds that on three dates of observation, April 25, May 15 and 23, the nucleus contributed only about one thirty-seventh of the total light emitted by the head. By comparing his values with the observed diameters of the nucleus and coma, respectively, he deduces that towards May 15 the mean intrinsic light of the nucleus was about nineteen times that of the visible part of the coma. Taking the theoretical increase of light of a comet as varying in the ratio $1/r^2\Delta^2$, and comparing his observed with the calculated values, M. Nordmann finds that between April 25 and May 23 the augmentation of the brilliancy of the nucleus was much less than provided for by the theory. Finally, by the employment of his colour-screen method, M. Nordmann found that the distribution of energy in the spectrum of the nucleus was very similar to the distribution in the solar spectrum, and hence he concludes that the light of the nucleus is almost exclusively, if not entirely, reflected sunlight.

Mr. Leach, Malta, reports that, after finding the comet so faintly distinguishable on June 14, he gave up all hope of seeing it again. On June 25, however, he saw it quite clearly at 9 p.m., and was able to follow it each evening until the day of writing, June 30; with field-glasses, a tail 2° or 3° in length was clearly visible.

EPHEMERIS FOR COMET 1910*a*.—In No. 4422 of the *Astronomische Nachrichten* Prof. Kobold gives a continuation of his ephemeris for comet 1910*a*. The position is changing very slowly, and for July 7 is 21h. 40·5m., +33° 21·4′; an observation by Prof. Barnard on June 7 gave a correction of +7s., +1·6′, and showed the magnitude to be about 16·0.

PHOTOGRAPHS OF MOREHOUSE'S COMET.—From the Tokio Observatory we have received part vi., vol. iii., of the *Annales*, in which are reproduced nearly fifty excellent photographs of Morehouse's comet, 1908*c*. Messrs. Hirayama and Toda briefly describe the separate photographs, and discuss the remarkable changes which took place in the comet's tail. By comparing their results with those obtained at the Yerkes and Heidelberg Observatories, they find that between October 1 and 2 a recognised detached mass, at a mean distance of 2·4° from the head, was receding at an hourly rate of 8·5′; other values are:—October 15, 1° from head, northern mass 3·1′, southern mass 3·4′, per hour; October 15–16, 1·4° from head, 3·1′ per hour. As is pointed out, the accumulation of such data will serve to determine the nature of the repulsive force. A discussion of the photographs also discloses that on November 13, 14, 15, and 16, the outer streamers of the tail appeared to change in phase, predominating southwards on November 13 and 15, and northwards on November 14 and 16. This might be ascribed to a rotation of the head, with a period of forty-eight hours, but further discussion is necessary to establish this; in any case, the photographs show that if such a rotation existed it was not uniform throughout the tail, for the outer and inner streamers did not rotate with the same angular velocity.

THE DETERMINATION OF POSITION NEAR THE POLES.—As an excerpt from the *Geographical Journal* for March, we have received a copy of a paper by Mr. Hinks dealing with the methods of determining an observer's position when near the poles. Mr. Hinks suggests that a theodolite, say a 3-inch, read on both faces, would prove the most suitable instrument, and then proposes a modification of Sumner's method for the reduction of the observations. Two observations of the sun at two different known G.M.T.'s give two circles of equal altitude which intersect at the observer's position; a simple graphical method may be used for the reduction. A most interesting discussion, by well-known explorers, followed the reading of the paper and dealt, with varying conclusions, with the several points raised by Mr. Hinks; the chronometer difficulty appears to be an important one, and some curious refraction anomalies have to be considered.

The same subject was discussed by Herr Charlier in a paper which appeared in No. 4393 of the *Astronomische Nachrichten*.

THE VARIATION OF LATITUDE.—The usual provisional results obtained by the International Latitude Bureau are published, for 1908·0–1910·0, by Prof. Albrecht in No. 4414 of the *Astronomische Nachrichten*. A marked increase in the amplitude of the departure of the momentary, from the mean, pole took place during 1909, the previous curve, 1907–9, having shown a regularly increasing spiral form. During the ten years that the International Service has been at work the curve has been fairly regular, with maxima in the years 1903 and 1909; the latter is clearly shown on the chart published with the results.

NEW CANALS AND LAKES ON MARS.—Seventeen "canals" and two "lakes" which were seen at the Hem Observatory, and which M. Jonckheere has been unable to identify from previous records, are enumerated in No. 4420 of the *Astronomische Nachrichten*. This brings M. Jonckheere's total of new "canals" up to forty, the previous lists having appeared in earlier numbers of the same journal. One of the "lakes," at the junction of Aethiops and Cambyse, is described as small and feeble, and the other, at the junction of Astaboras and Anubis, as large and diffuse.

THE INTERNATIONAL CONGRESS AT DÜSSELDORF.

THE fifth International Congress of Mining, Metallurgy, Mechanical Engineering, and Practical Geology met at Düsseldorf on Monday, June 20. Whilst, strictly speaking, this is the fifth congress, it is only the third that has assumed a really international character. The first congress was held in Paris in the year 1878, in connection with the Great Exhibition of that year, its initiation being due to the efforts of a number of prominent French mining and metallurgical engineers, and more especially to that well-known French association, the Société de l'Industrie minérale. The next great Paris Exhibition of 1889 again provided the occasion for a second congress, but both these first two congresses were attended mainly by French engineers, and could scarcely be called international. At the Paris Exhibition of 1900 a vigorous effort was made to interest foreign as well as French engineers, and was supported warmly by both their English and their German colleagues, our Iron and Steel Institute and Institution of Mining Engineers both taking an active part in forwarding the scheme. This congress was thoroughly international in all respects, and at its closing meeting it was decided to hold a quinquennial international congress, the next, that of 1905, to be held at Liége, in connection with the International Exhibition planned for that year. This congress, again, was completely successful, and its members gladly accepted the invitation of the Rheno-Westphalian Mining and Metallurgical Industry to hold the next meeting at Düsseldorf. This town is in many respects the centre of the above industries, and is remarkable not only for its great industrial development, but also for its highly advanced artistic culture; it is, furthermore, well situated on the main railway system of central Germany, affording ready communication with all neighbouring countries, and is thus admirably adapted for the purpose of such a congress. On the opening day the congress numbered 1762 members, of whom 1128 were Germans and 634 foreigners, the latter comprising 94 from France, 74 from Great Britain, 65 from Austro-Hungary, and 57 from Belgium. The number of entries in the different sections were:—Mining, 1141; metallurgy, 1140; engineering, 939; geology, 784. Of course, it will be understood that many members had entered their names in more than one section.

The great majority of the members of the congress had arrived in Düsseldorf on Saturday and Sunday, June 18 and 19, and on Sunday evening there was an informal open-air gathering at the Zoological Gardens, this being an excellent opportunity to make and renew many acquaintanceships. The actual work of the congress began next morning, the meeting-place being the *Tonhalle*, a concert-hall belonging to the town of Düsseldorf, the large main hall of which was admirably adapted for the general meeting of the congress. There are several smaller lecture-rooms available for the meetings of the sections, although it must be admitted that the accommodation thus provided was in some cases barely sufficient for the large audiences that assembled to hear some of the more important of the papers. The geological section met in a suitable room close to the *Tonhalle*.

The general meeting was opened on Monday morning by the president of the organising committee, Mr. Edward Kleine, who welcomed the congress in a short address, in which he referred more particularly to the increase in the production of coal and iron that had taken place since the last meeting of the congress. His speech was translated, first into French and then into English, by Mr. E. Schaltenbrand, chairman of the board of management of the Steelworks' Association. The Prussian Minister of Commerce, His Excellency Mr. Sydow, also welcomed the members of the congress in the name of the Prussian Government and of the Imperial Chancellor.

The honorary consultative committee of the congress was then formed, after which the meeting broke up into the various sections, of which there were five, namely, i., Mining; ii*a*., Practical Metallurgy; ii*b*., Theoretical Metallurgy; iii., Mechanical Engineering; iv., Applied Geology.

The official list of papers submitted to these sections is as follows:—

Section i., Mining.—W. Zäringer (Nordhausen), the freezing process and its latest developments; F. Bruchausen (Dortmund), shaft sinking by the process of petrifaction; H. Grahn (Bochum), the use of compressed-air locks in sinking; — Viebig (Kray), the use of reinforced concrete in mine workings; Prof. J. Stumpf (Berlin), the steam-engine with unidirectional flow of steam, with especial reference to its use as a winding engine; W. Schultze (Essen), recent improvements in pumping plant; O. Pütz (Tarnowitz), the present position of hydraulic stowage in Germany; Dr. W. Kohlmann (Diedenhofen), the mining development of the Minette iron-ore district; P. Nicou (Nancy), the present position of the Minette mining industry in French Lorraine; Prof. K. Haussmann (Aachen), modern improvements in mine surveying; Prof. G. Franke (Berlin), conveying of coals from the working face; J. Loiret (Clermont-Ferrand), value of a rescue-chamber in an outburst of carbonic acid gas at the Singles Colliery, July 26, 1909; sudden outbursts of carbonic acid gas in the collieries of the Central Plateau of France; S. v. Bolesta-Malewski (Nalenczow), critical observations on the existing methods of winding, and a proposal for their modification; F. Schember (Vienna), the development of machine kirving in coal mining; Dr. H. Bruns (Gelsenkirchen), to what extent does coal mining contribute to the dissemination of infectious diseases? F. Trippe (Dortmund), hydraulic impregnation of the coal-face in the solid, and hydraulic coal-getting by the Meissner method; J. Taffanel (Lens), the French experiments upon coal-dust; W. E. Garforth (Pontefract), the British coal-dust experiments.

The last two very important papers were admirably illustrated, that of Mr. Garforth by a very fine series of coloured lantern-slides, and that of Mr. Taffanel by lantern-slides and by the kinematograph.

There were further presented to this section two reports on the testing of colliery ropes, namely, Prof. H. Louis (Newcastle-on-Tyne), report on the testing of colliery ropes in England; L. Denoel (Liége), the testing of winding ropes in Belgium. These are to form part of a complete international report on the standardisation of rope-testing.

Section ii.a, Practical Metallurgy.—Dr. Blasberg (Dahlhausen), changes in the composition of fire-brick; G. Arnou (Paris), notes upon electro-steel; P. Breuil (Couillet), rail-steel; — Esser (Differdingen), the present position of the Thomas process in Germany; Prof. G. Franke (Berlin), the present position of the briquetting and nodulising of iron-ores in Germany; R. Genzmer (Julienhütte), the open-hearth ore process in Germany; J. Hofmann (Witkowitz), gas-producers; H. Terpitz (Hubertushütte), the employment of various kinds of gas in the open-hearth furnace, and their respective influence on the quality of the products; O. Friedrich (Julienhütte), recent improvements in the construction of open-hearth furnaces; C. Grosze (Metz), the present position of the methods of purifying blast-furnace gases in Germany; Prof. F. Herbst (Aachen), on the development of coking as regards the construction of coke ovens and the improvement in mechanical appliances; Prof. E. Heyn (Gross-Lichterfelde), contribution to the subject of rusting; C. Irresberger (Mülheim), present-day iron-foundry practice in Germany; O. Mauritz (Nürnberg), the economics of the various forms of working blowing-engines in steel works; Dr. B. Neumann (Darmstadt), the existing processes for the production of electro-steel in Germany; H. Ortmann (Völklingen), improvements in the construction of rolling-mills during the last decade; Dr. R. Passow (Aachen), the value of the microscope in judging blast-furnace slags; Dr. J. Puppe (Dortmund), the results of recent investigations in rolling-mill practice in Germany; Dr. O. Rau (Aachen), the advances in the recovery of by-products in coke-oven plants; Dr. B. Schück (Berlin), a new process for the generation of hydrogen, and its application in metallurgy.

Section ii.b, Theoretical Metallurgy.—Dr. C. Benedicks (Upsala), the synthesis of meteoric iron; Prof. W. Borchers (Aachen), the reactions in the melting and refining of copper, their acceleration, and their simplification by electric smelting; Dr. K. Bornemann and P. Müller (Aachen), the electrical conductivity of alloys in the liquid state; Dr. H. Braune and E. Hubendick (Stockholm), the generation of producer-gas, free from tar, from uncoked fuel, from the point of view of organic chemistry; C. Brisker (Leoben), the theoretical and practical importance of the electric blast-furnace; G. Charpy (Montluçon), the part played by carbon and carbon monoxide in metallurgical reactions; Dr. W. Conrad (Vienna), the current and the voltage in the electric furnace; Dr. G. Gillhausen (Aachen), the balance of heat and of matter in the blast-furnace; Dr. P. Goerens (Aachen), the gases contained in the various kinds of iron; Dr. H. Grossmann (Berlin), the volumetric estimation of nickel and cobalt; Prof. Guillet (Paris), the thermic treatment of special steels; certain practical and theoretical observations upon cementation; — Joisten (Aachen), the influence of heat treatment upon the dimensions of the grain of iron; Prof. J. W. Richards (South Bethlehem), Gruner's ideal working of a blast-furnace; the *rationale* of dried blast; E. Richarme (Zarizinsky Savod), the dephosphorisation of iron in the presence of carbon; Prof. R. Ruer (Aachen), the iron-nickel system; O. Thallner (Remscheid), the relations between the thermic effect, the metallurgical phenomena, and crystallisation in basic and acid processes of electric fusion; F. Weyl (Aachen), cementation *in vacuo*; Dr. H. Winter (Bochum), the influence of galvanisation on the strength of wire; Prof. F. Wüst (Aachen), the causes of the economy of fuel and the increased production in the blast-furnace by the use of heated and dried blast; Prof. F. Wüst and — Felser (Aachen), the influence of segregation on the strength of ingot-iron.

It need only be said here that the division of the metallurgical section into two portions was rendered necessary by the large number of metallurgical papers presented, and even so the sections were somewhat overweighted with work.

Section iii., Mechanical Engineering.—M. Androuin and C. Stein (Paris), the influence of the improvements in heating on the development of machine forging; T. v. Bavier (Düsseldorf), the development of ventilators and compressors in German mining; P. Bernstein (Cologne), hydraulic compressors; P. Bodenstein (Kalk), modern ore-dressing; W. Ellingen (Cologne), aërial ropeways of great capacity; — Giller (Mülheim), haulage by compressed-air locomotives in mines; G. v. Hanffstengel (Leipzig), the cheapening of the cost of transport by means of wire-rope and electrical aërial railways;— Heym (Wetter), the influence of electricity on the development and efficiency of lifting appliances in mines and works; Dr. H. Hoffmann (Bochum), the working of motor engines, especially for winding engines, rolling-mill engines, and dynamos; Prof. P. Langer (Aachen), recent experience in large gas-engine plants; K. Maleyka (Berlin), electricity in metallurgy; W. Philippi (Berlin), electricity in mining; C. Matschoss (Berlin), the position of mining and metallurgy in the history of machine construction; Dr. Rateau (Paris), turbo-compressors; — Stach (Bochum), the development of independent and of central condensation; heat accumulators for the utilisation of waste steam; F. Tillmann (Saarbrücken), underground haulage.

It will be noticed that very few of these papers deal with purely engineering subjects; some of them are in the main metallurgical, and most of them are upon mining subjects. The only reason for their inclusion in this section lies in the fact that the other sections were overcrowded.

Section iv., Applied Geology.—Dr. C. Barrois (Lille), the origin of the clastic coal deposits and of the erratic pebbles found in the north of France; Dr. Beyschlag (Berlin), communication on the iron-ore supplies of the world; C. Capacci (Florence), the gold deposits of Abyssinia and Erythrea; Dr. G. Fliegel (Berlin), the tectonics of the Lower Rhine basin, and their importance in the development of the lignite formation; — Holz (Aachen), the utilisation of water-power, with special reference to Germany and Scandinavia; M. Krahmann (Berlin), the modern policy respecting mineral deposits, and its problems; P. Kukuk (Bochum), the tectonic conditions of the coal deposits of the Lower Rhine and Westphalia in the light of the most recent investigations; E. Link (Essen), the dams of the Ruhr district, and particularly the dam of the Möhne valley; A. Macco (Brühl), the science of mining economics, its objects and its limits; L. Mintrop (Bochum), on artificial earthquakes; H. Mortimer-Lamb (Montreal), the unique mineral resources of Canada; Dr. M. Mourlon (Brussels), a synthesis of Belgian geology as obtained from documents; Dr. H. Potonié (Berlin), the origin of coal; Prof. A. Renier (Liége), the state of our knowledge of the general stratigraphy of the Belgian coal-formation; B. Schulz-Briesen (Düsseldorf), the scientific and economic importance of practical geology; Dr. G. Steinmann (Bonn), the composite mineral veins in the South American Cordilleras; Dr. O. Stutzer (Freiberg), recent springs; H. Werner (St. Andreasberg), the silver-bearing veins of St. Andreasberg in the Harz; Dr. W. Wunstorf (Berlin), the coal-bearing formation in the region of the Rhine and the Maas; Dr. S. Papavasiliou (Naxos), on Grecian emery.

All this formidable list of papers was disposed of by the various sections in three sessions, on Monday morning and afternoon and on Tuesday morning. Whilst the standard of the various papers was, on the whole, a high one, some being, indeed, of especial interest, the discussions were disappointing, being, in general, brief, and of no great importance; the great majority of the papers were not discussed at all. This was probably due to the large number of papers set down for reading. It would have been far better to have limited their number, or to have read them only in the briefest abstract, so as to have left time for adequate discussion, this being usually the most interesting feature of such gatherings.

Tuesday afternoon, June 21, Wednesday, and Thursday were devoted to excursions, of which there was a list of more than forty, which gave an opportunity to see all the more important collieries and iron works of this flourishing industrial region. A special set of geological excursions was arranged for the members of section iv. An interesting series of trips had also been arranged for the ladies accompanying the members to a number of points of interest in and near Düsseldorf. The social functions included a reception on Monday evening, given by the town of Düsseldorf, a leading feature of which was an admirable speech by Mr. Marx, the Mayor of Düsseldorf. On Tuesday evening an official dinner was given in the large hall of the *Tonhalle*, after which a little allegorical play was performed. The conception of this was due to Dr. Schrödter, one of the general secretaries of the congress, and both the idea and its execution were in every respect beyond praise. On Wednesday evening a trip on the Rhine was made in one of the large steamers that ply on this river. This was rendered especially interesting by the presence of Count Zeppelin, who had come over in the forenoon from Friedrichshafen in his latest airship, the *Deutschland*.

The closing meeting of the congress took place at Essen under the presidency of Mr. Kleine. The secretaries of the various sections presented short reports on the work of each section. The only resolution submitted to the General

Meeting was one from the Mining Section, declaring that it was urgent that some international system for the unification of mining statistics should be adopted. This resolution was unanimously agreed to, and it was decided that steps should be taken to bring it to the notice of the various Powers that had sent representatives to the congress. An invitation to hold the next quinquennial congress, namely, that of 1915, in London was then submitted to the meeting by Prof. H. Louis (Newcastle-on-Tyne), and supported by Mr. G. C. Lloyd, secretary of the Iron and Steel Institute, and Dr. J. B. Simpson, president of the Institution of Mining Engineers. The invitation was tendered on behalf of the University of London, the Imperial College of Science and Technology, the Geological Society of London, the Institution of Mechanical Engineers, the Iron and Steel Institute, the Society of Chemical Industry, the Institution of Mining Engineers, the Institution of Mining and Metallurgy, and the Institute of Metals, and it was unanimously and enthusiastically accepted.

This ended the business of the congress proper, but a reception was given in the evening by the town of Essen, and on the following day a numerous contingent of members left in two special trains for Brussels, where arrangements had been made to receive them at the exhibition now in progress there.

From every point of view the Düsseldorf Congress may be pronounced a brilliant success. The local members exerted themselves to the utmost to entertain their visitors, and, thanks in no small degree to the excellent system of organisation that pervaded the whole affair, everything went without a hitch. It is a matter of sincere satisfaction that English technologists will now have an opportunity afforded them of returning the splendid hospitality of their foreign colleagues, but they will have to exert their utmost endeavours if they propose to maintain the high standard of excellence that has been set by the congress of 1910.

THE TUBERCULOSIS CONFERENCE AND EXHIBITION.

THE annual meeting of the National Association for the Prevention of Tuberculosis and the conference is still in full swing, though by the time that this goes to press most of the work, except the exhibition and the public lectures, will have been completed. A local committee, consisting of the Right Hon. Lord Balfour of Burleigh, K.T., Sir Alexander Christison, Bart., as chairman, Dr. R. W. Philip, treasurer, and Drs. W. Leslie Lyall, Geo. A. Mackey, and James Miller, secretaries, and a number of public and medical men, prepared an admirable programme for the large number of members, old and new, which has been carried out both fully and successfully.

The exhibition, which is probably the best of the kind that has yet been seen in this country, containing not only the ordinary travelling specimens, but a number of very fine preparations from Edinburgh and Cambridge illustrating the various phases of the tuberculous process in man and in animals, was opened on Friday, July 1, by the Countess of Aberdeen, whose interest in this work induced her to send over the Irish exhibit that has done such excellent service in Ireland. On the evening of the same day Prof. McWeeney, of Dublin, gave an interesting lecture on "Consumption: what it is and how it can be prevented."

On Saturday morning the teachers and scholars in the various school centres were addressed by the Countess of Aberdeen at one, by Dr. Jane Walther at another, and by Drs. Gray, McWeeney, Squire, and Woodhead at others. These addresses, according to the newspaper reports, appear to have been followed with keen interest by both teachers and scholars.

In the afternoon, the Royal Victoria Hospital Farm Colony at Springfield, Lasswade, a beautiful and healthful spot, was opened by Lady Dunedin. This farm is for convalescents from phthisis, and is to be a kind of training ground for those who have to earn their living after their recovery. As it is only at the stage of opening, little of the plan of operations could be seen, but it appears that Frimley is the model on which it is to be carried out.

On Sunday there was a special service for university students in the McEwan Hall (the "Aula" of the University). Dr. Norman McLeod presided, and Dr. Kelman and Dean Wilson both took part in the service. Prof. Osler, of Oxford, spoke of man's redemption of man, referring to the great work done during the last fifty years by those who had set themselves to the amelioration of the sufferings and disease of their fellows. Then followed a short service in memoriam of Robert Koch, in which Dr. Hermann Biggs, of New York, and Drs. Woodhead and Philip took part. The whole service was most impressive, and was attended by a very large congregation.

On Monday evening the annual meeting of the National Association for the Prevention of Consumption, presided over by Lord Balfour of Burleigh, was a most successful gathering, and, like all the other meetings, was very largely attended.

This was followed by a reception given by the Right Hon. the Lord Provost, Magistrates, and Council of the City of Edinburgh, in the splendid Museum of Science and Art, at which the members of the association and their friends were most hospitably entertained.

The four conference meetings, at which such subjects as "The Avenues of Infection in Tuberculosis," "The Prevention and the Administrative Control of Tuberculosis," "The Incidence of Tuberculosis in Childhood," and "The Working Man in Relation to Tuberculosis," were well attended, and the subjects were well discussed. These discussions should be productive of much good in the way of disseminating information on the various points raised. Popular lectures were given on Friday, Saturday, and Tuesday, and others will be given up to the end of the week, each lecture being in charge of an authority on his subject.

This conference and exhibition is an advance on anything of the kind that has yet been attempted, and its usefulness and popularity should encourage the executive of the association to repeat the experiment of a provincial meeting.

INTERNATIONAL UNION FOR COOPERATION IN SOLAR RESEARCH.

THE fourth conference of the International Union for Cooperation in Solar Research will take place on Mount Wilson, California, between August 29 and September 6. The meeting promises to be a very successful one, about forty astronomers and physicists from Europe having signified their intention of being present, as well as a large number of Americans.

The members of the union and others who have accepted Prof. Hale's invitation are invited by the Astronomical and Astrophysical Society of America to attend a meeting of that society which will be held at Harvard College Observatory on August 17. At the end of this meeting the astronomers will be taken from Boston to California by the train leaving Boston on August 20. One day will be spent at Niagara Falls, and another at Chicago, where, however, the time will not be sufficient to visit the Yerkes Observatory. The journey from Chicago to Pasadena will be made by the southern route, and a visit will be paid on the way to the Lowell Observatory at Flagstaff, while two days will be spent at the Grand Canyon. The party will reach Pasadena on August 27.

After the meeting, it has been arranged that visitors who may wish to join shall travel by way of Santa Barbara and Monterey to San José, from whence the Lick Observatory may be visited.

Those intending to travel with the party from Boston to Pasadena, or join the party at any point on the way, are requested to send in their names to Prof. S. I. Bailey, Harvard College Observatory, Cambridge, Mass., at as early a date as possible, in order that the necessary railway arrangements may be made.

As regards the meeting itself, it is proposed that the visitors should stay in Pasadena until Tuesday, September 13, on which day they will leave for Mount Wilson, the journey occupying about seven hours. The meeting will be held during the four remaining days of the week, and the return journey will take place on Sunday, September 4.

On September 6 it is intended to make an excursion to Los Angeles, and the meeting will conclude with a banquet after returning to Pasadena.

MODERN SUBMARINE TELEGRAPHY.[1]

THIS lecture relates to modern submarine telegraphy, and, therefore, I shall omit the historical part of the subject and start with the cable itself, as we deal with it now. The signals to form the messages are sent over the submarine cable as electric currents. The cable consists of a central copper wire; this is the conductor for the current, and to prevent the electricity escaping from the wire it is insulated along its entire length by gutta-percha.

Gutta-percha is chosen for submarine work because of its very high insulating properties and its not being acted on, or suffering chemical change, under water. The gutta-percha-covered wire is called the core; this core, before it can be laid at the bottom of the sea, must be surrounded by jute serving and steel wires for protection when being laid and during its existence after.

When dealing with the electrical properties of a cable, the core only is considered, and for all practical purposes it may be taken that the return conductor to the current is the water immediately outside the gutta-percha. A core of any given length has a certain time rate of signalling;

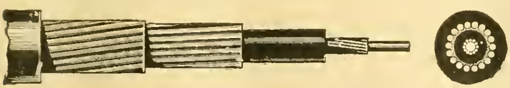


FIG. 1.—Atlantic 1894 Cable.

that is to say, when a voltage is applied at one end, the effective current, that as a consequence flows in the wire, does not arrive at the distant end instantaneously, but takes time to grow.

The time rate of signalling is inversely proportional to the product of the resistance of the wire and the electrostatic capacity of the core. This is termed the "K.R." or capacity resistance law, a law first pointed out by Lord Kelvin. It follows from this law that if you double the length of any given kind of cable you reduce its speed for signalling to one-quarter.

The time rate is inversely proportional to the resistance multiplied by the capacity. If you make a certain sized core (size of gutta-percha) with a large copper, up to a certain point you decrease the resistance and increase the capacity; but there is a critical value giving the minimum K.R. This critical limit, or the point when the size of the copper is reached to give the lowest K.R., is when the diameter of the copper is to the diameter of the core as 1 : 1·65.

There is another advantage in keeping the resistance low for any K.R.; the time constant only determines the time when the current at the far end reaches a certain percentage of the possible maximum after the application of the voltage at the sending end. Of course, the quantity of current after any given time is determined again by the voltage of the sending battery, and is inversely as the resistance of the cable.

For instance, if two cables were constructed of equal K.R., but one had a larger copper of half the resistance of the other, with equal sending batteries, the one with the lower resistance would deliver twice the current at the receiving end, at the ends of equal times, and could therefore be made to work at a faster rate. It should also be a cheaper cable, because copper is less expensive than gutta-percha.

Against these electrical advantages should be placed several mechanical disadvantages; the reduction of the thickness of the insulation might result in a greater liability to faults developing after the cable was laid. With such a heavy wire, which would naturally have to be well stranded, to reduce the stiffness, the liability of the decentralisation during manufacture would be greater than with existing cores.

These mechanical difficulties could, I feel sure, be overcome, say, by greater care being taken in the manufacture or by substitution for the present yielding gutta-percha of dry cotton or similar material well impregnated with gutta-percha compound.

[1] Discourse delivered at the Royal Institution by Mr. Sidney G. Brown.

I take an Atlantic cable laid in 1894 (Fig. 1) as having the greatest size of copper for size of core; I take this core to illustrate the improvement that might result by increasing the copper up to the largest size electrically permissible:—

1894 *Cable.*

Diameter of core	0·466 inch
Diameter of copper	0·202 inch
Resistance per nautical mile... ...	1·684 ohms
Capacity per nautical mile	0·420 microfarad

The cable is 1852 nautical miles long and its K.R. is 2·41, and its speed of working under the capacity block system of duplex, about 205 letters per minute.

The Ideal Core. (FIG. 2.)

Diameter of core	0·466 inch
Diameter of copper	0·282 inch
Resistance per nautical mile	0·864 ohm
Capacity	0·700 microfarad
K.R. for 1852 nautical miles ...	2·06

The speed of working with the same duplex system is about 240 letters per minute, and the current received with this speed would be twice as strong as in the actual cable, so that a still greater speed than that given would result, perhaps a speed of 260 letters per minute, a sending battery of 40 volts to be used on both cables.

The copper conductor offers resistance to the electric currents that flow along it; this resistance by itself would, with sufficiently sensitive receiving instruments, not affect the speed of signalling; it produces what is termed "attenuation," or a weakening of the signalling current.

There is also a lateral storage of electricity along the outside of the copper due to the capacity of the insulating material to absorb a charge of electricity; this property is termed the electrostatic capacity of the core.

To allow this to be more fully understood, I shall take mechanical analogies. *Resistance* in electricity is equivalent to *friction* in mechanics, *capacity* to *elasticity* of a spring, and *self-induction* to *inertia*. If I force water through an iron pipe, the friction in the pipe offers resistance to the flow of water; the same quantity that is forced in flows out at the receiving end, but the energy accompanying the flow of water suffers attenuation, as part is wasted in overcoming the frictional resistance.

Suppose that, instead of taking an iron pipe, I take a soft india-rubber pipe, a new kind of phenomenon will be noticed. As I force the water in, the resistance that the

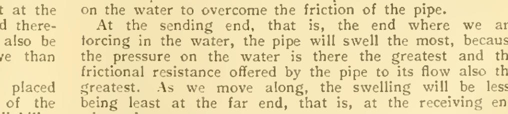

FIG. 2.—Ideal Cable.

water encounters in flowing along the pipe causes the rubber to swell, and the rubber will continue to swell until it has acquired sufficient strain to press with sufficient force on the water to overcome the friction of the pipe.

At the sending end, that is, the end where we are forcing in the water, the pipe will swell the most, because the pressure on the water is there the greatest and the frictional resistance offered by the pipe to its flow also the greatest. As we move along, the swelling will be less, being least at the far end, that is, at the receiving end where the water escapes.

At the instant that we start forcing the water in, practically none escapes at the receiving end, the pipe commences to stretch and the water begins to flow out, continuously increasing in quantity, until it obtains a steady value; this steady value is reached when the pipe has ceased to expand.

The time taken for the pipe to expand and for the water to reach a steady value is termed the variable period. The less the elasticity of the pipe and the less the resistance to water flowing through it, the less the time taken to reach the steady value. This is equivalent to our submarine cable, where the less the capacity and the less the resistance, the less the time constant, or the quicker the rate of signalling.

Now the swelling of the pipe or the capacity effect of the cable does not destroy the energy in the water or of the electricity respectively; this is very different from the waste of energy through resistance, and if by some method we could compensate for the capacity we could signal

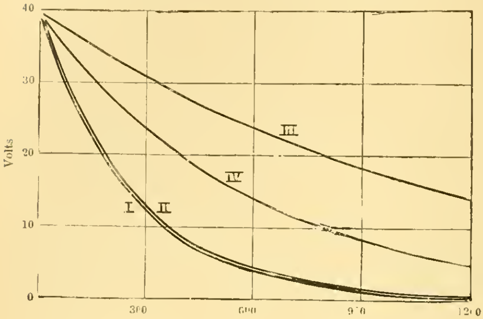

FIG. 3.

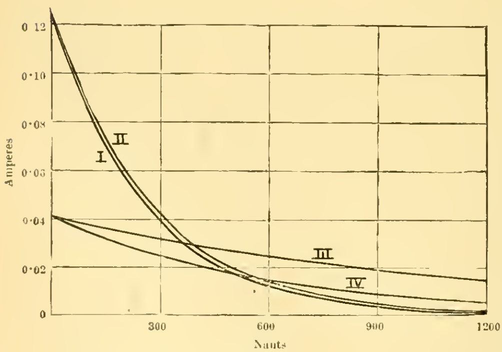

FIG. 4.

The above curves are plotted from the results given in Table I.

through the conductor at any rate we liked, being limited only by the strength of our battery and the sensitiveness of our receiver. I may say that the current usually received would be 1000 times greater if we had no capacity but only the resistance to deal with.[1]

As before stated, the cable has resistance; the current therefore suffers attenuation. It also possesses capacity; the signalling currents through it therefore suffer distortion. Before dealing with this distortion, I must refer you to the diagram of the signals as they are sent into the cable (Fig. 5) and received from it on the siphon recorder. You will notice that the signals, arranged to form the alphabet in the cable code, are of varying lengths, being 1, 2, 3, 4, and 5 times the length of the individual or shortest signal. Sending and receiving on this principle is electrically equivalent to working the cable with varying electrical frequencies of 6, 3, 2, &c., complete periods per second.

[1] I must here refer to the fact that Mr. Heaviside twenty years ago showed that by giving series inductance to a cable we could greatly increase our rapidity of signalling.

This will be understood from Table I. and Figs. 3 and 4 showing curves.

Unfortunately, we see no practical method of carrying out Mr. Heaviside's suggestion, so that I must go on considering the submarine cable as it really is.

TABLE I.

Nauts (x)	I.		II.		III.		IV.	
	Volts.	Amps.	Volts.	Amps.	Volts.	Amps.	Volts.	Amps.
0	40 0	0·1264	40·0	0·1264	40·0	0·0408	40·0	0·041
300	12·25	0·039	12·7	0·042	31·0	0·0316	23·7	0·0244
600	3·8	0·0125	4·4	0·0137	23·9	0·0244	14·2	0·0147
900	1·1	0·005	1·5	0·0055	18·5	0·0189	8 3	0·0088
1200	0·35	0·0012	0·48	0·00155	14·2	0·0146	5·1	0·0051
1500	0·15	0·00065	0·2	0·00083	11·0	0·0112	3·04	0·0031
1825	0·0453	0·000143	0·0418	0·000132	8·32	0·0085	1·71	0·00175
Total lag behind V_0	371°	371°	392°	347°	1717°	1714	1714°	1714°

Except in Case I. (near its end), the lag in every case is proportional to x.

Frequency, 6·36 per second

Submarine telegraph cable $-r=1·684$ ohms per naut, k 0·42 mfd. per naut. The current received by recorder would be 82 times this if we had no capacity

At x nauts from sending end these are the volts and amperes:—

I. There is a recorder with 317 ohms resistance at the end of 1825 naut cable.

II. Infinite cable.

III. Infinite cable, 0·4 henrys per naut; no leakance. Not much distortion.

IV. Infinite cable, 0·4 henrys per naut; leakance, $1·768\times10^{6}$ ohms per naut to give *no* distortion.

(See Figs. 3 and 4.)

The lower the frequency the less the capacity affects the current, so that the higher frequencies of 6 and 3 a second are more attenuated than those of 2 and less. The signals that form the letters in the alphabet are differentially attenuated; the quicker signals, such as those forming a C, are much weaker when they arrive to operate the receiving instrument than the slower signals that form the letters M, O, and so on for the other and longer signals.

Submarine cable signalling of the present day affords us an electrical illustration of the fable of "the tortoise and the hare" or the principle of "more haste, less speed."

As the slower signals get through the cable with more vigour than is necessary, the ingenuity of experimenters is to retard them and to assist as much as possible the quicker ones so that all the signals, whatever their period, shall arrive with exactly the same strength.

Cromwell Varley in 1862 patented a system for the reduction of distortion on cables by inserting condensers of suitable capacity in series with the conductor at each end of the cable.

The reason for the abolition of distortion is obvious; the condenser absorbs the signals of slow frequency, while the cable transmits them. The condenser allows the signals of high frequency to pass through it, although the cable has attenuated them. It is therefore possible so to arrange the condensers at each end of the line that the condensers and the cable together will more or less correct one another and the distortion be reduced.

Unfortunately, the absorption of a series condenser is relative, and is inversely proportional to the frequency; it absorbs more of the slow than the quick signals; at the same time it does absorb some of the quick, and so far as that is concerned it is harmful; it diminishes distortion, but at the same time it adds to the attenuation.

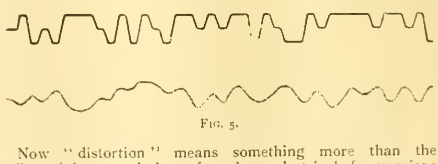

FIG. 5.

Now "distortion" means something more than the differential transmission of various electrical frequencies; it also means the "phase relation" of the current to the voltage, and this "phase relation" varies with the various frequencies, so you see that "distortion," looked at from all sides, is rather a complicated phenomenon. By "phase relation" we mean the position of the current with regard to the voltage producing it. To understand what "phase relation" means, let us take the analogy of a pendulum in motion.

The force keeping the pendulum swinging is a maximum at the end of each swing, while the greatest velocity resulting from this force is at the middle of the swing; obviously the times of greatest speed and greatest force are not coincident; the one is out of phase with the other by what mathematicians would determine, in the case of the pendulum, as 90°, or a quarter period.

Now the current leads the voltage at the sending end of the cable by 45°. If a series condenser is introduced to diminish distortion, it still further increases the lead, and reduces the effective power into the cable. The effective power can only be a maximum when the current and voltage are exactly in step, or in other words, when there is no "phase relation."

A receiving condenser is also harmful for the same reason as a sending condenser. By abolishing the sending condenser and replacing the receiving one by a magnetic shunt placed across the suspended coil of the siphon recorder or relay in 1898, the speed and accuracy of signalling were materially increased.

A magnetic shunt, as employed on the cables, consists of an insulated copper wire wound round a closed circuited iron core. The resistance of the shunt is about 30 ohms; its inductance varies up to a maximum of from 20 to 40 henrys, and its weight from 1 to 3 cwt. In the case of a siphon recorder used as the receiver, the shunt short-circuits the suspended coil and the series condenser is abolished. In the case of a cable relay, the series condenser is usually retained, to ensure that earth currents are effectually stopped, but the condenser is made large.

A shunt inductance has a similar time action on the incoming current to that of a series condenser, but with this improvement—that it helps to reduce the phase distortion of current with voltage rather than accentuate it, as is the case with the condenser.

Having obtained the best value of the shunt alone, the following curious effect was discovered: that adding a condenser as an additional shunt, the size of the signals on the recorder got larger and more distinct. The mathematical reason for this is as follows: that for any particular frequency, say the highest frequency of the cable signalling, the shunts of inductance and capacity when properly proportioned act as a shunt of infinite resistance. For frequencies much below this it is as if we had no condenser at all. For frequencies much above this, it is as if we had no inductance, but only a condenser.

To reduce still further the harmful effect of phase displacement, series inductances have lately been introduced at the ends of cables, particularly at the sending end. By placing an inductive coil of low resistance in series with the battery at the apex of the duplex bridge, not only has the speed of signalling been increased, but the effect of what is known as "jar" on the duplex balance has also been greatly reduced.

Before proceeding to describe the instruments that work the cables, I will say a few words about "duplexing." All cables are now duplexed, that is to say, are arranged so that messages can be sent and received, at the same time, at each end simultaneously. The first cables were duplexed by Stearns, and later ones by Muirhead and Taylor. Duplex reduces the speed of simplex, or of working one way only, by 20 per cent., but the total carrying power of the cable, irrespective of direction, is raised by some 70 per cent., and is for this reason valuable, and repays the trouble in maintaining the balance.

Cables are duplexed by arranging an artificial or imitation cable, which is an exact electrical copy of the real, in parallel with the real cable. The current from the sending battery flows through two equal arms of capacity or inductance of a Wheatstone bridge arrangement and into the real and artificial cables.

The inductive or magnetic bridge which I have applied lately is, I think, the best to employ, because it gives in practice higher speeds than any other form of bridge. The receiving instrument is joined to the commencement of the cables, and is thus not interfered with by the sending currents, because there is no tendency for the current to flow one way or the other, the real and artificial cables having exactly the same electrical properties and acting on the sending current in the same way; but the current that is received flows only from the real cable, and is not balanced by any from the artificial, so that the receiving instrument is worked by it.

When duplex is properly adjusted it is said to be in balance, from its similarity to the adjustment of an ordinary balance used for weighing goods. Take the ordinary balance as an illustration of the electrical one. Let one scale-pan represent the cable, the other the artificial; if equal weights are placed in each pan the beam will not turn, but the beam will turn if, while equal weights are or are not in the pan, a small weight is added or placed on one pan.

In the cable "duplex," the receiving instrument will not be affected by the sending current, because the voltage is always the same on each side of the instrument, but will turn to indicate a signal when a voltage is received or is added to or subtracted from the voltage already on the cable side, due to a voltage being applied to the cable at the far end.

In Fig. 6 is shown the simplest diagram of a cable "duplex," and Fig. 7 illustrates its mechanical equivalent; the lettering is similarly related.

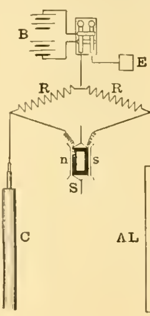

FIG. 6.

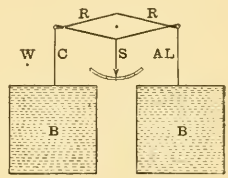

FIG. 7.

RR are the two resistances or the arms of the balance; S is the receiver or indicator, which shows a difference of voltage or weight; B is the battery voltage or weights in the pan; C and AL are cable and artificial line respectively, or the two pans of the balance.

If the battery B sends equal currents into cable and artificial line, as it should do if there is a perfect balance, no current will flow through S, and thus the receiver S is unaffected by the sending voltage; or, if the pans of the balance have equal weights B placed on them, the indicator S will not move. On the contrary, if a voltage is received from the cable C, this voltage is added to or subtracted from whatever voltage may be in C at the time, due to the sending battery, and thus there will be a difference of potential across S, and the receiving instrument will be worked from currents sent from the far end of the cable, and from these currents only.

In the mechanical analogy a small weight W is added to or taken from one of two equal weights in the pans C and AL, and the beam will be tilted and will be moved by this weight only however the weights B B are varied.

The voltage of the battery as applied to the sending end of a cable is very much greater than that received from the cable to work the instrument, say in the relation of 40 volts to 1/20 volt in the case of a moderately long cable, or as 800 is to 1, and the sending and received currents resulting from the same follow a similar proportion.

In the mechanical illustration I have therefore indicated the weights B and W as squares having this proportion to give a visual indication of what this means in the balance. The proportion I have given is only the relation of the sending voltage to that received. If the balance were out to this proportion, the sending voltage would affect the receiver with disturbances equal in size to those due to the receiving voltage; the duplex would then be very badly indeed out of balance.

To receive properly, the sending voltage must produce no movement of the receiver whatever; that is to say, any disturbance due to this cause must certainly be less than one-tenth of that due to the arrival current.

Taking the figures I have given, we see that the balance must be obtained and maintained so that, applying 40 volts to the cable and artificial line, the two currents dividing must not vary more than what will produce 1/200 volt; that is, must be balanced to an accuracy of 8000 to 1.

If, after the duplex has been established, the artificial line varies in its electrical properties as much as 1/8000 of its value, the balance would require adjustment so as to keep it useful for receiving. The sensitiveness under these conditions may be considered as equivalent to the sensitiveness of an ordinary metal balance that with 8 grams in each pan must turn accurately with 1 milligram.

It is now found necessary to maintain still more perfect balances for my new method of "high-speed working of cables"; in fact, a balance that must be maintained to within the proportion of 72,000 to 1. To do this, the very greatest care has to be directed to questions of insulation and temperature correction, and special appliances are supplied to obtain this high degree of accuracy. In fact, the future of "high-speed working of cables" is locked up very much with this question of more delicate and accurate balances; and if still more perfect balances could be obtained, still higher working speeds of cables would immediately be possible.

I now come to the instruments employed to work the cables, starting with the sending end. As before pointed out, the various letters of the cable alphabet are composed of combinations of + and − electrical impulses, or of the records that these impulses produce. The letter *e* is a + impulse, *t* a − one; *a* is composed of two impulses, a + and −, and so on for all the other letters. The operator has, therefore, first to translate the message to be sent into the cable code, and then to tap on the sending-key the order of the impulses that make up the code message. A sending-key consists of two levers; the depression by the finger of either one or the other determines which end of the battery, the + or − end, is joined to the cable.

Sending messages by hand is open to two objections: one the want of speed, the other the want of accurate spacing of the letters. A good trained clerk can send at the rate of about 140 letters per minute; but as most cables are capable of being worked at greater speeds, automatic or machine transmission has now become universal.

An automatic transmitter is an instrument that does the work of the clerk in sending; the two levers of the hand key are now operated upon by mechanism driven by a motor, through the agency of a perforated ribbon. Everyone who is acquainted with the pianola or automatic piano-player knows that the music to be played is punched as holes in a broad paper strip; this strip is run through the machine, and determines which levers are to press upon the keys of the piano.

The operation of the automatic transmitter is precisely like this, only instead of the extended keyboard there are two keys, a + and −, and the paper strip is a narrow ribbon with only two rows of holes to work the levers.

To send a message, the clerk first of all, by means of a hand perforator, punches the message as combinations of holes in the paper ribbon; this ribbon, after being perforated, is fed through the automatic transmitter.

The automatic transmitter is a motor-driven instrument, adapted to feed the perforated ribbon over the ends of a pair of blunt needles. These needles are kept perpetually moving up against and away from the moving ribbon, but if there is a hole in the paper, that particular needle over which it is fed will find it, and the needle will move a little way through the hole. Attached to the two needles are contact levers which connect the cable with one or the other pole of the sending battery.

When there are no holes in the paper ribbon, the needles move up against the paper, the further movement is arrested, and the contact with the battery is not closed, but the battery circuit is closed when there is a hole in the paper, because there is nothing now to block the needle, and the further movement through the hole enables the contact lever to close the battery circuit and thus send the signal.

The sending levers do one or other of two things: they join the cable to earth (in other words, they short-circuit the cable end) or they disconnect the cable from earth and connect it to the battery, so that the battery may send a signal. At the end of each signal the cable is automatically put to "earth."

Every signalling impulse due to each hole in the paper is, therefore, divided into two parts, the battery or signalling and the earthing portion. These two portions are adjustable relatively to one another; when the best relationship has been found, it is maintained at that adjustment. The object of earthing the cable after the battery contact is to allow the cable to discharge itself, and thus clear itself for the next signal. Automatic transmitters constructed on this principle are called "plain" automatics, and are in universal use.

The "curb" was a device applied to an automatic transmitter to sharpen the signalling impulse, and thus gain greater definition and increased speed by reversing the battery at the termination of every battery period. The reverse battery voltage helped to neutralise the charge already in the cable, and thus discharge the cable in quicker time than by simply earthing the cable, as in the "plain" automatic.

Unfortunately, the use of the "curb" results in a greater voltage stress on the sending end of the cable, for the reason that the reverse voltage of the "curb" is added to the voltage already in the cable ready to discharge, and the rapid reversal of current resulting upon the application of the "curb" is liable to cause "jar" disturbances on the duplex balance. For these reasons "curb" automatics are not now employed.

Instruments adapted to receive messages at the end of long submarine cables must of necessity work at the highest possible speed that the cable will allow, and are of extreme sensitiveness, and as a consequence are of great delicacy.

There are two kinds of receivers now commonly employed, viz. the siphon recorder and the "drum" cable relay. The siphon recorder, invented by Lord Kelvin in 1867, is an instrument that inks the message as received on a moving band of paper. The "drum" cable relay, by means of an electric contact-making device, brings in a fresh source of energy from a local battery, so that the electric signalling impulses are multiplied many times over in power, and are thus enabled to do many useful things besides inking the message, such as working signalling keys to re-transmit the message on to another line, or to guide the levers of an automatic punching machine to perforate the message. The siphon recorder requires the constant attention of a clerk, the "drum" cable relay does not.

The siphon recorder consists of a bent glass siphon tube nearly as fine as a human hair. The siphon is suspended by a fine bronze wire; one end of the tube dips in a reservoir of blue aniline ink, the other end can move across the surface of a travelling band of paper, upon which it inks its movement. If the end of the siphon touched the paper, the friction thus introduced would be fatal to the proper working of the instrument, because of the loss of sensitiveness; it is therefore kept in a state of constant vibration by attaching the tube near its end by means of a silk fibre to an electromagnetic vibrator. The message is thus recorded as a close row of ink dots on the moving paper, and the glass tube is quite free to swing sideways under the action of the received signals.

The siphon tube is joined by two silk fibres to a rectangular suspended coil of fine insulated copper wire, which coil hangs in a strong magnetic field. The currents from the cable flow through the wire of the suspended coil, and the reaction of these currents with the magnetic field causes the coil to oscillate to one side or the other, depending upon the direction of the current. The motion of the coil is transmitted by means of the two fibres to the siphon, and thus the signals are recorded as received.

Ever since the invention of the siphon recorder, efforts have been made to turn it into a relay, but two difficulties had to be faced. The extreme feebleness of the received signalling currents was such that they were incapable of opening and closing a battery circuit so as to do useful work in that circuit.

The reason for this is that a certain force is required to press the relay contacts together to complete the circuit and a certain force to break the circuit when formed; these forces of "make" and "break" are too great for the cable relay to supply under normal working conditions.

The second difficulty was the want of definition in the signals received to operate a relay; they were too ill-defined, and the zero line wandered too greatly to ensure that a relay with a fixed mechanical zero would work satisfactorily.

These two difficulties were overcome by the invention of my "drum" cable relay and my magnetic shunt. The drum cable relay (Fig. 8) is very similar to the siphon recorder. It is the same, so far as the suspended coil and connecting fibres are concerned, but in place of the siphon tube a relay contact arm is provided.

The end of this arm is arranged to press upon the surface of a revolving drum. The outer drum surface of gold or silver is divided into three parts: a central insulated portion, upon which the end of the contact arm normally rests when no signals are received, and portions one on each side of the central one. These outer divisions are included in the circuit of a local battery and two post-office pattern relays.

When the relay arm is deflected to one side or the other, upon the receipt of the signal, it slides or skates into contact with one or other of the outer portions of the drum, and thus closes circuit of the battery through one or other of the post-office relays; this second relay is thus operated, and in turn works a "sounder" key to re-transmit the signal into a second cable.

To reduce the electrical resistance that is found to exist in the contact between the relay pointer and the revolving drum, and to allow a large current to pass, condensers are placed across to short-circuit the contact.

These short-circuiting condensers are very important to the proper working of the relay, as without their aid very little current indeed could be obtained in the local circuit to do useful work. The cable relay is a delicate instrument, and mechanical effects had to be produced by means of energy four-millionths of that required to produce one candle-power of an ordinary carbon lamp. The operation of the relay throughout is quite automatic and trustworthy, and no clerk is required to supervise.

The drum relay has two properties that peculiarly fit it for cable work:—(1) the relay contact is always made, because the contact arm never leaves the surface of the drum; (2) by the rotation of the drum, the friction between the arm, to side motion, and the surface of the drum is reduced in a most wonderful way, so that the arm may be moved by the extremely feeble forces received at the end of the cables.

The relay has a fixed mechanical zero, the centre of the insulated portion, to which the end of the arm must return after every signal or group of signals, and the zero of the electrical signals has been made by electrical adjustment to coincide with the mechanical zero. If there were not this coincidence there would be mutilation of the re-transmitted signals.

The working of the relay is complicated by the requirements of the service, which demand that a condenser should be included in the suspended coil circuit. The object of this condenser is to exclude the possibility of interference from "earth" currents, which sometimes flow along the cable.

The presence of the "earth" current is due to outside electrical influences, atmospheric or celestial.

Now these "earth" currents, if allowed to flow through the suspended coil, would produce deflections that would interfere with the proper working of the relay.

The magnetic shunt which is always placed across the coil does shunt the "earth" current to a very great extent, but does not always get rid of it, and so to make matters sure the "unshunted" series or Varley condenser is included in the system.

The condenser, unfortunately, polarises or charges up under a series of signalling impulses of the same polarity or sign, and for this reason itself causes a wandering of the electrical zero of the signals. We are therefore trying to stop one kind of variable zero effect by a device that produces another one of its own.

The effect of the wandering zero due to the series condenser can be cured, because the wandering, unlike that of the "earth" currents, follows a regular law, viz. the law of the signals themselves. The relay produces the signals and combination of signals in its local circuit, precisely the same as the signals or combination sent through the cable that work it, and are at the same time causing the variable zero. Current is therefore taken from the local circuit and passed through an electrical retarding device, which is called the "local correction circuit," consisting of a series of inductances and shunting resistances. The local circuit is so adjusted in its value that the current at the far end rises exactly as there is a drop in the received signalling current through the series condenser.

The correction current is passed through a separate winding on the suspended coil of the relay, and produces an effect on the coil exactly opposite to that produced on the main winding by the variable zero itself, that is to say, two variable zeros of equal strength but of opposite directions are superimposed on the suspended coil, and thus neutralise one another. The variable zero of the signals themselves is thus eliminated.

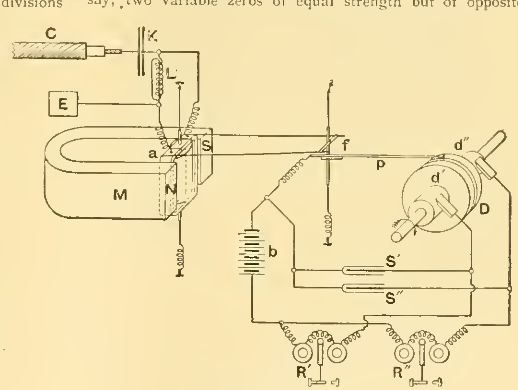

FIG. 8.—Drum Cable Relay.

Local correction is a very important part of the relay adjustment, and cannot very well be dispensed with.

The Eastern Telegraph Company generously lent me their lines for a trial of my "high-speed" system of working. The cable over which the tests have taken place stretches from Porthcurnow in Cornwall to Gibraltar, and is normally worked at 170 letters per minute, each way, with the siphon recorder as receiver. With the new method, using a special relay (Fig. 9), traffic has been carried continuously, duplex, at 230 letters per minute. On special trial runs, not carrying traffic, and not sending into the cable at the receiving station, although on duplex conditions, a speed of 280 letters per minute has been obtained.

The principle of operation is as follows. When a submarine cable is forced much beyond its normal speed of working, the quick-changing signals, such as make up the letter *c*, are the first to fail, or in other words, do not arrive with sufficient strength to work the receiver.

It was found on trial that allowing more of the current from the cable to flow through the receiver, say by increasing the size of the receiving condenser, the first and last signal of a series of reversals could be obtained with sufficient strength efficiently to work the relay.

The relay, once started, is arranged to bring in fresh energy from its local battery, through a special retarding circuit, to add to the strength of the quick-changing currents on its own coil, and thus the reversals are made strong enough to give a record, which without this aid they would have been unable to do.

By these means weak signals are built up at the receiving end of the cable, and the speed of working can thus be materially increased.

It is fortunate that the class of signal that has the greatest difficulty in getting through the cable is the

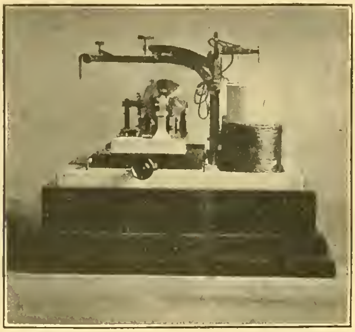

FIG 9.—High-speed Relay (side view). The pointer is constructed of quartz fibres kept in tension by a thin copper wire, the whole weight of the pointer being not more than one or two grains.

easiest to be added to when received. The "high-speed" relay works, therefore, not from the signals received from the cable only, but also from those that it transmits through its own local circuit, the record that it makes being the combined action of the two.[1]

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DUBLIN.—Mr. M. W. J. Fry has been appointed professor of natural philosophy at Trinity College.

LIVERPOOL.—Mr. E. C. C. Baly, F.R.S., assistant professor of chemistry and lecturer on spectroscopy at University College, London, has been appointed Grant professor of chemistry at the University of Liverpool in succession to the late Prof. Campbell Brown.

LONDON.—Miss H. L. M. Pixell, demonstrator in zoology at the Bedford College for Women, has been elected by the Reid trustees to a Reid fellowship, tenable for two years. Miss Pixell proposes to spend some months next year in Vancouver, investigating the marine fauna of the Georgian Straits.

OXFORD.—Mr. R. R. Marett, secretary to the committee for anthropology, has been appointed reader in social anthropology.

Mr. C. H. Manley has been elected to a Bracegirdle exhibition, following on an examination in chemistry. The exhibition is tenable for three years.

THE honorary degree of Doctor of Science has been conferred upon Sir John Murray, K.C.B., F.R.S., by Harvard University.

A PROFESSORSHIP of commercial geography has recently been established at the Export-Akademie of the Imperial Austrian Handelsmuseum at Vienna, and Dr. F. Hiederich has been appointed the first holder of the chair.

[1] A man of science of my acquaintance tells me that I ought to put things in this way. A fluttering current arrives too weak to make a signal, but all it can do is *just to hint* that it wishes to make a signal, the hint is recognised, and the local battery makes the signal required.

DR. A. C. CRAWFORD has been appointed professor of pharmacology at Stanford University, and Prof. G. H. Cox has been placed in charge of the department of geology and mineralogy at the Missouri School of Mines, Prof. L. S. Griswold having vacated the chair of geology at that institution.

THE United Services' College at Windsor possesses an aviation workshop, built and furnished by Mr. P. Alexander, in which instruction is given in the making of model aëroplanes. Hitherto the use of the workshop made by the students has been voluntary, but in the next term aviation is to be made a special subject of instruction.

AN annual prize (to be known as the "Howard T. Ricketts prize") has been established at Rush Medical College, of the University of Chicago, in memory of Dr. H. T. Ricketts, who recently died in Mexico of typhus fever while investigating that disease. The prize will be awarded to the student presenting the best thesis embodying the results of original investigation on some topic relating to dermatology.

IN continuation of the successful evening courses in aëronautics at the Northampton Polytechnic Institute, Clerkenwell, during the session 1909–10, extended courses of a more complete and practical nature are being arranged for next session, and Mr. F. Handley Page has been appointed to take charge of them. The institute has under consideration the establishment of full-time day courses in aëronautical engineering extending over four years, further particulars of which will be published later.

THE model for the memorial in the Medical School of Trinity College, Dublin, to the late Prof. D. J. Cunningham, F.R.S., is now completed, and the bronze portrait panel will, it is hoped, be placed in position by the time of the opening of the school for the coming winter session. As it is proposed shortly to close the subscription list, it is hoped that friends and pupils of Prof. Cunningham who desire to contribute will communicate with the honorary treasurer or honorary secretaries of the Cunningham Memorial Fund, Trinity College, at an early date.

THE Essex Education Committee has arranged for a twelve days' visit (ranging from July 14 to 26) of agriculturists and horticulturists to Ireland. The programme is a comprehensive one, and will afford the party opportunities of seeing the organisation and practice of agriculture and horticulture on farms and holdings varying in size from four or five up to three hundred and fifty acres; also of studying the schemes of instruction and agricultural institutions of the Department of Agriculture, the work of the Congested Districts Board, and the Irish Agricultural Organisation Society. This is the first time the Essex Education Committee has organised a visit to Ireland, but successful tours in Denmark, Holland, Hungary, and Scotland have been undertaken under its auspices in recent years.

THE Secretary of State for the Colonies has selected Dr. Joseph Pearson as director of the museum at Colombo, Ceylon, in succession to Dr. Arthur Willey, now appointed professor of zoology at McGill University, Montreal. Dr. Pearson has for some years held the post of chief demonstrator and assistant lecturer in the zoological department of the University of Liverpool, and previous to that he had held appointments on the zoological staffs at Cardiff and at Belfast. His original work has been chiefly in marine biology, including several reports upon Holothuroidea of tropical seas, and an exhaustive memoir upon Cancer, the edible crab. Dr. Pearson's removal has created a vacancy in the zoological staff at the University of Liverpool which will be filled by the appointment of Mr. R. Douglas Laurie as senior demonstrator and assistant lecturer, while Dr. W. J. Dakin will join the staff as second demonstrator.

EARLY in the present year University College, Reading, appointed a deputation to visit certain universities of Canada and of the United States with the object of investigating methods of agricultural education and research, and also other aspects of university development. The deputation left England on May 6, and was absent six weeks. The tour included the McGill University at Montreal, the Macdonald College, St. Anne de Belle Vue, the State Experimental Farm at Ottawa, the University of Toronto, the Ontario College of Agriculture at Guelph, Cornell University, Wisconsin University, and Harvard University. In each case the members of the deputation made it their principal object to acquaint themselves with the agricultural activities of the institution visited, and their work was greatly facilitated by the cordial assistance of the Government and other authorities both in Canada and in the United States. It is hoped to publish a report during the course of the ensuing autumn containing the substance of the information gained and emphasising certain conclusions.

The 1910 report of the council of the City and Guilds of London Institute to the members of the institute is now available. As usual, full particulars are provided of the work done during the previous year at the Central Technical College, the Finsbury Technical College, the other schools and colleges in connection with the institute, and the department of technology. In the section of the report dealing with the department of technology, it is pointed out that the preliminary education of candidates who enter technical classes is evidently very often the reverse of satisfactory. It was noted in the last report that the institute, in conjunction with the Board of Education, was taking active steps to encourage the attendance of young persons engaged in different trades at evening continuation classes, with the view of their acquiring a competent knowledge of English, arithmetic, drawing, and elementary science before entering upon their first year's course of training in technology. The committee regrets, however, to state that it has been found very difficult to enforce the regulations introduced in 1908, by which, in certain textile subjects, students of registered classes in technology were only to be admitted to the first year's examination on satisfying the institute that they possessed the necessary preliminary knowledge. Notwithstanding the growth of group courses and the increased facilities for the attendance of students at evening continuation classes, it has not been found possible to insist on evidence of attendance at continuation classes prior to the admission of students to a technical school. It has proved necessary to decide that the full enforcement of the regulations in question should be postponed until 1912. Commenting on the results of the examinations conducted throughout the country by the institute, the report says the independent criticisms from examiners in wholly distinct subjects show that many teachers, while undoubtedly using their best efforts to acquaint the students with the technical details of their trade, fail to obtain good results owing to their giving instruction on wrong lines, paying too much attention to description and too little to the theory of the subject and to the principles underlying the work in which they are engaged. This may be partially due to lack of experience in teaching and failure to realise the difficulties of their students. The institute concurs in a suggestion made by its inspectors that if the education authority could send a comparatively inexperienced teacher to visit some of the schools at which successful classes are conducted and see their methods of work, such a visit would amply repay its cost.

SOCIETIES AND ACADEMIES.

London.

Geological Society, June 15.—Prof. W. W. Watts, F.R.S., president, in the chair.—Dr. W. **Cross**: The natural classification of igneous rocks. The author reviewed the various systems of classification which have been proposed. He discussed the origin of the difference of composition of igneous rocks due to:—(1) primæval difference, (2) magmatic differentiation, (3) assimilation, and pointed out that differentiation and assimilation are in a measure antithetical processes. The following general conclusions were formulated:—The scientific logical classification of igneous rocks must apparently be based on the quantitative development of fundamental characters, and the divisions of the scheme must have sharp artificial boundaries, since none exist in nature. Chemical composition is the fundamental character of igneous rocks, but it may be advantageously expressed for classificatory purposes in terms of simple compounds, which represent either rock-making minerals or molecules entering into isomorphous mixtures in known minerals. It is probable that the magmatic solution consists of such molecules, and that the norm of the "quantitative system" is a fairly representative set of these compounds. The actual mineral and textural characters of igneous rocks are variable qualifiers of each chemical unit, and should be applied as such to terms indicating magmatic character.—H. **Bury**: The denudation of the western end of the Weald. There are two main theories of Wealden denudation:—(1) attributing the removal of most of the Chalk to marine planation; and (2) denying planation, and relying solely on subaërial denudation. Prof. W. M. Davis's suggestion of a subaërial peneplain forms a sort of connecting link between the two. The evidence in favour of planation which Ramsay and Topley brought forward is inconclusive, and might plausibly, if it stood alone, be attributed to pre-Eocene causes. On the other hand, Prestwich's arguments against planation are equally weak, while the Chalk plateau to which he directs attention strongly supports Ramsay's views. The distribution of chert is fatal to Prof. Davis's hypothesis, and very difficult to account for, except on the marine theory. In the case of the river Blackwater it can be proved that, long after the Hythe beds of Hindhead were uncovered, the river-system remained extremely immature, and this affords very strong grounds for the acceptance of the marine hypothesis. The evidence of the other western rivers is less conclusive, though the Wey and the Mole both provide minor arguments pointing in the same direction. The anomalous position of the Arun, at the foot of the northern escarpment of the Lower Greensand on either side of the Wey, is almost certainly due to comparatively recent captures from the latter river, and affords no ground for assuming a river-system of great age matured on a Miocene peninsula. There is no proof that any of the existing connections between rivers and longitudinal folds are of a primitive character, and, on the other hand, there are many alleged examples of transverse disturbances having served as guides to consequent rivers. This again, on the whole, supports the marine hypothesis, especially if, as there are reasons for believing, the longitudinal folds are older than the transverse.—Dr. J. W. **Evans**: An earthquake model. This model is designed to show the successive conditions that result in an earthquake shock:—(1) slow relative movement between two extensive portions of the earth's crust lasting over a long period, and causing (2) a state of strain in the intervening tract, leading to (3) fracture which relieves the strain and allows (4) the adjoining portions of the rock on either side to fly back by virtue of their elasticity, so as to resume, so far as possible, their original relation to the rock-masses with which they are still connected. This movement of release may give rise to two kinds of periodic disturbance: (5) short-period vibrations, due to a sudden arrest by an obstacle and constituting the earthquake properly so called, and (6) a slower backward and forward swing of the rock about the position of equilibrium.

Royal Microscopical Society, June 15.—Prof. J. Arthur Thomson, president, in the chair.—Prof. J. Arthur **Thomson**: Some alcyonarians collected by Mr. J. Murray, of Sir E. Shackleton's Antarctic Expedition. The species, of which there were four, were *Clavularia rosea*, Studer, *C. chuni*, Kükenthal, *Alcyonium paessleri*, May, and *Ceratoises delicatula*, Hickson.—E. M. **Nelson**: Apparatus for increasing the power of an achromatic condenser.—E. B. **Stringer**: The use of the mercury vapour lamp in observing the rings and brushes in crystals.

Linnean Society, June 16.—Dr. D. H. Scott, F.R.S., president, in the chair.—Dr. R. N. **Salaman**: Male sterility in potatoes, a dominant Mendelian character, with remarks on the shape of the pollen in wild and domestic varieties. The paper was based upon experiments made by the author in his own garden at Barley, near Royston, Herts, during the past four years; but on this occasion the author confined his remarks to the pollen, leaving other points for some future occasion. He pointed out that "dead" pollen-grains, or none, were usually associated with flowers of heliotrope colour.

Royal Anthropological Institute, June 28.—Sir H. Risley, president, in the chair.—W. J. Lewis **Abbott**: The classification of the British Stone age, and some new and little known horizons and cultures. After pointing out that the implementiferous deposits have not always been laid down in an unbroken chronological sequence, so that the number of feet at which an implement is found above Ordnance Datum is not always enough in itself to determine its age, the author urged that none of the systems of classification which have been formulated upon the conditions which obtain on the Continent are applicable in this country, where the conditions do not necessarily obtain. He suggested that nature in the first instance furnished man with the prototypes of his tools, and that subsequently he discovered new methods of working flint, and these gave rise to new sets of shapes. In the author's opinion, therefore, these groups of implements, representing various cultures or industries, must enter as basal units in the classification. The author then went into details of two such industries, which he has named the Prestwichian and Ebbsfleetian respectively. Each of these is characterised by a set of special implements worked in a special manner. Although the author had been working at this industry for many years, it was only recently that a large deposit of them was found; this was at Northfleet, where the deposit fills a hollow some six acres in extent. The principal implement of this industry is a large weapon, weighing sometimes as much as 7 lb., and resembling a gigantic spear-head. For this implement the author proposed the name Prestwich. The great peculiarity of this implement was that, when finished, another implement was struck off it without impairing its efficacy. This latter the author has named after Sir John Evans. The author suggested that these may have been used as tallies in a bargain, as it seems clear that they were religiously kept. The implements occur in enormous numbers, and include large axes, with a rounded edge and triangular, heavy side choppers, spear-heads of peculiar type and of large size, and knives, many of which are more than a foot long.

Edinburgh.

Royal Society, June 6.—Prof. Hudson Beare, vice-president, in the chair.—Dr. R. A. **Houston**: Two relations in magnetism. By a simple application of the two laws of thermodynamics, relations were established between each pair of the quantities, magnetic force, stress, and temperature. The chief novelty lay in the manner in which the relations were deduced.—A. D. **Ross**: A new method of differentiating between overlapping orders in mapping grating spectra. The method consisted in photographing the Zeeman effect in the spectrum, a thin plate or lens of optically active quartz or other allogyric substance being introduced between the source of light and the slit. The plane of polarisation of the components was thus rotated by amounts depending on the wave-length. Owing to the selective or polarising action of the grating itself, the intensity ratios between the components in triplets, quartets, &c., gave an indication of the approximate wave-length. The method had been successfully applied to the mapping of spectra of certain rare elements. It greatly reduced the cost of the work, and might be expected to reveal, incidentally, series among the spectrum lines.—Dr. H. **Walker**: The variation of Young's modulus under an electric current, part iii. In this continuation of previous papers a number of new results were given. In particular, the effect of increasing tension on the phenomenon was investigated. The peculiar law of variation of Young's modulus under increasing currents, as shown in the cases of the four metals iron, nickel, copper, and platinum, gradually changed as the tension was increased, until, finally, all peculiarity vanished.—Prof. W. **Peddie**: Continuous and stable isothermal change of state. James Thomson's form of continuous isothermals was discussed, and was shown to be inapplicable below the triple point. For example, water free from ice-nuclei and vapour-nuclei must pass either to the solid or to the vapour state. If it follows the paths of Thomson's curves, two such paths must exist; but no physical distinction remains to determine which shall be selected. A modification of Thomson's form of isothermal was suggested, in which no unstable part occurred. In the liquid state, under decreasing pressure, the volume would increase until, without change of density, a molecular re-arrangement would take place and the substance become solid. Under increasing pressure the volume of the solid would decrease until, by molecular re-arrangement, the vapour state would be reached. The applicability of this representation above the triple point, when solid does not exist, was shown to be complete.

Calcutta.

Asiatic Society of Bengal, June 1.—Dr. L. L. **Fermor**: A Palæolithic implement of manganese ore. The paper gives a description of a Palæolithic implement which is unique in that it is made of manganese ore.—F. D. **Ascoli**: Rivers of Dacca district. The paper deals with the changes that have taken place in the courses of the rivers of the Dacca and Faridpur districts since the desertion by the Brahmaputra of its old channel north of Dacca. The author attributes the origin of these changes to the incursion of the Teesta into the Brahmaputra in 1787, and shows that the principal changes now going on are not, as Fergusson anticipated, in the Ganges at and above the confluence at Goalundo, but further to the south in the Rajnagur area.—D. **Hooper**: Medicinal lizards. The dried lizard sold in the bazaars of northern India is *Scincus mitranus*, Anderson, and not, as quoted by writers on Indian materia medica, *Lacerta scincus*, Linn. References are given to the uses of this lizard in medicine, and to the use of other saurians in Europe and China.

DIARY OF SOCIETIES.

FRIDAY, July 8.

Physical Society, at 5.—A Thermo-electric Balance for the Absolute Measurement of Radiation: Prof. H. L. Callendar, F.R.S.—The Convection of Heat from a Body cooled by a Stream of Fluid: Dr. Alexander Russell.—On Hysteresis Loops and Lissajous' Figures, and on the Energy wasted in a Hysteresis Loop: Prof. S. P. Thompson, F.R.S.—The Energy Relations of certain Detectors used in Wireless Telegraphy: Dr. W. H. Eccles.

THURSDAY, JULY 14, 1910.

TOTEMISM UNVEILED.

Totemism and Exogamy: a Treatise on Certain Early Forms of Superstition and Society. By Prof. J. G. Frazer. In four vols. Vol. i., xix+579; vol. ii., ix+640; vol. ii., ix+583; vol. iv., v+379; eight maps. (London: Macmillan and Co., Ltd., 1910.) Price 2*l.* 10*s.* net the four vols.

PROF. FRAZER is a great artist as well as a great anthropologist. He works on a big scale; no one in any department of research, not even Darwin, has employed a wider induction of facts. No one, again, has dealt more conscientiously with each fact; however seemingly trivial, it is prepared with minute pains and cautious tests for its destiny as a slip to be placed under the anthropological microscope. He combines, so to speak, the merits of Tintoretto and Meissonier. What, then, we may ask, of the philosophical result, of the theory which should emerge from all this acreage of minute workmanship?

In "Totemism and Exogamy" (so far the most voluminous of his anthropological treatises) he admits—the passage is an interesting one—that he has

"never hesitated either to frame theories which seemed to fit the facts, or to throw them away when they ceased to do so; my aim in this and my other writings has not been to blow bubble hypotheses which glitter for a moment and are gone; it has been by a wide collection and an exact classification of facts to lay a broad and solid foundation for the inductive study of primitive man."

To the mind of the truly scientific inquirer, the theory of a subject is a continuously modified machine, the object of which is at once to sort the elements of a combination and to re-combine them, so that by a turn of the handle the observer can reproduce the original process in all or any of its parts. Such a machine only arrives at perfection after a long evolution guided by the "method of trial." Prof. Frazer in anthropology, as Darwin in biology, is content to try new models, and to fit new parts, not with the meticulousness of static curatorship, but with the abandon of experimental genius.

This method and its result are illustrated in a very perfect way by that portion of the book which is concerned with totemism. This portion (if we may express our own belief at the risk of offending Prof. Frazer's characteristic modesty), is actually "The Complete History of Totemism, its Practice and its Theory, its Origin and its End." Commencing with a reprint of the first (1887) edition of "Totemism," a model of its kind, a brief and digested survey of the then known facts (and in its working hypotheses innocuous enough to serve as an introduction for the complete treatise), he next reproduces his first tentative theory in "The Origin of Totemism" (*Fortnightly Review*, 1899), namely, that the essence of it is the "external soul," as suggested in "The Golden Bough" of 1890, only to discard it, in the light of the remarkable discoveries made by Messrs. Spencer and Gillen in Central Australia, for another form, a system of magic, "designed to supply a community with all the necessaries of life, and especially with the chief necessary of all, with food," a notable picture of cooperation tinged with superstition. Next, in the reprint, "The Beginnings of Religion and Totemism Among the Australian Aborigines" (*Fortnightly Review*, 1905; articles expanded from "Observations on Central Australian Totemism," in the Journal of the Anthropological Institute, vol. xxviii., 1899), he reproduces his third hypothesis.

As this, in the present writer's opinion, when completed by the discoveries of Dr. W. H. R. Rivers, and fully expounded in vol. iv., is the final explanation of the mystery of totemism, and as even its author admits that "here at last we seem to find a complete and adequate explanation of the origin of totemism," it calls for detailed attention. In 1899, Messrs. Spencer and Gillen described the Arunta and Kaitish method of determining the totem.

"A person derives his totem neither from his father nor from his mother, but from the place where his mother first became aware that she was with child. Scattered all over the country are what Messrs. Spencer and Gillen call local totem centres, that is, spots where the souls of the dead are supposed to live awaiting reincarnation, each of these spots being haunted by the spirits of people of one totem only; and wherever a pregnant woman first feels the child in her womb, she thinks that a spirit of the nearest totem centre has entered into her, and accordingly the child will be of that local centre, whatever it may be, without any regard to the totem either of the father or of the mother."

This Prof. Frazer terms conceptional totemism.

"The theory on which it is based denies implicitly, and the natives themselves deny explicitly, that children are the fruit of the commerce of the sexes."

He gives probable reasons for this apparently strange ignorance.

Turning now to the summary and conclusion in vol. iv. of the present work, we read:—

"Obviously, however, this theory of conception does not by itself explain totemism. . . . It stops short of doing so, by a single step. What a woman imagines to enter her body at conception is not an animal, a plant, a stone, or what not; it is only the spirit of a human child which has an animal, a plant, a stone, or what not for its totem. . . . For the essence of totemism . . . consists in the identification of a man with a thing, whether an animal, a plant, or what not. . . . Absolutely primitive totemism . . . ought to consist in nothing more or less than in a belief that women are impregnated without the help of men by something which enters their womb at the moment when they first feel it quickened."

The "missing link" was found in the Banks' Islands by Dr. W. H. R. Rivers. Here the natives

"identify themselves with certain animals or fruits and believe that they themselves partake of the qualities and character of these animals and fruits. . . . The reason they give for holding this belief and observing this conduct is that their mothers were impregnated by the entrance into their wombs of spirit animals or spirit fruits, and that they themselves are nothing but the particular animal or plant. . . ."

The theory, as thus completed, "accounts for all the facts (of totemism) in a simple and natural manner."

Hence, as secondary results, the practice of abstaining from killing and eating the totem, and conversely of occasionally eating a little; the belief that men have a magical power over their totems, particularly that of multiplying them; the belief that people are descended from their totems, and that women sometimes give birth to these animals or plants; the fact that people often confuse their ancestors with their totems; and, lastly, the fact that totems comprise an immense range of organic, physical, and artificial objects, the reason being

"that there is nothing from the light of the sun or the moon or the stars down to the humblest implement of domestic utility which may not have impressed a woman's fancy at the critical season and have been by her identified with the child in her womb."

One great merit of the theory, it will be seen, lies in this—that it rests upon a psychical phenomenon of universal occurrence. In a very interesting section, the author connects the facts of totemism with the "longings," the *envie,* of pregnant women. The persistence of the belief and the difficulty of explaining away the physical results of "maternal impressions" on the offspring are most significant. As the author observes, if totemism existed to-day in England, the child of the lady who had a "longing" for raspberries, would, being marked with a raspberry, clearly outlined on the back of the neck, have had a raspberry for its totem. The possibilities latent in such world-wide ideas may explain, suggests the author, the remarkable preservation of clan type in clan exogamy.

"The children of each clan take after their mothers or their fathers, as the case (that is, of residence) may be, according as the mental impressions made on pregnant women are derived mainly from their own clan or from the clan of their husband."

We are glad to see that the author recognises, and continually emphasises, the primary independence of totemism and exogamy; they "are fundamentally distinct in origin and nature, though they have accidentally crossed and blended in many tribes." Throughout the book exogamy is treated as an accidental adjunct of totemism. Yet a complete explanation of its origin and evolution is attempted. In our opinion, this explanation is unconvincing. By a curious irony, J. F. Mclennan, the discoverer of both institutions, never essayed an explanation of totemism, but concentrated his mind on an explanation of exogamy, now shown conclusively to be erroneous. Prof. Frazer, on the other hand, found in totemism his first interest, and his explanation of it constitutes his greatest triumph, while in dealing with exogamy he seems to be engaged on a secondary problem. An excellent discussion of theories is followed by a comparison of the action of exogamy to that of scientific breeding. His account of the development of exogamy from an original prohibition of the "marriage" of brothers and sisters is masterly enough, and we are grateful for it. That the later prohibitions were deliberate we cannot doubt; it is when he follows Messrs. Howitt, Spencer, and Gillen in asserting that the first dichotomy of the primitive group, for the prevention of brother-sister unions, into two halves was also deliberate, that we feel unsatisfied. He rests on an assumed and unexplained superstition (as to the evil effects of incest) in the primitive mind. Nor does he explain how a group, however small, could be divided into two. On what *principle* could it be done? Here he ignores Mr. J. J. Atkinson's theory of primal law.

Nearly two thousand pages are occupied with an ethnographical survey of totemism, an invaluable compilation. The maps, including that of the distribution of totemic peoples, are a new and useful feature. The notes and corrections bring the reprints up to date. A. E. CRAWLEY.

A THEORY OF PREHISTORIC RHODESIA.

Prehistoric Rhodesia. By Richard N. Hall. Pp. xxviii+88. (London: T. Fisher Unwin, 1909.) Price 12*s.* 6*d.* net.

MR. R. N. Hall, the South African excavator, is not very tolerant of criticism. He is up again, and running full tilt against Dr. Randall Maciver, who, in "Mediæval Rhodesia," dared to try to demolish his prehistoric Semitic Zimbabwe theory. Whether Dr. Maciver was right in all his contentions as to the stratification of Zimbabwe, the Nankin china found in it, and so forth, cannot be decided until after he has replied to Mr. Hall's objections as stated in this book. We have little doubt that his reply will finally dispose of these objections, which, of course, Mr. Hall was perfectly justified in advancing if he felt that Dr. Maciver had not handled the evidence rightly. It is, however, a pity that in doing this Mr. Hall allows a certain tone of bitterness to appear in his references to his antagonist.

Mr. Hall is still dominated by the idea that he can find Semitic traces in South Africa. But, again, he brings forward no satisfying proofs of any tangible Semitic influence there. Round towers with conical tops are no proof of Semitic connection. It is not only the Semites who have built such. "Cones" are no speciality of the Semites. In support of the idea that Cones mean Semites, Mr. R. N. Hall brings forward references to Messrs. L. W. King and H. R. Hall's book, "Egypt and Western Asia." Mr. R. N. Hall's note referring to this supposed support for his theory reads as follows:—

"In King and Hall's 'Egypt and Western Asia' reference is made to 'the great cone' at Sinai in the Elamite kingdom (p. 159); to the remains of a 'temple-tower' at Ninib at Babylon (p. 166); to the 'temple-towers' erected by Gudea at Shirpurla in southern Babylonia (p. 217); to 'massive temple-towers' at Samarra on the Tigris (p. 284); to 'cones' in Assyria (p. 392); and to the 'temple-tower' of Ashur (p. 410)."

Now, apart from the extraordinary solecisms "at Sinai in the Elamite kingdom," and "at Ninib at Babylon" (does Mr. R. N. Hall not know where Elam was, where or what Sinai is, or that Ninib was a god?), on referring, incredulous, to the work of Mr. L. W. King and his coadjutor, Mr. R. N. Hall's namesake, we find that this note of the South African Mr. Hall's is one of the oddest farragos of misquotations and miscomprehensions that we have ever seen. The "'great cone' at Sinai in the Elamite kingdom" (which is as if one were to say "at Mont Blanc in Russia") is the representation of a mountain-peak on the well-known stela of the Babylonian king Naram-Sin, which represents that monarch conquering his enemies in a mountainous country, presumably Elam. How Mr. Hall has got Sinai in appears from a neighbouring sentence, in which Messrs. King and H. R. Hall say that Naram-Sin "made an expedition to Sinai." But that does not matter; what does matter is that Mr. Hall quotes Messrs. King and Hall as speaking of this "great cone" as if it bore out his theory, as if it were a building, whereas what they actually say is "the great cone in front of Narâm-Sin, which is probably intended to represent the peak of the mountain." What right has Mr. Hall, then, to refer to the authors of "Egypt and Western Asia" at all? If he disagrees with them as to the interpretation of the cone on the monument, let him say so. But the relief showing the king before the "cone" in question is dead against him in that case.

The "'temple-tower' at Ninib at Babylon" is the "ziggurat" or "temple-tower" of the temple *of Nabû at Birs Nimrûd,* which is the site of the ancient Borsippa, not Babylon; and these ziggurats were not conical at all, nor do King and Hall, either in connection with that at Borsippa or that at Shirpurla, mention anything like a cone in connection with them!

The "'massive temple-towers' of Samarra on the Tigris" are a gem. Samarra is a comparatively modern city, with mediæval walls, over which one sees the gilt domes of two mosques, and a peculiar minaret rather like that of Ibn Tulún, at Cairo. Messrs. King and Hall, writing picturesquely, say:—

"Such a picture as that of the approach to the city of Samarra, with its mediæval walls, may be taken as having its counterpart in many a city of the early Babylonians. The caravan-route leads through the desert, and if we substitute two massive temple-towers for the domes of the mosques that rise above the wall, little else in the picture need be changed."

Mr. Hall has too hastily assumed that these massive temple-towers were conical, or even domed, like the modern mosques. The analogy need not be taken so literally as all that!

Finally, the "'cones' in Assyria" which Mr. R. N. Hall says are mentioned on p. 392 of Messrs. King and Hall's book are the objects thus referred to on that page:—

"Last year a small cone" [*sic:* Messrs. King and Hall do not speak of "cones" in the plural, as Mr. Hall misquotes them] "or cylinder was found, which, though it bears only a few lines of inscription, restores the names of no less than seven early Assyrian viceroys whose existence was not previously known."

These small objects, measuring about nine inches or a foot long, are usually called cones, but they are more properly nail-shaped. What they have to do with Mr. R. N. Hall's theory of conical buildings being Semitic it is hard to see.

The examination of this footnote was interesting, but is not calculated to strengthen one's faith in Mr. Hall's theory, and his authorities do not seem to bear him out so much as he thinks. A more careful study of Semitic lore will probably lead him later to see, himself, the weak points of his dogma. As for the supposed Semitic traits of the Makaranga, on which he lays such stress (p. 400), we fail to see in the long list given by Mr. Hall any peculiarity which is common to Semites and Makaranga only; most of these characteristics are shared by every negro tribe in Africa, and the fact that some of them were also shared by the Semites proves no more than that primitive people all the world over have similar customs, especially with regard to marriage, ritual cleanliness, and the like matters. In this list, also, Mr. Hall shows an inability to distinguish between strong and weak evidence. What is the use to his thesis of such an absurdity as his thirty-eighth resemblance between the Makaranga and Semites,

"Iron rods were the insignia of old Ma-Karanga chiefs, and it was illegal for any ordinary member of the tribe to own such an article. These iron sceptres have their parallel in Semitic countries, where gold was of more value than iron, and are mentioned in the Scriptures"?

What is the point of the solemn information "where gold was of more value than iron" in this particular connection?

We really believe that Mr. Hall does himself and his theory an injustice in his unskilled manner of presenting his ideas and his inability to distinguish between good and bad evidence. Thus the rather "muzzy" photograph facing p. 398 which purports to show the "Semitic Appearance of a Karanga, Zimbabwe," is absolutely bad evidence. Where is this supposed Semitic appearance? In this negro's rather large nose? Does not Mr. Hall know that the purest Semites of Arabia have straight noses, not at all like the "Jewish" type?

Were it pruned of these and other absurdities, Mr. Hall's theory would command serious attention, for it is by no means impossible that Arab traders may have penetrated as far south as Sofala, even so early as the time of the Himyar kingdom, and have exercised a civilising influence on the negro tribes, as the Portuguese did on the tribes of Benin. But granted what one knows now of the capability of certain negro tribes to evolve cultures of their own, Mr. Hall is a bold man to deny the possibility of the truth of Dr. Maciver's theory, that the buildings of Zimbabwe are the work of a native race of comparatively modern times, independent of foreign influence. In any case, until the question of the "Nankin china" is finally settled, it is of little use for Mr. Hall to go on drawing "evidence" of supposed Semitic connections in South Africa, which are presumably no older than the early Middle Ages, from "cones" in Mesopotamia of any date between 3000 and 1500 B.C., especially since these "cones," when examined, turn out to be either mountains, or square, flat-topped towers, or votive offerings, a few inches high, which are shaped like nails!

THE MARINE FAUNA OF JAPAN.

IT has been known for some time to zoologists that the southern coasts of Japan possess a very rich and varied marine fauna. The *Challenger* expedition gave us some indication of it, and various special memoirs by Japanese writers that have appeared in recent years have served to maintain and stimulate our interest in it. But the nine memoirs dealing with the collections made by Dr. F. Doflein in the Sagami and Sendai bays during the years 1904–5 bring home to us with great effect the amazing wealth with which our Japanese friends are favoured in respect of their submarine zoological treasures.

Dr. Doflein is a fortunate, and also undoubtedly a skilful, collector, for he has not only obtained a very large quantity of material, and succeeded in bringing it home in an excellent state of preservation, but he has been able to enlist the services of a number of eminent zoologists with special knowledge of the various groups, and to publish these memoirs in sumptuous style. Judging from the series already published, there can be little doubt that the results of Dr. Doflein's expedition will form a very important contribution to our knowledge of the systematic zoology of the Japanese waters.

For the three memoirs on Alcyonaria, Prof. Kükenthal, of Breslau, is very largely responsible, and those who are interested in this group of Cœlenterata will find in them descriptions of a large number of new species, profusely illustrated by coloured plates and photographs. Prof. Kükenthal is so well known as a leading authority on the Alcyonaria that it is hardly necessary to remark that his elaborate descriptions of the new species and his profound knowledge of the history and literature of the group give his contributions to the series a very high position. But although there is a great deal that is new in these three memoirs, there is no new genus that strikes us as being particularly interesting or important. Among the Alcyonacea, the genus Spongodes (which has been re-named Dendronephthya by the author) is represented by fifteen species, of which six are new to science, and Nidalia by seven species, of which five are new. The genus Alcyonium, on the other hand, is represented by only one species, which is described under the new specific name of *Alcyonium gracillimum*. A new species of Siphonogorgia having been found in Sagami bay, the author takes the opportunity of giving us a very valuable summary of the characters of all the known species of the genus, including in the list the species formerly separated under this generic name Chironephthya.

The title "Japanische Gorgoniden" given to the other two memoirs on Alcyonaria is rather misleading, as the family Gorgonidæ has not yet been dealt with; but it is nevertheless in the suborder Gorgonacea rather than in the Alcyonacea that the richness of the Japanese fauna is so pronounced. The genera Chrysogorgia, Melitodes, and Plumarella appear to be particularly well represented, and in the family Plexauridæ two new genera, Anthoplexaura and Paraplexaura, are described, as well as several new species of the older genus Euplexaura.

The memoir on the hydroid polyps by Stechow is in some respects the most remarkable and valuable of the series, and special attention may be directed to the interesting introductory statement, and particularly to his valuable tabular scheme of the classification of the hydrozoa. Many previous attempts have been made to bring into one system the hydroid and medusoid forms belonging to this class. On careful analysis and consideration, this system will probably be found by systematists to be the best that has yet been suggested. Of the many interesting hydroids that are described in this memoir, the most remarkable is the one to which the new generic name Hydrichthella is given. It was found epizoic on the new alcyonarian Anthoplexaura described by Kükenthal. It is a curious coincidence in zoology that the only other example of a hydroid epizoic upon an alcyonarian was also described last year. On January 30, 1909, a paper by Miss W. Coward was read before the Koninklijke Akad. van Wetenschappen of Amsterdam on a new hydroid (Ptilocodium) epizoic on specimens of the genus Ptilosarcus collected by the *Siboga* expedition. In the same year Stechow described the genus Hydrichthella on Anthoplexaura. There can be little doubt that the two genera are very closely related, but it is more than probable that it will be found advisable to join them in one generic group. If this be done the question of priority will arise, and the name will be Ptilocodium or Hydrichthella according to the publication of Stechow's memoir before or after January 30.

The genus Dendrocoryne of Inaba found in Japanese waters has created some special interest of recent years owing to its relationship to the genus Ceratella, that occurs in Australian waters, on the east coast of Africa, off Hawaii, and elsewhere. The points of difference between Dendrocoryne and Ceratella do not appear to some authors sufficiently important or constant to justify their separation into two genera, but a very strong protest must be made against this author's practice of reviving the obsolete generic name Solanderia for Ceratella and throwing the literature into confusion thereby. M. Haime, who examined the type-specimen of Solanderia (Duch. and Michel.), declared that it was undoubtedly a Gorgonid. The genus was therefore rightly ignored by Gray, and the magnificent memoir by Baldwin Spencer on *Ceratella fusca* has firmly established the proper generic name once and for all time.

Of the other memoirs in this series, the space at our disposal does not allow us to make more than passing notice. We observe some excellent coloured plates in the account by Maas of the Japanese medusæ, and we are glad to observe that the wandering genera Gonionemus and Olindioides are becoming more definitely settled in the order Trachomedusæ. The Ctenophora do not seem to be very well represented in the Japanese fauna, but Dr. Fanny Moser's memoir on this group is a very important contribution to our knowledge of several of the important genera, as the author takes the opportunity to give a critical summary of all the known species of the Lobatæ, Beroidæ, and Cestidæ.

Silberfeld adds to his account of the few new Japanese Antipatharia a useful list of all the species of the order that have been described since the publication of Brook's *Challenger* monograph.

The memoirs by Augustin on the Holothuria, and by Wassilieff on the sea anemones, fully maintain the high standard of excellence that marks the earlier numbers.

S. J. H.

THE CAMBRIDGE PUBLIC ORATOR.

Orationes et Epistolae Cantabrigienses (1876–1909). By Dr. John Edwin Sandys. Pp. xiv+290. (London: Macmillan and Co., Ltd., 1910.) Price 10s. net.

THIS very attractive volume, bound in the light blue which stands for the colour of Cambridge, contains the Latin speeches and letters which for thirty-three years Dr. Sandys has delivered as public orator for the University of Cambridge. In 1909 Dr. Merry, the public orator of Oxford, published his admirable orations, delivered in the Sheldonian Theatre during thirty years, and in the same year, by a curious chance, appeared a volume containing 141 brief speeches delivered by three successive public orators of Trinity College, Dublin—Drs. Palmer, Tyrrell, and Purser.

It was a strange coincidence that in the course of a year the two great universities of England and the most ancient university of Ireland should have given to the world these characteristic effusions of university sentiment. This form of literary composition will appeal in a different way to different minds. But none will fail to see in it a somewhat interesting specimen of an art now obsolescent and destined, perhaps, soon to pass away, which recalls the time when Latin was the *lingua franca* of the learned world, and when the universities affected to convey their sentiments only in the learned tongue.

So long as this time-honoured custom is observed, it will recommend itself by the happy classical turn of phrase and the ingenious adaptation of Latin idiom to very post-classical themes, to which the public orator must often have recourse; and of these arts Dr. Sandys is a past-master. His career in Cambridge was most brilliant, and among other distinctions he won the coveted Porson prize. He was at once designated successor as public orator to that great composer in Greek and Latin, the late Sir Richard Jebb. His orations are characterised by an elegance of Latinity and a felicity of allusion quite worthy of his distinguished predecessor. The public orations not only excite the interest of scholars, but sometimes evoke humorous comment from the undergraduates, as when Dr. Travers-Twiss at Oxford found a flight of superlatives (in which such speeches naturally abound) capped from the gallery by a new adjective. "Illustrissimus, præclarissimus," said the orator; "et Travers-Twissimus" was the contribution of an inglorious undergraduate rival.

The *éloges* in the volume before us are not only charming examples of polished Latinity, but they are admirable specimens of brief and pointed criticism. A man's work is often summed up in a few words which could not be bettered in as many pages. One specimen of this delicate art will serve *instar omnium*. The great poet and critic, Matthew Arnold, writes thus to Dr. Sandys:—

"A thousand thanks for the printed copies of your speeches which you have so kindly sent to me. I am glad the speeches are in this permanent form. For myself I can only say that I could wish the next age (if the next age inquires at all about me) to read no other and no longer character of me than yours."

The reader should turn to the *éloge* (No. 71, p. 39) to see that the words of Matthew Arnold are justified. For those who have not the book we will make an extract, which shrewdly characterises Arnold's dealings with the Philistines, his εὐτραπελία, "cultured insolence," as Aristotle calls it, and another which compares his style to the Thames by which he was born, "Though deep yet clear, though gentle yet not dull":—

"Quam suaviter subamarus est quotiens Attico quodam lepore et salibus quicquid insulsum est irridet, Graeca quadam elegantia quicquid barbarum est contemnit. De gravioribus vero argumentis, quanto animi candore, quanta subtilitate, disputat. Idem poëta quam venustus, quam varius."

"Equidem crediderim Thamesin ipsum inter rura illa fluentem, ubi poëta ipse natus erat, alumno suo exemplar suum praetulisse, suum ingenium inspirasse; qui amnis, poëtarum laudibus celebratus, tranquillus at non tardus it, profundus at pellucidus idem est."

How happily he alludes to the work of Huxley:—

"Olim in oceano Australi, ubi rectis 'oculis monstra natantia' vidit, victoriam prope primam, velut alter Perseus, a Medusa reportavit; varias deinceps animantium formas, quasi ab ipsa Gorgone in saxum versas, sagacitate singulari explicavit; vitae denique universae explorandae vitam suam totam dedicavit."

And we must quote his reference to Joseph Chamberlain's "grand refusal" of the Home Rule Bill, and his allusion to the great statesman's love for orchids.

"tdem cum nova quaedam de Hibernia consilia sibi periculosa esse viderentur, maluit a duce suo, maluit etiam ab amico suo, discedere quam insulas nostras in uno coniunctas, quod ad sese attineret, sinere divelli. Ipse inter senatores suffragiis electos partium suarum ductor constitutus, socios suos quam fortiter ducit, adversarios quam acriter oppugnat! Etenim, quamquam in rerum natura eos potissimum flores diligere dicitur, qui solis a radiis remoti in horto secluso ab aperto caelo delicate defenduntur, ipse vitae publicae solem atque pulverem numquam reformidat, quolibet sub caelo ad dimicationem semper promptus, semper paratus."

But we cannot indulge in quotations which would reach to infinity. In nearly six hundred specimens of the art of Dr. Sandys there is hardly one from which could not be quoted some felicitous phrase or allusion. The letters written in the name of Cambridge are as happy. Among these, specially interesting are the letter to the American Cambridge and that to Lord Morley. The volume is one to which the scholarly reader will recur again and again with interest and admiration. R. Y. Tyrrell.

PSYCHICAL RESEARCH.

Spirit and Matter before the Bar of Modern Science. By Dr. Isaac W. Heysinger. Pp. xxviii+433. (London: T. Werner Laurie, 1910.) Price 15s. net.

The venue of Dr. Heysinger's elaborate though very readable work is the debatable land where three rival powers meet—religion, philosophy, and science. He shows very clearly that these three explainers are to some extent merging; the sharp distinctions are vanishing. Religion is freeing itself from rigid metaphysical dogmas, philosophy is becoming more concrete, and science is becoming more philosophical—is recognising that it cannot provide ultimate explanations of anything. The hope of the future is in a spiritual interpretation of the universe. This interpretation is being forced upon us as the only possible one by the recent advances in psychology and psychical research.

In dealing with spiritualism and occult phenomena generally, Dr. Heysinger takes up a sane and scientific position. He demolishes Hume's argument of "impossibility," quoting Huxley in support of the view that nothing can safely be called impossible outside mathematics and formal logic. As to miracles, either ancient or modern, the really scientific man will say:—"It is a question of evidence; I will make no *a priori* decision, either for or against." The evidence brought forward during the last twenty-five years, by such men as Sir Oliver Lodge, Sir William Crookes, Prof. James, Dr. A. R. Wallace, F. W. H. Myers, and other careful investigators, seems sufficient to establish at least a *prima facie* case. Nevertheless, as the author is careful to point out, it must not be rashly conceded that all psychic phenomena are due to the agency of disembodied spirits; many of these phenomena are probably the work of the subliminal consciousness of some living person, or even of some impersonal world-soul, as many philosophers have thought; but, in many cases, the evidence seems to be sufficient to justify at least a provisional hypothesis that the minds of discarnate people are somehow still producing effects in our material world, by some such process, perhaps, as telepathy. The phenomena are various in kind, from planchette-writing to "apparitions"; but they point in the same direction—to survival of human personality past the wrench of bodily death, and consequently to a spiritual interpretation of experience.

The present reviewer is a member of the Society for Psychical Research (though belonging to its "sceptical wing"), and has devoted much time and thought to the subject for many years. He is dubious about "materialisations," and has lurid opinions about "slate writing by spirits" (or, rather, about the mediums who produce it), but personal experience has convinced him that things do happen, sometimes, which seem inexplicable by orthodox hypotheses. The thing to do is to maintain a rigorously scientific attitude, to observe the phenomena with all possible keenness and precaution against fraud or illusion, and to beware of drawing hasty inferences. Darwin collected facts for many years before he "permitted himself to speculate" concerning explanations. It is perhaps too much to expect that such caution should be shown by psychical researchers, for the subject is more intimately connected with our deepest interests; but it is nevertheless desirable. On the other hand, it can truthfully be said that there is more foolishness shown by the ignorant disbeliever who has never investigated than by the man who has learnt a little and is apt to believe too much.

Dr. Heysinger's book may be warmly recommended. Not the least of its good features is its tremendous armoury of quotations—showing very wide reading—from all the leading investigators. J. A. H.

PSEUDOCYTOLOGY.

The Plant Cell, its Modifications and Vital Processes. A Manual for Students. By H. A. Haig. Pp. xxx+799. (London: C. Griffin and Co., Ltd., 1910.) Price 6s. net.

Writers of elementary text-books might be expected to take some trouble to ensure that their statements are, at any rate as far as possible, accurate and clear. It is a matter of common experience that failures in both respects are not uncommon, and the author of the book before us has compiled a volume which may have some merits, but they are hardly those which the ordinary student will appreciate.

To start with, we may remark that some of the illustrations and photographs are decidedly good, but that the text strikes us as useful chiefly as an exercise in criticism for more advanced students. What are we to make, for instance, of such statements as the following:—"The various forms of 'pits' occurring in the walls (of tracheids) may possibly be of use in sap conduction, but, as a matter of fact, these pits function more as a means of exit for the protoplasm after it has finished its work in the Xylem elements." The confusion (on p. 115) between normal and homotypic nuclear division is absurd. *Germination* of pollen, &c., is wrongly and very misleadingly described as *maturation*.

The development of the angiospermic embryo seems to be confused with that of the fern, and the development of the archegonium (called by the author the oogonium), so far as it is intelligible, is quite incorrect. By the way, the chemiotactic substance emitted from the archegonium is said to be "malic acid or an enzyme."

Few botanists will agree with the view that the homosporous fern-prothallium can be properly, or otherwise than misleadingly, regarded in the light of a "fusion of two prothallia produced by the germination of a potentially double (male and female) spore."

Turning to the part of the book dealing with physiological topics, we find the statement that "Much of the reserve starch in the tuber is formed at first in plastids, and by the time the tuber is full grown, all the plastids have been converted into starch," and, *in a footnote,* we are further gravely informed that "some of the starch is, however, formed in the tuber by the translocation of carbohydrate from the cells of remote parts." It would have been of interest to know what proportions of the starch do and do not respectively owe their origin to this process.

The above citations, which could easily have been added to, may suffice to exhibit the side of the book which a teacher would find defective or effective according to the use he made of it with his students.

But it may be said that it is not fair to judge a book on the "plant cell" by the same canons that would apply to a work more ostensibly on botany, structural, morphological, and physiological. But, as a matter of fact, the volume is really compiled on these lines, and if it were to be criticised from a cytological standpoint the verdict would be far more disadvantageous. It is a pity that the author has not more fully and carefully surveyed his proposed field of work before writing a book. He has evidently aimed at clearness, and, with more knowledge and care, may still produce a useful contribution.

BIOLOGY AND HUMAN LIFE.

Science from an Easy Chair. By Sir Ray Lankester, K.C.B., F.R.S. Pp. xiii+423. (London: Methuen and Co., Ltd., 1910.) Price 6*s.*

IN this volume of forty-three collected papers, the popularisation of science surely reaches high-water mark. To be vividly interesting without offending against accuracy, to season an abundance of solid fact with ideas so that the result is an intellectual feast, to illustrate scientific method by stratagem so subtle that the reader does not know he is being educated—that is what Sir Ray Lankester has achieved. He calls it "Science from an Easy Chair," and so be it; but we hope the delighted reader will realise that it is science from a rich experience of lifelong observation and research. Since Huxley, no one has had a deeper influence on British zoology than the author, and even these parerga show the hand of a master.

Some of the papers are good tracts for the times. The first one, entitled "Science and Practice," with the hygienic triumphs at Panama for its text, illustrates what science can do, if it be allowed, for "the establishing of the kingdom of man." The pages headed "Darwin's Theory Unshaken" should be of use to those who mislead the public by declaring that Darwinism is dead. Other papers show, very briefly, of course, what a living Darwinism has to say about the re-stocking of our villages, the feeble-minded, and various disquieting features of our British birth-rate and death-rate. Apart from such serious questions, it is interesting to notice how many of the papers have a practical point—the poison-vine in England; oysters; the heart's beat; sleep; cholera; sea breezes, mountain air and ozone; oxygen gas for athletes and others; hop blight; phylloxera; clothes moths; and more besides. This is symptomatic of our times, but it is also what we expect from the author of "The Kingdom of Man," that masterly exposition of the sound doctrine that science is for life—*savoir, prévoir, pourvoir!*

Another set of papers deals with subjects in regard to which much progress has been recently made. Among these we find the extraordinary story of the common eel, illustrated by a beautiful coloured drawing which shows the contrast between the mature "silver" eel and the immature "yellow" eel. Another of this type is the account of the human skull from the Chapelle-aux-Saints, in the Corrèze, of the Heidelberg lower jaw, and other recent additions to the data from which the pedigree of man is being patiently worked out. We may also notice the interesting account of the new fresh-water medusoids. A third set—not that we are attempting to classify the forty-three—includes a number of delightful natural-history sketches, such as one on gossamer (where, by the way, it seems to be suggested that the somewhat mysterious parachute-making habit is confined to autumn), or another on honey-dew, or another on the jumping-bean. It seems to be a rotatory easy-chair from which this pleasant science comes, for the author takes the whole world for his province, from microbes to comets, from the land of azure blue to "the starres that wonne on highe," not forgetting either to write of dragons. Quite by itself, with a delightful *note personnel,* is the account of Metchnikoff's day with Tolstoi last year. We hope for many more volumes of the "Easy Chair Series." J. A. T.

ALPINE FLOWERS.

(1) *Alpine Flowers and Gardens, Painted and Described.* By G. Flemwell. Pp. xiv+167. (London: A. and C. Black, 1910.) Price 7*s.* 6*d.* net.

(2) *Summer Flowers of the High Alps.* By Somerville Hastings. Pp. xxvi+85. With an index and 39 colour plates from direct colour photographs by the author. (London: J. M. Dent and Sons, Ltd.; New York: E. P. Dutton and Co., n.d.) Price 7*s.* 6*d.* net.

(1) A SERIES of twenty well-executed colour prints appears to be the *raison d'être* of this volume on alpine flowers and gardens. The author, who is also the artist, knows his Alps and alpine flowers well, and has contrived to write an interesting and instructive account of the alpine flora in its various aspects. He

is without doubt an enthusiast on the subject, and something of a poet as well, but it is unfortunate that poetical descriptions and Latin names of plants are but ill-assorted companions, and the frequency of the necessary names detracts considerably from the purely æsthetic pleasure of perusing the volume.

The Alps, with their flora, are described at the different seasons of the year, and the beauties of each are duly eulogised; to our thinking, however, the concluding chapters on the abuse and protection of alpines, and on some gardens in the Alps, are the most worthy portions of the volume. In the former chapter the good work done by the "Swiss League for the Protection of the Natural Beauties of the Alps" receives well-deserved commendation, for it is largely owing to its efforts that much wanton destruction of alpine plants by the thoughtless tourist and so-called lover of plants is gradually being stopped. In the final chapter the Thomasia gardens, near Bex, Rambertia, at the summit of the Rochers de Naye, and Linnæa, at Bourg St. Pierre, are described.

The author wonders why we in England have not attempted to create alpine pastures; he seems to forget the peculiar beauty of English pasture as it is with its buttercups, cowslips, and orchis, daisies and red sorrel. Very possibly he might find that English grasses ere long would hold the field where once his less resisting alpines were planted. On laying down this book we cannot but feel that Mr. Flemwell is more at home with the brush than with the pen, and that in writing a book on alpine flowers and gardens he would have produced a more useful volume had his fancies been more restrained.

(2) This work is an interesting contrast to the preceding, and affords an example of the present limitations of the art of colour photography. In a few cases, as, for instance, the plates of *Trifolium alpinum* (plate xi.) and *Saxifraga aizoides* (plate xx.), the results are good, but in many of the others the green of the leaves or of the background has come out badly. Blue and violet flowers are perhaps the least successful; it may be that the original photographs have suffered considerably in reproduction, but from the examples before us we cannot entirely agree with the author that "the pictures are true portraits of the flowers 'at home.'" A page or so of descriptive text accompanies each illustration, and there is a general introduction to the volume occupying sixteen pages which in some places needs textual revision; for instance, we do not imagine that the author means to suggest that Baedeker or Bradshaw is either an efficient or an inefficient plant press.

OUR BOOK SHELF.

A Manual of Practical Farming. By John McLennan. Pp. xi+298. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 6*s.* 0*d.* net.

THE number of books dealing with special branches of science applied to agriculture is great and is steadily increasing; we have books on agricultural chemistry, botany and entomology, on the soil, on fertilisers and feeding-stuffs; there are also a number of large treatises and encyclopædias on agriculture. But only few writers have attempted to produce a small, handy book on practical agriculture dealing with the subject as a whole; the majority have been deterred by the difficulty of reducing so wide and complex a subject to the necessary small dimensions.

Mr. McLennan has essayed the task that many have avoided. His aim has been to give the farmer useful practical instruction, and also to set forth "the results of scientific research as far as known and as far as they square with practical experience." In the first object he will probably be found to have succeeded; he clearly knows the men for whom he is writing, and furnishes facts and illustrations that will be useful and will also show what has been accomplished by competent workers. The average American farmer does not yet get all he might out of his land. To some extent the untrained amateur is a factor in the case, as he is beginning to be in England, and our author has something to say about the would-be poultry farmer who came out from the city without any knowledge, but "full of literature on the subject, built elaborate houses, runs, brooders, and incubators, purchased high-priced eggs and costly fowls. He could figure out a comfortable living for himself and family, with freedom from city cares. He usually remained two years; the feed bills exceeded the receipts for eggs; the roup got his hens, and lice got his chickens; his enthusiasm waned, and he went back to his counter."

In his second object—the presentation of the scientific aspects of agriculture—our author is less successful. He shocks us on the very first page by saying that "the soil and the subsoil are primarily composed of molecules; that is, minute grains of rock of varying size and forms. These are simply a result of the action of the elements, such as frost, rain, wind, and heat, in breaking down and disintegrating the surface rock." This is a typical example of the "science" set out for the reader. If the author could persuade some scientific friend to read through the book and make the necessary alterations for the second edition its value would be much enhanced.

Leitfaden der Mineralogie. By Prof. Julius Ruska. Pp. viii+144. (Leipzig: Quelle und Meyer, 1910.) Price 2 marks.

THIS "Guide to Mineralogy" is intended for the use of younger boys in German schools who have not yet received instruction in mathematics, physics, and chemistry. Although it is customary to defer the study of mineralogy until after the latter subjects have been started, it is the author's belief that it is a subject that of itself can be made intelligible and interesting to younger boys. After a brief introduction of four pages, in which hardness and specific gravity are dealt with, he plunges into the subject, explaining such terms and principles as are necessary when occasion arises. The order in which the more common minerals are described follows the usual classification into elements, sulphides, oxides, carbonates, &c. Commencing with sulphur, an opportunity is given to explain some of the principles of crystallography in connection with the rhombic system of crystals; and under the sulphides, galena, zincblende, and iron-pyrites, the three important classes of the cubic system are described. A large amount of information is given in a very concentrated form, and possibly such an essence of mineralogy might not agree with quite young boys.

A striking feature of the book is its wealth of illustrations. Besides the sixty-nine figures on the coloured plates, there are 215 figures in the text, all of which appear to have been specially drawn for the book, and many are quite original. The coloured figures are reproduced by the three-colour process, and are on the whole satisfactory, though one or two are scarcely recognisable. The text-figures include line-drawings of the forms of crystals, and excellent half-tones representing actual crystals and mineral specimens.

To the English student of mineralogy such a book might be used with advantage as a German reading book. The sentences are short and not involved.

A Synopsis of the Orthoptera of Western Europe. By Dr. Malcolm Burr. Pp. 160. (London: Oliver Janson, 1910.) Price 3*s*.

The present work appeared in instalments from 1903 to 1909 in the *Entomologist's Record*, and in its present form will be extremely useful as an introduction to the subject, and as a tourist's guide, especially as its small size renders it more convenient than Brunner von Wattenwyl's work on European Orthoptera, or that of Tümpel's on those of Central Europe. Dr. Burr's work includes all the countries west of (and including) the neighbourhood of Vienna. For eastern Europe we have (for those who can use it) the great Russian expansion of Tümpel's book by Jacobsen and Bianchi, which includes all the Orthoptera of central and eastern Europe, and Palæarctic Asia.

Dr. Burr has given short but careful descriptions of genera and species, and also tables of species under the genera, and he has very properly included the more important naturalised species, such as *Periplaneta australasiae*. Orthoptera are, however, very liable to be carried about from one place to another, and mere casual visitors are very properly only mentioned by name, as on pp. 17, 18, &c. A long-legged Japanese grasshopper, *Diestrammena marmorata*, not mentioned by Dr. Burr, has several times been captured recently in London.

Prehistoric Man. By Joseph McCabe. Pp. viii+128. (London: Milner and Co., Ltd., n.d.) Price 1*s*. net.

This book gives an excellent popular exposition of the present state of our knowledge of prehistoric anthropology. The chapters on Palæolithic man and his implements are full of interest. Within the last few years a considerable number of more or less complete Palæolithic skeletons have been discovered in France and elsewhere, and great additions have been made to our knowledge of man in this distant epoch. In this little volume will be found a lucid description of the latest discoveries. The author is not content to give a mere list of more or less disconnected data, but always endeavours to weave his material into a continuous evolutionary story. This tendency, though admirable in a popular writer, appears in some cases to lead to a slight distortion of the facts in order to make them fit into the theory. For example, the Palæolithic race represented by the Grimaldi, Galleyhill, and other remains is assigned to the later Palæolithic, though the geological evidence appears to be pretty clear that these remains belong at least to the middle Palæolithic. The Gibraltar skull has recently been shown by Dr. Keith to have been the first Palæolithic skull found (1843) in Europe, and to represent one of the most primitive races. This discovery does not appear to have been known to the author.

The chapters on the Neolithic and Bronze ages show that our knowledge of these periods is still in a very unsatisfactory condition, but that is not, of course, the fault of the author of this work.

(1) *Metallografia applicata ai Prodotti Siderurgici.* By Umberto Savoia. Pp. xvi+205. (Milan: U. Hoepli, 1909.) Price 3.50 lire.

(2) *Lo Zinco.* By Prof. R. Musu-Boy. Pp. xiv+219. (Milan: U. Hoepli, 1909.) Price 3.50 lire.

Both these little treatises belong to the excellent series of "Manuali Hoepli," and, like other members of the series, are written by specialists in their respective subjects. They possess the merit, common to practically all other works of this series, of imparting in the fewest possible words the most essential facts and principles. The treatise on the metallography of iron is essentially a practical guide for the laboratory worker. Its author was sent from Italy to study the methods adopted in the laboratories of Le Chatelier, Fremont, and Guillet, and on returning home established the metallographical laboratory of the Milan steel works. The author has selected for description the methods he has found best suited in practice, and has illustrated the work by nearly 100 of his own microphotographs of steel in its different states.

The treatise on zinc is of a more general character, and calls for little comment. It deals with the ores, methods of extraction, history, statistics, and uses of the metal.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Ooze and Irrigation.

May I be allowed to reply to some inquiries?

(1) It is thought by some that my remarks applied especially to foreign lands. Let me point out that the ooze of our English rivers is often just as fertile as that of the Nile, and that the number ot annelids found in the ooze is enormous. This may be illustrated by reference to the Thames. The late Frank Buckland tells us that when he kept fish he "fed them with red worms collected from the Thames mud. These worms cost 4*s*. 6*d*. a quart; the price of Thames worms, like everything else, has increased considerably." Now whether these worms were true annelids, or merely the larvæ of insects, the point is the same. In the case of Tubifex and its allies, a quart would mean many hundreds of thousands. Mr. Shrubsole, myself, and others, have frequently examined the ooze from various parts of the Thames, and the number of different species of mud-frequenting worms is very great, while it is utterly impossible to estimate the total of individuals.

(2) Another interesting point is continually coming under my observation. When a number of annelids taken from the ooze is examined, it is found that the tail, which is in constant rhythmical motion in the water, is festooned with numbers of symbiotic vorticels. These move to and fro in the water, and are constantly capturing the bacteria and other lowly forms of life with which the putrid water is laden. So far as I am aware, no biologist has ever given this fact, or the action of the vorticels, any detailed study with a view to ascertaining their action, and their relation to their host on the one hand, and the water and soil on the other.

(3) It would be of great value to science if someone would carefully examine the ooze before and after passing through the bodies of annelids, and ascertain what is the nature of the change that has taken place. Is there any difference between the quantity of nitrogen in pure mud and that which has been digested?

These and many other problems having a vital bearing on agriculture need attention, and it is to be hoped that at least a small portion of the time of the new commission will be devoted to a subject of such importance.

Malvern. HILDERIC FRIEND.

IN some interesting remarks upon this subject (NATURE, pp. 427, 489), the Rev. Hilderic Friend suggests—and I believe he is correct in assuming for the first time—that the alluvial mud of such a river as the Nile derives its fertility, not from the nature of the sediment itself, as usually supposed, nor entirely from bacteria, but from the multitudinous remains of annelids that live in the mud.

That there is "need for careful study of the alluvium of rivers from this point of view," and any other, is to be freely admitted. If we except the study of pre- and post-Pleistocene deposits carried out by Mr. Clement Reid, and summarised in his "Origin of the British Flora," there is scarcely another work that can be mentioned dealing with the subject. It is true that lately the Geological Survey have become alive to the necessity of introducing details as to the fertility or otherwise of the soils derived from the geological formations surveyed. But these are isolated, and are but the necessary outcome of previous activities of agricultural experimental stations. But neither have these latter undertaken any systematic study of the character and constituents of river alluvium. The nearest approach to a treatise on the subject is Darwin's "Earthworms," and his work, whilst dealing with terrestrial forms and their influence in fertilising, renewing, and enriching the soil, strangely enough bears out Mr. Hilderic Friend's suggestion as to the cause of alluvial fertility.

For without earthworms, what would the soil be? *Ergo*, without fluviatile annelids, what would the alluvium be—but a sterile accumulation of sand? Here we may add that where worms are too plentiful on land bad results follow, so too we may assume, accepting the worm-fertilising theory as correct, that an excess of annelids tends to cause, as on land, putrefaction, as may be illustrated by the case of ponds overstocked with blood-worms, causing the appearance of blood, which was a fruitful source of superstition in former days, notably at Garendon in this district.

But apart from theoretical considerations, based on the hypothesis that Tubifex and other annelids do tend to increase fertility, we may attempt to draw an analogy with former conditions, and so to some extent corroborate Mr. Friend's very probable theory.

All who have made any study of the palæontology of the Trias (referring here specially to Britain) are familiar with the extreme barrenness of great thicknesses of both Lower and Upper Keuper relieved alone by certain limited horizons at which a definite flora and fauna is to be met with.

It has been assumed, and there is *apparently* no great reason against this on a purely faunistic basis, that the Trias is a desert formation; but on other grounds, and also from a study of the flora and fauna, I have come to the conclusion (during a study of the Midland Trias, in which I am aided by a Government grant from the Royal Society) that the whole of the Triassic formation is a *delta* formation, in other words, that from the Bunter (first suggested to be a delta deposit by Prof. Bonney) upwards conditions similar to those in the Nile area prevailed during Triassic times, and were responsible for its *formation.* Locally, wind acted on rocks, but formed no deposit.

Now it is a remarkable fact that in the deposits in the British Keuper, in which alone plant-remains have so far been discovered, or where carbonaceous deposits occur, that a common associate of the plant-remains is a form of track or casting which has usually been ascribed to annelids or crustacea; and we must not overlook the fact that annelids alone are not the predominating component of the fauna of alluvial tracts, but Protozoa in their myriads, occasionally sponges, Crustacea (minute and large), insects, scorpions, and molluscs form a large proportion of the bulk of alluvial deposits. Of these, annelids and Crustacea are most likely to be preserved, and are most often discovered in the rocks. So that it seems that only where annelid life in Triassic times was abundant was plant-life in evidence, just as now only where the Nile is alluvial does it yield productive results, due, apparently, to the same cause. The analogy I have drawn strengthens Mr. Friend's theory, and, moreover, if the worms be found to be actually conducive to fertility (by experiment or otherwise), my case for the delta-origin of the Trias will receive additional confirmation.

It would seem to us that no more fitting study could be made by the lake surveys that are now going on in different parts of the kingdom than the very probable connection between worms and alluvium, for it seems that Mr. Friend has more or less proved his case without much need for argument. This affords another instance of the utility of beings hitherto supposed to have no useful part to play in the history of time or things.

July 2. A. R. HORWOOD.

A Singular Mammal called "Orocoma."

IN a letter of the Jesuit Father Cat at Buenos Aires, dated May 18, 1729 ("Lettres édifiantes," éd. Lyon, 1819, tom. v., p. 406), the following passage occurs:—

"Outre ces animaux, il en est un qui m'a paru fort singulier: c'est celui que les Moxes appellent *orocoma* [or *ocorome*, according to the "Abrégé d'une Relation espagnole," in the same tome, p. 66]. Il a le poil roux, le museau pointu, et les dents larges et tranchantes. Lorsque cet animal, qui est de la grandeur d'un gros chien, aperçoit un Indien armé, il prend aussitôt la fuite; mais s'il le voit sans armes, il l'attaque, le renverse par terre, le foule à plusieurs reprises, et quand il le croit mort, il le couvre de feuilles et de branches d'arbres, et se retire. L'Indien, qui connoit l'instinct de cette bête, se lève dès qu'elle a disparu, et cherche son salut dans la fuite, ou monte sur un arbre, d'où il considère à loisir tout ce qui se passe. L'orocomo ne tarde pas à revenir accompagné d'un tigre qu'il semble avoir invité à venir partager sa proie; mais ne la trouvant plus, il pousse des hurlemens épouvantables, regarde son compagnon d'un air triste et désolé, et semble lui témoigner le regret qu'il a de lui avoir fait faire un voyage inutile."

In asking what mammalian species this "orocoma" is, and whether there is the slightest foundation for this story, I fully know I am showing my great ignorance. I hope the Editor and his readers will forgive me, taking into account the entire absence of a scientific reference library in this part. KUMAGUSU MINAKATA.

Tanabe, Kii, Japan, June 15.

Pwdre Ser.

WHEN a boy, at the latter end of the 'thirties of last century, I was told by a well-known man of the name of West—lock-keeper on the river Witham at Lincoln—that he had seen a star fall on the south common there, where he had a cow grazing, and that, on going up to it, he found nothing but a lump of jelly. At this distance of time I cannot recall all he said, but I remember he described the object as shining and as about the size of a plate. I have no recollection of his calling it luminous.

Up to this time I have always thought my informant was under an illusion, but, after Mr. McKenny Hughes's article, there seems to be something more than I was aware of in the account he gave me.

F. M. BURTON.

Curve Tracing and Curve Analysis.

I HAVE unwittingly done an injustice to Mr. R. H. Duncan's book on "Practical Curve Tracing" (vol. lxxxiii., p. 461). I judged by the review of it in NATURE of June 9 that it deals only with the subject indicated by its title. After writing to you regretting that no author deals with practical curve analysis, I bought Mr. Duncan's book, and find that, after describing each class of curve and how to trace it, he gives clear directions for reversing the process and deducing a formula from a given curve. So far as it goes, the book excellently meets the want which I expressed, and my only regret is that the author has not developed the subject a little further.

A. P. TROTTER.

London, July 5.

THE AKIKUYU OF EAST AFRICA.[1]

IT may be said at once that this is a very valuable contribution to the ethnology of Africa. In its thoroughness it recalls work characteristic of the latest German school. A trifling defect is the trick which both authors have of separating their African words into syllables, no doubt to facilitate immediate pronunciation by the unlearned; but, although this plan might be recommended in certain important words at their first appearance, it becomes irritating to the eye when perpetuated throughout the book, and sometimes the separation of syllables cuts athwart the etymology of root-words. The same remarks apply to the introduction of the apostrophe after the initial "m" or "n." To anyone really versed in Bantu studies this apostrophe is anathema, as it is quite unnecessary. A writer fastidious about Bantu prefixes supplies a *hyphen* between the prefix and the root, and not an *apostrophe*.

Perhaps, without ungraciousness, another criticism might be added—that the book would have been even more valuable than it is if the authors had either been more widely read in regard to other African studies or had submitted their MS. to a specialist in comparative African ethnology in England or Germany, who could have explained many points which are acknowledged as obscure by the authors, and enabled them to have instituted the most interesting comparisons. The book is such a good one, so likely to take a permanent place as a standard work, that it is to be hoped in a further edition these suggestions may be taken note of.

The Akikuyu (*A-* is a corruption of the plural prefix, *Ba-*, *ki-* is probably the eighth prefix often applied to "languages," "sorts," or "kinds," and the root of the name is really *kuyu*) are a collection of clans of Bantu-speaking negroes which inhabit the elevated plateaus of equatorial East Africa on the eastern side of the great Rift Valley. In language, and perhaps partly in racial origin, they are akin to the Bantu tribes round the slopes of Mount Kenia and the riverside people of the Tana River; also, less markedly, to the A-kamba of the East African plains between these highlands and the sea coast. The Akikuyu specially are greatly interfused with Masai blood, so that many of them have a strong facial resemblance to the Masai, though not so tall in stature. It is very seldom that one meets amongst them the rather prognathous Pigmy type observable here and there amongst the nomad Ndorobo, who dwell on the fringe of their territory to the north. Obviously, they are a remnant of the Bantu invasion of East Africa, of a generalised negro type which at one time or another has intermixed very freely with the Masai, retaining, however, their own Bantu dialect. This, by some centuries of comparative isolation, has become distinctly peculiar in the form of its prefixes and some elements of its grammar. The dense forests of their plateau country have enabled them to resist complete extermination and absorption at the hands of the Masai, when some century ago that bold offshoot of the Nilotic peoples overran the countries between the Victoria Nyanza and the Indian Ocean.

According to the traditions collected by Mr. and Mrs. Routledge, the Akikuyu were preceded in their occupation of these forests by a diminutive race known as the Agumba, and also by the Ndorobo. The last-named is a nomadic people of very mixed elements—composed partly of Bushmanlike Pigmies and degraded Hamites—which ranges in scattered hunting colonies all over equatorial East Africa. The Agumba may have been the Bushmanlike Pigmy race which seems to have inhabited East Africa in ancient times, and to have left many traces of its presence in existing tribes between Abyssinia on the north and Nyasa on the south. Or, again, the Agumba may have been a branch of the Congo Pigmies, the physical type of which can apparently be traced as far east at the present day as the western slopes of Mount Elgon. According to the traditions collected by the authors, these Agumba finally went westwards to "a big forest."

FIG. 1.—Costume of a Neophyte as he dances prior to Initiation to Manhood. From "With a Prehistoric People."

Mr. and Mrs. Routledge think that the root-word *kuyu* refers to the great fig-trees which are abundant in the forests of the Akikuyu country, fig-trees, probably, that produce bark cloth. But it may also be a word meaning "up above," the lofty region, from the Bantu root kulu, gulu, or zulu, the letter *l* being

[1] "With a Prehistoric People. The Akikūyu of British East Africa." Being some Account of the Method of Life and Mode of Thought found existent amongst a Nation on its First Contact with European Civilisation. By W. Scoresby Routledge and Katherine Routledge (born Pease). Pp. xxxii+392. (London: Edward Arnold, 1910.) Price 21s. net.

much disliked in many of these East African Bantu dialects, and either dropped or changed into a y sound. Certainly, according to the traditions of the Akikuyu, their upland country was until a hundred years ago (more or less) a region of unbroken forest (we may add, West African in its flora and fauna) which was nourished by an exceedingly heavy rainfall. This great equatorial forest of Africa obviously extended at one period right across the continent to the shores of the Indian Ocean. It has left traces of its peculiar flora and even fauna in the islands of Zanzibar and Pemba, and on the north coast of Lake Nyasa. This must have been a forest which contained not only the West African antelopes and pigs, birds, spiders, and butterflies, still found in Kikuyuland, but the gorilla and chimpanzee, and other types which once ranged uninterruptedly between West Africa and Further India. Consequently, Kikuyuland, from the point of view of palæontology, would, if there were any Tertiary or alluvial deposits (dried-up lakes, &c.), probably yield as interesting results in its exploration from that point of view as in ethnology and botany.

FIG. 2.—A Medicine Man. From "With a Prehistoric People."

The book under review, besides giving these interesting details as to the traditions and chronology of the Akikuyu, describes the people and their pursuits, their food and cookery, agriculture, domestic animals, arts and crafts, warfare and weapons, blood-drinking, betrothal and marriage, and general position of women, dances, initiation ceremonies, religion, conceptions of God, notions as to life after death, medicine, folk-lore; and also the position of this interesting people under the new British Administration. The authors have received much assistance from Mr. C. W. Hobley, one of the principal officials of East Africa, who is so very well known for his own ethnographical and linguistic studies of East African peoples.

Specially noteworthy are the illustrations and description of the Kikuyu "bull-roarer" used in various ceremonies, the modelling of fetishes (human figures), blacksmith's work, and initiation ceremonies, with their appropriate dances and costumes. In the interesting article on the medicine-man, the etymology of his name—Mundu Mugū—is not quite rightly hit off (in the quotation from Mr. McGregor). Mugū is really a contraction of the prefix and root of the widespread Bantu word Mu-logu, or Mu-logo, meaning magician, either good or bad. This root *-logo* ranges mainly over western Bantu Africa, and assumes sometimes very altered forms, such as -doki, -lozi, -roho. It is a parallel to the equally widespread root *nganga;* but *-logo* has to do rather with the evil side of magic or of spiritual influence, while *nganga* may well have been in its origin applied to some new wisdom from the north, something to do with iron-working or superior knowledge of a practical, material kind. (For instance, *Bu-nganga* in some Bantu languages means "gunpowder.")

There is an appendix to the book which gives an interesting note by the late Colonel J. A. Grant on iron-smelting in East Africa.

In their bibliography dealing with the Kikuyu and their language, the authors omit any reference to the present writer's vocabulary of Kikuyu in his work on the Uganda Protectorate. For various reasons, this vocabulary, though short, is of interest, as it represents the dialect of the westernmost part of the Kikuyu range, and is therefore interesting for comparison with the nearest (but very dissimilar) Bantu dialects of the regions immediately to the east of the Victoria Nyanza.

H. H. JOHNSTON.

TEMPERATURES IN THE FREE ATMOSPHERE.[1]

DR. WAGNER has given us a comprehensive discussion of the temperature results obtained with registering balloons in Europe during the period July, 1902–June, 1907, and has incidentally furnished an excellent practical tribute to the collective publication

[1] "Die Temperatur Verhältnisse in der freien Atmosphäre [Ergebnisse der internationalen unbemannter Ballonaufstiege]." By Dr. Arthur Wagner. Beiträge zur Physik der freien Atmosphäre. Bd. iii. Heft 2–3. (Leipzig: Verlag von Otto Nemnich.)

of the international observations under the direction of Prof. Hergesell. The author's primary object was to deal with the annual variation of temperature, but he has found room also for the consideration of many associated questions. Altogether 380 ascents were considered, all of which reached 8 km. and twenty-nine of which reached 16 km. Doubtful observations were rejected.

The principal features in the annual variation of temperature are as follows. From the surface up to 3 km. the date of minimum temperature gets later and the annual range decreases by about 4° C. From 3 to 10 km. the minimum temperature occurs at the beginning of March, but at still greater heights there is a comparatively sudden jump back to the beginning of January. The annual range increases from 3 to 7–8 km. by about 4° C., then decreases up to 10 km. by about 6° C., and finally remains nearly constant from 11 to 16 km. The results agree, on the whole, with those obtained by the present writer and Harwood from a slightly different period of observation. Dr. Wagner deduces, from a consideration of the first two terms of the Fourier series expressing the variation, that the difference between the maximum and the mean temperature exceeds that between the mean and the minimum, and that this asymmetry increases with height; it appears doubtful if it is justifiable to neglect the third term, which increases with height and tends to diminish the asymmetry mentioned.

The effect of water vapour on the gradient of temperature is shown in the differences between winter and summer. The following table gives the gradients for summer (June, July, August) and winter (December, January, February), (1) from the present paper; (2) from the report of the present writer and Harwood; (3) for ascending saturated air:—

Height km.	(1) Winter	(1) Summer	(2) Winter	(2) Summer	(3) Winter	(3) Summer
1–2	3·3	5·3	2·2	5·6	5·6	5·1
2–3	4·5	5·0	4·3	5·6	6·5	5·4
3–4	5·7	5·6	5·6	5·4	6·8	5·5
4–5	6·2	6·1	6·5	6·0	7·3	6·0
5–6	7·0	6·6	7·0	6·3	7·9	6·5
6–7	6·9	6·9	7·3	7·1	8·6	7·1
7–8	7·0	7·4	7·6	7·3	9·0	8·0
8–9	5·9	7·2	6·6	7·3	9·3	8·5
9–10	5·0	6·1	5·1	7·1	9·6	9·0
10–11	3·5	3·9	3·6	4·3	—	—

From 3 to 8 km. the gradient is less in summer than in winter, while the difference between the "saturated" adiabatic gradients is greatest from 2 to 8 km. The approximation to the adiabatic state is closer in summer than in winter.

Dr. Wagner attributes the annual variation to convection and conduction from the earth's surface, to condensation of water vapour, and to radiation, solar and terrestrial. A further cause ought to be included, viz. the transference of energy in a horizontal direction. The effect of conduction might fairly be neglected, since even at 100 m., if conduction alone were active, the amplitude of the yearly variation would be less than 1/1000th of the amplitude at the surface. The decrease of the amplitude up to 3 km. appears to be a result of the action typified by v. Bezold's law. The increase above 3 km. is probably rightly attributed to the effect of the increased water vapour on the average gradient in the summer months. Condensation of water vapour is, moreover, held responsible for the relatively slow cooling of the middle layers from summer to autumn, but it is probable that the above-mentioned horizontal transference of energy and the radiation also contribute to this effect. The radiation tends to increase the temperature of the earth and lower atmosphere when the amount of water vapour is increased, if the effect is not counterbalanced by increased reflection of solar radiation from clouds. In this connection it may be pointed out that there is no experimental evidence to justify the assumption repeatedly made that the air between 3–4 and 8 km. may be regarded as diathermanous. At 5 km. the average vapour pressure is not much below 1 mm., and the experiments of Paschen and Rubens and Aschkinass show that for a vapour pressure of 1 mm. half the radiation of a full radiator between 12 and 20μ would be absorbed by a path of about 400 m., and half that between 5 and 8μ by a path of 50 m., while the CO_2 absorption would add slightly to the absorption in the former region; and these results are affected but little by the later experiments of Scheiner and von Bahr.

Dr. Wagner finds that the departures of the temperature in different localities from the general mean values are small except for south Europe, where the temperature is considerably above the mean in the convective region, and for east Europe, where the converse is the case. The peculiarity in the latter region is largely due to the influence of Pavlovsk, lat. 60°, which is the only station in the region besides Koutchino, lat. 56°.

The mean value of H_c, the height at which the advective region is reached, for different regions is as follows:—

Central	North	South	East	West Europe
10·54	10·18	11·07	10·22	10·62 km.

Dr. Wagner deduces from these results that the value of H_c decreases from ocean to continent, as well as from equator to pole. It is true that radiation effects alone would tend to make H_c less over a dry continental area than over the ocean at the same or a higher temperature, but it is doubtful if such an effect can be traced in these figures, according to which north Europe (Berlin and Hamburg) has a lower value than east Europe (Pavlovsk and Koutchino).

In considering the variation of temperature with the pressure distribution, Dr. Wagner wisely adopts the plan of eliminating the annual variation, and as he uses no ascents from east or south Europe, the correction for the local variation of temperature is inconsiderable. It ought, however, to be remembered that, although the mean temperatures of the year are not far different, say, for Paris and Vienna, the corrections to be applied to ascents made in the same month at those two places are not necessarily the same. Dr. Wagner's results corroborate those previously found in proving that cyclones are in general colder than anticyclones, but a consideration of special cases led to the important conclusion that for rapidly moving systems these conditions were reversed, a result foreshadowed by the work of Hanzlik.

The mean temperature in October at 2 km. over Berlin on p. 95 is wrongly given as 0·6° C., and this error is mainly responsible for the peculiar change in the half-yearly variation at that height. In differentiating Δb on p. 99 the variation of T is not negligible. It is simpler to proceed from the fundamental equations, which lead to the result that the height at which Δb is a maximum is given by

$$h = RT_M^2/T_h = RT_0 \text{ nearly,}$$

where

$$\frac{h}{T_M^2} = \int_0^h \frac{dh}{T^2}$$

and T_h is the temperature at the height h and T_0 that at the surface.

The paper includes useful tables giving the pressure and the density at different heights, the variation of temperature on surfaces of equal pressure, and the temperatures in different quadrants of cyclones and anticyclones.

It is full of interest, and stands as an example of the "thorough" policy of Prof. Hann, to whom, indeed, it would not do discredit. E. GOLD.

THE GULF STREAM DRIFT AND THE WEATHER OF THE BRITISH ISLES.

ALTHOUGH it has been known for very many years that the climate of these islands and of northern Europe generally is far milder than it would otherwise have been owing to a large body of warm water flowing past its shores from the south-west, it is only within recent years that attempts have been made to trace any detailed connection between the state of the Gulf Stream Drift [1] and the weather.

Now that systematic hydrographic observations have been accumulating for a number of years it is becoming possible to attack seriously this interesting problem, and the results so far obtained certainly look promising.

The immediate causes of the weather in the British Isles are undoubtedly to be sought in the various atmospheric disturbances which arrive from the Atlantic, but there can be no doubt that another very important factor to be considered is the temperature of the adjacent seas. This is influenced by the Gulf Stream Drift.

The problem is, however, complicated by the fact that there is some doubt as to whether the Gulf Stream Drift may not be a direct result of the atmospheric circulation in the huge cyclonic system which rests over the North Atlantic, with its centre at Iceland.

Be that as it may, there is undoubtedly a very intimate connection between the oceanic and atmospheric circulations in the North Atlantic region, so that if the atmospheric circulation becomes more vigorous, the Gulf Stream Drift moves faster, and *vice versâ*. This is well shown in a paper by Meinardus in the *Meteorologische Zeitschrift*, xxii., 398, 1905. Such a connection was, however, to be expected, not only if the Gulf Stream Drift were directly due to the atmospheric circulation, but also if, as seems more probable, both were due to the same cause, namely, the excessive cooling at the poles of the earth, coupled with the rotation of the earth about its axis. On this view both the oceanic and atmospheric circulations are of the nature of convection currents, and primarily due to the same cause, but in the course of ages these two distinct circulations have so adjusted themselves that any change in the one rapidly causes a corresponding change in the other.

It seems probable, therefore, that the Gulf Stream Drift, owing to its inertia and its great heat capacity, should have a similar effect to that of the flywheel of an engine, and tend to obliterate the disturbances due to the more unstable and variable atmospheric circulation. In this case the Gulf Stream Drift should have a very considerable regulating influence on the *general* type of weather prevailing in the British Isles.

Let us consider the probable influence on the temperature and on the rainfall. In the winter the temperature of the Gulf Stream Drift is higher than that of the land, while in the summer it is lower. Consequently during the winter time the winds blowing from the Atlantic tend to raise the temperature of the land, while in the summer they tend to lower it, and it is clear that variations in the temperature of the Drift must be expected to affect the temperature of the winds blowing over it, and consequently the temperature on land as well. Such effects on the land temperature will probably be far more important in the winter than in the summer, owing to the relatively greater power of the solar radiation during the summer.

The effect on the rainfall will be equally marked, for the amount of moisture carried by the winds and available for precipitation as rain depends largely upon the temperature of the sea over which they have blown. The warmer the sea the more moisture is taken up and the more precipitation may be expected on the neighbouring land.

In this way, for instance, it is possible to account for the low rainfall last year in the western parts of Great Britain and Ireland—parts which are usually very wet—for during 1909 the temperature of the Gulf Stream Drift was below the normal, and hence the winds blowing from it were not so heavily charged with moisture as usual.

The somewhat lower land temperature seems to have just about compensated for this by the time the winds reached the east of Great Britain, so that the rain fell there instead of in the west. The result of this was an abnormally high rainfall in the east, and with the low one in the west the rainfall over the British Isles as a whole was exactly equal to the average.

It will be very interesting to see if this is what may be generally expected in years when the Gulf Stream Drift is weaker than usual.

There is clearly a possibility of being able to predict the *general* character of the weather in these islands several months in advance from the results of hydrographic observations. It is, of course, a very complex question, and at present one cannot be too confident, but I am certainly of the opinion that such predictions will be possible.

In another place I have thrown out the suggestion that, as the February hydrographic observations made in the Irish Sea this year were almost identical with those of last year, there was some probability that the weather during 1910 would be somewhat similar to that of last year. It was never expected that the suggestion would attract the attention it has done, but it is interesting to note that the May hydrographic observations are also very similar to those of last year—if anything, even less favourable.

H. BASSETT.

[1] The warm water flowing round the British Isles to Scandinavia used to be called the Gulf Stream. The Gulf Stream proper is now considered not to extend further east than Newfoundland, while its fan-like extension which crosses over to Europe is known as the Gulf Stream Drift.

PROF. G. V. SCHIAPARELLI.

PROF. SCHIAPARELLI, whose death we briefly announced last week, for many years occupied a prominent position in the world of science. Half a century has passed since he began his career as second assistant in the Brera Observatory of Milan, and nearly as many since he was elected to fill the position of director. In that position he exhibited much energy, and increased the reputation of the observatory. But his greatest success came to him early, and though he worked long and diligently, giving evidence of patient industry and practical skill as an observer, he will be remembered mainly for having satisfactorily established the connection between meteors and comets. It was a brilliant discovery founded on acute penetration and sound reasoning. It was, moreover, a discovery that the public were able to appreciate, and by popular applause he was lifted at once into the front rank of astronomers. He was entitled to all the renown which he acquired. For though others may have entertained similar views and expressed them more or less distinctly, they fell short of demonstration. Prof. Kirkwood, for example, had put the pertinent question, "May not our periodic meteors be the débris of ancient but now disintegrated comets, whose matter has become distributed around their orbits?" At a moment when we are remembering with gratitude the eminent services of the distinguished Italian astronomer, there is no necessity to stir old controversies; but when so many, from the time of Halley, have been so near a solution of the puzzle, it may quicken our appreciation of his genius to remember that he carried the question one step beyond his predecessors, removing it from the grounds of conjecture to the certainty of conviction. In this connection it is not out of place to recall the remarkable series of letters that Schiaparelli addressed to Father Secchi in 1860, models of close reasoning leading to a successful result. But as is frequently the case when a brilliant discovery is made, it is possible to detect a certain amount of luck contributing to the final outcome.

Schiaparelli's crowning success was the recognition of the similarity of the orbit of the August meteors with that of the comet of 1862. That this particular comet of long period should have returned to the sun only a few years previously to the discovery, and that its path had been well determined, was a most fortunate circumstance, and one that not only strengthened the evidence of identification, but affected the popular estimate of the certainty of the result. Similarly, with the near coincidence of the return of the comet of 1866 with the great November shower, and less conspicuously that of the 1861 comet with the April Lyrids, astronomers had the advantage of dealing with trustworthy elements. If these comets had passed through perihelion without being observed an important link would have been wanting in the chain of evidence. As it is, these earliest cases of identification are the most conspicuous and the surest examples of a relation, as significant as it was unexpected. For his part in the happy result Schiaparelli was deservedly awarded the gold medal of the Royal Astronomical Society in 1872.

In some other directions the work of Schiaparelli has not received the same complete recognition. In 1877, when Mars was in a favourable position for observation, he announced the detection of the famous canals which have since been the subject of fierce dispute and controversy. Whether these "canals," interrupting the continental areas, are existent and permanent phenomena has been much questioned; though the doubts expressed do not relate so much to the existence as to the interpretation that has been placed upon them. Schiaparelli regarded the "gemination" of the canals as a periodical phenomenon depending on the seasons, and was firmly convinced of their alternate obliteration and reappearance. The only point on which we need insist here is the effect that his industry and acuteness of vision have had on the development of astronomical observation. It has been the means of attracting a vast amount of attention to the planet, has enormously increased the activity of observation, and led to the training of a class of observers, who have taken up the subject of planetary markings with avidity. Schiaparelli has written much on the appearance of Mars, and a very large literature has collected round this subject, due largely to his initiative.

Another subject with which his name will be connected is the attempt to derive the times of rotation of Mercury and Venus. Our information on this topic is vague, and the data uncertain. Notwithstanding the care bestowed on the observations, and the plausible nature of his deductions, his results have been accepted with some hesitation. From his patient watching, and from the length of time devoted to the study, his conclusion that Mercury turns on its axis in the same time that it revolves round the sun is entitled to very great consideration. This result was published in 1882, and it was not until some years later, 1890, that he declared that Venus behaved in a similar manner to Mercury. The long interval showed that Schiaparelli did not jump to conclusions, and the limits he assigned to the rotation, between six and nine months, prove that he was not inclined to accept a hypothesis, however specious, in favour of the results of observation.

These three conclusions, having reference to the connection of meteors with comets, to the surface markings of Mars, and to the velocity of rotation of the interior planets, are no small achievement in the life of one astronomer. It need not be said that they do not exhaust his scientific activity. A vast amount of routine work, of double-star measurement, and of the position of planets, stands to his credit. He was the author of some 250 papers in various journals, and his memory is as much entitled to our respectful homage for his industry as for his originality.

W. E. P.

PROF. J. G. GALLE.

WITH deep regret we have to announce the death, on July 10, at ninety-eight years of age, of the veteran astronomer Prof. J. G. Galle, the doyen of the Associates of the Royal Astronomical Society, into which body he was elected in 1848. For many years he had been connected with the Berlin Observatory, and will be remembered as the last of the little band of astronomers who were associated in the discovery of Neptune. Galle it was who had the good fortune to carry to complete fruition the successful analyses of Adams and of Le Verrier. It was his lucky chance to compare Bremiker's map with the sky, to detect the planet, and establish its identity by determining the motion. He long outlived all his companions and associates in that historic scene enacted in the Berlin Observatory on September 23, 1846, the antecedents of which have been told so many times that it is unnecessary to refer to them here more particularly. It is more pertinent to recall, as more likely to have been forgotten, that he was one of the first to have seen the "crape" ring of Saturn. When this discovery was announced in 1850, simultaneously by Bond and Dawes, Galle directed attention to some observations he had made twelve years earlier, in 1838–9, in which he had actually measured the diameter of this interior dusky ring. The observations were communicated at the time to the Berlin Academy, but Galle did not insist on their importance, as he could not persuade himself that the phenomenon was permanent and not due to the effect of contrast.

From Berlin, Galle went to Breslau, and there he proposed that method of determining the solar parallax, by observations of small planets, which has since proved so successful. His earliest attempts in this direction were applied to measures of Phocaea, and later, from observations of Flora, he deduced the value of 8·87″. This was at a time when astronomers were beginning to discard Encke's value of 8·58″ in favour of Le Verrier's 8·95″. In another direction it is not possible to overlook a very distinct service which Galle rendered to astronomy. His catalogue of cometary orbits has long been a standard work of which many astronomers have proved the usefulness. But comets and meteors long had great attractions for the aged astronomer. It will be remembered that he was among the first to point out a connection between the April meteors and Comet I, 1861, and to direct attention to the fact that Biela's comet would explain the appearance of the Andromeda shower.

Galle remained at Breslau in full scientific activity until 1897, when he retired to Potsdam after a long life earnestly devoted to astronomy, the interests of which he did much to forward by his zeal and energy.

THE HON. CHARLES STEWART ROLLS.

It is with deep sorrow that we have to record the death of the Hon. C. S. Rolls by an accident on Tuesday last, during the aviation meeting at Bournemouth. It seems that Mr. Rolls went up in his biplane for the alighting competition, and during the descent the newly fitted tail-piece of his aëroplane suddenly broke, and the whole machine collapsed and fell to the earth from a height of forty or fifty feet. Mr. Rolls was picked up unconscious and died almost immediately from concussion and laceration of the brain.

Charles Stewart Rolls was the third son of Lord and Lady Llangattock, and was born in 1877 and educated at Eton and Trinity College, Cambridge. From his early youth he was deeply interested in things mechanical, and his brief career, so sadly brought to an end, shows how successfully he utilised his mechanical capacity.

Different from many men, Charlie Rolls, as his friends called him, when he set about doing anything, always entered deeply into the subject in a thoroughly scientific manner. Whether the object on hand was connected with cycling, ballooning, motoring, or aeroplaning, in the last two of which he was a pioneer, it was always the same, and his mind was continually bent on finding out the "whys" and the "wherefores," and improving the existing state of things. The thoroughness with which he was always associated was strongly brought to my notice in the many balloon trips that I made with him, and his inquiring turn of mind was often displayed when perched up aloft in the clouds. Perhaps the best example is instanced in the quiet manner in which he spent weeks in practising gliding before finally mounting the full-sized aëroplane.

It has been said of Rolls that he was born restless, and those who knew him know how true this description was. Yet he was never flurried, but always calm and collected. It was this trait in his character that probably made him so successful in his manifold ventures.

In the death of Rolls, Britain has lost her most daring and brilliant aviator, and his friends mourn the loss of a dear comrade. William J. S. Lockyer.

NOTES.

We congratulate Sir William Crookes, F.R.S., on the new honour conferred upon him, namely, that of appointment to the Order of Merit, announced in the *London Gazette* of Friday last.

The death is announced, at the age of forty-eight years, of Prof. Hugo Erdman, professor of inorganic chemistry in the Berlin Technical High School.

The annual meeting of the Imperial Cancer Research Fund will be held at the Royal College of Surgeons on Wednesday, July 20, Mr. A. J. Balfour presiding.

The *Globe* states that Herr Frick, who for many years has been engaged in exploration and scientific research, particularly in South America, where he studied the habits and customs of the Indian tribes, has been murdered by Indians in southern Bolivia.

The death is announced in the *Athenaeum* of Prof. T. Zona, of the University of, and observatory at, Palermo; also of Prof. A. P. Sokoloff, formerly the holder of the chair of geodesy at St. Petersburg, and more recently the vice-director of the Pulkowa Observatory. Prof. Sokoloff retired from the latter position in 1905 in consequence of ill-health.

The following officers of the Royal Society of Medicine were elected last week for the year beginning on October 1 next:—*president*, Sir Henry Morris, Bart.; *honorary treasurers*, Sir W. S. Church, Bart., and Sir F. H. Champneys, Bart.; *honorary librarians*, Mr. R. J. Godlee and Dr. Norman Moore; *honorary secretaries*, Dr. A. Latham and Mr. H. S. Pendlebury.

At the annual business meeting of the Museums Association, held last week in York, Mr. H. M. Platnauer was elected president, and Messrs. C. H. Hunt and Deas vice-presidents. A resolution was adopted by the meeting expressing the desire that, in any revision of the grants-in-aid to provincial museums, the Board of Education would consider the advisability of continuing assistance towards the purchase of science objects.

Among the communications to be brought before the eighth International Physiological Congress at Vienna in September next are the following:—demonstration of method of testing colour perception spectrometer and demonstration of lantern test for colour-blindness, by Dr. Edridge-Green; the changes produced by radium in normal cells, by Dr. A. S. Grünbaum; and the summation of stimuli, by Drs. F. S. Lee and M. Morse.

The thirty-ninth meeting of the French Association for the Advancement of Science will be held at Toulouse on August 1 to 7. The president for the year is Prof. C. M. Gariel. Among the names of the presidents of the numerous sections, we notice the following professors of the University of Toulouse:—Prof. Emile Mathias, physics; Prof. Victor Paquier, geology; Prof. M. Leclerc du Sablon, botany; and Prof. Ch. Fabre, agronomy. M. Émile Marchand, the director of the Observatory of Pic du Midi, is the president of the section of meteorology.

The annual meeting of the British Pharmaceutical Conference will be held at Cambridge on July 26 and 27. In his presidential address, Mr. F. Ransome will deal mainly with the cultivation of medicinal plants and with medicinal plant investigation. Among the subjects of papers promised for the meeting are:—the bacteriological testing of disinfectants; an insect pest in belladonna; the proposed essential oil monographs; phosphoric acid and ammonium phosphate; the limitations of water analyses reports, both bacterial and chemical; and note on the periodicity of the properties of the elements: new arrangement.

We have been favoured with a copy of the preliminary programme of the fifth International Congress of Photography, which is to be held in Brussels on August 1 to 6 next, from which we learn that section i. (organised by the Société française de Photographie) will deal with photo-chemistry and the scientific applications of photography; section ii. (organised by the Association belge de Photographie), the technique of photography and the industrial applications of photography; and section iii.

(organised by the Institut international de Bibliographie), photographic documents and legislation relating to documentary photography. As has already been stated in these columns, the correspondent for the United Kingdom is Mr. Chapman Jones, 11 Eaton Rise, Ealing, W.

The death occurred at Washington, on June 26, of Prof. Cyrus Thomas, a veteran authority on the diverse subjects of ethnology and entomology. He was born in Tennessee in 1825, and from 1850 until 1865 he practised law. For the next four years he was pastor of a Lutheran Church. He was then successively an assistant on the U.S. geological surveys of the territories, professor of natural sciences at the Southern Illinois Normal University, State entomologist of Illinois, a member of the U.S. Entomological Commission, and (since 1882) a member of the staff of the U.S. Bureau of Ethnology. His earlier writings were on entomological topics, but his most numerous and best known works were concerned with the North American Indians of prehistoric times.

A list of the Civil List Pensions granted during the year ended March 31, 1910, has just been published as a Parliamentary Paper. Among the pensions granted in recognition of scientific work we notice the following:—Mr. Thomas Bryant, in recognition of his services towards the advancement of surgery, 100*l.*; Mrs. M. L. Gamgee, in consideration of the valuable contributions to physiological science of her husband, the late Prof. Arthur Gamgee, 70*l.*; Mrs. E. J. Seeley, in consideration of the valuable writings on geology and palæontology of her husband, the late Prof. H. G. Seeley, 70*l.*; Miss H. S. Murphy, in consideration of the services rendered by her father, the late Prof. E. W. Murphy, in furthering the use of chloroform, 50*l.*; Mr. J. Sully, in recognition of his services to psychology, in addition to his existing pension, 95*l.*; Mrs. Joanna Calder Fraser, in consideration of the value of the investigations in anatomy and embryology of her husband, the late Prof. A. Fraser, 70*l.*; Miss Julia Dobson, in recognition of the important services rendered by her brother, the late Surgeon-Major G. E. Dobson, F.R.S., to zoological science, in addition to her existing pensions, 15*l.*

Prof. T. H. Core, formerly professor of physics in the Owens College, Manchester, died on July 9 at Withington, near Manchester, in his seventy-fourth year. When the late Balfour Stewart was appointed professor of natural philosophy in the Owens College in 1870, Mr. Core came from Edinburgh to take up the post of professor of physics, a post which he held until his retirement in 1905. Up to the appointment of a professor of applied mathematics in 1881, he took charge of the more mathematical parts of the physics teaching, but as time went on he withdrew from the more advanced work, and for several years before his retirement only lectured on experimental mechanics. He was an extremely clear lecturer, and many Owens' men who have distinguished themselves in science owe their first love of their subject to Prof. Core. He was in great demand as a popular lecturer on scientific subjects throughout the cotton towns around Manchester, and acted as examiner to many of the better schools of the district. He was of a retiring disposition, and never took a prominent part in university politics. Outside his teaching work, his principal interest lay in astronomy, and he was one of the founders, and the first president, of the Northern Astronomical Association.

It is with regret that we learn of the death of Dr. Wilhelm Winkler, who since 1887 made valuable observations of sun-spots, double stars, comets, &c., at his private observatory at Jena. Born at Eisenberg in 1842, Dr. Winkler studied at Leipzig, and developed a practical, as well as mathematical, ability, which displayed itself in the making of watches and clocks. Then in 1875 he set up a 4½-inch Steinheil refractor at Gohlis, and made position-measures of comets, observations of occultations, &c. Later, in 1878, he commenced daily observations of the solar surface, communicating his results to Prof. R. Wolf and then to Prof. Wolfer. As ill-health prevented him from observing regularly, he directed observations made by his wife, and so kept up the continuity of the records. Removing to Jena in 1887, he employed a 6-inch refractor, fitted with clock, circles, and micrometers, for the observation of double stars. Unhappily, about two and a half years ago, a sarcoma necessitated the removal of his left eye, and this, with other serious complaints, considerably curtailed his astronomical work and caused him much suffering, which lasted until his death on June 17. Dr. Winkler's genial presence and devoted labours will, however, be sorely missed by his numerous friends and fellow workers.

We notice with regret the announcement of the death, on July 9, of Mr. Harry W. Cox, at the age of forty-six. Mr. Cox was one of the first in this country to realise the importance to the medical profession of Röntgen's discovery, and to take up the design and manufacture of X-ray apparatus. He commenced at once to manufacture coils, interrupters, and accessory apparatus for the application of the X-rays in medical diagnosis, and to import X-ray tubes and other adjuncts to enable medical men in this country to apply the new discovery. He was always ready to work out new ideas and designs, and probably his most noteworthy achievement was to place on a practical basis the stereoscopic method of localising foreign bodies, with its corollary, the cross-thread method of localisation. The stereoscopic method also enables a picture to be obtained of the position of parts in cases of fracture and dislocation. In his investigations he exposed himself freely to the action of the X-rays, and, like so many of the pioneers in this work, he contracted X-ray dermatitis in a severe form. The disease progressed slowly but relentlessly, and he died after several years of suffering. Now that the danger of undue exposure to X-rays is understood, and efficient protective apparatus has been constructed, there is no need for an operator to take any risks, while patients run no risk whatever; for the exposures necessary for purposes of diagnosis are short, while for purposes of treatment the dose can now be accurately measured and regulated. There is thus great cause for gratitude and honour to those who, at the expense of permanent injury to themselves, have enabled their successors to work in this field in safety.

A tablet in memory of Richard Hakluyt was unveiled in Bristol Cathedral on Thursday last. Among those present were Sir Clements Markham, K.C.B., F.R.S. (representing the Royal Geographical Society), Sir W. Lee Warner (representing the India Office), Admiral Sir Lewis Beaumont (of the Navy Records Society), Mr. W. Phillips (of the American Embassy), and Mr. A. Gray (of the Hakluyt Society). Sir Clements Markham said that Westminster Abbey, where Hakluyt was buried, or Christ Church, Oxford, where he was a student, would have formed a fitting place for that memorial, but, on the whole, Bristol had the better right. It was from that ancient port that there were sent the first voyages of discovery which occupied Hakluyt's thoughts and researches. At Bristol he was canon for more than thirty years, and there he must have conducted his researches and collected information. The most important feature in Hakluyt's character was his strenuous continuity of aim through life. He set himself to remedy two great evils of his time—the ignorance of English seamen in matters relating to the scientific branches of their profession, and the loss of records and stories of ancient voyages and travels. Besides writing and lecturing, he travelled a great deal, collecting stories and information, and set on foot work such as was now carried on by the Royal Geographical Society and other organisations. He was one of the founders of our Colonial Empire.

In distributing the prizes last week to the students of Guy's Hospital Medical School, Prof. Howard Marsh said that medicine had now become a department of biology, and it had given a powerful impetus to the study of biological science. The result had been the discovery of a new world of micro-organisms, of the existence of which nothing was known before the days of Pasteur and Lister. By far the greater number of diseases were due to the presence of micro-organisms. Who could doubt that in the next thirty years tuberculosis, which in England caused the death of 70,000 persons every year and the spoiling of the lives of probably twice that number, would be entirely swept away? Science was the acquisition of facts, and the results of research had been one of the marvels of our time. How should research be carried out? Could the man in the street tell them that? Was any man who knew nothing of biology in a position to save life? How was such a man justified in bringing charges of inhumanity and cruelty against men of science, and saying that what was being done ought to be put down by the strong hand of the law? When the public knew what advances had been made, and were told by such men as Lister and Paget that they had been gained by the only method by which they could have been achieved, who was competent to contradict them? And when it was understood that what was being done was done under Government supervision, and that no man could perform an experiment without a special licence, would not the public be satisfied that the matter was in safe hands? Would they not go further, and be grateful to those who, with unending labour, rendered such great services, and would they not extend to them their full confidence and support?

The Milan correspondent of the *Daily Chronicle* states that an Italian Royal Commission, appointed to inquire into the condition of the Leaning Tower of Pisa, has reported that the structure is in danger of collapse. The tower was begun in 1170, and took nearly a couple of centuries to complete. "Our explorations," say the members of the commission, "led to the wholly unforeseen and distressing discovery that, instead of being founded upon a massive, spacious base, as was generally believed since Grassi, in 1831, and Rohault de Fleury, in 1859, published their collections of plans, the actual foundation simply consists of ring-shaped masonry exactly corresponding in girth to the huge cylindrical mass superimposed thereon. In fact, the diameter of the inner ring foundations is 7 metres 40 centimetres, which is precisely that of the space inside the tower. This discovery, taken together with the further astonishing fact that the foundations are merely 3 metres (9 feet 9 inches) beneath the surface, constitutes henceforth incontrovertible proof that the campanile was originally built perpendicularly, and that its leaning propensities, which are becoming more and more accentuated, are due to other causes than the intention of its constructors." It is stated that the tower is farther from the vertical than it was eighty years ago. The reasons given for this difference are principally that the base of the tower has always been immersed in water, and that a deep cistern dug quite near seventy years ago with the unsuccessful object of draining a basin around the foot of the tower made matters worse. The tower was also considerably weakened by earlier excavation for a basin for mensuration purposes.

In a letter to the current issue of the *Lancet*, Dr. H. W. Thomas, of the Liverpool School of Tropical Medicine, gives an interesting account of the special screening against mosquitoes which has been effected on a freight boat of the Booth Line sailing from Liverpool to Porto Velho, a small place up the Rio Madeiro, a tributary of the Amazon. The screening of the ship is so arranged that the living quarters of the crew and officers are protected from mosquitoes. Each port-hole is provided with a movable screened frame, which is so adapted that the port-hole can be closed and screwed down without withdrawing the screen. The entrances to the main deck are protected by wire gauze spring doors, and at each side of the ash-shoot, which is of necessity open to the ingress of mosquitoes, extra sets of screened doors are placed. The doors and port-holes of the outside bridge deck cabins are also screened; the doctor's quarters and the hospital are situated further aft, and are thoroughly screened. The interior arrangements permit of no old-fashioned water reservoir over the wash-basin in the cabins, and running water is supplied everywhere. The slops from the basins run into pipes emptying directly over the side. This arrangement very satisfactorily deprives the Stegomyia larvæ of breeding places in the cabins. The ventilator pipes in the cabins and along the alleyways are each protected by a wire gauze screened frame, which slips into a grooved moulding fixed round the shaft, and is kept in place by three small buttons. The screening is composed of 18-mesh phosphor-bronze wire, a material which is more suitable for a moist, humid climate than brass or copper.

The *Journal of Hygiene* for April (vol. x., No. 1) contains a report on an investigation of "grouse disease" by Drs. Cobbett and Graham-Smith. It was found that the diseased birds generally harbour large numbers of intestinal worms, in particular a "strongylus" (*Trichostrongylus pergracilis*), which may occur in hundreds or even thousands. The conclusion is that the disease does not appear to be a specific bacterial infection, but that those birds which are more or less severely affected by strongyli suffer injury, partly by interference with nutrition, partly by the absorption of irritating or poisonous substances, which weakens them, and in bad weather may prevent them from gaining a living, and also renders them susceptible to various bacterial infections. Messrs. Hewlett, Villar and Revis also contribute a second part of their investigations on the nature of the cellular elements present in milk. Further evidence is presented showing that the cells are not leucocytes, that they may be present in enormous numbers in perfectly healthy cows, and that they are not necessarily indicative of any inflammatory condition.

In the first part of *Folk-lore* for the current year Dr. W. H. R. Rivers publishes a paper on the position of the father's sister in Oceania, particularly with reference to Banks' Island. The problem to be explained is the close connection between an individual and his father's sister in the case of people among whom the rule of matrilinear descent prevails. This relation closely resembles that of a man with his maternal uncle in patrilinear races, and it has therefore been suggested that the relation in Banks'

Island may be a survival in mother-right of a preceding condition of patrilinear descent. This theory Dr. Rivers dismisses as quite opposed to all known facts. The theory which he finally adopts is that when, for instance, a fragment of a man's umbilical cord and parings of his nails are given to the sister of his father, the intention is to entrust them to her as the representative of a group which, according to rules of descent, is necessarily foreign, and therefore hostile, in the hope that she may be able to prevent any member of that group from working black magic against her nephew. It is also possible that this strange relation indicates an increasing recognition of the kinship of the father, who deputes his sister to perform certain acts as an assertion of his paternity, thus bringing her functions into line with those which, according to one view, belong to the Couvade.

The remains of the gigantic extinct Australian marsupial, Diprotodon, have just been re-arranged in a newly constructed wall-case in the Geological Department of the British Museum (Natural History). The restored skeleton of the animal, for which bones and plaster casts were given by the South Australian Museum, through Dr. E. C. Stirling, F.R.S., occupies the greater part of the case. It displays especially well the massive carpal and tarsal bones and the diminutive toes, which are so characteristic a feature. The limb-bones from Queensland, described by Owen, are arranged on a shelf above the skeleton, and include the first discovered femur, which was originally mistaken for that of an elephant. The skull, as described by Owen, was purchased in a restored state in a saleroom, and has now been carefully divested of all superfluous plaster, proving that the restoration erroneously increased its length by 4 inches. With the skull are several well-preserved jaws showing all the teeth. Palæontologists are still awaiting with interest the promised complete description of Diprotodon by Drs. Stirling and Zietz, of the South Australian Museum.

Among other additions to the exhibited collection in the Geological Department of the British Museum (Natural History) may be mentioned a new model of the skull and mandible of the gigantic extinct lemur, *Megaladapis insignis*, from Madagascar. Thanks to the explorations of Dr. H. F. Standing in the swamps, the model is no longer in any respect hypothetical. It clearly suggests an animal adapted for an aquatic life, and the characters of the known limb-bones confirm this suggestion. To the table-case near the fossil lemurs has just been added a plaster cast of the much-discussed Palæolithic human skull from Galley Hill, in Kent. The original specimen still remains in a private collection.

In the *Entomologists' Monthly Magazine* for the current month, the Rev. F. D. Morice records a male saw-fly from Brockenhurst new to the British fauna. Provisionally the specimen is referred to *Neurotoma mandibularis*, a Continental species hitherto known only by the female. A detailed description, in Latin and English, is appended.

British Birds for July opens with an obituary notice, accompanied by an excellent portrait, of the late Mr. Boyd Alexander, who, it will be remembered, was murdered on April 2 by hostile natives in the heart of Africa to the north-west of Abeshr, in the Wadai. In another article Mr. W. Farren records, with illustrations, the nesting of the marsh-warbler in Cambridgeshire in June, 1909; only one previous instance, and that many years ago, is known of the species breeding in that county.

It has been pointed out by a correspondent that in a note upon a paper by Prof. Steinmann on ammonite phylogeny (Nature, vol. lxxxii., p. 289, January 6) the author was somewhat misrepresented. It was stated "that, in place of being a member of the 'Circumnodosi' group, Heterotissotia is really related to the Triassic Ceratites, of which it is to be regarded as the Cretaceous descendant." It should have read "that Heterotissotia is nearly related to the Triassic Ceratites, and especially the 'Circumnodosi' group, of which it is to be regarded as the Cretaceous descendant."

In the May number of *Spolia Zeylanica* Mr. T. Southwell records the capture of a large female saw-fish (*Pristis cuspidata*) on the Ceylon pearl-banks in December last. The specimen, which measured 15 feet in length, and weighed about 17 lb., was of special interest on account of containing twenty-three intra-uterine embryos. All these embryos were in a horizontal position; but while some had their beaks close to the aperture of the cloaca, others were exactly opposite. They measured 14 inches in length, and in each the yolk-sac was united to the abdomen by a placental stalk 5 inches long. The teeth, from twenty-three to twenty-eight in number on both sides, were arranged irregularly, varying between alternation and a distribution in pairs.

In the same issue (*Spolia Zeylanica*, vol. vi., p. 174) Mr. H. O. Barnard states, as the result of personal observation, that the alleged partiality of cobras for music is a myth. "The sole effect, so far as I could see, was to arouse their curiosity, as they would project their heads out of their holes equally well for any kind of noise, from the shrill piping affected by snake-charmers down to the tinkling noise made by dragging a chain past their dwelling, or even that made by light and repeated tappings with a switch close to their holes. It would appear, however, that the tone must be high, as grave sounds, such as tom-tom beating or deep notes from a flute, had no effect upon them." Mr. Barnard likewise confirms the observations, made in the London Zoological Gardens, as to the absence of a "fascinating" influence of serpents on birds.

In No. 1745 of the Proceedings of the U.S. National Museum Prof. T. D. A. Cockerell discusses the bees of the genus Nomia, with the description of several new species. All the American members of the group are referred to the typical genus, although an alternative classification is mentioned, in which Nomia would be excluded from the American fauna. If this scheme were adopted, there would, however, be difficulties with regard to the non-American forms, which are not easy to classify. "The group," it is added, "is a peculiar one, and apparently its little morphological jokes must not be taken too seriously."

The gipsy moth is so important a pest that a laboratory has been established at Melrose Highlands, Massachusetts, known as the Gipsy Moth Parasite Laboratory, where a complete study may be made of the parasites. Mr. J. C. Crawford has issued a description of several members of the families Chalcididæ, Perilampidæ, Pteromalidæ, and Eulophidæ occurring in the United States or introduced from Europe or Japan and known to be parasitic on the moth. The paper is published by the United States Department of Agriculture, Bureau of Entomology.

The *Agricultural Journal of British East Africa* does not confine itself entirely to agriculture, but includes papers on other subjects connected with the Protectorate. Part iv. of vol. ii. contains, as special agricultural papers, accounts of the Guayule rubber industry and of Ceara rubber in German East Africa, in addition to papers on tea cultivation at Limoru. Among the more general papers is an interesting diary of a journey made by Mr. E. Battiscombe down the Tana River; photographs are reproduced showing typical views and native huts.

THE current issue of the West Indian Bulletin (No. 4, vol. x.) contains a description by Mr. Joseph Jones of some cacaos grown at the Dominica Botanic Station. The root disease of sugar-cane (*Marasmius sacchari*) is also discussed, and found to be prevalent in all districts of Antigua, although planters do not readily recognise it, and therefore cannot apply remedial treatment as early as is desirable. There is an interesting paper by Mr. G. Moody Stuart on implemental cultivation, in which attention is directed to the necessity for using the best and most efficient tillage implements, some suitable types of which are described.

THE theoretically ideal method of dealing with insect pests is to encourage their natural enemies, but it is of limited application, because complications invariably set in sooner or later. The natural enemies of the sugar-cane pests were recently described in the *Agricultural News* (No. 209). Several parasites are known of the sugar-cane borer (*Sphenophorus obscurus*), one being a Tachinid fly, one a Histerid beetle, and one a beetle of the family Elateridæ. Attempts are being made in Hawaii to introduce the natural enemies of the pests occurring there.

WE have received a little booklet, "How to Use Nitrate of Soda," with a preface by Dr. Bernard Dyer, in which summaries are given of various field trials with this fertiliser. Several old misconceptions are dealt with; it is shown that nitrate of soda is not a mere stimulant, but a true plant food, and that it does not exhaust the soil. The necessity for potassic and phosphatic manuring and for periodical liming is also emphasised. Whilst primarily intended for practical men, the pamphlet is also of interest as showing what has been done with artificial manures.

A REPORT describing the experiments made during 1909 at the Harper Adams Agricultural College, and in the counties of Staffordshire and Shropshire, has lately been issued. One of the most notable features is the cropping power of a wheat, Browick grey chaff, recently introduced to the district by the college authorities; other wheats selected from Fife are also under investigation. We have also received the report on experiments with potatoes made in 1909 by Mr. Stewart, of the Edinburgh and East of Scotland Agricultural College. The effect of a change of locality on the vigour of the plant was well marked; apparently the best change is from a later or colder district to one earlier or warmer. Thus in the south-east of Scotland it was found advantageous to procure seed from the north, just as in England it is found profitable to procure seed from Scotland or Ireland.

REFERENCE is made in the *Kew Bulletin* (No. 5) to the flowering of the Burmese rose, *Rosa gigantea*, in the Himalayan section of the temperate house, this being the first record for the gardens. Another interesting item is the production of carpophylls on a plant of *Cycas Micholitzii*, which is being cultivated in the water-lily house.

THE current number of the *Kew Bulletin* (No. 5) opens with a report, by Dr. J. M. Dalziel, on the botanical resources of Yola province, northern Nigeria. Shea kernels (*Butyrospermum Parkii*) and gum are the chief commercial vegetable products. The author was not able to trace the sources of the gum beyond recognising that it is obtained from species of Acacia and Combretum, notably *Acacia senegal* and *Combretum verticillatum*, with admixtures of inferior gum from such sources as *Anogeissus leiocarpa* and species of Albizzia. Odorous resin is obtained from two species of Boswellia—new to science—and *Daniella thurifera*. Diagnoses of new Lauraceæ from the Malayan region, by Dr. J. S. Gamble, include a dozen species of Cryptocarya and ten of the genus Beilschmiedia.

IN the first issue of the meteorological chart of the North Atlantic for July, published by the Meteorological Committee, the synchronous weather charts show that from June 9–12 inclusive an area of high barometric pressure remained nearly stationary in the neighbourhood of the Azores, and afterwards travelled slowly eastward and north-eastward, causing a gradual improvement in the weather over the British Isles. Icebergs have been sighted with increasing frequency on the Banks of Newfoundland, drifting south, but the total number is below the normal. It is stated that navigation opened earlier this year than for some years past, owing to the exceptionally favourable conditions of the ice, not only in the St. Lawrence, but also in the White Sea and the Baltic. The first steamer reached St. Petersburg on April 18, only a week later than the earliest date of arrival there on record.

THE Bulletin of the Manila Weather Bureau for November, 1909 (recently received), contains particulars of two notable typhoons which crossed the Philippine Archipelago during that month. The first, on November 6–7, was remarkable for the unusual violence which it displayed in the Visayas and the China Sea, and for the changes in direction of the track while traversing the China Sea. Attention is directed to the occurrence at two stations of ball-lightning, which is said to be extremely rare in the neighbourhood of a cyclonic vortex. The second storm, November 12–23, was distinguished by the extraordinary development which it acquired in the China Sea, and especially by the fact that for several days it remained practically stationary to the east of the Paracel Islands; from November 18 to 21 the mean velocity of translation was only about 1·5 miles per hour. The tracks of the typhoons are laid down, and isobaric charts drawn from all available observations and reports; much credit is due to the Weather Bureau for its persistent efforts to throw light on the behaviour of these destructive storms.

THE present summer has so far proved cool and unsettled, and to the present it has given cause for suspicion that the season may prove as unfavourable as that of last year. The summary just issued by the Meteorological Office for the five weeks ended July 9 shows the mean temperature for the period to be in fair agreement with the average, but there has so far been a marked absence of high day temperatures. The rainfall has been in excess of the average over the whole of England and Ireland, but there has been a slight deficiency of rain in Scotland. The greatest excess for the five weeks is 1·69 inches in the south-east of England and 1·54 inches in the Midland counties, whilst in nearly all districts the excess is more than an inch. The duration of bright sunshine is deficient in England and Ireland, but there was a slight excess in Scotland. At Greenwich, the mean conditions for June were for the most part in fair agreement with the normal, but the weather was by no means agreeable. The rain fell at the commencement and end of the month, the aggregate measurement being 2·11 inches, which is only 0·07 inch more than the average, but rain fell on sixteen days. The mean temperature was about 1° above the normal, and the duration of bright sunshine was twelve hours less than usual.

Messrs. R. W. Paul have issued a pamphlet entitled "The Equipment of a Modern Elementary Electrical Laboratory," in which a standardisation of instruments is advocated with the view of attaining an interchangeability of instruments, shunts, and multipliers so that any one instrument may be easily adapted for measuring a wide range of currents and voltages. The instrument recommended for the use of elementary students is the unipivot galvanometer, which has a range of 240 microamperes unshunted, and may therefore be used instead of a mirror galvanometer for many experiments. An appendix gives a list of experiments suggested for an elementary course in electrical engineering and the apparatus required for carrying them out. We think that Messrs. Paul advocate too strongly the advisability of making the carrying out of experiments easy to the student. A great part of the benefit to be derived from an experimental course lies in learning to overcome practical difficulties, and students brought up on experiments that are so carefully prepared as to eliminate such difficulties do not, as a rule, become skilful experimenters in the more advanced stages.

Vol. vii. of Contributions from the Jefferson Physical Laboratory of Harvard University contains 463 pages of reprints of fifteen papers which have appeared in the American scientific periodicals during the past year. Of these papers, we have already noticed one in these columns, that on certain thermal properties of steam, by Mr. H. N. Davis. Another of exceptional interest, by Mr. H. W. Morse, deals with the evaporation from a solid sphere. The spheres experimented on were of iodine, and had radii between 0·2 and 1 millimetre. They were supported on a thin lamina of glass attached to the end of a thin fibre of glass, the other end of which was clamped firmly in a horizontal position, *i.e.* the micro-balance of Salvioni. The evaporation took place in a large box with glass sides, through which the deflection of the micro-balance was measured by means of a microscope. The rate of evaporation proved to be proportional to the radius of the drop, and not to its surface.

An advance copy has reached us of the catalogue of mathematical and scientific instruments to be on view at the International Exhibition at Brussels this year. This catalogue has been prepared under the auspices of the Board of Trade by the National Physical Laboratory; it refers only to the exhibits of British manufacturers. It includes detailed descriptions and illustrations of many of the instruments. A glance through this catalogue gives a very good idea of the rapid advances that are being made in the design of physical apparatus. It is invidious to select any names of exhibitors; it is enough to say that most of the leading makers of electrical, optical, surveying, navigational, and meteorological instruments are amongst them, and that the addition of historical references and lists of original publications makes the book a valuable one for reference. The price is only sixpence post free on application to the director, Exhibitions Branch, Board of Trade, Broadway, Westminster. We may add that the catalogue has been compiled free of cost to the exhibitors, and it is hoped that the prospect of the publication of a similar catalogue for the International Exhibition at Turin next year will induce other firms to avail themselves of the many facilities which the new Board of Trade department now affords to exhibitors.

We have received from Messrs. Baird and Tatlock (London), Ltd., a copy of the gas-calculator designed by Dr. R. C. Farmer. The diagram consists of four vertical lines; the two on the left are graduated in temperatures for wet and dry gas respectively; the line on the right is graduated in pressures (mm.). A celluloid strip bearing a black ruled line is laid across the observed pressure and temperature of the gas, and the corrected volume of 1 c.c. of gas is read off directly on the middle line. The latter is also graduated to read the logarithm of the weight of 1 c.c. of nitrogen. It is claimed to give the volume with an accuracy of 1 part in 5000, and this we have found to be the case if 0·00367 be taken as the coefficient of expansion of the gas in question. The diagram is extremely rapid and convenient in use, but it should not be lost sight of that an accuracy of 1 in 5000 is not possible with the more expansible gases.

The synthesis of camphoric acid, as announced by Komppa in 1903, is adversely criticised by M. Blanc (of the Sorbonne, Paris) and Dr. J. F. Thorpe in a recent communication to the Journal of the Chemical Society. One of the critical stages in the synthesis consists in the methylation of a diketoapocamphoric acid with the view of completing the total of ten carbon atoms present in the molecules of camphor and of camphoric acid. Using the ester of the acid, the methylation-product is a crystalline substance melting at 85° to 88°, and was supposed by Komppa to have the new methyl-group attached to carbon; it is now shown that the methyl-group is easily removed by cold caustic potash, and is undoubtedly attached to oxygen and not to carbon; the reduction of the compound to camphoric acid would therefore involve an important molecular re-arrangement, and even if it were effected could scarcely be regarded as a direct building up of the camphor molecule.

We have received from the Thermal Syndicate, Ltd. (Wallsend-on-Tyne), its list of pure fused silica ware. The manufacture of articles from fused silica has engaged the attention of experimenters for a long time; but, owing to the high fusing point of quartz, the difficulties met with in manufacturing articles were very considerable. The Thermal Syndicate has developed a most successful process for fusing and working silica in an electric furnace. Only in 1904, a basin of 25 cubic centimetres capacity was considered an achievement; but at the present time, pipes 12 inches in diameter and 30 inches long, and vessels of 50 litres capacity, are being manufactured. The articles manufactured by the Thermal Syndicate which are placed on the market under the trade name "Vitreosil" are of very varied character. The ware is used in the manufacture of sulphuric acid, for nitre pot pipes, and for the basins for cascade concentrators, of which there are more than 600 in use in the British Isles, representing an output of about 22,000 tons of acid. It is also used to a smaller extent in the manufacture of nitric acid, and for making the pipes which carry the gases from the roasters in the manufacture of hydrochloric acid. It can be used for making condenser worms, small electrolytic tanks where the process requires the maintenance of a high temperature, and so on. The great advantage of "Vitreosil" is that it is practically unaffected by temperature changes, the coefficient of expansion being about one-seventeenth that of glass. Owing to this property, its high fusibility and its resistance to acids, quartz is now being very largely used for the manufacture of laboratory apparatus.

The issue of the "Statesman's Year-book" for 1910 has been published by Messrs. Macmillan and Co., Ltd. This is the forty-seventh annual publication of an invaluable work of reference. The information throughout the 1500 pages has been corrected to the latest available date, and the changes made necessary by the death of King Edward VII. and the accession of King George V., as well as those arising out of the Union of South Africa, have been recorded. The proposed changes in the administration of the Belgian Congo are indicated; the sections on China and on the Anglo-Egyptian Sudan have been improved. Among matters of current interest, reference may be made to the articles on "Second Chambers" and the results of the census of production. As usual, the annual provides a number of new maps, and among them may be mentioned those showing the development of the Congo, the proposed Central Scotland and Georgian Bay Ship Canals, the United South Africa and South African railways, and South America, showing the railways. Altogether, this edition of the "Year-book" is well up to the high standard one associates with Dr. Scott Keltie's editorship. The price of the book is 10s. 6d. net.

Messrs. Rebman, Ltd., hope to publish during the present month a new book by Dr. Bernard Hollander entitled "The Mental Symptoms of Brain Disease," with a preface by Dr. J. Morel, Belgian State Commissioner in Lunacy.

A second edition of Dr. Washington's "Manual of the Chemical Analysis of Rocks" has been published by Messrs. John Wiley and Sons in New York and Messrs. Chapman and Hall, Ltd., in this country. The first edition appeared in 1904, and was reviewed in these columns on January 5, 1905 (vol. lxxi., p. 219). The present issue has been revised and somewhat enlarged.

OUR ASTRONOMICAL COLUMN.

Halley's Comet.—Dr. Ebell's ephemeris for Halley's comet is continued in No. 4423 of the *Astronomische Nachrichten*, and gives the positions, &c., up to September 18. On July 16 the comet will be in R.A. 10h. 59·4m., dec. $-4°$ 2·7′, and its estimated magnitude will be 6·3, so that further observations in these latitudes are impossible. The distances from the earth and sun, on that date, will be 197 and 162 million miles respectively.

Owing to its apparent proximity to the sun, the comet could not be extensively photographed at any one observatory, but it is hoped that when the results from various observatories come to be compared, there will be a fairly continuous record which will enable the changes in the tail to be closely followed. An example of such change is afforded by the negatives secured at Johannesburg on April 21 and Kodaikanal on April 22, the latter showing, among other changes, a large contorted streamer on one side; the similarity to the tail of Morehouse's comet is thus emphasised.

A spectrum of the comet, taken at Mount Wilson, was described by Prof. Fowler, at the last meeting of the Royal Astronomical Society, as being of the usual type. Dark Fraunhoferic lines, due to reflected sunlight, are shown in the narrow strip of the spectrum due to the nucleus, and in that of the coma the bands at λλ 473, 421, and 388 are seen. Prof. Fowler suggested that the unequal intensities of the five heads in the cyanogen, 388, band were, possibly, indications of a rather low pressure condition. A comparison of this spectrum with that of Daniel's comet (1907), taken by Prof. Campbell, shows that they are practically identical.

In the *Comptes rendus* (No. 1) for July 4 Prof. Eginitis describes the appearance of the comet at Athens since its inferior conjunction. An increased activity of the nucleus ejected large masses of matter to great distances, and on May 31 an aigrette was seen, which was brighter than the nucleus itself and turned away from the sun; this was made up of straight streamers 50″ long diverging to form an angle of 60°. It was also noticed that, after the passage, the tail became much more brilliant than before, an effect which the author ascribes, in great part, to the change in the relative positions of the comet, the sun, and the observer. From this he deduces that the brilliancy of the tail is largely due to reflected sunlight, and suggests that it affords further evidence that the tail is, to an appreciable extent, made up of fine, solid particles.

Photographic and visual observations of the spectrum, made at the Madrid Observatory since the conjunction, are described by Father Iniguez. Photographs taken on June 1, 3, and 6 show the continuous spectrum and seven superposed monochromatic images of the coma. The three least refrangible of these were observed in May, and of the four new ones the two brightest are in the extreme ultra-violet, beyond the continuous spectrum. The plate taken on June 1 shows each of the three less refrangible bands doubled. Three of the four more refrangible bands are well defined, and their wave-lengths are given as 437, 425, and 391; the other is broad, extending from λ 399 to λ 407. The visual observations indicate an intrinsic change in the band recorded as λ 567 on May 27 and as λ 559 on May 30; on the former date the red edge was sharp, whereas on the latter it was diffuse, and was not the most intense part of the band. The green band at λ 512 on May 27 and λ 516 on May 30 was sharp and apparently composite, and the difference of wave-length is attributed to a relative change in the intensities of the components *inter se*. Apparently the band at λ 472 did not change. The visual and photographic observations of the tail showed various, although not pronounced, changes, which are discussed in the note; until May 6 the tail was of the first type, but from then until the passage of the comet it was of the second, reverting to type i. after the passage.

Prevention of Dew Deposit upon Lens Surfaces.—In a paper published in No. 7, vol. lxx., of the Monthly Notices, Mr. Franklin Adams states that the Mervel Hill photography of the northern hemisphere stars could have been completed in two years instead of nearly six if some means had been devised for preventing the deposition of dew on the lens surfaces.

He then describes a method by which the difficulty has now been overcome. An air-pump, driven by a motor, delivers a current of dried air on the lens surfaces, inside the camera, and on the film of the plate, thus preventing the dew deposits. The air is dried by forcing it over pumice stone soaked in sulphuric acid and then over glass wool.

A Variable Star as a Time Constant.—Having regularly observed a variable star, No. 33 in the Harvard list, in the cluster M. 5 (Libra), Prof. Barnard discusses its light-changes in No. 4409 of the *Astronomische Nachrichten*. This star was compared with a neighbouring star, which is designated k, and for ten years its period has apparently remained unchanged. Therefore Prof. Barnard suggests that it, and other similar variables, might prove useful for providing a check on the constancy of the earth's rotation, or any other possibly variable elements of the solar system. It rises sharply to a maximum, at which it seems to remain for only a few minutes, and then declines quickly until it is as bright as k; after that the decline is more leisurely. At minimum the magnitude is 14·6, and the increase is rather more than 1·2 magnitudes, the period being 0·50147+d. To facilitate observations of this interesting time-standard, Prof. Barnard gives an ephemeris which is useful up to the year 1918.

Radiation and Absorption.—In discussing various astronomical phenomena, the observer often has to study numerous laws concerning radiation and absorption, and this frequently necessitates looking them up especially. To obviate waste of time in this direction, Prof. Humphreys brings together, in No. 4, vol. xxxi., of the *Astrophysical Journal*, the chief laws, and discusses the general formulæ by which they are expressed. Thus the equations for the Doppler, Maxwell-Bartoli, Zeeman, and other effects are explained, and the most convenient formulæ for general use are collected in an invaluable summary which should prove of great convenience.

THE FIFTH INTERNATIONAL CONGRESS OF ORNITHOLOGISTS.

THE fifth International Congress of Ornithologists took place in Berlin from May 30 to June 4. Like all the former congresses of its kind, it was well attended, although only a single American and comparatively few English ornithologists were present.

The opening address of the president, Prof. Anton Reichenow, of Berlin, was a lucid, though necessarily short, review of the progress of ornithology within the last 150 years and its present status.

The Hon. Walter Rothschild delivered a lecture on the former and present distribution of the so-called Ratitæ, embracing also some very interesting recent investigations by Mr. C. W. Andrews on the egg-shells of certain ostriches, especially some pieces of the egg of a fossil ostrich, found last year by Messrs. Rothschild and Hartert in the Algerian Sahara. Baron Loudon gave descriptions of the bird-life in Talysch and Transcaspia; Prof. Koenig narrated his journey up the Nile to Lado and Gondokoro; Dr. Otto Hermann explained the activity of the Royal Hungarian Central Bureau of Ornithology; Dr. Thienemann that of the "Vogelwarte Rossitten," especially the method and results of his experiments with "ringed birds"; while the other lectures held in the general meetings were about bird-protection and the preservation of "nature's monuments" as connected with bird-life. Numerous communications were made and lectures delivered in the various sections, their number being so great that in some of the sections the time available was hardly sufficient, and discussions had sometimes to be cut short. Of the lectures in the sections, mention can only be made of a few, as most of them were only of interest to specialists.

The proceedings of section i. (systematic, palæontology, anatomy, and geographical distribution) were opened with a lecture by Dr. Hartert, on "what we ought to do and what we ought not to do." The speaker pointed out many evils and shortcomings in the technical treatment of modern bird-study; he specially urged greater care to avoid new synonyms, demanded better descriptions, more cooperation, &c. He pointed out the necessity of liberality in lending specimens to competent persons and institutions, and regarded museums which did not lend material to others as behind the times. He also made clear the necessity of greater care in preparing and preserving the material for study, especially bird-skins, held that they should be more exactly and more securely labelled, and discussed various other technical details.

Mr. Friedrich Rosenberg spoke about the development of the Colymbidæ, Prof. Jacobi discussed the development and systematic position of the "Impennes," and Geheimrat Prof. Virchow gave the results of his study on the mobility of the nuchal vertebræ in the Spheniscidæ.

Prof. Neumann discussed zoogeographical problems, specially referring to the necessity of careful geographical study in connection with the description of subspecies of birds, and their distribution.

In section ii. (migration) a number of lectures were given, of which that of Rittmeister von Lucanus, about the height at which birds migrate, appeared to be of special interest.

In section iii. (biology, oology, acclimatisation), Mr. Lucanus also made very important statements regarding the psychology of birds. Dr. and Mrs. Heinroth lectured on the biology of certain Anatidæ, and on the breeding in captivity of Caprimulgus and Locustella.

Graf Zedlitz dealt with the breeding-seasons of African birds.

Dr. Weigold gave interesting details about the former and present status of bird-life on Heligoland, and recommended the continuation of regular observations on that island "before it would be too late."

In section iv. (bird-protection) the necessity for the prohibition of the introduction of feathers and bird-skins for millinery purposes was urged, and the question of international bird laws discussed.

Section v. was devoted to poultry and other domesticated birds, and appeared to be well attended.

At the meeting of the International Ornithological Committee it was decided that the *Ornis* should not be continued in the form of a regular periodical, but of irregular volumes containing the proceedings of the various ornithological congresses, and special scientific treatises, in the event of material and means being available for the purpose.

In every town a congress has its peculiar features. While some of the characteristics of the fourth Congress of Ornithologists in London were the excursions to Tring and Woburn Abbey, and the visit to the Bempton Cliffs, with their breeding-colonies of sea-fowl, the congress at Berlin was remarkable for the various liberal entertainments in the town. The city gave a dinner in the famous Town Hall, the Zoological Garden Society a luncheon, the Ornithological Society a supper, and one evening was pleasantly spent in the natural history theatre, called "Urania."

An illustrated guide and excellent map of Berlin were presented to every member, also a reprint of Lichtenstein's very rare "Verzeichniss einer Sammlung von Säugethieren und Vögeln aus dem Kaffernlande," of 1842, a description of the "Vogelwarte Rossitten," and various other pamphlets and booklets. E. H.

THE DANGERS OF FERRO-SILICON.[1]

FERRO-SILICON, averaging about 13 per cent. silicon and made in the blast-furnace, has been used in steel works, and to a certain extent in iron foundries, for many years. Steel castings were made with about 0·3 per cent. silicon to help in the prevention of blow-holes, and at the same time to aid in giving the properties required by engineers; and in foundries the ferro-silicon is used to add to mixtures of iron, such as those containing large percentages of scrap, that would otherwise yield a hard casting, as the added silicon has the effect of changing the combined to free or graphitic carbon on cooling. Within the last few years much richer ferro-silicons have been made in electric furnaces, and have found a ready sale. They are useful for special crucible steels and for certain steels for electrical work, and also for adding silicon in the ladle in the case of basic open-hearth practice, as there it is impossible to do this efficiently on the hearth, though it is easily done in the acid process.

With the electrically produced high-grade ferro-silicon came trouble. The present writer remembers the great interest taken in the earliest recorded case of this trouble as given by Dr. Dupré and Captain Lloyd at the Iron and Steel Institute in May, 1904. Owing to a fire having occurred on a vessel, the cargo, including 50 per cent. grade ferro-silicon brought from Trieste, was discharged on December 17, 1903. On January 12, 1904, the forty-eight drums containing the ferro-silicon were removed to a warehouse in Bootle, and whilst being rolled from the truck on to the concrete floor one drum exploded. Dr. Dupré and Captain Lloyd, after careful investigation, pronounced the explosion to be due to PH_3 evolved owing to the action of damp air, and gave a weighty and serious warning with regard to the handling and storing of this comparatively new product.

So explosions and spontaneous ignition came in the train of the new material; but it was to make its powers felt in another way. On the S.S. *Vaderland*, Antwerp to New York, over a hold in which ferro-silicon was stored, fifty steerage passengers were made ill and eleven died, of whom nine were buried at sea, and two corpses landed at New York, as plague was feared. In March, 1906, two children died on a Rhine boat. On October 21, 1905, two children died on board a "keel" on the Keadby Canal; the father and mother were taken seriously ill, but recovered *on deck*. In February, 1907, on the *Olaf Wyjk*, Gothenburg to Antwerp, four passengers died. In May, 1908, on the S.S. *Uleaborg*, Stockholm to St. Petersburg, the crew and second-class passengers were taken ill, and two died. On October 29, 1908, on the keel *Harry*, Captain Bamfield and the mate, his grandson, started from Goole with ferro-silicon on board, apparently consigned as "scrap iron." On the night of Friday, October 30, the mate was

[1] "On the Nature, Uses, and Manufacture of Ferro-silicon, with Special Reference to possible danger arising from its Transport and Storage." Local Government Board Report, 1909. By Dr. S. M. Copeman, F.R.S., S. R. Bennett, and Dr. H. Wilson Hake. Pp. viii+115. (Cd. 4958.) Price 1s. 11d.

taken seriously ill and removed. The captain took his wife and grandson on board and proceeded, but all three were taken ill. Bamfield died on November 6 and his grandson on the previous day. The cause of death was certified under that convenient term "ptomaine poisoning," but was afterwards proved to be due to fumes from the ferro-silicon of 50 per cent. grade (actual analysis, 53·9 per cent. silicon).

It required, however, yet another tragedy, with the added scare of cholera, to compel investigation, and this was provided by the case of the S.S. *Ashton* in December, 1908, on which, after a voyage of twenty-four hours only, from Antwerp to Grimsby, all the occupants of the emigrant quarters, fortunately only five in number, died between 6 p.m. on December 12 and 12.30 p.m. on the following day. This time cholera was feared, but examination by the Government bacteriologist at once negatived this view. Mrs. Bamfield wrote on December 17, 1908:—"It has occurred to me since reading the account of this poisoning that there may be some of this (scrap) in the S.S. *Ashton*." Immediately these deaths were reported in the newspapers, Mr. Hodgson, Mrs. Bamfield's son-in-law, wrote to Dr. Simpson, medical officer of health for Grimsby, making a similar suggestion, and that this was the cause of the deaths (p. 20):—"It was apparently in consequence of this letter that attention came to be directed to the possibility of the deaths on the S.S. *Ashton* having been due to the presence of the ferro-silicon on board, suspicion having arisen, in the first instance, that the fatal illness of the passengers was due to cholera." This was abundantly proved, and resulted in the elaborate investigations of which this report is the record.

The report is a valuable one, showing that the authors have recognised the difficulties and grappled with them. The original should be in the hands of all interested in ferro-silicon from a medical, a shipping, or a metallurgical aspect. As the authors themselves state, further investigation is yet required, although rules that will almost ensure safety have been found.

Ferro-silicons of low grade, containing not more than 15 per cent. silicon and made in the blast-furnace, are beyond suspicion, and as safe to handle and to store as ordinary pig iron. The high-grades, 25 to 95 per cent. silicon, made in the electric furnace, and imported to the extent of about 4000 tons per annum, mostly from France, but to a less extent from Austria, Scandinavia, &c., include the dangerous varieties. The bulk has been made to 50 per cent. grade for little apparent reason other than ease in calculation of mixtures, a matter that may excite surprise until it is remembered that a manager, with his hundred worries per day, tries to avoid the hundred-and-first, in case it might prove "the last straw." The gases given off may at first have included acetylene, owing to the ferro-silicon being made in calcium carbide furnaces, but as that is never done now the poisonous gases given off are phosphoretted hydrogen and arseniuretted hydrogen, roughly 90 to 95 per cent. of the former to 10 to 5 per cent. of the latter. All are agreed that until more is known of the fundamental causes, those varieties around 50 per cent. silicon are most dangerous, and should neither be made nor bought. La Chambre Syndicate des Forces hydrauliques states that 30 to 40 per cent. and 47 to 65 per cent. grades should be avoided, but the remarkable omission of 40 to 47 per cent. grades is not supported by any experimental proof. The authors recommend the manufacture or use of only those varieties below 30 per cent. or above 70 per cent. silicon content for the present.

The section on the functions of ferro-silicon in steel manufacture hardly gets to the root of the real idea sometimes, but is near enough for general readers; and technical men are not likely to refer to this section of the report. It will be read for the results of the experiments and general investigations carried out and the opinions formed on the results, and these can be recommended. The report contains, besides matter already indicated, reports of conferences with Sheffield firms using ferro-silicon, investigations at places of manufacture, a description of the manufacture of ferro-silicon, conclusions and recommendations, Dr. W. Hake's chemical investigations, and Mr. Bennett's report on the composition and structure of ferro-silicon.

As the PH_3 is only formed in contact with moisture, the material used to be packed in sealed drums, and sometimes was coated with paraffin wax; but this does not deal with the gas present in the cavities, and only transfers the danger, for drums exploded on opening and men removing the paraffin were made ill, so that these methods should be abandoned.

The report recognises an important point that is still obscure (p. 109):—"Dr. Heroult expressed himself as decidedly of opinion that the specially undesirable qualities exhibited by this particular grade (50 per cent.)—tendency to spontaneous disintegration and evolution of poisonous gases—were related to the amount of *aluminium* present in the alloy. He was unable . . . to advance any definite reasons for the opinion he had formed." Mr. Bennett later expressed the same opinion, and suggested that, as the heat of formation of Al_2O_3 is very great, the presence of a large percentage of aluminium is indicative of very high temperature reactions in the furnace, and that these reactions are favourable to the formation of compounds which readily break up into poisonous and explosive gases."

This can hardly be so, for Prof. Arnold, who, it is understood, will present a report later, has had one lot of ferro-silicon divided into two portions and melted in two crucibles. When molten, to one only was added 3 per cent. aluminium, and the two portions were cast into separate ingots. The present writer, being interested in the experiment, broke a piece off each ingot, and, dipping them in water, noticed that one had no particular odour, but the other smelt very strongly, the latter proving to be that to which aluminium had been added. A too enthusiastic repetition of the experiment as a test produced just a feeling of discomfort which the fresh air soon dispelled, this last being a point of much importance, as where lives were saved it was practically the governing remedy. "Two of the passengers also left their cabins and, although very weak, succeeded in getting on deck. These two survived" (p. 15). No. 5 of suggested regulations may be quoted:—"Storage places at docks or at works where ferro-silicon is used should have provision for free access of air, and should be situated at a distance from work-rooms, messrooms, offices, &c." (p. 115).

The main conclusions of the report have been mentioned, but all interested in the subject should obtain a copy, as the details of the investigations are well worthy of study.

A. McWILLIAM.

THE POSITION OF THE NEGRO AND PYGMY AMONGST HUMAN RACES.[1]

A FULL analysis of the structural features of the negro shows that in many points he is more highly specialised than the less pigmented races of mankind, while in other characters he has remained more primitive. Although on the Continent there is a decided tendency amongst anthropologists to trace the descent of the human race through a non-anthropoid stock, yet those most familiar with the anatomy of the Primates still agree with Huxley's doctrine that the community of structure shared by man and anthropoids pointed to a direct community of origin. The deeply pigmented skin was a primitive feature; the gorilla was the negro amongst anthropoids; the three species of chimpanzee varied as the period of life at which pigmentation appeared. All available evidence points to a pigmentation of the early human stock, but speculations are handicapped by an ignorance of the functional value of pigment. It appears to protect the deeper tissues from certain injurious rays which are intermediate to heat and light. The skulls of Palæolithic Europeans show so many resemblances to those of Australian aborigines that a legitimate suspicion may be raised as to whether or not they did not also share some degree of the aboriginal pigmentation. The Palæolithic Gibraltar woman, whose skull is preserved in the Museum of the College of Surgeons, shows no community with the negro in the characters of her nose. The nose of that skull is altogether unlike that of any human race now known; it shares some features with the gorilla, while

[1] Abstracts of four Hunterian Lectures on "The Anatomy and Relationships of the Negro and Negroid Races," given at the Royal College of Surgeons, England, by Prof. Arthur Keith.

in others it appears to foreshadow the prominent nose of the modern European.

The evidence of the nose of Palæolithic man leaves the question of pigmentation of the early European open. The distribution of pigmentation among modern races could be explained best by supposing that the appearance of the fairer races—the Caucasian and Mongolian—was one of the more recent events of human evolution, and that the site of their evolution was in the central populations of the more northern parts of the Old World. The frizzled hair of the negro was a highly specialised feature. Their thick everted lips, unlike the thin anthropoid lips, at first sight seem also to be so, but when the arrangement of the labial musculature is examined, it is seen that the negro's lips are more anthropoid than the European's; but the European form, notwithstanding their apparent thinness, appears to be a modification of the negro form. The high and prominent cheek-bones of the negro are due, not to an absolute greater breadth of the face, but to the fact that the muscles of mastication have become specialised in different directions in the negro and European; in the negro the masseter muscle, which arises from the cheek-bone, is particularly large, whereas in the European it is the temporal muscle, which has its fixed basis on the side of the skull, that retains the greatest relative development.

The apparent breadth of the negro's face is largely owing to the fact that the basal part of the skull, to which the neck muscles are attached, is small. The small attachment of neck is a feature of the young of all Primates, and also one in which the negro has assumed a less anthropoid form than the European. The prognathism of the negro is due to several factors; it is chiefly due, not so much to a larger, but to a healthier dental development, which ensures a due forward revolution of the jaws during the eruption of the permanent teeth, thus providing an ample air-way in the pharynx. In Europeans the revolution forwards of the jaws showed a distinct tendency to become arrested prematurely, thus contracting the pharynx. The negro condition was the more Simian, but it is also one which modern Europeans would willingly share with him, because of its functional merits. Sir William Flower's method of estimating prognathism gave misleading results. The most accurate method of stating the development of the jaws was to give the area of the palate and the total size of the teeth.

Some of the most characteristic features of the negro race were to be seen in their foreheads. While Palæolithic Europeans showed the Simian beetling brows and receding forehead, features still shown in some degree by modern white races, the great majority of African negroes were characterised by prominent foreheads and a complete absence of that condition which might be described as supra-orbitalism. It is true that some tribes on the west coast, the oceanic negroes, and the Tasmanians still retain this primitive character. Indeed, the outstanding feature of the negro's skull is a tendency to retain characters of the immature skull of other races. Those who know the psychology of the negro best ascribe to his brain the boyish nature here ascribed to his skull.

The pygmies, usually described as Negritos, are true negroes in which the tendency to assume immature characters has become hereditary to an extreme degree. They are widely distributed. Sir Harry H. Johnston has shown how they are scattered amongst the forest tribes from the west coast almost to the east coast of Equatorial Africa; they stretch southwards almost to the Cape, and isolated communities are found as far eastwards as the Philippines and New Guinea. Two explanations may be offered for their distribution:—(1) they are remnants of a race that was spread formerly throughout the southern half of the Old World; (2) they are modifications produced locally from the larger negro. The second explanation is apparently the correct one, for the Congo pygmies share all the physical features of the Bantu except size; the Bushman has the characters of the Hottentot, while the pygmies of the far east find their nearest representatives in the negroes of the Oceania. Recent advances in our knowledge of human pathology make this supposition of the origin of pygmies more probable. Disturbances in the secretion of certain glands, such as the pituitary and thyroid, lead to the production of the characters of Palæolithic features in some individuals and true dwarfism in others. In the Miocene period the large-bodied Primates had already appeared; primitive men were certainly not pygmies in size.

An analysis of the cranial features of the aborigines of Tasmania and of Australia shows that we have in these two races an early stage in the differentiation of the negro and negroid races of mankind. The Tasmanian is the most primitive type of *negro* yet discovered; the Australian, on the other hand, although deeply pigmented and less Simian in some features than the Palæolithic European, is the most primitive representative of the *negroid* race. Negroid as he is, the native Australian represents a stage in the evolution of the dominant non-negroids of the northern hemisphere. It is a remarkable fact that the negro and negroid races occur side by side, not only in Austral-Asia, but in Asia proper and in Africa. The negro Semangs of the Malay Peninsula live with the negroid Sakai as neighbours; the Veddahs of Ceylon are not far from the negro of the Andamans; even in Quaternary Europe the negro race discovered by Dr. Verneau in the caves of Grimaldi were early successors, if not contemporaries, of Palæolithic man. The Grimaldi negroes find their nearest modern representatives in the Oceanic, not the African, negro; equatorial Africa and northern Europe were the probable centre in which the black and white races had reached their present degree of structural evolution. The two centres were linked together, and always had been linked, by racial zones which showed intermediate characters. Modern anthropologists are inclined to ascribe the characters of intermediate races to intermarriage. Interbreeding had certainly played a part, but probably a small one. The truer explanation seems rather to lie in regarding intermediate races as representing intermediate stages of physical and mental evolution.

TREES AND FORESTS.

THE botanical gardens at Peradeniya, Ceylon, are celebrated for their vegetation splendour, so that a list of beautiful flowering trees recommended by the curator, Mr. H. F. Macmillan, will appeal to many outside the range of those for whom the Circular (vol. iv., No. 20) of the gardens is immediately intended. In the author's opinion, the leguminous tree *Amherstia nobilis* is not to be excelled, although *Lagerstroemia flos-reginae* passes under the name of "pride of India," and *Poinciana regia* is the famous "flame-tree." The Amherstia was introduced to Ceylon from Burma, and it is remarkable how many of the plants mentioned have been imported from the tropics of the New and Old World. *Gliricidia maculata* is a recent introduction from the West Indies; *Solanum macranthum*, the "potato-tree" from Brazil, is noteworthy as the only species of the order that grows to the size of a tree.

A description of the indigenous trees of southern Rhodesia, together with their vernacular names and products, is provided by Mr. C. F. H. Monro in the Proceedings of the Rhodesia Scientific Association (vol. viii., part ii.). An important matter is the production of timber suitable for mining, construction, and agricultural purposes. The most useful timbers are yielded by *Copaifera mopani*, *Pterocarpus angolensis*, *Photinia mahobohobo*, and *Parinarium mobola*. *Baikiaea plurijuga* is known as Rhodesian teak; *Afzelia cuanensis* supplies the local mahogany, while a somewhat similar, handsome wood is furnished by *Faurea saligna*, a species of Proteaceæ. The woods of some of these, as also of *Callitris Whytei* and *Terminalia sericea*, are said to be ant- and borer-proof.

Two forest pamphlets (Nos. 12 and 14) recently issued by the Government of India relate to *Berrya Ammonilla*, a tree, belonging to the family Tiliaceæ, that is found principally in Burma, and *Pterocarpus macrocarpus*, a leguminous tree yielding Burma padauk timber. Regarding the former, logs up to 20 feet in length, and measuring $4\frac{1}{2}$ feet in girth, can ordinarily be obtained. The timber is tough, elastic, and straight-grained; it works and finishes well, so that it would appear to be suitable for export; but the annual outturn is only computed at 1500 tons, and there is a good local demand for construction work, for carriage shafts, draught poles and various agricultural implements. Burma padauk must be distinguished from Andaman padauk, obtained from *Pterocarpus dalbergioides*, which is noted for the brilliant red colour of select logs. Although inferior in colour, Burma padauk is much superior in strength and durability, and is regularly supplied to the Ordnance Department for spokes and felloes of wheels, poles, yokes, and other purposes. Timber which does not comply with the stringent requirements of the Ordnance Department is quite suitable for wheel work, furniture, and interior decorations. Both kinds of padauk have been imported to England and America, but various causes have militated against their successful exploitation in this country.

A forest pamphlet (No. 16) issued by the Government of India is devoted to an account of experiments conducted by Mr. R. S. Hole with the view of determining the best season for coppice fellings of teak. The rainy season—mid-August to October—is frequently selected for felling, although it might be expected that, vegetative activity being then at its height, the development of coppice shoots would be poor. However, the trials carried out, with many precautions, indicate that the worst period for the fellings is from the time, April to August, when vegetative activity commences, up to and for a short time after the full development of the foliage, and that reproduction is most vigorous in the months of March and September. Incidentally, the author notes that good fertile seed has been obtained from nine-year-old coppice shoots of teak.

It is a coincidence that information regarding the importance of trees belonging to the Dipterocarpaceæ should be forthcoming simultaneously from Burma and the Philippines. In the *Philippine Journal of Science* (Botany, vol. iv., part vi.) Mr. H. N. Whitford presents some striking estimates regarding the preponderance of the family in the Philippine forests, according to which Dipterocarp trees may be expected to yield three-quarters of the total volume of merchantable timber growing in a virgin forest area computed at 30,000 square miles. He directs special attention to the value of the woods known locally as "lauan," yielded by species of Pentacme, Shorea, and Parashorea, and "apitong," yielded by species of Dipterocarpus; the former are slightly harder but similar to white pine, while the latter compare with the hard pines.

A paper on Indian State forestry, by Mr. S. Eardley-Wilmot, late Inspector-General of Forests, is published in the Journal of the Society of Arts (April 1). He mentions that the forest department has control over an area of 240,000 square miles—about one-fifth part of British India—from which 4½ million tons of timber and 180 million tons of bamboos are extracted annually. A rough demarcation of the forests is indicated as follows. They range from a height of 14,000 feet, where birch and firs supply the chief constituents, to the mangrove belts situated at sea-level. At an altitude of 8000 feet rhododendrons, oaks, cedars, and pines flourish in different regions. *Dalbergia Sissoo* and *Acacia Catechu* grow in the submontane forests. The deciduous forests at a lower elevation supply teak, sál, ebony, and ironwood, while important evergreen forests are found near the coast or further inland.

A number of interesting problems receiving attention at the Swedish Royal Forestry Institute are detailed in the Proceedings (*Meddelanden från Statens Skogsförsöksanstalt*, part vi., 1909), such as the examination of the native forests from an ecological standpoint, the best trees to plant on heath or swamp land, and the improvement of regeneration by the selection of seed. In connection with the last problem, Dr. N. Sylven communicates the results of his attempt to identify different races or types of the spruce; he distinguishes five types, according to their mode of branching, of which the so-called "kamm" type is recommended as the best seed-bearer. An extensive paper by Mr. E. Wibeck deals with the extent of the beech forests in Sweden, showing that the area has decreased greatly in a period of 200 years, having been reduced partly by human agency, by fires, for the manufacture of potash, and by excessive cutting, and partly by natural causes, such as the intrusion of the spruce.

Two articles by Mr. R. Thomson on the Jequié Manicoba rubber tree, *Manihot dichotoma*, published in the *Indian Forester* (vol. xxxvi., Nos. 1–3), contain suggestions which appear to be worthy of careful consideration. This species, indigenous to the State of Bahia, in Brazil, forms a tree about 20 feet in height, and develops a stem 20 inches in circumference. The author contends that, being much smaller than the Para rubber tree, there is less production of useless material, and that it could be planted more closely, so that by planting 1200 specimens to the acre he estimates a production of 600 lb. of rubber per acre in the fifth year. It is further suggested that climatic difficulties might be overcome by a system of cultivation in rough sheds, such as is adopted in California for growing pineapples.

TINCTORIAL CHEMISTRY, ANCIENT AND MODERN.

IN his recent presidential address to the Society of Dyers and Colourists Prof. Meldola touched upon several matters of general interest and importance. Referring to the substitution of synthetical for natural dyes, which has entailed great changes in the dyer's methods, he said:—"Such a revolution in an industry of venerable antiquity as has been effected in about half a century has, perhaps, never before been witnessed in the history of applied science. Scientific discovery has, it is true, called new branches of industry into existence, and has thus opened up new fields of human enterprise and outlets for capital and labour. But in this case there has been no new creation; an ancient industry at the touch of science has become transformed.

"If it be asked to what cause or causes this rapid development is due, there can be only one answer—the development of the science of organic chemistry. From the time of Perkin's discovery of mauve in 1856, down to the very latest patents for new dyestuffs, it has been science, and nothing but science, all along the line."

It is, of course, equally true, as Prof. Meldola has himself pointed out elsewhere, that the development of the science of organic chemistry has been greatly accelerated by the large amount of research work carried out in the laboratories of the large German colour manufactories. In regard to the general question of the interdependence of science and industry, he has been one of the chief propagandists for the last twenty-five years, on the platform and in the Press; and on this matter he said:—"It has long been familiar to students of economics—whether we in this country recognise the doctrine or not—that industrial development is ultimately dependent upon scientific development. Fiscal considerations may have some influence in promoting or retarding an industry, but primarily the financial economist, as well as the political economist, is dependent upon the materials supplied by productive industry, and the production of these materials in the most advantageous way and the addition of new materials to the resources of civilisation is the business of scientific research, and it is, therefore, scientific activity which is the real and solid basis of national prosperity. The nation which fails to realise this principle is bound to go under in the long run in that industrial struggle which is certain to become keener with the progress of science and the severity of competition arising therefrom."

This primarily important matter cannot be too often brought forward, but, at the same time, although we have much leeway to make up before we come abreast with our chief industrial competitors, there are signs that at last the nation *is* "waking up" to realise the position. The daily Press, as reflecting the average interests of the public, is now paying an increasing amount of attention to scientific matters. It is no doubt an easy matter to be adversely critical in regard to the quality of the science which is served up in our morning paper, but that is easily remedied, and the all-important matter is that science is fast achieving a prominent place as a current newspaper topic.

An adequate historical survey of the modern science of tinctorial chemistry has yet to be written. In his address Prof. Meldola supplied one chapter of such history by relating his personal experiences during the fifteen years (1870–85) he was directly connected with the manufacture of synthetical dyestuffs. It is not possible to summarise this historical survey in the space now at disposal, but the hope may be expressed that Prof. Meldola will find opportunity to write the complete story of the art of dyeing. It would be equally as fascinating as his well-known contributions to Darwinism.

Having given his personal reminiscences of the most prolific period during the rapid modern development of the industry, Prof. Meldola reverted to remote antiquity, and summarised the ancient industrial history of dyeing as described by the elder Pliny in his "History of Nature," written about the beginning of the Christian era. Indigo has probably been used by the natives of India for at least 3000 years, and by processes essentially the same as those used to-day; in fact, until Perkin's discovery of the first coal-tar dye in 1856, the art of dyeing has made comparatively little progress since the ancient Briton stained his body with woad.

The most important dye in ancient times was the Tyrian purple, the use of which was at first confined by law to the Imperial House—hence the expression "born in the purple."

"The modern sequel to this ancient chapter of tinctorial art," said Prof. Meldola, "has been supplied by P. Friedländer, who has extracted the colouring matter from the Mediterranean *Murex brandaris*, and has proved it to be dibromindigo.[1] And thus ancient observation, which found practical application in the utilisation of a certain mollusc as a source of colour, has led to a remarkable biochemical discovery; but we have had to wait some 2000 years for the answer to the question, What was the purple dye of the ancients? Shall we have to wait another 2000 years for the answer to the question, How does the living shell-fish synthesise the generator of dibromindigo?"

Much has been written, and many diverse opinions have been expressed, as to the cause or causes of the loss of the coal-tar colour industry to England. This has been variously attributed to defects in our Patent Laws, to our heavy excise duty on alcohol, and to our unsuitable industrial conditions. In this matter Prof. Meldola sounded no uncertain note. "The answer to this last question has been staring us broadly in the face for over thirty years. It is amazing that there should have ever been any doubt about, or any other cause suggested than the true cause, which is *research*—writ large! The foreign manufacturers knew what it meant and realised its importance, and they tapped the universities and technical high schools, and they added research departments and research chemists to their factories, while our manufacturers were taking no steps at all, or were calmly hugging themselves into a state of false security, based on the belief that the old order under which they had been prosperous was imperishable. It is true that when the effects of the new discoveries began to make themselves felt, one or two factories did add a research chemist to the staff, but the number and the means of work were totally inadequate. I happened to be one of them, and so I speak with some practical knowledge of the conditions. We were but as a handful of light skirmishers against an army of trained legionaries. What could three or four—say half a dozen at a liberal estimate—research chemists, working under every disadvantage, do against scores, increasing to hundreds, of highly trained university chemists, equipped with all the facilities for research, encouraged and paid to devote their whole time to research, and backed up by technological skill of the highest order? The cause of the decline of our supremacy in this colour industry is no mystery—it is transparently and painfully obvious. In the early stages of its decadence it had little or nothing to do with faulty patent legislation or excise restrictions with respect to alcohol. The decay of the British industry set in from the time when the Continental factories allied themselves with pure science and the British manufacturers neglected such aid, or secured it to an absurdly inadequate extent in view of the strength of the competing forces."

It still remains to inquire the reason for this different attitude towards chemical research which was, and is still, though in lesser degree, adopted by our manufacturers. At the time we lost the industry the skill of the British workman and the enterprise of the British manufacturer were the admiration of the world, but the colour industry did not develop here because our industrial leaders did not lay the foundation of success by subsidising and cultivating chemical research. Why? The answer to this question is to be ultimately found in the utter lack of appreciation of the value and importance of scientific method which existed at that time amongst the public in this country. It would then have been impossible to convince any body of shareholders that it was a sound business proposition to expend yearly many thousands of pounds in research work the outcome of which was problematical. It would, indeed, not be an easy task even in these more enlightened days.

WALTER M. GARDNER.

[1] *Berl. Ber.*, 1909, vol. xlii., p. 765. For this research 12,000 molluscs were extracted, the total yield of pure colour being 0·4 grms. The dibromindigo is formed from its colourless generator, which is a vital product of the organism, by the action of light. The actual compound is shown to be the 6:6ʹ-dibromindigo, but the nature of the intermediate generator has not yet been determined.

THE MEDICAL INSPECTION OF SCHOOL CHILDREN.[1]

LESS than three years ago there did not exist a medical department of the Board of Education. To-day there lies before us a Blue-book, of 170 pages, detailing, with much substance, the work undertaken or done to establish and regulate the vast system of medical inspection of schools and school children now operative over the length and breadth of England. In modern social history no movement has come so rapidly to maturity as the system of inspection here, for the first time, placed in a connected way before the general and official public. In a lucid preliminary section Dr. Newman briefly sketches the relation of our present developments to the efforts, both here and on the Continent, towards a systematic medical supervision of school children. "In the latter year (1865), the report of the School Commission in Norway did something to bring the importance of school hygiene once more before the general public, and in 1866 Hermann Cohn undertook his classic researches into the eyesight of over 10,000 children at Breslau" (p. 2). Cohn, now dead, was one of the venerable figures at the first International Congress of School Hygiene at Nuremberg. He was still full of energy and enthusiasm. Much occasional and disconnected local work followed, but "the Wiesbaden system marks the introduction of a new conception and understanding of the problem. This system, which has been widely adopted in Germany, treats the child as the centre of interest and his well-being as the end of reform, to which even the most satisfactory school environment is only a means. . . . Throughout the German Empire a large number of school doctors have been appointed, and so some 350 towns and communities have undertaken in a greater or less degree the work of medical supervision of school life" (p. 4)—a good result since the first appointments in Wiesbaden in 1896.

The English movement, though prepared for by many workers in personal and public hygiene, dates from the report of the Royal Commission on Physical Training (Scotland) in 1903. Dr. Newman does not make it perfectly clear why, at this particular juncture in British history, such a report should have been called for; but there is no doubt that the Commission arose out of the revelations of physical inefficiency made during the great South African war, particularly at the recruiting stations. There was then a rising wave of opinion on the need for better physical training in the early stages of life. Incidentally, and, as it were, casually, the supreme need for medical inspection was revealed, and, up to date, this

[1] Board of Education. Annual Report for 1908 of the Chief Medical Officer of the Board of Education. Pp. 170. Cd. 4986. (London: Eyre and Spottiswoode, 1910.) Price 8½d.

is the chief result of the Scotch Commission and the many further inquiries set going by it. Physical training has shared in the benefits of more scientific direction. The rest of the history is written in the statutes and administrative orders and circulars now current in Great Britain. A movement so wide and so costly could have emerged only from a great national awakening, and this report, the first of the new medical department, shows how far advanced the organisation already is. The report contains all the administrative detail necessary to enable the interested sociologist to grasp the significance of the movement.

Naturally, in a first report, questions of organisation and administration bulk relatively large. Dr. Newman makes very clear the relation of the new school medical officers to the public health service. This was a matter of great concern at the outset, but the solution of difficulties seems to have gone forward smoothly, and to-day any dissociation of services is the exception, not the rule. Subordination of the school medical officer to the medical officer of health, or some definite form of cooperation, seems to have been established practically in every educational area. "There is an interdependence and solidarity in these matters which can only be ignored or neglected at the price of inefficiency and failure" (p. 17).

Whole-time medical assistants are the rule, part-time assistants the exception. "There have been no cases of Authorities commencing with a few whole-time assistants and changing to many part-time assistants" (p. 19). This is a very significant fact. Of the 307 educational areas, 160 have been provided with one school medical officer each—the minimum necessary under the Code. In the other 147 areas, "there are in all 616 assistant medical officers"—122 whole-time, 494 part-time. The arrangements for twenty-one other areas have not yet been finally approved, but, approximately, 1084 medical officers are at work "in the school medical service in England and Wales" (p. 18). This is certainly a splendid record. The qualifications of officers, the part played by the teacher, the school nurse, the general scope of the work, all are discussed with quantitative references. It is estimated that, for England and Wales, not fewer than 1,328,000 children were medically inspected during 1907–8, and when to these are added 250,000 "specials," that is, children specially brought under the medical inspector's notice as needing attention, the total amounts to not less than 1½ million children. The general experience with parents is that they have appreciated the work warmly, and sometimes enthusiastically, there being a few, but only a few, complainers.

As to treatment, the facts are, of course, very meagre as yet, but not discouraging. So far as facts are available, the number medically attended to through the parents themselves runs from 20 to 60 per cent. of those brought to their notice by the education authorities. There is here abundant room for organisation and propaganda. The cost of medical inspection, so far as salaries go, runs from 4·79*d*. per child in average attendance in the counties to 7·64*d*. in the municipal boroughs and 7·56*d*. in the urban districts, or, in the same order, from 0·15*d*. of rate to 0·23*d*. and 0·28*d*.—no great outlay for so great a service.

The rest of the volume is taken up with details of the results of medical inspection in the discovery of defects or diseases. The results are necessarily "tentative and fragmentary" (p. 39), but more than enough to justify the institution of the system and to indicate the immense amount of administrative energy now directed to the amelioration of evil conditions, both environmental and personal. Cleanliness is steadily improving under the pressure of definite administrative direction. For instance, in 124 London schools Dr. Kerr found, of 92,185 children examined, 16,060 verminous, and 2228 were excluded for prosecution—the parents of 255 children being prosecuted, and fined in sums varying from 1*s*. 6*d*. to 20*s*. As a rule, the first "notice" is enough to secure cleansing. Ringworm is diminishing. Teeth are beginning to be treated, as, for instance, in Cambridge. Many other diseases now familiar to the general public are here recorded—adenoidal growths, ear discharges, short sight, &c. There is a good series of paragraphs dealing with tuberculosis, in particular with phthisis. The results in percentages for phthisis vary widely—from well below 1 to well above 4. Obviously there are differences both in the localities and in the methods of diagnosis. This is a disease that has not yet found its "level" in the professional mind. There are sections dealing with the new syllabus of hygiene, with schools for defective children, open-air schools, and many other matters of current importance.

The report, as a whole, reflects every credit on the system of medical inspection and on the Board of Education itself. Only the experienced administrator can read from these records the enormous difficulties to be overcome and the skill shown in overcoming them.

NOTES ON THE ORIGIN OF THE HAUSAS.[1]

NEXT to the Filani, the most important race in northern Nigeria is the Hausa, whose origin is undetermined. These people occupy at present most of the land between the ninth and fourteenth parallels north latitude, and the fourteenth and eleventh meridians east longitude. Their number is variously estimated; perhaps 4,000,000 is fairly accurate. They are the traders and soldiers of West Africa, and are very good agriculturists, and workers in brass and leather, but seem to have been unable to conquer under their own leaders.

The Hausas have not the fine features of the Filani, nor yet the very thick lips and flat noses of the coast negro; they are rather short and stumpy, with woolly hair. Their original country in northern Nigeria consisted of seven States, the "Hausa Bokkoi," to which an equal number, "Banza Bokkoi," were afterwards added. These States were independent of—though dependent on—one another. There are two principal theories as to their origin, viz. (1) that they were indigenous, and (2) that they came from Egypt or Ethiopia. I cannot see why these two apparently opposite ideas cannot be modified and reconciled.

It would seem that the following statements are permissible:—

(1) The religion is in too many points similar to that of the ancient Egyptians to imagine that it was formed quite independently.

(2) The Hausas have the trading and wandering instincts of the Semites, and have travelled voluntarily and without external pressure, whereas the people of most West African negro tribes have kept together, unless conquered and driven out of their country.

(3) The cephalic index is one which we would naturally expect in the descendants of a mixture of races, some having a greater, some a less, index. Because the Arabic element was in the minority, and because of the influence of environment, the Hausa cephalic index is nearer to that of the Egyptian Copts and mixed races than to that of the Arabs. The present Hausa race is a further mixture of the people who came, in A.D. 1000, with the aborigines.

(4) Arabic has had some influence in the formation of the Hausa grammar, as well as supplying about one-third of the words, and so some of the people who formed the Hausa vocabulary must have known Arabic. Again, since two-thirds of the words present no similarity to any Semitic language, it is evident that other elements are present, and some of these are related to Coptic. The word Habeshi was a term of contempt applied by Arabs to mixed races, and Hausa (Ba-haushe) is a modification.

(5) The people came from the East (ancient Ethiopia) and brought the horse. Arabs had horses at this time (1000 A.D.), and the mixture which arrived no doubt spoke a certain amount of Arabic. They may have been Hamites, but it is much more likely that they were a mixture of Hamites and Semites, together with elements of local populations encountered *en route*, and the original inhabitants of the country now forming the Hausa States. There is probably a little Berber blood also, and even a further addition of Arabic. Being ashamed of their humble origin, they invented one for themselves, and called their mythical ancestor Babushe, which is really Ba-(ha)beshi and Ba-hab(e)shi or Ba-haushe.

[1] From a paper by Capt. A. J. N. Tremearne in the Journal of the Royal Society of Arts, July 8

MODELS OF METEOROLOGICAL CONDITIONS IN THE FREE AIR.

THE photographs of which Figs. 1 and 2 are reproductions are views of two glass models constructed at the Meteorological Office to represent the temperatures and pressures in a block of atmosphere fifteen miles thick over a triangular portion of the British Isles on July 27 and 29, 1908.

Records of pressure and temperature were obtained by means of balloons carrying small meteorographs, designed by Mr. W. H. Dines, F.R.S. Corresponding values of pressure, temperature, and height were computed from the records.

Balloons were liberated at Ditcham Park, Petersfield; Pyrton Hill, Oxfordshire; Glossop, Derbyshire; Crinan, Argyllshire; and Birdhill, Co. Limerick. The courses of the balloons were in some cases traced for part of the way by means of theodolite observations.

The purpose of the models is to give a representation of the information thus obtained, and to exhibit the meteorological variations in three dimensions. Each model consists of a rectangular base, upon which is drawn an outline map of a portion of the British Isles on the scale of 25 miles to an inch, together with isobars and winds for 6 p.m. on one or other of the two days. Upon the base are erected vertical glass plates, secured at the top by a horizontal plate. In Fig. 1 (July 27) the vertical edges of the prismatic shell thus formed, from left to right, stand over the above-named stations in order, Birdhill being the corner shown at the back. In Fig. 2 (July 29) Ditcham is represented only by a standard bearing arrows to show wind direction. The recording instrument sent up from that station on that day has not been found.

Distances measured vertically along the glass sides of the models represent heights above sea-level on the scale of 5 miles to 4 inches. The vertical scale of the model is therefore twenty times the horizontal scale of the map. The total height represented is 24 kilometres (15 miles).

The observations from each station are plotted on the edges of the models. Isotherms (full lines) are drawn on the glass sides for every 5° C., the temperature being expressed in absolute measure. The space between the isotherms of 270° and 275° is filled in to indicate the position of the freezing point.

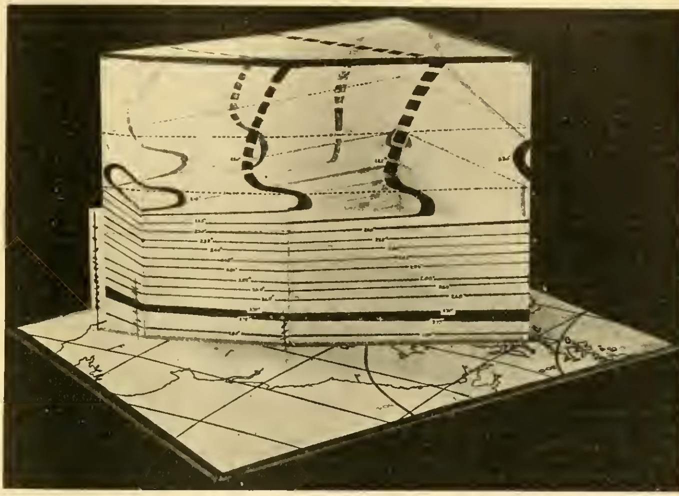

FIG. 1.—From observations taken on July 27, 1908. Block seen from the north-east. Isotherms are shown for each 5 Absolute from 280 A. to 215° A. The space between the isotherms of 270° and 275° is filled in; for other isotherms a thickness corresponding with ½° C. is covered. The beaded lines in the stratosphere are isobars for 0·2 megabar and 0·1 megabar respectively. The arrows on the standards face the wind as determined by observations with theodolites.

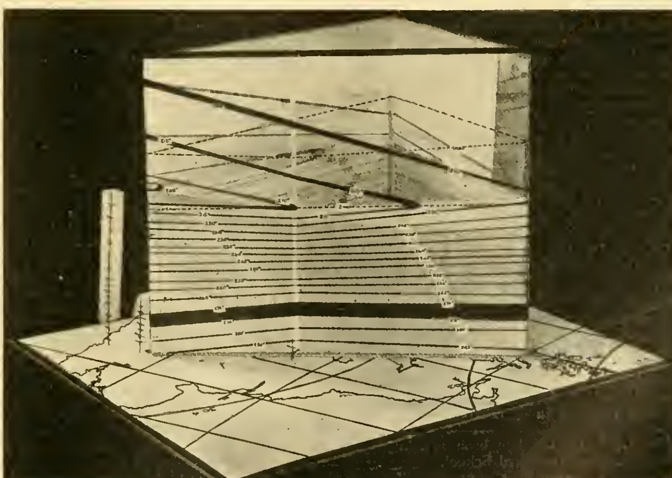

FIG. 2.—From observations taken on July 20, 1908. Block seen from the north-east. Isotherms are shown for each 5 Absolute from 285° A. to 205° A. The space between the isotherms of 270° and 273° is filled in; for other isotherms a thickness corresponding with ½° C. is covered. The beaded lines in the stratosphere are isobars for 0·2 megabar and 0·1 megabar respectively. The arrows on the standards face the wind as determined by observations with theodolites.

Both models show clearly the two main divisions of the atmosphere, viz.:—(1) "troposphere," or lower portion, in which temperature diminishes with height at a nearly uniform rate and the isothermal surfaces are approximately horizontal, and (2) "isothermal region," or "stratosphere," above the troposphere, in which temperature is nearly constant or increases slowly with height, and the isothermal planes tend to become vertical.

Isobars for one-tenth and one-fifth of an atmosphere (0·1 megabar and 0·2 megabar according to the nomenclature of the Paris Conference of Physicists, 1900) are shown by beaded lines in the upper parts of the figures.

Wind-direction observations are indicated by arrows facing the wind, carried on standards.

The chief points of difference between the two models are the following:—

	FIG. 1.	FIG. 2.
(1) Surface temperature ..	From 280° to 285°	From 285° to 290°
(2) Sea-level pressure... ...	From 1·016 to 1·023 megabar (30·0 to 30·2 in.)	From 1·026 to 1·033 megabar (30·3 to 30·5 in.)
(3) Height of lower surface of stratosphere	9 km.	10 km.
(4) Lowest temperature in stratosphere	About 215°	About 205°
(5) Wind direction at south-east angle	Nearly S. throughout	Nearly N. throughout

Both figures show that the position of the coldest air was at a height of 10–11 kilometres over the most southern portion represented.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—The chair of accounting vacated by Prof. Sidney Dawson has been filled by the election of Mr. Charles E. Martineau.

Mr. W. B. Grove has been appointed honorary curator of the fungus herbarium in the Botanical Department.

Prof. R. Saundby has been appointed to represent the University on the General Medical Council for a further period of five years.

Prof. Bostock Hill is to represent the University at the Conference on School Hygiene to be held in Paris in August.

The Pro-Vice-Chancellor (Alderman F. C. Clayton) is presenting to the University a statue of His Majesty King Edward VII., in commemoration of the opening of the new buildings by the late Sovereign. It is understood that the statue is to stand in the entrance hall of the main building.

LEEDS.—Arrangements have now been completed for the establishment of a professorship of coal gas and fuel industries at the University as a memorial to the late Sir George Livesey, upwards of 10,500*l.* having been subscribed to the fund initiated for the purpose by the Institution of Gas Engineers, and an advisory committee has been formed in connection with the work to be carried out by the holder of the chair.

Dr. J. K. Jamieson, hitherto chief demonstrator of anatomy, has been appointed professor of anatomy in the University.

LONDON.—Sir Henry Roscoe has resigned his membership as a Crown nominee, and Mr. F. D. Acland has been appointed in his place.

Mr. F. L. Golla has been appointed honorary demonstrator of chemical pathology and pharmacology in the physiological laboratory of the University, and Mr. A. D. Mitchell, of Sheffield University, has been appointed scientific assistant in chemistry in the University.

DR. J. D. COALES has been appointed principal of the Wolverhampton Technical School.

MR. J. A. JENKINS, for fifteen years registrar of the University College of South Wales, Cardiff, has resigned that position.

ON July 8, the honorary degree of Doctor of Laws of the University of Edinburgh was conferred upon Prof. John Chiene, emeritus professor of surgery in the University; Prof. Matthew Hay, professor of forensic medicine, University of Aberdeen; and Prof. W. H. Perkin, F.R.S., professor of organic chemistry, University of Manchester.

THE increasing popularity of holiday courses for teachers is an excellent indication of the growing desire of schoolmasters and schoolmistresses to acquaint themselves with improved methods of instruction, and to bring their knowledge up to date by attending during their holidays lectures by experts. The County Council of the West Riding of Yorkshire has arranged a series of vacation courses for teachers, to be held at the Municipal Secondary School, Scarborough, during August next. Among the items in a very attractive programme, we notice a course of ten lectures by Prof. A. Smithells, F.R.S., on solution, and the physics and chemistry of cleansing processes; twelve lectures on the teaching of general elementary science, by Mr. W. Mayhowe Heller; and eight lectures on nature-study, by Mr. O. H. Latter. Laboratory work and excursions have been arranged in connection with these courses. There will also be a course in educational handwork, organised by the Educational Handwork Association, during July and August at the same place, and it is possible for students to take a joint West Riding and handwork course.

ON December 21, 1909, the London County Council decided to make a maintenance grant of 8000*l.* to the Imperial College of Science and Technology, South Kensington. In return for this grant it secures the privilege of nominating twenty-five students for one year's free instruction at the Imperial College. These are now to be nominated for the first time. The instruction will be of an advanced nature, and therefore only advanced students who are qualified to enter on the fourth year of the course should apply. There is no restriction as to income, but intending candidates must be ordinarily resident in the Administrative County of London, and must be students at an institution aided, maintained, or approved by the council. The free studentships do not entitle the holders to any maintenance grants, but cover all ordinary tuition fees. No examination will be adopted for the final selection of the students from the applications received. The free studentships will be awarded on consideration of the past records of the candidates, the recommendations of their teachers, the course of study they intend to follow, and generally upon their fitness for advanced study in science applied to industry. It is quite possible that, in special cases, the free places may be extended to two or more years. Application should be made without delay, as entries will not be considered after July 23. Application forms (T. 2/268) can be obtained from the Education Officer, London County Council, Victoria Embankment, London, W.C.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 30.—Sir Archibald Geikie, K.C.B., president, in the chair.—Prof. A. D. **Waller**: A new method for the quantitative estimation of hydrocyanic acid in vegetable and animal tissues. The method is colorimetric, and depends on the reaction between potassium cyanide and picric acid, first studied by Hlasiwetz (*Liebig's Annalen*, cx., p. 289 [1859]), and recently applied by Guignard to the detection of minute quantities of hydrocyanic acid (*Annales Sci. Pharmacol.*, 1906, p. 415) and by H. E. Armstrong to the rapid detection of emulsin (Proceedings, March 10). The colour-scale is prepared by mixing equal volumes of a recently titrated solution of 1/10000 hydrocyanic acid and of picrate mixture (equal volumes of 0·5/100 picric acid and 5/100 sodium carbonate). From this stock solution (T 50), after twenty-four hours in an incubator at 40°, a colour-scale is prepared by further dilution with picrate mixture, to contain, e.g., 1, 2, 3, &c., parts of HCN per million, of tints T 1, T 2, T 3, &c. The estimation is made by matching the colour of the given fluid or of its distillate into picrate mixture (after suitable dilution if required), with that of the colour-scale. Thus, *e.g.*, if the tint of a distillate from 10 c.c. of blood (dil. $\times 5$) into 25 c.c. of picrate is found $=$ T 5, and the volume of picrate+distillate is 40 c.c., the amount of HCN in the distillate $= 5 \times 40$ millionths gram, *i.e.* 0·000200. A second distillation shows whether or no the whole of the HCN present has been taken over in the first distillate. Results of the application of the method to (1) a leaf of *Prunus Laurocerasus*; (2) the blood and tissues of a cat after death by a known amount of HCN; (3) the blood and tissues of a person "found dead."—Prof. A. **Dendy**: The structure, development, and morphological interpretation of the pineal organs and adjacent parts of the brain in the tuatara (*Sphenodon punctatus*). The "pineal complex" consists of the dorsal sac, the paraphysis, the pineal sac ("epiphysis"), the pineal eye, the pineal nerves and their central connections. There is a well-developed choroid plexus, with special blood-supply, on the roof of the dorsal sac, possessing histological features of considerable interest. The paraphysis is a compound tubular gland, with special blood-supply, differing markedly in histological character from the choroid plexuses. Its lining epithelium forms a syncytium, and its opening, which, in the embryo, lies just in front of the commissura aberrans, becomes shifted upwards in the adult on to the anterior wall of the dorsal sac, by the formation of a "supra-commissural canal," the original opening being blocked up by the anterior choroidal blood-vessels. The histological structure of the pineal sac points to a sensory rather than a glandular function. Its wall is essentially similar in structure to the retina of the pineal eye, consisting of radial supporting fibres, sense-cells, and ganglion-cells and nerve-fibres, and pigment may occasionally be deposited in it. The retina of the pineal eye consists of the same histological elements arranged in essentially the same way, with the sense-cells on the inside and the nervous elements in the middle. The pigment is not lodged either in the sense-cells or in the supporting fibres, but is brought into the retina by wandering pigment-cells. The pigment granules escape from these wandering cells on entering the retina, and stream inwards between the radially arranged elements. The inner ends of the sense-cells project into the cavity of the eye, and are covered each by a little cap, formed apparently by the internal limiting membrane of the retina. The developing lens of the pineal eye increases in size partly as a result of mitotic divisions in a marginal zone of undifferentiated cells. As they approach the centre the cells elongate, and some of them degenerate into a kind of mucus, which is secreted from the inner surface of the lens into the cavity of the eye, where it takes part in the formation of the vitreous body. This process of secretion continues in the adult. The nerve of the pineal sac is from its first appearance median. It joins the roof of the brain between the posterior and superior commissures. The nerve of the pineal eye is shown, especially by its development, to be primarily connected with the left habenular ganglion, which even in the adult has a different shape from that of its fellow of the opposite side. Both nerves persist in a well-developed condition throughout life. The view that the pineal sac and pineal eye are respectively the right and left members of a primitive pair of sense-organs, serially homologous with the lateral eyes, is strongly supported. Altogether six pairs of diverticula are given off from the fore- and mid-brain, viz. the cerebral hemispheres, the optic vesicles of the lateral eyes, the recessus thalami prenucleares, the pineal sense-organs, the recessus geniculi, and the optic lobes. These may all be serially homologous with one another, and each may possibly indicate a separate neuromere. There is no commissura mollis and no unpaired plexus medianus in the third ventricle. Reissner's fibre and the sub-commissural organ are very well developed.—J. A. **Crowther**: The scattering of homogeneous β rays, and the number of electrons in the atom. (1) The scattering of a homogeneous pencil of β rays has been measured for various substances and for rays of different velocity. It has been shown to obey the following statistical laws:—(i) for rays of given velocity the intensity I of the radiation contained within a given cone may be expressed by the equation $I/I_0 = 1 - e^{-k/t}$, where t is the thickness of material passed through, and k a constant depending upon the angle of the cone; (ii) for rays of given velocity the most probable angle of emergence is proportional to the square root of the thickness of material traversed by the rays; (iii) for rays of different velocities, the probable angle of emergence divided by the square root of the thickness traversed is inversely proportional to the product of the mass of the incident β particle into the square of its velocity. (2) From equations given by Sir J. J. Thomson, the number of electrons contained in atoms of different elements is deduced. It is thus found:—(i) that the ratio of the number of electrons per atom to the atomic weight is constant, the ratio being very nearly 3·0 for all the elements examined; (ii) that the positive electricity within the atom is not in an electronic condition, but is distributed fairly uniformly over the space occupied by the atom. (3) Experiments are described on the absorption of homogeneous β rays. It is shown that the first stage in the absorption of a pencil of homogeneous β rays consists in the scattering of the rays according to the laws already considered. The absorption of the completely scattered radiation is then shown to take place according to an exponential law.—F. **Isaac**: The spontaneous crystallisation and the melting- and freezing-point curves of mixtures of two substances which form mixed crystals and possess a minimum or eutectic freezing point.—Mixtures of azobenzene and benzylaniline. The results obtained in this research may be thus summarised:—(1) The freezing- and melting-point curves for mixtures of azobenzene and benzylaniline have been determined, and it has been shown that these substances possess a minimum or eutectic point at 26° for the mixture containing 19 per cent. azobenzene and 81 per cent. benzylaniline, and form a series of mixed crystals on one side only of the eutectic, viz. that with excess of azobenzene. This is, therefore, a limiting case of Roozeboom's Type 5, in which two substances, A and B, possess freezing- and melting-point curves which exhibit a minimum eutectic point, and form two series of mixed crystals, *i.e.* mixed crystals containing excess of A, and mixed crystals containing excess of B. (2) The melting-point curve has been confirmed by actual analysis of the mixed crystals. (3) The supersolubility curve, or curve of spontaneous crystallisation, has been determined for these mixtures by two methods:—(i) by noting the temperature at which a liquid mixture of known composition crystallises spontaneously in a sealed tube; (ii) by noting the temperature at which a known liquid mixture attains its highest refractive index and gives a dense labile shower when placed in the trough of the inverted goniometer. It has been shown that each mixture possesses a definite temperature of spontaneous crystallisation. The supersolubility curve shows a minimum for liquids having approximately the eutectic composition, and runs approximately parallel to the freezing-point curve. It crosses the melting-point curve three times. The nature of the mixed crystals which first separate spontaneously from any liquid mixture on the supersolubility curve has been investigated. The composition of such crystals has been determined by separating them from their mother liquor and finding their melting points. (5) A few thin sections have been ground from the solid mixtures in the neighbourhood of the eutectic, and their structures examined. These structures do not appear to be permanent. After the lapse of some months they completely changed, new crystal needles appearing all over the sections. These changes, however, appear to be very gradual, and to take place with change of temperature.—E. C. **Snow**: The determination of the chief correlations between collaterals in the case of a simple Mendelian population mating at random. This paper investigates the values which should hold for the correlations between (*a*) siblings, (*b*) uncle and nephew, and (*c*) first cousins, on the Mendelian hypothesis of "unit-characters." The correlations both for gametic and somatic characters are found. For the former, values independent of the distribution of the dominant and recedant characters among the population are obtained. These are (*a*) 0·500, (*b*) 0·250, and (*c*) 0·250. In the case of the somatic correlations, however, the results depend upon the relative numbers of the population possessing the dominant and recedant attributes before crossing. By varying this proportion, different values of the correlations can be obtained, but these are always less than the corresponding gametic ones stated above. The investigation brings out the important point that, on the Mendelian theory of heredity, the similarity between first cousins is quite as close as, or closer than, those between uncle and nephew. Biometric results previously reached have pointed to the same conclusions. This is of great interest from the medical point of view. In medical diagnosis, a man's uncles and aunts, but not his cousins, are generally considered; but the results of the present paper show that his cousins, usually more numerous, give just as good a knowledge of his constitutional tendencies as do his uncles and aunts.—C. J. T. **Sewell**: The propagation of sound in a fog. This paper is intended as a sequel to the author's previous paper on "The Extinction of Sound in a Viscous Atmosphere by Small Obstacles of Cylindrical and Spherical Form," in which the loss of energy from the primary waves owing to viscosity was investigated. In the present paper the author has included the additional loss of energy due to heat conduction. The work proceeds on much the same lines as before, and the results obtained are of the same order of magnitude. The chief interest consists in the application of the results to the effect of atmospheric fog upon the propagation and audibility of sound. Waves of high frequency suffer most. If the diameter of the drops of water in a dense fog is assumed to be 0·02 mm., and the density of the fog amounts to $4\frac{1}{2}$ grams per cubic metre, the intensity of sound of wave-length 100 cm. is reduced in the ratio of 1 to e before the sound has travelled a distance of 100 metres. If the wave-length is 1000 cm., this distance is increased to about 350 metres. In any case, the results seem to show that the presence of fog at sea must diminish quite appreciably the audibility of sound.—L. **Southerns**: A determination of the ratio of mass to weight for a radio-active substance. A determination has been made of the ratio of mass to weight for uranium oxide by comparison with the known value for a normal substance (lead oxide). It had been supposed by Sir J. J. Thomson that a radio-active substance might possess greater mass than the same weight of a non-radio-active substance, on account of the greater store of potential energy which is associated with the former. In the case of uranium oxide, the increase in the ratio of mass to weight would be about 1 in 16,000. The investigation has been made by means of a rigid pendulum fitted with two knife-edges and a hollow bob, into which could be packed either of the substances used. Special means have been employed in order to eliminate errors due to slight variations in the position of the centre of gravity of the pendulum, and to other causes. The results show that the ratio for the uranium oxide does not differ from the normal value by more than 1 in 200,000, and thus that the contemplated effect is absent.—F. P. **Burt** and F. L. **Usher**: The relative atomic weights of nitrogen and sulphur. The object of the research was to determine the combining weights of nitrogen and sulphur by the analysis of nitrogen sulphide. The method adopted was briefly as follows:—A weighed quantity of nitrogen sulphide, purified by sublimation *in vacuo* over silver at 100° C., was decomposed by subliming over red-hot quartz wool contained in a quartz tube. The sulphur was deposited a few inches beyond the wool, and the nitrogen was pumped off and estimated in a constant-volume gas burette. Assuming the density of nitrogen, the relative weights of nitrogen and sulphur could be calculated, the sulphur being obtained by difference. The problem was complicated by the impossibility of starting an experiment with the quartz wool in the reaction tube in a gas-free condition. The difficulty was overcome by measuring in blank experiments the quantity of air removable from the hot wool *in vacuo*, and by estimating traces of more condensable gas present by exposing the nitrogen to potash and re-measuring it. The final corrected N/S ratios are as follows, the weight of a "normal litre" of nitrogen in London being taken as 1·25144 grm.:—0·436847, 0·436875, 0·436839, 0·436857, 0·436897, 0·436878, 0·436898. The mean is 0·436870, and the greatest deviation from the mean is 1 in 14,000. From this ratio the atomic weight of sulphur becomes 2·067, if nitrogen be given the very probable value 14·009.—Dr. F. W. **Edridge-Green**: The relation of light perception to colour perception. It may be easily shown that light perception and colour perception are quite distinct. In fact, we can divide cases of colour-blindness into two classes, according as the defect is (*a*) one of light perception, or (*b*) one of colour perception or differentiation without any defect in light perception. Of course, both defects may be present in the same individual. The investigation of these two classes of defective vision is much facilitated by the use of a spectrometer which the author has devised for the purpose. This instrument is a spectrometer so arranged as to make it possible to expose to view in the eye-piece the portion of a spectrum between any two desired wave-lengths. Tested with this instrument, a normal individual will, as a rule, name six distinct colours, namely, red, orange, yellow, green, blue, and violet, and will mark out by means of the shutters about eighteen monochromatic patches. Occasionally we come across individuals with a greater power of differentiating hues, to whom, as to Newton, there is a distinct colour between the blue and violet, which Newton called indigo. Such individuals will mark out a greater number of monochromatic patches, from twenty-two up to twenty-nine. Those who have defective light perception for certain rays, with normal hue perception, behave exactly in the same way as a normal-sighted person with those rays removed or reduced to the same intensity, and not as if a light-perceiving substance which was sensitive to rays from a considerable range of the spectrum had been removed. Those with defective hue perception mark out with the spectrometer a smaller number of monochromatic patches than the normal, and say that there are five, four, three, two, or one colour instead of the normal six. They behave in every way as if their colour sensations were correspondingly limited. Therefore, if the normal be designated hexachromic, then pentachromic, tetrachromic, trichromic, dichromic, or monochromic correctly describes their colour-vision.—M. G. **Sykes**: The anatomy and morphology of the leaves and inflorescences of *Welwitschia mirabilis*. An account is given of the anatomy of the leaves, and of the inflorescence axes, cones, bracts, and flowers of both sexes. It is shown that the male and female inflorescences are essentially similar in their method of vascular supply and in their detailed anatomy, and it is concluded that they are homologous. Various characters suggest comparison with the Cycads and the Medulloseæ. From the position of the embryo-sac relatively to the two coverings of the ovule at various stages of development, they are regarded as two integuments. The seed can be closely compared with that of Lagenostoma; its differences from this primitive type are referable to changes dependent on the evolution of siphonogamy and possibly insect fertilisation. In both these seeds the free outer integument is regarded as a primitive character, in contrast with the fused integuments of Cycas and Cardiocarpus. In all these cases the entire vascular system appears to be integumental. The connection between Welwitschia and the Cycads, the Bennettitales and the Angiosperms, is discussed.—Colonel Sir David **Bruce**, C.B., Captains A. E. **Hamerton** and H. R. **Bateman**, and Captain F. P. **Mackie**: (1) The natural food of *Glossina palpalis*; (2) mechanical transmission of sleeping sickness by the tsetse-fly.—V. H. **Veley** and Prof. A. D. **Waller**: The comparative toxicity of theobromine and caffeine as measured by their direct effects upon the contractility of isolated muscle. It is shown by measurements of the contractility of isolated muscle that the toxicity of theobromine, the base of cocoa, is greater than that of caffeine, the base of coffee and tea, in the proportion of 3 : 2. The introduction of a second methyl group into the oxy-purine residue, namely, the formation of caffeine from theobromine, thus diminishes the toxic value, a result which is the converse of that observed in the case of the paraffinoid alcohols. The toxic effects of coffee and tea extracts are also studied, and it is shown that the effect of the former is mainly due to the caffeine contents, and not to the tannic acid.—Prof. W. B. **Bottomley**: The assimilation of nitrogen by certain nitrogen-fixing bacteria in the soil. —Prof. A. B. **Macallum**: The inorganic composition of the blood in vertebrates and invertebrates and its origin. —Mary T. **Fraser** and J. A. **Gardner**: The origin and destiny of cholesterol in the animal organism. Part vii.— The quantity of cholesterol and cholesterol esters in the blood of rabbits fed on diets containing varying amounts of cholesterol.

CAMBRIDGE.

Philosophical Society, June 6.—Mr. W. Bateson, president, in the chair.—H. H. **Brindley**: Further notes on the procession of *Cnethocampa pinivora*. Lantern-slides were shown illustrating observations on the procession of the caterpillar of this Eupterotid moth, which infests the pines of the Landes. The caterpillars march in single file from the nest tree over the sand on fine days in late March and early April, ending the last day's procession by burrowing for pupation. The general impression left by observation of processions is that the larvæ in head-to-tail contact act as one individual, and as such their course of action is very difficult to disturb by artificial interference in respect both of direction of march and general behaviour. Though removal of the leader hardly, if at all, checks the progress of a procession (in a procession of six, for instance, the leaders were removed successively and placed at the rear of the procession six times in fourteen minutes without the procession stopping), the "circulating mass" seems invariably formed on the initiative of the leader. The reason for this frequently occurring event, as, indeed, also the stimuli which determine the behaviour of a procession, remains obscure, while no explanation is forthcoming of the remarkable temporary independence of some larvæ. As in the observations by T. G. Edwards, no irritation of the skin by the poison hairs of the larvæ, in spite of frequent handling, was experienced (Fabre lays much stress on the inconvenience he suffered from this source, so the liability to irritation probably varies in different individuals).—Dr. **Graham-Smith**: The habits of *Musca domestica*.—Dr. N. H. **Swellengrebel** and C. **Strickland**: The development of *Trypanosoma lewisi* in the rat flea (*Ceratophyllus fasciatus*). A development of *T. lewisi* was found to take place first in the mid-gut, later in the hind-gut and rectum of the flea. The forms observed resembled very much the forms of *T. lewisi* in an artificial culture, except that the later stages in the flea, a return to a trypanosome form ("small trypanosomes"), are never found in culture. No such developmental forms were found in a large number of control fleas.—Dr. F. **Ransom**: The absorption of tetanus toxin.—H. **Ackroyd**: The fate of uric acid in the dog.—Dr. **Cobbett**: The absence of living tubercle bacilli from old tuberculous lesions. The author has on several occasions, while working for the Tuberculosis Commission at Stansted, as well as in Sheffield and Cambridge, found that old caseous and calcareous deposits, which were undoubtedly of a tuberculous nature, might contain no tubercle bacilli capable of infecting the guinea-pig.—W. E. **Dixon**: The action of potash salts taken by the mouth. The non-toxicity of potash salts taken by the mouth was shown to be due to the very easy excretion of these salts by the kidneys, so that their concentration in the blood was but slightly increased.—Prof. Sims **Woodhead**: The results of sterilisation experiments on the Cambridge water. Sterilisation by chlorine and chlorine compounds had given most startling results. In a series of preliminary experiments, carried out in the laboratory, it had been found that one part of available chlorine to two million parts of water was sufficient to kill all non-spore-bearing bacteria of the *Bacillus coli* type, and therefore of the typhoid bacillus type, and probably also of the cholera bacillus type, within half an hour even in the presence of the appreciable amount of organic matter that was necessarily added along with the cultures of *Bacillus coli*. Water to which had been added some hundreds of the *Bacillus coli* per c.c. was found after treatment to contain not a single living colon bacillus in 50, 60, and 100 c.c. (The unimportant spore-bearing organisms were not killed.) Having obtained these results in the laboratory, a large experimental plant capable of sterilising more than 80,000 gallons of water per twelve hours, erected at Fulbourn, was used, and three sets of experiments were carried out, one a preliminary series in which the apparatus was run at intervals as required, and then two series of experiments in which the apparatus was run for twelve hours daily for more than a fortnight in each series. The standard of the London Water Board, that there shall be no *Bacillus coli* in quantities of water less than 200 c.c., was taken as the one to be aimed at. In every case, however, quantities of 500 c.c. were examined, and after certain preliminary difficulties had been surmounted, water was obtained in which none of the observers could find the *Bacillus coli* in 500 c.c. The amount of chlorine used in these experiments varied from one part in a million to one in six million parts of water. In the earlier experiments, where up to one part of chlorine in four million parts of water was used, it was thought necessary to neutralise any remaining chlorine by the addition of sodium bisulphite. After further experiments, where smaller quantities of chlorine were used, this addition was dispensed with, as the water treated, though sterile, did not retain the slightest taste of chlorine. It was suggested, of course, that water so treated might have some effect upon the human organism. All those who were working at Fulbourn drank considerable quantities of this water, and everyone who tried it accepted it as a first-class drinking water.—F. J. M. **Stratton** and R. H. **Compton**: Accident in heredity, with special reference to right- and left-handedness. An examination of the manner in which the inheritance of Mendelian characters would be affected by the action of a constant environmental factor. The assumption is made that a certain proportion of individuals have their characters inverted in appearance by accidental causes, and an application is made to the statistics dealing with the inheritance of the mode of clasping the hands. —R. H. **Compton**: Right- and left-handedness in barley. A study of the two kinds of seedlings of barley, the folded first leaves of which are related to one another as an object to its mirror image. A considerable numerical excess of one kind is found in all the varieties studied. The dimorphism in question is not found to be hereditary, and it appears to be governed neither by the direction of twist of the last foliage leaf below the spike nor by the position of the seed on the spike.—F. T. **Brooks**: The development of *Gnomonia erythrostoma*, the cause of the cherry-leaf scorch disease. The present investigation concerns an examination of the life-history of this fungus from the cytological standpoint, very little work on the Pyrenomycetes having hitherto been done from this point of view.—Dr. A. C. **Dixon**: Jacobi's double-residue theorem in relation to the theory of point-groups.—N. R. **Campbell**: Discontinuities in light emission, ii. The paper is a continuation of one recently presented to the society under the same title. The main object of the research has remained impossible to attain. The subsidiary results do not lend themselves to summary.

Paris.

Academy of Sciences, June 27.—M. Émile Picard in the chair.—Ph. **van Tieghem**: A new classification of the Inovuleæ group.—J. **Boussinesq**: The conservation of true masses in different phenomena, principally luminous, where there appear fictitious variable masses.—Armand **Gautier**: The action of a red heat on formaldehyde. Experiments show products of decomposition to be carbon monoxide, and hydrogen, with a trace of methane.—B. **Galitzine**: A new type of seismograph for the vertical component.—Charles **Nordmann**: The brightness of Halley's comet, and the composition of its light.—Jules **Baillaud**: Photographic observations of a small planet. —L. **Letombe**: A geometrical study of distribution in machines with separate distributors.—H. **Larose**: The propagation of a discontinuity on a telegraphic line furnished with a transmitter.—A. **Debierne**: The atomic weight of the radium emanation. The author shows that by the loss of an α particle, and consequent departure of an atom of helium of atomic weight 4, the radium of atomic weight 226·5 becomes the emanation of atomic weight 222·5.—G. A. **Hemsalech**: The duration of the emission of spectral rays by luminous vapours in the electric spark.—Gabriel **Sizes** and G. **Massol**: A photographic record of the vibrations of a diapason.—Edmond **Bauer**: The emission of gases.—E. **Henriot**: The rays of potassium.—A. **Besson** and L. **Fournier**: The action of hydrogen on sulphur chloride and thionyl chloride under the influence of an electric discharge.—Witold **Broniewski**: The electrical properties of aluminium-silver alloys.—M. **Kohn-Abrest**: The nitrides and oxides obtained from aluminium heated in air.—G. **Urbain**, M. **Blondel**, and M. **Obiedoff**: The extraction of germanium from blende.—L. J. **Simon**: The acid character of oxalacetic ether.—M. **Lespieau**: The hydrogenation of acetylene compounds.—A. **Béhal**: A new tertiary menthol, and the passage of pinene into menthene. —André **Meyer**: The condensation of phenyl-isoxazolone with mesoxalic ester.—René **Maire** and Adrien **Tison**: Some Plasmodiophoraceæ.—C. **Gessard**: Blood fibrin.—

Maurice **Nicloux**: The products of decomposition of chloroform in the organism.—M. **Caullery** and A. **Lavallée**: Experimental investigation on the initial phases of infection of *Amphiura squamata* by *Rhopalura ophiocomae*.—Alfred **Angot**: The earth tremor of June 24, 1910.—P. **Vialla** and P. **Pacottet**: The culture of the Rœsleria of the vine.—A. **Marie**: The neutralising properties of a substance isolated from a normal brain.

July 4.—M. Emile Picard in the chair.—J. **Boussinesq**: The probable applicability, to rays or kathode currents, of the principle of mass constancy.—Ch. **Lallemand**: The probable exactness of different evaluations of the altitude of Lake Chad. Taking all accounts into consideration, a shore of 240 metres, in round numbers, seems nearest the truth.—D. **Gernez**: The nature of the product called by the name of black phosphorus.—Armand **Gautier** and P. **Clausmann**: The action of iron and its oxides, at a red heat, on carbonic oxide. Application to some geological data. The resulting products are carbides of iron, free carbon, and carbon dioxide, together with certain iron oxides.—Th. **Schlœsing**, fils: The production of nicotine by the cultivation of tobacco.—E. L. **Bouvier**: The pycnogonids with five pairs of paws collected by the Jean Charcot expedition on board the *Pourquoi-Pas?*—A. **Calmette** and C. **Guérin**: The re-absorption of tuberculous bacilli by cattle following on the injection of mixtures of serum of animals rendered hyper-immune, and bacilli cultivated in series on beef bile.—A. **Perot**: A study of the variation of the wave-length of solar light at the sun's circumference.—D. **Eginitis**: Some phenomena shown by Halley's comet after its passage across the sun. It seems evident that much of the shortening of the tail was due to the angle under which the comet was seen, besides it being not unlikely that some disintegration was brought about by the earth itself.—Fr. **Iniguez**: Physical observations on Halley's comet.—Serge **Bernstein**: Mechanical equations and the calculus of variations.—F. **Ducretet** and E. **Roger**: An apparatus for receiving time on land and on board ship by wireless telegraphy.—P. **Beaulard**: The electric absorption exercised by some alcohols.—Mdlle. L. **Blanquies**: The constituents of radio-activity induced from actinium.—A. **Dufour**: The rotation of a mercuric arc in a magnetic field. Observations on Döppler's phenomenon.—Louis **Malclès**: The appearance of certain dielectric anomalies by changing the state of the insulating medium. Pure vaseline, an insulator at ordinary temperatures, but a conductor in the liquid state, acts as a medium charged with free ions of both signs, the mobility of which, while non-existent when the substance is semi-fluid, only shows itself on the attainment of a clearly liquid state.—Jean **Villey**: An electrometric micromanometer.—Maurice **de Broglie**: The exclusive presence in the gases evolved from some hydrogenated flames of ions altogether analogous to those produced by Röntgen rays. It was observed, notably in the case of hydrogen, ether, aldehyde, acetone, &c., that the flames of combustion gave ions closely agreeing with Röntgen radiation in velocity.—V. **Auger**: Manganate of sodium and its hydrates. It is possible to obtain manganate of sodium by the decomposition of the corresponding permanganate by means of excess of soda.—M. **Barre**: The decomposition of thorium sulphate by water.—Léo **Vignon**: The adsorption of certain colouring matters.—E. **André**: Acetylenic ketones. The author gives the various physical constants for acetyl, propionyl, butyryl, isovaleryl, and caproyl-phenyl-acetylene. —A. **Backe**: Researches on *iso*-maltol. The author considers the probable formula of this substance to be

$$\begin{array}{l} \quad\;\; CH\text{—}O\text{—}CH \\ \quad\;\; \| \qquad\qquad \| \\ CH_3\text{—}C\text{—}CO\text{—}C\text{—}OH. \end{array}$$

—Em. **Bourquelot** and Mdlle. A. **Fichtenholz**: The presence of a glucoside in the leaves of a pear tree, and its extraction.—Paul **Becquerel**: The abiotic action of ultra-violet rays, and the hypothesis of the cosmic origin of life. Although the effect of dryness, low temperature, and cold may serve to retain the vitality of living spores in inter-stellar space, yet the fact that this space is full of ultra-violet radiation, which is shown to have a most destructive effect on spore life, goes far to discredit any theory of the cosmic origin of life.—Maurice **Arthus**: Cobra poison and curare.—M. **Szreter**: The oxidation of pure oxyhæmoglobin by pure oxygenated water.—Pierre **Girard**: The electrostatic mechanism of osmosis.—C. **Viguier**: The very rapid maturity of a Spionid larva.—Edmond **Hitzel**: A double bend in the south wall at the base of the peak of Platé, near Chedde (Haute-Savoie).—L. **Cayeux**: The existence of calcareous phosphates in diatoms from Senegal.—L. **De Launay** and G. **Urbain**: The formation of blende, and minerals derived from it.—M. **Ferret**: Some oscillations of the sea observed at Bonifacio.

NEW SOUTH WALES.

Linnean Society. May 25.—Mr. C. Hedley, president, in the chair.—E. C. **Grey**: The fatty acids of brain lipoids, part i.—E. **Meyrick**, F.R.S.: Revision of Australian Tortricina. The author dealt with the Tortricina of Australia (and New Zealand) in two papers contributed to the society's Proceedings for 1881 (vol. vi., pp. 410 and 629), the number of Australian species therein recorded being 132. The revision increases the number to 434 species, of which about 232 are described as new; the present paper, the first instalment of the revision, is concerned with 290 species, comprised in the Carposinidæ, Phaloniadæ, and Tortricidæ. For this result the author is greatly indebted to the aid of a number of Australian correspondents who forwarded collections; these, together with the material which he had himself accumulated, were taken to the British Museum, and a close comparison instituted with Walker's types, with the result, it is believed, that every one of these was identified satisfactorily. The Tortricina are considered to have originated from the Hilarographa group of the Plutellidæ.

THURSDAY, JULY 21, 1910.

A STANDARD TREATISE ON PHYSICS.

Traité de Physique. By O. D. Chwolson. Translated from the Russian and German editions by E. Davaux. Second volume, fourth fascicule. Pp. 641–1188. Third volume, first fascicule. Pp. vii + 408. Fourth volume, first fascicule. Pp. vii + 430. Figures in text. (Paris: Hermann et Fils, 1909.) Price 17, 13 and 12 francs respectively.

SINCE this is a French translation of a work which has already been reviewed in part as a German translation (from the Russian), we will not do more than examine those parts in which it differs from its previous forms or which have not previously been reviewed here. It is by no means a mere translation. Extensive additions have been made under Prof. Chwolson's supervision with the object of maintaining the book level with the rapid advances in physics that have taken place. These have been made with the author's usual discriminative ability. If there is one quality more than another which strikes us about this text-book it is the rare combination of knowledge and good judgment which everywhere characterises it. Other volumes which we know may be more encyclopædic. If our object is to find out *all* that has been done on any special subject we may be disappointed if we turn up the subject here. But if our object is to find a judicious selection of the best that has been thought and written on physical questions, then we know of no better source from which our object can be attained. In other words, this is a text-book of a preeminent order, written by one who has a unique command over all branches of physical science, and who is as alive to the most recent developments as to those portions which have now become classical.

Of the additions to the fourth fascicule, which deals with diffraction, double refraction, and polarisation of light, we may point out the account of recent work by Dufet on the remarkable anomalous dispersion of the optic axes in the case of the sulphates of neodymium and praseodymium which is exhibited in the region of optical absorption. Several additional pages are devoted to an account of the optical properties of liquid crystals as studied by Lehmann and others. Two lengthy paragraphs are added by the translator dealing with the reflection and refraction of polarised light according to Green, and with the gyrostatic theory of light. These paragraphs certainly supplement the rest of the chapter into which they are inserted, and, as many readers will be glad to have them, no exception can be taken in regard to their insertion. But it may be intimated that they are considerably more mathematical than the greater part of the book, and they therefore do not harmonise very well with the rest.

We are certainly surprised to find that what is essentially a distinct treatise is bound up with this fascicule, and constitutes the end of the second volume. This consists of a note on the theory of deformable bodies, by MM. E. and F. Cosserat. This note is 220 pages long, and it does not in any sense harmonise with the work with which it is incorporated. Prof. Chwolson's work is emphatically experimental in character; the note is as strikingly mathematical. We do not wish in the slightest degree to discredit either the matter or the manner of the note taken by itself. But there does not seem to be any justification for loading a text-book which is necessarily very bulky by matter which will probably never be consulted at the same time as the body of the book itself. The MM. Cosserat's note is a distinct and useful treatise, and should be quite able to stand on its own feet.

The changes in the first fascicule of the third volume are not so considerable. This part deals with thermometry, specific heats, thermochemistry, and thermal conductivity. So far as we can find, there is only one additional section, which treats in a general way of the problem of Fourier, and gives a short account of the allied researches of M. Poincaré. This is a very useful addition.

The first part of the fourth volume has not yet been reviewed in these columns, and it deserves a more extended notice. Its subject-matter is the stationary electric field. The introduction to this part is specially noteworthy. It has seemed to Prof. Chwolson necessary to commence by giving a summary of the singular and exceptional situation in which the science of electrical and magnetic phenomena now is. At the present time one may distinguish no fewer than three various points of view from which these subjects are regarded. We have, in the first place, to deal with the *external structure* of a very great number of different phenomena which, perceived by our senses, awaken in us a representation more or less definite of what is proceeding, or, more exactly, of what seems to us to proceed in a given direction and under given conditions. Thence arises a description of phenomena and of the laws and rules by which those phenomena are regulated. Secondly, we may place ourselves at another point of view, and consider the practical applications; or, thirdly, we may endeavour to *explain* these phenomena by showing that they are the necessary consequence of the existence of a certain substratum to which the laws of mechanics and thermodynamics are applicable. In regard to this third point of view, Prof. Chwolson declares that—

> "Without wishing to exaggerate, we may say, after having glanced rapidly over the facts, that there does not exist at this moment in the part of this science which has for its object the *explanation* of phenomena, any theory which is firmly established upon which we may rely in a manner free from all possible doubt to give an account of *all* phenomena."

He recognises, however, three fundamental conceptions which excite three distinct images or pictures which give a more or less exact representation of the intimate cause of phenomena. These he designates by the letters A, B, and C. The image A, adopted in a general manner up to the year 1870, was constructed on the notion of two electricities, enjoying the property of acting instantaneously at a distance.

D

Though retained in elementary expositions, serious science has abandoned it for ever.

The image B (1870 to 1890) left entirely on one side the conception of a special electrical substance, and sought to explain electrical phenomena by the properties of the æther alone. But although this picture enabled one to form a representation of radiant electrical energy, it, too, has been found insufficient to explain a great number of phenomena.

The image C is based on the notion of *electrons*, and forms, to some extent, a combination of A and B. It supposes the existence of a special substratum, and preserves the idea of modifications produced in the body of the æther; but the electrical substance is now considered as the origin of these modifications in the æther.

We have summarised these distinctions because they characterise the entire fascicule. Prof. Chwolson adheres to these distinctions throughout, and the result is that he is able to produce a final picture which is more free from confusion than if he had attempted to remove the dividing lines between them. Again, the student will leave his perusal of these pages with a far wider conception of the general lie of the land than if one or other of these points of view had been purposely blocked out. We do not wish to disparage any recent books which emphasise one of these pictures to the practical exclusion of others. They serve their purpose. The pioneer is necessarily preoccupied with his own line of march. But there is a danger that, in the enthusiasm created by recent discoveries and the success attending the contemplation of picture C, the rest of the landscape will be forgotten. We can wish for no better training for a student than a perusal of Prof. Chwolson's treatise.

Of the general character of the book in its French form we may say that we do not like it quite so well as the German. The illustrations, which are taken from the German translation, do not show up as satisfactorily on the paper selected. But the production of a French translation will be welcomed by many to whom German is not intelligible; and it may be said without any hesitation that, in the form in which it now appears, we have a text-book of physics which is second to none in the French language. It should be in the library of every physical laboratory, and students who are taking up the subject of physics seriously will find it one of the best text-books of which to obtain private possession.

FLOWER POLLINATION.

Handbook of Flower Pollination. By Dr. P. Knuth. Based upon Hermann Müller's work, "The Fertilisation of Flowers by Insects." Translated by Prof. J. R. Ainsworth Davis. Vol. iii. (Band ii., Teil ii., of the German edition), Observations on Flower Pollination made in Europe and the Arctic Regions on Species belonging to the Natural Orders. Goodenovieæ to Cycadeæ. Pp. iv+644. (Oxford: Clarendon Press, 1909.) Price 28s. net.

VOL. III. of the English translation, which has now appeared, concludes that portion of Knuth's handbook for which that author was himself responsible. The later volumes, issued after Knuth's death by Dr. E. Loew, deal with observations on flower pollination made beyond the confines of Europe, while the earlier volumes contain the observations made in Europe and the Arctic regions, vol. iii. dealing with species belonging to the orders Goodenovieæ to Cycadaceæ.

The English translation, appearing, as it does, ten years after the publication of the original German edition, has been brought up to date in many respects. The arrangement of the Natural Orders has been altered in consonance with more recent classification, and some Orders have been merged as Sub-orders in the larger Families. In many instances new observations have been added, and additional literature is referred to, as, for instance, in the case of the primrose, the pollination of which has been much disputed, and also in the case of Pentstemon, of which genus Loew has latterly made a very considerable study.

This volume, like its predecessor, must be regarded as a most valuable book of reference, yet here and there are points of more general interest to which, perhaps, reference should be made. On p. 434, when dealing with the flower of the snowflake (Leucojum), Knuth gives an interesting summary of the method he has adopted to detect the presence of a nectary, when the position of that organ is not obvious at first sight. By suitable treatment of flowers with Fehling's solution or Hoppe-Seyler's sugar reagent he was able to detect the nectar-secreting part of most flowers. Sometimes even fairly conspicuous flowers, as, for instance, those of *Pyrola uniflora,* were found to be nectarless, and in this case, though the flower is otherwise obviously adapted to insect pollination, no insect visitors are recorded in the handbook. Indeed, this volume, like the preceding one, would yield much valuable information to anyone in search of opportunities of enriching botanical science by accurate observations in the field, for a number of plants, some of them quite common, still require their insect visitors to be recorded.

Some of the orders, like the Ericaceæ, are of interest, because in some genera, *e.g.* Calluna, Erica, and Cyclamen, the flowers, though adapted to insect pollination, and very eagerly visited by insects, are during their later stages anemophilous, the pollen becoming dry and powdery, and being readily carried by wind. On the other hand, some flowers normally adapted to wind pollination, like the sweet chestnut (Castanea), also attract insects, and are no doubt pollinated by them.

The translator has omitted to note the observations made recently on the dog's mercury (Mercurialis), which indicate that this plant is provided both with nectaries and sticky pollen, so that though apparently anemophilous, and probably at times wind pollinated, it is adapted to the visits of insects, and, as Knuth records, is often visited by them.

The anemophilous Gramineæ, too, offer many points of interest in connection with the frequent occurrence of cleistogamy and self-pollination of their flowers. Insect visits are occasionally observed in this group. Ludwig considered that the succulent shining lodicules of many grasses sometimes attract flies, which are often imprisoned by the rapid closing of the glumes. These flies seem often affected by the entomophthora disease, and it is suggested that when so suffering they are often compelled by thirst to seek the juice of the lodicules. In other cases, no doubt, they visit the flowers for the purpose of collecting pollen.

A very valuable appendix, occupying about 100 pages, is added to the volume, and gives a systematic list of the various insects which have been observed visiting flowers and the flowers which they usually frequent. This carefully compiled list will be as informing to the entomologist as to the botanist. The index of plants described in the volume which figures in the German edition has not been added in the translation, but is probably held over for the final volume.

The style of the English rendering is fluent, and generally free from the flaws that mark some translations, though the volume opens with a serious blunder in describing the flowers of Lobelia as actinomorphous. Hälftig-symmetrisch is, of course, bilaterally symmetrical or zygomorphic, as is, indeed, indicated by the concluding portion of the sentence which describes the bifid upper and the trifid lower lip. It is unfortunate that the translator has retained the use of the word œcology as a synonym for biology, in dealing with observations on flower pollination. Though formerly used in that sense, œcology has of late years been so definitely and much more correctly applied to the study of plant-life in relation to environment that it seems out of place when used for floral biology.

Apart from such minor defects, the translation will be welcomed as rendering Knuth's monumental work accessible to a wider circle of readers and students of plant biology.

PRACTICAL WORK FOR ELECTRICAL LABORATORIES.

Leitfaden zum elektrotechnischen Praktikum. By Dr. G. Brion. Pp. xiv+404. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 11 marks.

THE laboratory has always been regarded as a necessary complement to the class-room so far as physics and chemistry are concerned, but for engineering subjects it is a comparatively modern institution. There are still engineers amongst us who have had to go through their university training without enjoying the use of a laboratory, but within the last generation all technical universities and colleges have recognised the immense importance of laboratory work, and have fitted up hydraulic, heat, mechanical, and electrical laboratories on a more or less extensive scale. Teachers, as well as engineers in practice, are agreed on the necessity of supplementing the theoretical work of the class-room by experiment, and there is keen competition between the different institutions as regards the best equipment, each trying to profit by the experience of the others, and to adapt the plant to the special industrial requirements of its district.

The best equipped laboratory would, however, be of little value without good organisation in its use and scientific instruction in the way of carrying out experiments. The book under review is an attempt, and, let us hasten to say, a very successful attempt, to supply such instruction. Of all Continental technical high schools, Dresden has at the present moment the best equipped electrical engineering laboratory, and since its head, Prof. Goerges, is not only an accomplished teacher, but also an engineer of high reputation, we may expect that a book, treating of laboratory work as carried on under him, will prove a most useful publication. The author is lecturer at Dresden, and in the preface says that the methods described have been worked out from time to time by various members of the staff. This does not mean that the methods described, or even a majority of them, are new, but simply that all the methods described have actually been used in that laboratory, and that in this way the educational value of each has been put to the test.

If an author describes the equipment of and work done in the laboratory in which he works himself, there is danger that he will produce a somewhat one-sided account, but from such a reproach Mr. Brion is entirely free. All the author has to say on testing applies to any well-equipped laboratory, and there is a remarkable absence of references to special apparatus. He evidently does not hold with the custom of giving the student cut-and-dried instructions, such as "take Messrs. So and So's testing set, connect in such a manner, then turn the handle and read off the result." Wherever possible he not only lets the student build up his apparatus, but he gives him also a short theory of the test. The object of the student's work in the laboratory is primarily to verify by experiment certain physical relations of which he has heard the theory in the class-room. Since, however, the simple and fundamental physical relations are in practical machinery often overshadowed by secondary disturbing causes, it is important that these should be pointed out to the student, and that he should thus be trained to scrutinise his results so as to separate that which is important from that which is merely accidental or disturbing. In this direction, Mr. Brion has given us good advice in sufficient detail. To give such advice it is, however, necessary to introduce a certain amount of theoretical matter on a mathematical basis.

A casual glance through the pages of this book gives one more the impression of a text-book than of a laboratory manual, but on closer inspection one finds that only as much theory is introduced as is necessary for intelligent working. Among the good features of the book are the diagrammatic representations of circuits, machines, and apparatus. With a correct appreciation of the probability that the students who work now in the laboratory will in a year or two be working in practice, Mr. Brion has adopted in his diagrams the symbolic representation recommended by the Verband Deutscher Elektrotechniker. He also uses thick lines to represent wires which carry main currents and thin lines for wires carrying shunt currents or for voltmeter wires. This is apparently a small matter, but anyone who has to trace out the circuits in some complicated electrical connection will appreciate the advantage of making the distinction. It is, however, to be regretted that in the matter of notation the author is too intensely German. He puts P for force, A for energy, L for power, D for torque, and so on, all letters which have internationally already a significance. The reader is thus put unnecessarily to the trouble and mental strain to substitute for symbols he is accustomed to use (and which, to a certain degree, have already received the sanction of the International Electrotechnical Commission) others which are unfamiliar to him.

It is not necessary to enumerate the contents of this book in detail; suffice it to say that it broadly covers the subject of laboratory tests such as are necessary for students. As to the question of which tests are necessary and which may be omitted, opinions will always differ. It would be easy to give a list of tests which, in the reviewer's opinion, ought to have been included, but such criticism would hardly be fair, for a book on testing cannot contain every possible test, but only a selection of those which the author himself has found suitable. On the whole, the author has given us a very representative and useful selection, covering a wide field. His book will be found to be a most helpful guide to electrical laboratory work generally.

Gisbert Kapp.

ANCIENT HINDU CHEMISTRY.

A History of Hindu Chemistry from the Earliest Times to the Middle of the Sixteenth Century A.D., with Sanskrit Texts, &c. By Prof. Praphulla Chandra Ray. Vol. ii. Pp. xcvi+293+152+xxi. (Calcutta: The Bengal Chemical and Pharmaceutical Works, Ltd.; London: Williams and Norgate, 1909.) Price 10*s.* 6*d.* net.

In the first volume of this book, which was published in 1902, and reviewed in these columns on May 21, 1903, Prof. Ray dealt with all the oldest (pre-Buddha) Hindu MSS., and many of the later ones. A number of MSS. remained untouched, and now that these have been examined, the concluding volume has been issued. It has been a labour of love which has occupied all Prof. Ray's spare time for the last fifteen years, and the great value of the results of his patient and laborious researches will be fully appreciated by all students of the history of chemistry.

The difficulties of determining the extent of Indian chemical lore in ancient times are profound. There is no doubt that at a very early period the Arians attained great proficiency in the manufacturing industries, which must have rested on a good practical knowledge of chemical reactions. The famous sword-blades, called by the Greeks "marvellous swords," and by the Western world "Damascened blades," were brought to Europe by way of Damascus, but were made in India. The making and polishing of glass in India, including lenses and mirrors of various kinds, spherical, oval, &c., was a well-known industry. Pliny mentions that the best glass ever made was Indian glass. In pharmacy, in dyeing, in the manufacture of perfumery and cosmetics, complicated chemical operations must have been carried out even before the time of Buddha, which is placed about B.C. 500.

There is, however, little or no trace of these things in the literature of the period. The caste system was radically opposed to the formation of a science in which practice is based on theory. The chemical industries were exercised by a despised caste, that of the *çudras*, and their labours were no doubt deemed unworthy of being described by the caste of the *Brahmins*, or priests, who alone understood the art of writing. Thus Hoefer, for example, remarks that amongst the Sanskrit manuscripts in the Bibliothèque Imperiale, of Paris, no document occurs which can be of interest to the historian of chemistry, and Berthelot in his "Origines de l'Alchemie" practically ignores India.

The MSS. patiently examined by Prof. Ray appear to consist largely of religious or philosophical reflections, with occasional somewhat obscure references to chemical subjects made for the purpose of illustration. Thus in a document called "Rasaratnakara," written by Nagarjuna, who was the High Priest of Buddha about A.D. 150, such texts as the following occur:—

"What wonder is it that cinnabar digested several times with the milk of the ewe and the [vegetable] acids imparts to silver the lustre of gold glowing as saffron?"

And a little further on:—

"Silver alloyed with lead and fused with ashes becomes purified,"

which is a clear allusion to cupellation.

It is probable that the pundits, when referring to metal-working, often knew very little of the subjects they mentioned, but Nagarjuna was celebrated as an alchemist. Prof. Ray argues at some length in favour of the indigenous origin of Indian alchemy, and, however degrading it may have been to work, it does not appear to have been derogatory to the dignity of the sages to discuss the manufacture of gold or silver. Thus—

"Tin is to be melted and one-hundredth part its weight of mercury to be amalgamated with it. This [fraudulent substitute for] silver can be used for purposes of exchange, and one can thus amass wealth."

The last 150 pages of the book consist of a reproduction of original Sanskrit texts, taken from many different MSS.

T. K. R.

AN ENCYCLOPÆDIA OF THE SCIENCES.

Instruments optiques d'Observation et de Mesure. By Jules Raibaud. Pp. 380. (Paris: O. Doin et Fils, 1909.) Price 5 francs.

This volume is a unit in a somewhat extensive undertaking, no less than an encyclopædia of all the sciences, pure and applied, physical and biological, material, mental, and moral. The scheme is of a somewhat novel character; its magnitude may be judged from the fact that it involves a total of some thousand volumes, arranged in forty sections or "bibliothèques," the whole to rival, we are told, the largest encyclopædias of this or any other country—and not only in size. The novelty lies mainly in the fact that each volume is to be independent, and have its own individuality; each will be a monograph dealing with a special branch of the particular section to which it belongs. The size and price will be uniform, the number of pages approximately so. One among the advantages of the scheme will be that each volume can be brought up to date independently of the rest.

The forty sections are classified in the two main divisions of "pure sciences" and "applied sciences." Each of these is again subdivided into mathematical, inorganic, and biological sciences. Each subdivision comprises a certain number of sections, and each section has its own editor. The general editor is Dr. Toulouse, of the École des Hautes Études, and among the editors of sections are included such names as Painlevé, Mascart, Leduc, Lacroix, Bertrand.

The volume under review belongs to the section of "Industries physiques" in the division of applied sciences—subdivision, inorganic. The section is to include volumes on such subjects as "Industrial Electricity" (two vols.), "Electric Motors," "Electric Traction," "Electric Lighting," "Rheostats," "Wireless Telegraphy," "The Liquefaction of Gases," "The Industrial Production of High Temperatures," &c. This volume on "Optical Instruments for Observation and for Measurement" would seem to be the first volume of the section to be issued.

Judged from its position in this hierarchy of scientific knowledge, Captain Raibaud's volume is perhaps a little disappointing. One might expect to find details of the most recent technical advances, of such a character that the skilled optician might there find help, whether as regards difficulties of design, or of construction, or methods of ensuring accuracy. In the present instance, however, questions not only as to calculation of the optical system, but as to construction and methods of test, are definitely excluded; the aim is thus only to give a general account of the optical properties of various types of instrument, with brief particulars of individual instruments and designs. Expressed shortly, the work is rather an educational text-book than a technical handbook.

From this point of view, however, and for the general reader who wishes to obtain an intelligent knowledge of the more essential optical properties and possible defects of an instrument which he may be in the habit of using, the book can be cordially recommended. More especially, the general conditions governing the formation of satisfactory images by an optical instrument are carefully and clearly discussed. Thus the first part of the work, more than one-third of the whole, deals with the general properties of instruments, definition and resolving power, brightness of the image, extent of field of view in breadth and depth, distortion, magnification—subordinate, as is rightly emphasised, to resolving power and definition—and the functions and limitations of the eye in conjunction with an optical instrument. The characteristics of binocular vision and of vision through a binocular instrument are also examined, and, in regard to measuring instruments, the general conditions affecting accuracy.

In the second part of the book the instruments considered are those of the telescope class, the microscope, the photographic objective, instruments for measuring angles, surveying instruments and telemeters, and, finally, instruments based on the principle of auto-collimation. The list, of course, is by no means exhaustive; laboratory instruments, the spectroscope, interferometer, &c., and photometric apparatus generally are not included, nor does space admit of detailed consideration of any one type. The book is, however, written by one who has had experience in handling the instruments he describes, and thoroughly familiar, not only with the optical theory, but also with the practical points affecting their performance.

OUR BOOK SHELF.

Methods used in the Examination of Milk and Dairy Products. By Dr. Chr. Barthel. Translation by W. Goodwin. Pp. xii+260. (London: Macmillan and Co., Ltd., 1910.) Price 7s. 6d. net.

THIS edition contains several additions to the original work of Dr. Barthel, and it will be found very useful to those engaged in examining milk and dairy products on a large scale. The general remarks in it apply more exactly to milk of German or Swedish origin than to milk from some British breeds of cows.

In the notes on the physical examination of milk are useful hints as to the estimation of dirt. For the determination of fat Soxhlet's aræometer method is still given a prominent place, though in most places it is superseded by less complicated and more certain methods. Wollny's refractometer method for the fat estimation, if carried out under exact conditions, seems to give very accurate results, but it is so sensitive that the least departure from the necessary conditions influences the results seriously; one advantage it possesses is that as many as 150 determinations may be made in an hour with the proper appliances and accommodation. The Rose-Gottlieb method, and various modifications of centrifuge methods, including some not requiring the use of strong sulphuric acid, are described. Tests for adulterations, artificial colouring matters, and preservatives are given. Saccharate of lime is said to be one of the latest adulterations of milk and cream; it increases their viscosity and gives them the appearance of being richer in fat; a method for its detection is given.

Methods for the analysis of butter, cheese, preserved milk—including Buddised milk, that is, milk treated with a small quantity of hydrogen peroxide—condensed milk, and desiccated milk are given. We find also some account of the decomposition products of milk, butter, and cheese; and, in an appendix, several tables of figures useful in calculating the results of analyses.

Norwegian and Other Fish Tales. By Bradnock Hall. Pp. x+243. (London: Smith, Elder and Co., 1910.) Price 5s. net.

THIS is a frankly trivial book with a quite unintelligible dedication in place of a preface. The illustrations are excellent, and the text makes good holiday reading, notwithstanding its somewhat strained humour. As the author says, "the diaries of anglers are not as a rule interesting, even to sympathetic brethren of the craft," but we think that many of the author's own experiences at least come near to proving exceptions to his own generalisation. Incidentally, we are told of certain Norwegian fish:—"Everyone thought they were salmon, but both turned out to be sea-trout when the shape of the gill covers and the tail bones were examined." It seems a pity that the precise differences between salmon and sea-trout in the shape of the gill covers and tail bones are not divulged for the benefit of fishermen and naturalists; the counting of scales in a transverse series is none too easy, and an alternative method of diagnosis (if such really exists) would be welcome.

LETTERS TO THE EDITOR.

Experimental Study of Fulgurites.

FULGURITES, or the tubes of fused sand which are sometimes formed when heavy discharges of lightning strike on sandy soil, are not common enough to make their study very easy. It has been frequently remarked that they usually have a spiral or cork-screw form, but, so far as I know, it has not been decided whether or not this is accidental, and whether the direction of rotation of the spiral remains constant in the same fulgurite, or whether it is always the same in the case of various discharges. Through a fortunate accident I recently hit upon a way of extending our knowledge of these curious autographs of thunderbolts. The accident referred to was the circumstance that I was standing within about 50 feet of the spot on our lawn where a rather heavy discharge struck a day or two ago. I was about to walk across the lawn at the time, but was delayed a moment to reply to a question, when the bolt fell. The report was not deafening, resembling the explosion of one of the modern dynamite cannon crackers with which we have become familiar. There was a distinct flash of fire at the surface of the ground, and a column of steam or smoke 6 or 8 feet high. On examining the spot I found three patches of withered clover in a line about 18 inches apart. At the centre of one was a hole about an inch in diameter, and in the neighbouring one a smaller hole of perhaps a quarter the size. It had been raining hard for a hour or more, and we had had much rain for the past week, which made the ground an excellent conductor, and I was surprised to find that I could pass a straw down the larger hole a considerable distance.

I melted about 15 lb. of solder in an iron pot and poured it into the hole until it was full, and then carefully excavated the cast. In digging it out, I found a lateral tube several inches below the surface joining the two holes, and one or two lateral branches to the large tube, into which the solder had not penetrated. The cast obtained was nearly 4 feet in length, and the ground was soaking wet, which surprised me a good deal, for I imagined that the discharge would spread out and become dissipated long before reaching a depth of 4 feet in wet soil. The edges of the tubes were lined with small patches of white grains of sand fused together. The metal cast had an unmistakable spiral form, which could be followed for its entire length, and was especially conspicuous at the lower or smaller end. The diameter of the artificial fulgurite increased to a depth of about 2 feet, after which it diminished gradually. The spiral form can be seen in the accompanying photograph of the cast. It was clock-wise in the downward direction, that is, it was similar to that of a cork-screw. The surface was covered with small buds, which were arranged in straight lines along its length, some of the lines 7 or 8 inches long. One of these lines can be seen in the photograph immediately to the right of the label. These lines may be due to cracks in the tube, resulting from the explosive action of the steam. The localisation of a bright light at the surface of the ground is extremely interesting. Several members of my family, who were not looking at the spot at the moment the flash struck, turned round at the report, and said that they saw a bright light and a cloud of smoke. It will be interesting to hear if others have noticed this phenomenon. It may possibly be due to the combustion of a blast of gas generated by the passage of the discharge through the soil.

On the day after the storm I found another and much larger hole on the golf links, where a very heavy discharge had struck and demolished a wooden box of sand on the top of a banked-up tee, leaving no mark, however, on an iron cylindrical can of water standing beside and in contact with the sand box. Lateral branches had spread out in all directions over the top of the tee, making furrows similar to mole tunnels. I have not yet made a cast of this hole, which is probably 6 or 8 feet deep, pending the decision of the golf committee. Similar holes must be of very frequent occurrence, and their study by this method should prove interesting.

East Hampton, Long Island. R. W. WOOD.

Photograph of the cast of a hole formed in ground by a lightning discharge.

Ooze and Irrigation.

THE valuable contribution to this subject contained in the letter of Mr. Horwood (July 14, p. 40) shows the importance of communicating the results of research. I am, in consequence, submitting a few further facts which have not heretofore been made public. Up till the present time it has been assumed that our British Annelids were limited to a few species of earthworms, and a few aquatic forms usually lumped together as Tubifex. So far is this from being the case that we have at least four distinct groups of indigenous worms, to say nothing of the many foreign species found at Kew, Chelsea, Oxford, and elsewhere. These are, first, the true earthworms, of which we have nearly forty species, now ranged under upwards of half a dozen genera. Secondly, certain species of semiaquatic worms, including not only the well-known Allurus (Eiseniella), but two species of Helodrilus. Of these, *H. oculatus*, Hoffmeister, is now known to be British, while a second species, *H. elongatus*, Friend, new to science, is at present known to occur in Cornwall in streams and lily ponds. These are of peculiar interest, both because they necessitate a revision of nomenclature and because they link on the earthworms with the aquatic forms.

Next come the ooze formers, which are exceedingly numerous, and occur in almost all our lakes and ponds, our rivers, streams, ditches, and pools, doing an immense work as scavengers and mould-makers. Lastly, we have to notice another series, which may be conveniently spoken of as white worms (Enchytræids). It is in relation to these that I wish especially to make one or two observations. Some years ago I carefully examined the banks of the Eden near Carlisle. I then found, not only a large series of water worms engaged in making ooze, but, at particular seasons of the year, an equally varied assortment of Enchytræids (Fridericia, Heulea, Enchytræus, and others) at the roots of grasses. By careful observation I found that these were most abundant at the time when decaying vegetable matter was in a state of fermentation, and that they were apparently engaged in clearing off this fermenting matter.

I have recently further observed on the Malvern Hills that, if the stones are lifted which have for a time been covering the grass and causing it to decay, one finds that, when a given stage of decay is reached, certain white worms always make their appearance; and that these Enchytræids are, curiously enough, almost invariably associated with a species of earthworm (*Lumbricus rubellus*, Hoffm.). Other observations, such as that relating to the amphibious nature of the tiny aster-worm (*Enchytraeus parvulus*, Friend), and the action of other forms on decaying seaweed and the like, will call for fuller treatment elsewhere. Enough has been said to show that a very wide field of observation is opened up, and that, while it has its interests for the geologist, it is of supreme importance for the biologist and the student of agriculture. I am at present engaged in a series of observations which are bringing many new facts to light.

HILDERIC FRIEND.

Malvern, July 18.

The Sterilisation of Liquids by Light of very short Wave-length.

DURING the past year several articles have appeared in the *Comptes rendus des Séances de l'Académie des Sciences*, Paris, on the sterilisation of liquids by ultra-violet light. The notes of M. Billon-Daguerre have particularly attracted my attention, since he has endeavoured to utilise the region of the spectrum discovered by Schumann for the sterilisation of water. It is obvious that the question of the transparency of water for light of very short wave-length is important in this connection, and, as there seems to be no data which bears on the matter, I have recently made some experiments.

I used a vacuum grating spectroscope arranged in the same way as when I investigated the transparency of some solid substances. The water was distilled, but without any special precautions, and was enclosed in a cell with fluorite windows. Two of these cells were employed, one giving a water column of half a millimetre, the other giving a millimetre column. With the half-millimetre cell in the light path the spectrum was cut off at λ 1792 (Angström units), even after a prolonged exposure. It appeared that this limit of the spectrum receded rather slowly toward the red with increase in the thickness of the water column.

As M. Billon-Daguerre wished to use light of very short wave-length, he employed a vacuum tube filled with hydrogen. This substance is known to give a strong spectrum in the region between λ 1650 and λ 1030; it must not be forgotten, however, that no lines can be ascribed to it in the region between λ 2000 and λ 1650. Thus any action due to the radiation from the vacuum tube filled with hydrogen must be confined to a layer of water so thin that light of wave-lengths shorter than λ 1650 can penetrate it. Judging from my experiments, such a layer must be very thin indeed.

Several investigators have used the mercury arc in quartz as a source of light in sterilisation experiments. There are two facts which it may be interesting to mention in this connection. In the first place, fused quartz two millimetres thick is somewhat transparent so far as λ 1500; the transparency falls off rapidly with increasing thickness. In the second place, no lines more refrangible than the strong line at λ 1850 are known in the spectrum of mercury. In this second statement my own observations are confirmed by a recent investigation of Dr. Handke.

THEODORE LYMAN.

Jefferson Laboratory, Harvard University, July 8.

Elemental Weight Accurately a Function of the Volution of Best Space-symmetry Ratios.

IT is a fact little known, but of the first magnitude, that equal spheres or corpuscles cannot in space, as in one plane, be distributed at equal mutual distances. Tetrahedra, the four points of which alone are all mutually equidistant, cannot be packed so as to fill space, as their face-angles to fill one plane.[1] Icosahedral diffusion, with a central sphere, nearly achieves this, but by a cramping of the central point in the ratio 1 : 1·051460···.

Free magnetic needles in water, say five in number, may fall into position either thus :

or thus :

Their energies are a fixed quantity; so that, though they will assume either position, they are stabler in position (*a*), because here, on the whole, the lines are more equidistant; but (*b*) might become equally stable if each needle were a vortex possessing an energy v, capable, under heat and cold, of adapting itself to changed environment by cumulative indraught and outdraught, *i.e.* $v^{\pm\frac{n}{m}}$.

In one plane, equal spheres being equitriangularly arranged, each sphere forms a centre capable of supporting, by surface tension, an equal number of spheres around it. In space, the nearest approach to this perfect equilibrium is by means of the five best-symmetries, or so-called regular solids, whereof three dominate elemental crystals.[2] Alike as to points, faces, edge-lines, and circum-radial lines, these five contain only the factors 2 and 3 (crystalline) and 5 (non-crystalline), greatly complicated, however, by the last of these :

$$\text{Crystalline} \quad : hex\ \sqrt{2:1}\ ;\ tet\ \sqrt{8:3}\ ;\ oct\ \sqrt{4:3}$$

$$\text{Non-crystalline} : ic\ \sqrt{2\left(1-\frac{\sqrt{5}}{5}\right)}:1\ ;\quad do\ \sqrt{2\left(1-\frac{\sqrt{5}}{3}\right)}:1.$$ [1]

Now the problem of the volutional interconversion (on the principle $v^{\pm\frac{n}{m}}$) of the three first ratios 2, 3, and 5, yields to a simple and highly accurate solution,[2] whereas adding the two last, *ic* and *do*, the solution becomes complex; but, on the lines of the simple interconversion, there are contained several approximate interconversions with *ic* and *do*, the errors of which are the precise weights of $H^{1\cdots 4}$ by different syntheses :

$$\left.\begin{matrix} \frac{4}{3} \\ \text{or } oct^2 \\ \text{or } \frac{tet^2}{hex^2} \end{matrix}\right\} = \left\{\begin{matrix} \sqrt[12]{2} \\ \text{or } \sqrt[6]{hex} \\ \text{or } ic \times \text{H (i)} \\ \text{or } \sqrt[9]{\frac{hex^2}{oct^2}} \\ \text{or } ic \times \text{H (ii)} \end{matrix}\right\} \times \left\{\begin{matrix} \sqrt[7]{5} \\ \text{or } \sqrt[7]{3}\ ic \times \text{H}^3 \quad \text{(iii)} \\ \text{or } \sqrt[7]{2}\ ic^2 \times \text{H}^4 \quad \text{(iv)} \\ \text{or } \sqrt[7]{\frac{\text{O}(=16)\times do^2}{ic^4 \times oct^2}} \quad \text{(v)} \end{matrix}\right.$$

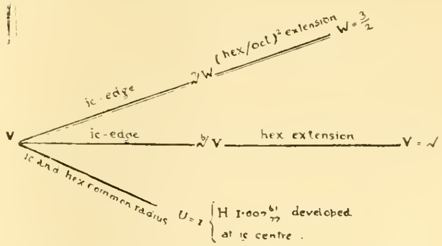
The numbers (i), (ii), (iii), (iv) refer to Morley's four experimental weights of H,[3] which the formula hits precisely :

(i) $H_2 : O$ mean $= 1·00761$	(iii) Gravimetry mean 1·00762
(ii) $H_2 : O$ max. $= 1·00777$	(iv) $H_2 : H_2O$,, 1·00765

Two basal equations are here involved,

$$(4/3)^x = 2^{\frac{x}{12}} \times 5^{\frac{x}{7}} \text{ and } 2^x(5/4)^{7x} = 3^{2x} \times 1·5^{\frac{x}{7}} —$$

7 and 12 being severally the combinable group and series numbers of the table. The main equation (*threes* strong) appears accurate to some 50 decimal points; the secondary (*fives* strong) rather less so. They meet at $\sqrt[7]{1·5} = \sqrt[12]{2}$; with an error of 0·00016, the crux of the hydrogen ranges. Their great accuracy points to a profound numeric and geometric principle. *Hex, hex²/oct², &c., compensation-vortices cannot evolve to their 6th and 9th roots without developing hydrogen, and thereupon compensating* ic, *&c.; and, inversely,* ic, *&c., cannot involve to their 6th and 7th powers without ultimately throwing off hydrogen and compensating hex, hex²/oct², &c.*



(i) The compensation-vortex at the end of the cubic (or tet oct) edge-line, pulls, as required, by $\sqrt{2:1}$ against the circum-cube radius. This crystalline symmetry being disturbed by heat, the vortex unravels or evolves to its 6th root, travelling down the line to the point marked $\sqrt[6]{v}$. It there precisely compensates the *icosahedral edge : circum-*

[1] See Barlow and Pope, Chemical Society Transactions, 1907, vol. xci., p. 1152.

[2] Retgers, Zeitsch. physical Chem., 1894, xiv., 1.

[1] *Tet, hex, oct, ic,* and *do* here stand for the ratios, or the weights compensating the ratios, *edge-line : circum-radius* (*i.e.* the radius of a circumscribed sphere) severally of the regular tetrahedon, cube, octahedron, icosahedron and dodecahedron.

[2] A log-algebraic problem of eight terms unknown, it was soluble only by reference to philosophical considerations anterior to those now discussed.

[3] Morley, confirmed by Thomsen, Keiser, Guye and Mallet. See International Committee's Report. *Chemical News*, February 12, 1897, May 5, 1899, June 11, 1897, and May 12, 1905; or Freund's "Chemical Composition," 1904, p. 220.

radius ratio; but so that there is developed at the icosahedral centre, a deficit or gravitative pull equal exactly to the hydrogen mean weight by $H_2 : O$, viz. 1·00761.

$$ic = 2^{\frac{1}{12}} [= 1·059462 \cdot \cdot] \div 1·00761.$$

(ii) The vortex compensating the ratio of cube-edge to octahedral-edge—*i.e.* $hex^2 : oct^2$—both having a common or equal circum-radius, unravels down the cube-edge to its 7th root, and at $\sqrt{w}$ becomes an icosahedral compensation vortex; the octahedral-edge becomes or equals the icosahedral circum-radius; and the hydrogen pull is developed at the icosahedral centre; but at $H_2 : O$ max. 1·00777. Cases (iii), (iv), and (v), and all the coalition permutations (see below), are to be interpreted like (i) and (ii), though more complex.

In cases (i), (ii), (iii), and (iv) we have severally $H^{1 \cdots 4}$; and, similarly, in the coalition formulæ *ic* or H are never in excess by more than the valency numbers 1 to 4 —1 to 8 in the cross-formula (No. 4).[1] This, probably, is attributable to the multiple radial lines. For we are concerned with powers, not multiples. Each central vortex does not need to pull against the sum of all its surrounding vortices as isolated units, because these latter too are themselves centres, and correspondingly weakened. The contraction of the crystalline ratios under heat is consistent with the entropic or adiabatic phenomena of H_2O; and for many reasons it is believed that the weight deviations are a function of entropy. When (see below) the line is crossed, the signs change, contraction becomes expansion, and along the lines of the *pari passu* increase of exponents, the VD, entropically disturbed, gradually becomes constant.

Morley's ranges are severally $\pm 0·00016$, $\pm 0·00033$, $\pm 0·0007$, and (*means*) 0·00004. By coalition of the fractures of the main formulæ, we derive the following, *in all which formulae, $\pm x$ being high, the mean is attained, and the maxima and minima when $\pm x$ is low; so that the formulae can never transcend the experimental range, and always tend to its means.* (Compare entropy):—

Formula	x high	Range
(1) $5 / 2^{\frac{27-x}{12}} = ic^{x+1} \times H^x$	H = 1·00761	$\pm 0·00033$
$2^{\frac{28+x}{12}} / 5 = ic^x \times H^{x+1}$		$\pm 0·00016$*
(2) $3^{\frac{4}{7}} / 2^{\frac{10-x}{12}} = ic^{x+1} \times H^x$	H = 1·00761	$\pm 0·00004$
$2^{\frac{11+x}{12}} / 3^{\frac{4}{7}} = ic^x \times H^{x+1}$		
(3) $5 / 2^{\frac{17-x}{12}} \times 3^{\frac{4}{7}} = (ic \times H)^x$	H = 1·00761	$\pm 0·00030$
$2^{\frac{17+x}{12}} \times 3^{\frac{4}{7}} / 5 = (ic \times H)^x$		
(4) $5^{\frac{3}{7}} / 2^{\frac{19-x}{12}} = ic^{x+1} / H^{7-x}$	H = 1·00761	$\pm 0·0005$
(5) $2^{\frac{6\pm x}{7}} \times 3^{\frac{3\pm x}{7}} = ic^{2\mp x} \times H^{3\mp x}$	H = 1·00777	$\pm 0·00015$
(6) $5^{\frac{6\mp x}{7}} / 2^{\frac{13\mp x}{7}} = ic^{2\mp 2x} / H^{1\pm 4x}$	H = 1·00765	$\pm 0·00017$
(7) $5^{\frac{6}{7}} / 2^{\frac{7+x}{7}} \times 3^{\frac{3-x}{7}} = ic^{4+x} \times H^{2+x}$	H = 1·00777	$\pm 0·00033$
(8) $5^{\frac{6+x}{7}} / 2 \times 3^{\frac{3+x}{7}} = ic^{4+x} \times H^{2+3x}$	H = 1·00762	$\pm 0·00020$

* $x = 2$.

A comprehensive deduction from the general formula is the following:

$$H\,(1·00761) \times \frac{do^2}{ic^3} = \frac{oct\ 4^2}{hex\ 3^2} = \frac{tet\ 4^3}{hex\ 5^{2}}, \text{ \&c.}$$

Provisionally, upon examination of four out of the eight combinable groups, the elemental weights are found expressible in like terms to these, *i.e. the elemental weights are such that, multiplied into the simple volution of one or more of the symmetry line-ratios, they yield accurately the simple volution of one or more other symmetry line-ratios, each expression having its exact equational variant, like elements yielding to like expression, but not mechanically so* (see *Chem. News*, April 22, May 6, and June 10). This is deduced from the basal-equations with x as $1 \cdot\cdot 8$, the formula not being constructed (or rather discovered) empirically to yield any given weight, but rationally to meet the whole problem of weight compensation. That, x being 1, the H weights were with perfect exactitude obtained, chanced to be a fact almost the last discovered.

Considering the hydrogen solution alone, the rational postulate of vortex compensation for inequidistance (as contrasted with the crude Democritan hard-atom hypothesis) hits precisely—with the odds 100,000 to 1 against each hit—in the four corners of the basal-equation, the four means of hydrogen; and by coalition, all their deviations. *The postulate is thus, on the one element, proved true by the odds* $100,000^4$ (10^{20}) *to* 1.

Corroboration is glimpsed in the spectrum-line ratios.

H. NEWMAN HOWARD.

[1] $H^{1 \cdots 4} + 0, 1, 2, 3$ are virtually $H_{1 \cdots 4}$

Electrical Discharge Figures.

MR. A. W. PORTER gave in NATURE of March 31 (vol. lxxxiii., p. 142) an account of his experiments on electric discharges over photographic plates, made in order to ascertain what is due to the luminosity of the discharge and what to the discharge itself. Knowing that the disruptive discharge carries metallic particles from the electrodes, and that in the silvering of mirrors by the wet processes the silver begins to set at every metallic particle which clings to the surface of the glass because of the action of local couples, I ventured to develop the invisible image of the discharge on a clean glass plate by the silvering solution.

Electrical discharge figure developed by wet silvering process.

The effect was a very striking one; instead of the broad band of the trunk discharge, a clean band was left, surrounded by two sharp, dense lines of deposited silver. The thin ramifications were still visible, but the splendid display of surrounding figures is lacking. The two unsatisfactory paper prints that I send [one is here reproduced] were made from developed plates, and are therefore negatives. It is impossible to get better results now, because the laboratory is closed for the summer holidays.

The acid intensifier for the collodion plates, acting in the same way as the wet silvering mixture, was also tried by me, but the result was worse.

W. LERMANTOFF.

University of St. Petersburg, Russia.

It is necessary to know more concerning the precise conditions under which the images referred to above were obtained before one can discuss them with safety; but they are interesting as apparently indicating that the axis of the trunk discharge *may* be free from metallic particles.

In this connection, however, it must be added that when one directly observes a negative discharge over a photographic plate from an electrode of zinc or magnesium, every line in the fan-like discharge is seen to have the bluish tint characteristic of the metal. Whatever, then, may be the reason for the absence of these fan-like figures from Mr. Lermantoff's images, it must certainly not be attributed to the absence of metallic particles from them.

ALFRED W. PORTER.

An Interesting Occultation.

MAY I direct attention to an interesting phenomenon which will take place on the morning of July 27, viz. the occultation of the star η Geminorum by the planet Venus, the particulars of which are as follows:—

Apparent place of η Geminorum (mag. 3·2–4·2), July 26, R.A. 6h. 9m. 26·6s.; dec. 22° 32′ 6·24″ N. Apparent place of Venus (geocentric), July 26, 14h. 57·7m. G.M.T., R.A. 6h. 9m. 26·6s., dec. 22° 32′ 7·2″ N. Declination at Greenwich, corrected for parallax, 22° 32′ 2·3″. Semidiameter 6·14″. At Greenwich the occultation commences at 14h. 55m., and ends at 14h. 58m. The planet rises at 13h. 43m., and the sun at 16h. 17m.

On the afternoon of July 28, Venus is in very close conjunction with μ Geminorum, the positions of the two bodies at 4h. 27m. being as follows:—

♀. R.A. 6h. 17m. 30·9s., dec. 22° 33′ 58″ N., declination (corrected for parallax) 22° 33′ 53″. μ Geminorum, R.A. 6h. 17m. 30·9s., dec. 22° 33′ 43″. As the semidiameter of the planet is 6·1″, the star will be within about 4″ from the southern limb. This, of course, occurs during daylight, but the planet will be above the horizon at the time. It sets about 6h. 8m.

Dr. Crommelin has kindly looked through these figures and verified them.

ARTHUR BURNET.

52 Prospect Terrace, Hunslet.

Pwdre Ser.

THE curious belief that shooting stars, when fallen to earth, become lumps of jelly may possibly be explained in the following manner:—

The jelly is very probably the plasmodium of a Myxomycete, such as Spumaria or Physarum. The plasmodia occur most frequently in damp weather, but are found in lesser numbers throughout the year. Shooting-stars are also seen at all times in the year, but most plentifully in the autumn. In these islands, the greatest rainfall is also in the autumn months.

Consequently, by a purely fortuitous coincidence, meteors and plasmodia are most plentiful in the latter part of the year, the former because the main meteor swarms, in their annual revolution, cross the earth's track at that time, and the latter on account of the greater rainfall. Two striking phenomena are forced on the rustic attention at the same time, the brilliant display in the sky and the mysterious jelly on the grass. Very naturally the two are considered as causally connected, and so the belief may have arisen. An analogous case is that of "cuckoo-spit," the frothy exudation of the larval frog-hopper, *Philaenus spumarius*, which appears at the time of the arrival of the cuckoo and disappears about the period of the bird's departure.

W. B. GROVE.
R. MILLARD GRIFFITHS.

University Botanical Laboratory, Birmingham.

IN connection with the article on "Pwdre Ser" in NATURE of June 23, it is interesting to find, in Admiral Smyth's "Sailor's Word-Book"—one of the richest repositories of quaint facts and fancies—the term "fallen-star" defined as "A name for the jelly-fish or *medusa*, frequently thrown ashore in summer and autumn."

C. FITZHUGH TALMAN.

U.S. Department of Agriculture, Central Office of the Weather Bureau, Washington, D.C., July 11.

HOUSE-FLIES AND DISEASE.

ALTHOUGH the verification of the belief that the commonest, most widely distributed and truly domestic of insects, *Musca domestica*, Linn., was capable of carrying the germs of certain infectious diseases has been one of the noteworthy accomplishments of medical science in the last decade, it is a mistake to attach all the credit to those who, within the last few years, have removed the idea from the realms of hypotheses into the world of facts.

As early as the seventeenth century, Sydenham associated unhealthy conditions with flies. Lord Avebury, in 1871, regarded flies as "winged sponges spreading hither and thither to carry out the foul behests of contagion." In addition to other early suggestions, Nicholas, in 1873, indicated the possible connection of flies with the dissemination of cholera from a case observed by him in 1850; Raimbert in 1869 experimentally proved that the house-fly and blowfly were able to transmit the anthrax bacillus; Davaine in 1870, and Bollinger in 1874, also showed that the blowfly could carry the anthrax bacillus, an important practical observation. Laveran in 1880 demonstrated the ability of flies to carry the infectious discharge of conjunctivitis in Egypt on their proboscides and legs. All these observers assisted in

FIG. 1.—*Musca domestica*, Linn.

the gradual growth of the belief; but it was in the 'eighties of last century, however, that several investigators adduced more convincing bacteriological proof as to the ability of flies to carry pathogenic and other bacteria. In 1886, Tizzoni and Cattani obtained the cholera spirillum from flies caught in cholera wards. In the same year, Hoffmann found tubercle bacilli in the excreta of flies caught in a room which had previously contained a phthisical patient. Two years later, Celli showed that the typhoid bacillus was able to pass in a virulent condition through the digestive tract of the fly.

Since the above observations, which are selected from many others, were made, it has been repeatedly shown and proved that house-flies are able to carry these and other bacterial and fungal organisms. What has not been demonstrated is the extent to which flies are *not* able to carry such micro-organisms. When the habits of flies are considered, it is not a little remarkable that no serious attention was paid to the possibility of flies having any considerable relationship to the dissemination of disease until within the last twelve years. The excessive mortality from typhoid which occurred in the Spanish-American war was the means of directing the attention of such observers as Vaughan and Veeder to the possible relationship of flies to this disease, especially as statistics showed that water was not a sufficiently important factor in, and was not explanatory of, the typhoid epidemics occurring in certain of the national encampments. Later, in the South African war, the same conditions were present, and enteric fever was responsible for a very heavy death-roll; those who were present directed attention on their return to these conditions, which, as circumstantial evidence, would convince the most sceptical as to the important *rôle* that flies played in the spread of the disease. These conditions are well known now; open latrines swarming with incredible numbers of flies in all stages of development; these latrines frequented by incipient cases of enteric; myriads of flies in the mess tents, defiling all kinds of food, and in many cases distinguishable by the lime which they bore on their appendages from the latrines, as were the typhoid patients in the hospitals also distinguishable by the number of flies clustering about their mouths while in bed.

From the setaceous character of the appendages and bodies of flies it is only to be expected that when allowed to have access to infected material they would be able to carry the bacilli on their appendages, bodies and in their digestive tracts, and the transference of flies from infected substances to culture media are really unimportant experiments compared with those of capturing the flies under normal conditions near sources of infection and determining the presence and identity of the micro-organisms on these insects, as certain investigators have done. It would be found impossible to obtain a specimen of *Musca domestica* which was not carrying bacteria or fungal spores.

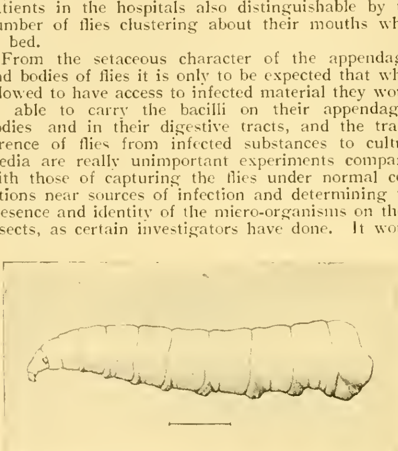


FIG. 2.—Larva of *M. domestica*.

Though externally they may be almost sterile when they emerge from the pupa, the fly after emergence immediately becomes contaminated, and during the remainder of its varied existence serves as a collector and disseminator of any bacterial or fungal organisms with which it comes into contact. One of the most important and convincing experiments is that of Güssow (hitherto unpublished), who obtained thirty colonies comprising six species of bacteria and six colonies comprising four species of fungi from a single fly caught in the living-room of a house and allowed to walk over a culture plate of agar-agar. From a fly caught in the open he obtained forty-six colonies comprising eight species of bacteria and seven colonies comprising four species of fungi. The tracks of a house-fly caught in a household dustbin yielded 116 colonies of bacteria comprising eleven species, and including such species as *B. coli*, *B. lactis acidi*, and *Sarcina ventriculi*, and ten colonies comprising six species of fungi.

Such experimental results render further argument as to the frequency with which house-flies carry bacteria and the spores of moulds and other fungi unnecessary. Flies captured near excremental products are most frequently found carrying bacteria characteristic of the alimentary canal or putrefactive bacteria, and it is only to be expected that should such sources of contamination be infected with pathogenic bacteria, for example, from an incipient case of typhoid or from a typhoid "carrier," the bodies of the flies would become infected. As an instance of this, Hamilton recovered *B. typhosus* five times in eighteen experiments from flies caught in two undrained privies, on the fences of two yards, on the walls of two houses, and in the room of an enteric fever patient, and others have obtained positive results in similar experiments.

The habits of these insects are most perfectly suited for the dissemination of pathogenic bacteria. On one hand, they seek all kinds of excrementous and decaying vegetable and other matter, chiefly for the purpose of depositing their eggs; and, on the other hand, they fly with perfect freedom on to food such as milk, sugar, &c., much of which forms an excellent medium for the deposition of whatever bacteria they may have become contaminated with during their ubiquitous wanderings.

Not only during the summer, but also during the winter months, house-flies, if they are active, normally carry on their bodies and appendages bacteria and the spores of moulds, and Fig. 3 shows an agar slope culture obtained by allowing a fly caught in the writer's laboratory at the end of January, 1910, to walk up the agar slope; the comparatively large number of colonies which developed in the tracks of a single journey can be easily seen.

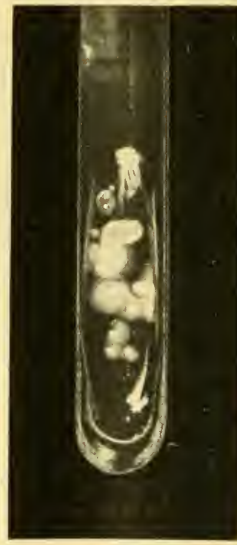

FIG. 3.—Agar-agar Slope culture of bacteria deposited by *M. domestica* in a single journey over the medium.

The eggs of the house-fly are deposited on most decaying vegetable substances, especially if they are in a fermenting condition; the influence of fermentation is of considerable importance; in one instance the maggots developed in germinating wheat. Of all substances they prefer horse manure, and this is most suitable for the development when it occurs in heaps as stable refuse, supplying as it does both moisture and heat, the two great essentials for a rapid development. They will also choose the excrements of man and certain other animals. Newstead found them in such animal and vegetable substances as rotting feathers, flocks, and paper, in which substances, when soiled with excrementous matter, they have also been found by the writer, and such conditions not infrequently occur in refuse heaps. Wherever there are collections of these substances, in such places will flies be found, not only depositing their eggs, but contaminating their appendages and bodies with putrefactive and other micro-organisms which abound there. Ficker and others have shown that typhoid bacilli can pass through the digestive tract of the house-fly and retain their virulence for more than three weeks, but the more recent discovery by Faichne, that flies bred from larvæ which have developed in infected material carry the typhoid bacilli in their digestive tracts, is one of great importance in its practical bearing.

The most important factor which affects the numbers, activity, and potential danger of flies is temperature. Experiments show that at a high temperature the whole life-history can be passed in eight days. Further, it was found that the second generation of flies are able to begin to deposit their eggs as early as the fourteenth day after emerging from the pupa; in short, the second generation of eggs may be deposited in about three weeks after the deposition of the first. Each fly is able to deposit from 100 to 150 eggs in a single batch, and at least six batches are laid during the lifetime of a single female. It is not difficult, in view of these facts, to understand the production of enormous numbers of flies during hot weather, and how the activity and numerical abundance of flies increases with the rise of temperature. During the hot months of July, August, and September flies are most abundant, and it is a significant fact that in those years when the temperature is high during those months, that is, during the third quarter of the year, there is almost invariably a high mortality from typhoid fever and the infantile disease, summer diarrhœa. In connection with summer or infantile diarrhœa, a curve prepared from statistics covering the last twenty years showed, with the exception of one year, that a rise or fall in the number of deaths per thousand living in a large English city was associated with a rise or fall respectively in the temperature.

The relation of flies to summer diarrhœa is practically based on epidemiological and other circumstantial evidence, since the specific cause of the disease has not yet been determined with certainty. Morgan, however, has found a bacillus occurring in a large percentage of the cases of the disease, and the same bacillus has been isolated from flies captured in infected houses. An objection has been made to the idea that the house-fly is a carrier of the cause of summer diarrhœa, this objection being founded on the fact that at the end of the summer the fall in the fly curve follows the fall of the curve representing the diarrhœa mortality, the flies being still more numerous than they were earlier in the season, when the diarrhœa curve was rising. In meeting such an objection it may be pointed out that we are not considering the numerical abundance of the flies in the houses only; it should be remembered that with a decline of temperature the activity of the flies, especially out of doors, which is important in this case, is not so great, even though their numbers may be considerable indoors. With the fall of the temperature, therefore, the possibility of their carrying the infection decreases without a necessarily corresponding decrease in their numbers, and the diarrhœa curve will fall in consequence.

The fly problem, which is more serious in the United States and Canada than in England, is one that may be attacked and solved in cities and towns, provided that the authorities will take the necessary steps. As in districts previously infested with mosquitoes, these insects have been reduced to a negligible quantity by the abolition of their breeding-places or the rendering of the same unsuitable for the larvæ; so also the number of flies and their danger could be lessened very considerably by the removal of their breeding places, by preventing their access to the breeding places, or by treating these with substances noxious to the larvæ or flies. Flies are a public nuisance, and, therefore, to maintain places where flies are able to breed should be made a misdemeanour. Stable refuse should not be left exposed for a longer period than six or seven days in the summer, but should be removed from the vicinity of dwellings or treated with such a substance as chloride of lime, which will prevent the breeding of the flies, the refuse being kept in a closed fly-proof chamber. The presence of mews and stables with their exposed rubbish heaps will always account for the abundance of flies. The household dustbin or other repository for kitchen refuse, unless securely closed or screened and regularly emptied, also forms an excellent breeding ground. Public tips on to which all kinds of organic and decaying matter is deposited produce their flies in myriads; it is invariably found, where actual investigation has been made, that the percentage of cases of zymotic diseases of an enteric nature is abnormally high in the neighbourhood of public refuse tips and depôts where rubbish is allowed to accumulate.

In considering the relation of house-flies to disease, although the one species of fly, *Musca domestica*, usually constitutes from 90 to 98 per cent. of the fly population of houses, certain other species are also found to occur. The lesser house-fly, *Homalomyia canicularis*, has the next place in the scale of frequency, and is generally mistaken by the uninitiated for a young house-fly, on account of its general resemblance. Although both the adult fly and the larva have pronounced structural differences, the habits of the larva and the economic relationships of the fly resemble those of *M. domestica*. The blood-sucking fly, *Stomoxys calcitrans*, is not infrequently mistaken for the true house-fly, which has adopted vicious habits. *M. domestica*, however, is unable to pierce the most delicate skin, and *S. calcitrans*, which frequently enters and is found in houses in the spring and also in the autumn, especially in rural houses, presents considerable differences, the chief being the possession of an awl-like, piercing proboscis, a more robust build, and its coloration. Not infrequently inflammatory swellings, sometimes of a serious nature, result from the "bite of a fly," and such cases are instances of the mechanical transference of such bacteria as the Streptococci from infected material to a healthy human being by a blood-sucking fly. Malignant pustule may be caused by the mechanical transference of the *Bacillus anthracis* by a blood-sucking fly, or it may be by a non-blood-sucking fly, such as the blowfly, *Calliphora erythrocephala*, if the skin is broken to provide entrance for the bacillus.

Wherever there is filth, suppuration, or purulent discharge, flies are invariably attracted, and as they are cosmopolitan in their attentions and no distinguishers of persons, they are potential disseminators of such bacteria as these substances may contain. It is not a question of eradication in the case of this insect; such is impossible. Control and prevention, however, are within the bounds of possibility, and these will be regarded as essential when the facts are more generally realised.

C. GORDON HEWITT.

THE NEXT TOTAL ECLIPSE OF THE SUN.

ON April 28 of next year there will occur a total eclipse of the sun which will begin on the earth generally at 7h. 49·2m. G.M.T., the central phase commencing at 8h. 46·1m. G.M.T. The path of the moon's shadow is restricted for the most part to the equatorial regions, and is confined to the longitudes between Australia and South America, so that as far as Europe or Asia are concerned the eclipse cannot be observed there even in a partial phase.

The actual line of central eclipse commences on the south-east portion of Australia, and passes in a north-eastern direction, crossing the equator in about longitude 154° W. It then sweeps round in an easterly direction, terminating in about longitude 90° W. just off the west coast of Central America. The line thus extends over the full width of the Pacific Ocean, and it is therefore from islands in that ocean that the expeditions which may be sent out will have to make their observations. While there is a great number of islands in this ocean, there are, unfortunately, remarkably few which lie in the narrow band of the totality track. Following the line from west to east, the first that one finds on the Admiralty chart is Tofua, in the Tonga or Friendly Islands. The next that is met with is Vavau, in the same group, and also close to the central line of totality. Much further eastward we reach Nassau, which lies a little to the south of the central line, but well within the central zone, and not far away are the Danger Islands, which are situated to the north, but further away from the central line. Thus, so far as is indicated on the chart, there are only four available points from which observations can be made.

In order to find out the suitability of these islands for eclipse parties, Mr. F. K. McClean determined to make detailed inquiries on this point on his way out to the recent eclipse, travelling from England *via* San Francisco and New Zealand specially to gather this information. Particulars are now to hand, and at his request they are published here so that intending observers may benefit thereby.

With regard to Tofua the information is brief and concise. It is that Tofua is an active volcano and high, and therefore unsuitable. As regards Vavau he says very little, because, as he knows, it is generally recognised as being a good place for observation. He adds, however, that there are hills there several hundred feet in height; that the island is called at by mail steamers; and, finally, that there are many small and low islands in the neighbourhood.

Coming now to Nassau and Danger Islands, these are described as "difficult, but possible by using owner's boat and landing tackle." As observing stations he defines them as "good." The mode of procedure to utilise these islands is suggested by him in the following words:—

A small steamer of several hundred tons (*The Dawn*), belonging to Captain E. F. Allen, runs to both Nassau and Danger. He does the whole of the landing and embarking of copra, &c. This steamer would have to be chartered at approximately 40*l.* per day when under steam and 20*l.* when not under steam. . . . Captain Allen says that he would undertake to get all cases on shore in good condition if they were water-tight, but he cannot undertake to keep them dry. If for any reason he could not land on one island, he could on the other in any reasonable weather conditions.

In most of the Pacific islands the chief difficulties to be met with are confined to the landing and embarking of the *personnel* and material. As many of the islands are fringed with coral reefs, with only small, narrow passages through them, in some cases natural, in others made by blasting operations, considerable skill is required in negotiating the breakers, and special surf boats are usually required. Mr. McClean's advice, therefore, is that it is almost imperative to employ someone accustomed to such work, "as certainly no one unused to the conditions could do it."

Should any of the parties who intend to go out on the occasion of this eclipse wish to locate themselves on some island other than Vavau, then Nassau and Danger Islands are their only alternatives. It is hoped, however, that one or other of these will be made use of, as they are sufficiently distant from Vavau to be subject to different weather conditions should the parties at Vavau be clouded out.

WILLIAM J. S. LOCKYER.

GLACIERS, GOLDFIELDS, AND LANDSLIDES IN NORTH AMERICA.[1]

As an example of organised public research, the U.S. Geological Survey is unparalleled in its activity. Bulletins, professional papers, monographs and reports flow from the Government Printing Office at Washington in a stream that is well-nigh overwhelming to the student who tries to arrest it for systematic examination. Written, or brought by capable editing, to a standard of lucidity that is positively monotonous, well printed, lavishly illustrated, and distributed with enlightened generosity, these publications contain a store of precise information which illuminates every branch of earth-knowledge. The range of subjects which they cover is no longer confined even within

FIG. 1.—Margin of Atrevida Glacier west of Esker Stream. Trees being buried by the ice.

the spacious limits of geology, palæontology, petrology, mineralogy and physiography;—it has overspread into many cognate branches of applied science, such as analytical chemistry, hydraulics, mechanics, engineering, metallurgy and mineral statistics.

The three handsome memoirs before us are good examples of the broad spirit in which the work is carried out; each, while dealing primarily with a particular district, is a notable addition to our knowledge of the continent as a whole; and each finds room for matter likely to be interesting to any educated reader, along with that which appeals directly to the specialist. In the first and third, the physio-

[1] Professional Papers of U.S. Geological Survey. (Washington, 1909.)
(1) No. 64. "The Yakutat Bay Region, Alaska: Physiography and Glacial Geology." By Ralph S. Tarr; "Areal Geology." By R. S. Tarr and Bert S. Butler. Pp. 183; with 37 plates and 10 figures.
(2) No. 66, "The Geology and Ore Deposits of Goldfield, Nevada." By F. L. Ransome, assisted in the field by W. H. Emmons and G. H. Garrey. Pp. 258; with 2 maps, 33 plates and 34 figures.
(3) No. 67, "Landslides in the San Juan Mountains, Colorado, including a Consideration of their Causes and their Classification By E. Howe. Pp. 58; with 20 plates and 4 figures.

graphical study of the subject is made paramount; in the second, petrology, mineralogy and mining receive the fullest treatment.

(1) Of especial interest is the professional paper first on our list, containing the results of Prof. Tarr's recent investigation of the great glaciers in the Yakutat Bay region of Alaska. We may congratulate ourselves, and Prof. Tarr also, on the happy mischance which took him to this region at a critical time in the history of its ice-fields.

Ever since the famous explorations of the late Prof. I. C. Russell, twenty years ago, we have known that where the greatest of these ice-rivers left the mountain valleys and deployed as "piedmont" glaciers on the low ground bordering the ocean, they were characterised by their peculiarly stagnant condition. The anomaly of dense living forests covering their surfaces over large areas where the ice was hidden beneath a thick blanket of moraine was one of the many surprises brought to our knowledge by Russell; and later investigations confirmed the idea that in such cases the ice was truly "dead" and would remain where it was, a waning relic of severer bygone times, until gradually dispersed by liquefaction.

Such was still the state of affairs when Prof. Tarr began his survey-work in the region in the summer of 1905, and he confidently planned a programme for the following year which depended for its fulfilment on the "deadness" of the ice. On his return in 1906 he was naturally astonished to find that all was in a turmoil of change—familiar features obliterated—routes impossible. The "dead ice" in many places had sprung to life again—the plains that had formed the highways of former travel were broken into an impenetrable wilderness of crevasses—the blanket of moraine was sliding out of sight into the yawning chasms—the green forests that covered it were sharing the same fate—the snouts of the glaciers were being thrust forward destructively into the timbered belt surrounding them—the enormously augmented streams issuing from the ice were impassable, and were flinging out huge delta-fans that buried everything in their path; and, altogether, nature in one of her most vigorous moods was enacting a grand transformation scene on the lonely shores of Yakutat Bay. All the eastern portion of the great Malaspina Glacier was a maze of crevasses, and its end—formerly an easy slope—an insurmountable cliff of tumbling ice, trees, and moraine. The Atrevida (see Fig. 1), the Variegated, the Marvine and the Haenke Glaciers were in the same state of rapid disruption; while others, including the Lucia and the Seward, though not so fully aroused, showed symptoms of impending change.[1]

FIG. 2.—View looking west from Hidden Glacier showing the Fosse and the Pitted Plain.

Yet there were other glaciers in the region that had not participated in this energetic outburst, but still kept to the habit of recession which had been regarded as the normal behaviour of all these Alaskan glaciers.

Here, then, was the unexpected problem that confronted Prof. Tarr in 1906 and richly recompensed him for the destruction of his original plans. His solution of it is remarkably simple, and seems to fulfil all the conditions. It is well known that in 1899 the region was affected by a sharp earthquake, which caused displacements recognisable on the coast-line

[1] In the *National Geographic Magazine* for January last Prof. Tarr and Prof. L. Martin give an account of their later visit to the region in the summer of 1909, when further changes were noted. The Lucia Glacier had become unpassable; the Hidden Glacier had undergone the full cycle of change; the Hubbard seemed to be on the eve of great movement; while the four mentioned above as active in 1906 had relapsed into stagnation.

and shook up the famous Muir Glacier so thoroughly that its seaward end was disintegrated, filling Glacier Bay with icebergs that barred out all shipping for some years. Prof. Tarr gathered evidence proving that the earthquake brought down huge avalanches of snow and rock from the mountain-sides into the glacier-basins, and he considers that the sudden accession of material has exerted a thrust which has swept slowly forward as a wave throughout the length of the glaciers. He strengthens his conclusion by showing that, at least in some cases, the unaffected glaciers are those fed from gentler slopes from which avalanches would be less likely.

The explanation raises many knotty points in the still imperfectly understood physics of glacier-movement, while the new facts constitute a very important element to be taken into account in all future discussions of ice-flow. In reading the descriptions we are reminded of the abnormal conditions found by Garwood and Gregory in the Booming Glacier of Spitsbergen (Quart. Journ. Geol. Soc., vol. liv., 1898, p. 207), and of the rapid advance and subsequent recession of the Hispar Glacier in the Karakoram Range (*Geographical Journal*, vol. xxxv., February, 1910, p. 108). Is it possible that a great mass of ice may become suddenly more mobile when its temperature as a whole reaches some critical point short of the melting stage? The glacial geologist could find ready application for some such proposition if it were presented to him with the requisite Q.E.D.

Besides these features of central interest, Prof. Tarr describes many other phenomena that will arrest the attention of the geologist; for example, the rock-channels cut by streams running along the margins of glaciers, which remind us of the old "overflow channels" lately recognised in many parts of Britain and Ireland; the "pitted plains," where morainic deposits have been spread out by streams in great "apron-fans" incorporating hidden masses of ice (see Fig. 2); the sudden slipping of a small mountain-glacier *en masse* from its high corrie into the waters of Disenchantment Bay, causing huge waves that swept destructively on to the land; and the spread of vegetation over the areas abandoned by the ice. His re-discussion of the efficacy of the glaciers as erosive agents should also be read by everyone who has shared in the long debate on this subject. The memoir concludes with a short account of the solid geology of the region, which is of less general moment.

We have scant space in which to deal with the other two memoirs, and must perforce dismiss them summarily.

(2) Mr. F. L. Ransome's monograph describes an area around Goldfield, on the hilly desert-plateau country near the border of south-western Nevada, which has recently sprung into prominence as a gold-mining centre. His historical narrative has a touch of romance in it—vast treasure lying close to the surface, yet passed over again and again by eager prospectors; then, in 1902, discovery—excitement—and disappointment; in 1903–5, renewed search crowned by success; great fortunes rapidly made and lost in the wild boom and its reaction, the feverish activity culminating in a fierce labour dispute which necessitated the calling up of federal troops at the close of 1907; and finally, the consolidation of interests and the systematic ransacking of the ground. It is estimated that the value of the precious metals recovered during the years 1904–7 from this small field was close upon 20,000,000 dollars.

As for its geology, the field is a low dome-like uplift of Tertiary lavas with associated lake-sediments, resting upon a sparingly-exposed foundation of ancient granitic and metamorphic rocks. The ore-bodies, apparently deposited in late-Tertiary times from "acidified" solutions at no great depth, are remarkable alike for their richness and for their irregularity. The structure, origin and mineralogy of the lodes, and the petrology and chemical composition of the rocks are fully discussed, and beautifully illustrated in the plates. In respect to the eruptive sequence, the author finds no proof of the regular order which J. E. Spurr has sought to establish for the lavas of the Great Basin. In criticising this scheme the author remarks:—"To some minds the conformity here shown may appeal as corroborative, but to others, impressed by the scanty representation of the numerous members of the ideal succession in any given locality, the capacity of the scheme for assimilating not only observed sequences, but imaginary ones, raises doubt whether it really represents natural processes" (p. 105). The criticism might be applied to many another ingenious scheme in science.

(3) The San Juan Mountains in south-western Colorado, like most steep mountains of similar structure, have been subject in the past, and are still subject, to extensive landslips. Many examples of these slips, both ancient and modern, are fully described by Mr. E. Howe in the third paper on our list, and are pictured in many fine plates which almost make description superfluous. A massive series of Tertiary volcanic rocks, often carved into huge cliffs, rests on a yielding base of soft Cretaceous shales; and, among the older sedimentary formations, are thick Palæozoic limestones resting on friable shales and sandstones. Attention is particularly directed to the curious "rock-streams" which have their origin in the high cirques; and to the influence of snow banks on the accumulation of talus at the foot of cliffs. The memoir concludes with a somewhat laboured classification of landslides in which foreign examples and their literature are freely cited.

G. W. L.

MOUNTAINEERING IN THE NORTH-WEST HIMALAYA.[1]

ONE would hardly suppose, after reading this simply-told narrative of physical achievements, that the senior member—and shall we say, with Mrs. Workman's permission, leader—of the party among the peaks and glaciers of the Nun Kun group was compelled some years ago to retire from his medical practice on account of ill-health. Evidently, at great altitudes, where the vitality is lowered by insomnia attending deficient oxygenation, and where mental depression and attacks of irresolution follow a disturbed circulation, the successful explorer depends wholly on having his muscles under the complete control of a resolute mind for that last supreme fight against the irresistible instinct to descend to his natural environment. The Arctic explorer can sleep, can eat, and is the better for work to do; the mountain climber handicaps himself by his load of protective non-conductors; his respiratory difficulties are increased when in the only position of rest left to the biped, and every momentary doze through sheer exhaustion is terminated by frantic efforts to avoid the intolerable feeling of suffocation. Anyone who has experienced these troubles, which beset all climbers—even the lucky few who are proof against mountain sickness—will admire the mental as well as the physical qualities of the altitude record-breaker; for, judging by the recent sordid controversy among Arctic ex-

[1] "Peaks and Glaciers of Nun Kun: a Record of Pioneer-Exploration and Mountaineering in the Punjab Himalaya." By Fanny Bullock Workman and Dr. W. H. Workman. Pp. xv+204. (London: Constable and Co., Ltd., 1909.) Price 18s. net.

plorers, "records" have still a market value among geographers.

Although previous achievements of mountain climbers are now eclipsed by the Duke of the Abruzzi's record of 24,853 feet in the Karakorum, the exploration of the Nun Kun group by the authors of this work is likely to remain for long of special interest, on account of the circumstance that Mrs. Workman broke even her own record for women by scaling the Pinnacle Peak of 23,300 feet. The reference to this feat, however, is but a passing incident in the narrative, less drawn-out, in fact, than the accounts of the perky eccentricities of the irrepressible, pugnacious little cock of the poultry-yard—the clown of the party, who, like the indispensable figure among the acrobatic performers of the circus show, "talks all the time," as the Kashmiri *khansamah* remarked.

swadeshi are among those that exemplify new varieties of well-known type difficulties that are invariably "discovered" by non-official travellers in the Indian region; but, in the present instance, the few difficulties faced and overcome are not of the kind which travellers' descriptions often naïvely show to the experienced Anglo-Indian to be due to the travellers' own stupidity and ignorance of local affairs.

The additions to topographical knowledge need not be reviewed; they will be fully appreciated by officers of the Indian Survey Department, who are more conscious than their critics suppose of the shortcomings of their maps in regions which are of little direct concern to their master, the tax-payer, who has as much right to be considered as the sportsman and traveller. The authors made the experiment of taking out six experienced Courmayeur porters under an

View at sources of Hispar Glacier at 17,000 feet. In foreground avalanche-nieve-bed, pinnacles mostly formed from avalanche-blocks. In middle-ground broken, horizontally stratified ice-masses. Behind these ice-wall covered with parallel subsidence-*névé*-ridges orienting with slope. In background southern Hispar boundary mountains. Reproduced with the permission of Dr. W. Hunter Workman and Mrs. F. Bullock Workman. From "Peaks and Glaciers of Nun Kun."

The book is not a mere narrative of travellers' experiences in a little-trodden region; it discusses definite and valuable additions to geographical knowledge; important topographical corrections are made on the Survey Atlas quarter-sheet No. 45 S.W.; one-fifth of the text is devoted to the character and origin of the different varieties of ice prominences on the *névé*-surfaces and glaciers, and on the glaciers below the *névé*-line; the principal part of a chapter is devoted to a discussion of the immediate physiological effects of high altitudes; while the extremely high temperatures in sunlight at high levels and the great diurnal variations are all precisely recorded. Incidents of human interest on the journey are not forgotten—the moral weaknesses of the Kargil coolie and the price of the Wazir's devotion to the cause of

expert guide, to replace the local coolies for work at high altitudes, where muscle alone is of little service, and this innovation has now been imitated by the Duke of the Abruzzi with successful results. The disturbing uncertainty of the malingering coolie being eliminated from the problem, Dr. Workman was able, with his trustworthy porters, to make satisfactory deductions from observations regarding the altitude limitations of human activity; and he shows that, in addition to the special danger of mountain sickness as a precursor of frost-bite, insomnia and the distressing moral and physical sequelæ of imperfect oxygenation may be sufficient alone to fix the stress-limit of the human organism at something distinctly below the greatest Himalayan heights.

The curious *nieves penitentes* first described by explorers in the Andes have been recognised by the authors also in the Himalayan region, though their conclusions have not been completely accepted by other travellers. They, however, bring together in this work observations made in the Nun Kun area during 1906, as well as others made before and since in other parts of the north-west Himalaya, and have a right, consequently, to generalise on the phenomena. The prominences grouped under the name *nieve penitente* are often roughly pyramidal in shape, and generally disposed in rows on snow and ice at altitudes at which the night temperature falls below the freezing point; they are due to the unequal melting of the superficial layers of snow and ice. The authors describe in detail eight varieties of *nieves penitentes*, which, judging by the descriptions given, might have been divided into the following two groups:—(i.) Those that are the outward and visible expression of an internal heterogeneity of physical structure induced in the snow and ice by (1) the scoring action of avalanches with a trend parallel to the dip-slope; (2) the shearing effects of slower subsidence along the slopes; (3) the development of pressure waves by the wind; and (4) the more or less regular fracturing on seracs. (ii.) Those that are due to the disposition of various adventitious covers, such as (5) thin patches of earthy material arranged by the wind, and of a kind facilitating the absorption of the sun's heat with consequent melting of the subjacent ice; (6) heavy rock-masses, which compress and protect the ice, giving rise, by melting of the clean ice around, to the well-known glacial tables; (7) thick layers of earthy material, having a protective effect similar to that of the large rock fragments, but giving rise to differently shaped prominences on account of the disintegration and fall of the marginal parts of the covers; (8) water-covers in depressed areas, where silt is deposited unequally on a previously sculptured surface. These phenomena have been discussed in greater detail by Dr. Workman in special papers published in the *Zeitschrift für Gletscherkunde* and in the *Alpine Journal*.

A notice of this book would not be complete without reference to the remarkably fine photographic plates with which it is illustrated, although the illustrations, specially selected to demonstrate the phenomena of *nieve penitente*, and perhaps the best in the book, are taken from other areas, mainly from the Hispar and associated glaciers, further north-west, in the chiefship of Nagar. One of these is here reproduced.

T. H. HOLLAND.

THE EAST AFRICAN NATURAL HISTORY SOCIETY.[1]

THERE has been founded in British East Africa a society for the study of natural history, and the activities of this society naturally extend to the adjoining Uganda Protectorate. This society recently produced the first number of a Journal, which, it is to be hoped, may run to many volumes if conducted on the lines of its first number. Mr. C. W. Hobley, C.M.G., a prominent official of British East Africa, whose service there dates from the earliest days of the British East Africa Chartered Company, has taken a considerable part in the founding of this local natural history society, and is one of the contributors to the first number of the Journal. Mr. Hobley's work in anthropology, in East African languages, in geology, in the exploration of the aquatic fauna of Lake Victoria Nyanza (it will be remembered that he was the first, or one of the first, to discover in that lake organisms akin to the supposed marine fauna of Lake Tanganyika, thereby lessening the acuteness of that problem), has been so remarkable that his association with the Natural History Society should be productive of interesting results.

[1] The Journal of the East Africa and Ugnada Natural History Society. vol. i., No. 1, January, 1910. (London: Longmans, Green and Co., 1910.) Price 5s. net.

This first number contains a very well-executed coloured illustration of a new species of francolin (*Francolinus hubbardi*). This accompanies an article on the francolins of East Africa and Uganda, which to ornithologists is of real value. The scope of this article also includes the allied genus Pternistes. Mr. Battiscombe gives some new and interesting information regarding the flora of British East Africa. There are several small errors in the nomenclature of this article; *Lobelia johnstoni* is given as *Lobelia johnsonii*; *Kniphofia thomsoni* appears as *K. thompsonii*, and *Musa livingstonii* is given as *M. livingstonia*. The generic name Sanseviera is misspelt—a very common fault in books dealing with Africa. But these are trifling defects in an account of East African botany which is of considerable interest.

The Rev. K. St. A. Rogers writes on East African butterflies. There are notes on the haunts and habits of the elephant on the Guas' Ngishu plateau by Mr. Hoey, and Mr. C. W. Hobley contributes two articles, the more important of which, from the point of view of new information, is that dealing with the Kariandúss deposits of the Rift Valley—deposits which form beds of a mealy, friable rock, amounting perhaps to millions of tons of diatomite. This is a siliceous deposit, principally of organic origin, mainly composed of the skeletons of minute, lowly plants—diatoms or bacillariæ—mere cells of green or brown protoplasm originally, which enclose themselves in a flinty casing fitting together like a box and a lid. Diatoms are, of course, found in fresh-water ponds and salt seas all over the world. Mr. Hobley considers the Rift Valley to have been the scene of tremendous volcanic activity from Tertiary times onwards, and that at one period in its history this enormously long depression in the surface of East Africa was covered by much larger lakes than at the present day. These beds of diatomite are the result both of the existence of these sheets of water and of the neighbouring eruptive volcanoes.

"Picture Suswa, Longenot, and Eburu all periodically in active eruption, and in addition to lava flows ejecting great clouds of volcanic dust and streams of mud mainly composed of siliceous fragments. This is almost certain to have been thus, as is the case in all volcanoes of this kind: the steam tearing its way through the magma which formed the flows of obsidian and trachytic tuffs would naturally blow large quantities into a state of very fine division, and this would be spread far and wide by the wind and also carried into the lakes by the torrential downpours which always accompany volcanic activity. The soda-laden water would dissolve the silica and place it ready for the diatoms to work upon, and with such rich material to build with one can quite see that this form of life could flourish with great luxuriance."

Mr. Hobley considers this diatomite or kieselguhr may be of some economic value. H. H. JOHNSTON.

NOTES.

THE Astley Cooper prize for 1910 has been awarded to Prof. E. H. Starling, F.R.S., for an essay upon the physiology of digestion, gastric and intestinal.

THE Mackinnon studentship in physical sciences has been awarded by the Royal Society for a second year to Dr. R. D. Kleeman for the continuation of his researches on radio-activity; and the studentship in biological sciences has been awarded to Mr. T. Goodey for an investigation of the protozoa of the soil.

THE council of the Royal Society of Edinburgh has awarded the following prizes:—(1) The Neill Prize for the biennial period 1907–8, 1908–9, to Mr. F. J. Lewis, for his papers in the society's Transactions "On the Plant Remains in the Scottish Peat Mosses." (2) The Keith Prize for the biennial period 1907–8, 1908–9, to Dr. Wheelton Hind, for a paper published in the Transactions of the society "On the Lamellibranch and Gasteropod Fauna found in the Millstone Grit of Scotland."

THE U.S. Congress has passed a bill granting 10,000*l.* to establish a biological laboratory for the study of diseases of fish, especially those related to cancer. The station is, says *Science*, to be established under the U.S. Fish Commission.

THE committee of the science section of the Japan-British Exhibition has issued invitations to an inspection of the collections at the White City to-morrow, July 22, at 3.30 p.m.

THE Geneva correspondent of the *Times* announces the death, at sixty-four years of age, of Col. Georges Agassiz, nephew of the famous naturalist. After completing his studies at the University of Lausanne, Col. Agassiz spent several years in America with his uncle in scientific work and researches. Recently he presented to the Cantonal Museum at Lausanne his collection of butterflies, numbering 18,000 rare specimens.

IT is stated that a bill is to be introduced into the French Parliament making Greenwich time compulsory instead of Paris time, which differs from it by about nine minutes. If the bill becomes law, France will thus be brought into line with the zone system of referring time to meridians differing by an integral number of hours from the Greenwich meridian. It is thus not so much a question of one country adopting the time standard of another as it is of France accepting an international system of time reckoning. M. Millerand, Minister of Public Works, has been asked by the French Cabinet to support the proposal to substitute Greenwich time for the time of the Paris meridian when the matter is brought before parliament.

IN the House of Commons on Tuesday, a bill "to prohibit the sale or exchange of the plumage and skins of certain wild birds" was brought in and read for the first time. In introducing the bill, Mr. P. Alden said that the object of his bill is to try to prevent the absolute extinction of a few rare birds. The bill that passed the House of Lords in 1905 prohibited the importation of the plumage of almost all birds. Mr. Alden includes in the schedule of the present bill only a few birds that are on the point of extinction, but which may be saved if this bill, or a bill drafted by the Board of Trade, be passed into law within the next year or two. There is a law in Australia to prevent the export of the plumage of certain rare birds, one of which is the emu, yet last year more than one thousand emu skins were catalogued for sale in London—all smuggled out of Australia. A number of species of humming birds are almost extinct. In Trinidad the number of species has been reduced from eighteen to five. The skins of 25,000 bumming birds have been catalogued for sale in London during the past year.

WE learn from *Science* that the University of Southern California, at Los Angeles, has established recently a marine biological station at Venice, Cal. The station is on the nearest beach to the university, some thirteen miles distant. It comprises an aquarium consisting of forty tanks with running sea water, and a series of laboratories for class work and research. The laboratories, which face the north, are provided with sea water and fresh water. The station is designed to afford: (1) facilities for demonstration to classes studying marine life; (2) opportunity for the students of the university to carry on advanced work in marine biology; and (3) a limited number of research laboratories, some of which are available, without cost, to investigators who are prepared to carry on research work in some of the phases of marine biology.

THE programme of papers and of demonstrations drawn up for the International Zoological Congress, to be held at Graz next month, includes a great variety of subjects. Prof. Boveri promises an address on Anton Dohrn; Prof. Delage will give an account of experimental parthenogenesis. Embryology will be treated by Profs. Lee, Julin, and Hubrecht. The geographical distribution of several groups of animals will be discussed, more particularly the cave-fauna of Carinthia. Prof. Gaupp will deal with the affinities of the Mammalia, Dr. Keller with the origins of domesticated races, and there are also many other memoirs promised that will attract workers in protózoology, genetics, and experimental embryology. The Graz meeting should prove a very successful one.

IT is officially announced that a submarine telephone cable of a novel type was recently laid across the Channel from Dover to Cape Grisnez by the British Post Office, in order to improve telephonic communication between this country and France, and also to determine the limits of possible improvement by the use of a new type, with a view to its application to telephonic communication between places which have hitherto been beyond telephonic range. This is the first cable of the kind laid in tidal waters and across the open sea, although a similar cable was previously laid in the Lake of Constance. The new cable will be brought into regular use as soon as the corresponding French land lines are completed, but the tests so far made have given very satisfactory results. The electrical conditions of submarine cables make telephonic communication through them difficult as compared with such communication carried on over land lines, and any improvement in their efficiency will have a marked effect in extending the distance through which telephonic speech is possible, and this more especially when the cable forms a considerable part of the total length of line through which communication has to be effected. In the case of the new cable just laid, the efficiency has been increased more than three times beyond the value which it would have if it had not been specially treated. This improved efficiency is due to the insertion of "loading coils" in the cable at intervals of one nautical mile. The coils reduce the distortion of the current impulses which correspond to the spoken sounds, and so render the speech more distinct.

IN the fourth number of the fifty-sixth volume of the Smithsonian Miscellaneous Collections Captain F. Schmitter, of the Medical Corps, U.S. Army, publishes a set of rough notes on the customs and folk-lore of the natives of the Upper Yukon, Alaska. It is remarkable that they are partly in the age of stone and partly in that of copper. The hammers which they use to break up bones for cooking and for making arrow-heads are rude lumps of stone, and of the same material are the axes which, at any rate up to quite recent times, they employed for cutting down trees; but their hunting-knives are of bone, ground flat, and sharp on both sides, or of copper welded in a similar fashion. Their chief weapon, the spear, is made by binding a hunting-knife of caribou horn to a pole 6 feet long.

In a paper recently read before the Royal Society of Arts (see p. 58), Captain A. J. N. Tremearne discusses the origin of that remarkable African race, the Fulah or Filani. The view which he finally adopts is that the tribe arose somewhere in the Central Sudan from the union of Berber males with negro women; that with this mixture of race a mixed dialect came into use, combining Berber, Arabic, and Bantu elements. In process of time this mixed race separated from the Berbers and formed various groups, one going east and south, and becoming the Wahuma, another migrating west to Morocco, and a third, moving south, became the Fans. The quasi-Semitic origin of the tribe has produced a spirit of nationality, and some of their legends now connect them with a Jew or Arab progenitor. At present they form the aristocracy of the Hausa States in North British Nigeria and in French territory to the south and west, their head being the Emir of Sokoto. They are a people with great possibilities, and will doubtless take a high place in West Africa when once they frankly accept British and French supremacy.

The Glastonbury Antiquarian Society has arranged for the publication of a work containing a full description of the excavations at the Glastonbury lake-village, by Mr. Arthur Bulleid and Mr. H. St. George Gray, with an introductory chapter by Dr. R. Munro. The work will also contain reports on the human and animal remains, bird bones, botanical specimens and seeds, and metal, by Prof. W. Boyd Dawkins, F.R.S., Dr. C. W. Andrews, F.R.S., Mr. Clement Reid, F.R.S., and the late Dr. J. H. Gladstone, F.R.S. The Glastonbury lake-village is regarded by archæologists as of primary importance in the history of pre-Roman Britain, giving as it does a vivid picture of native life before the arts of Rome penetrated to the west of England. The village is of the crannog type, the habitable area of about 3½ acres, originally in the middle of a mere, including some eighty dwellings surrounded by a border-palisading. The occupation of this area continued long enough to allow 5 feet of peat to accumulate in some parts during the occupation. The village had its origin in the early Iron age, and has contributed largely to our knowledge of the arts and industries of late Celtic times. The editors hope to be able to publish vol. i. of the work upon the excavations before the close of 1910. Vol. ii. will follow as soon as possible after vol. i., and probably within eighteen months. The work will resemble somewhat in style that of General Pitt-Rivers's "Excavations in Cranborne Chase." Any inquiries regarding the work should be sent (with stamped addressed envelope) to Mr. H. St. George Gray, Taunton Castle, Somerset.

The Dominion Museum at Wellington has issued a hand-list of New Zealand birds, including stragglers, and the first and second parts of a hand-list of New Zealand Lepidoptera.

We have received a copy of vol. vi., No. 9, of the University of California Publications in Zoology, containing a preliminary report, by Mr. G. F. McEwen, on the hydrographical work carried on by the Marine Biological Station at San Diego. Work of this nature was the main reason for the foundation of the Marine Biological Association of San Diego, but various causes prevented its being taken up in earnest until the summer of 1908, when the writer of the report before us became a member of the staff of the station, whose duty it should be to take charge for some portion of the year of water-investigations. The work of 1908 consisted of determinations of the temperature and density of the waters of the Bay of La Jolla and the ocean, the area covered lying between 33° 20′ and 32° 30′ N. lat., and extending from the coast to 118° 30′ long. In addition to this, two trips were made to the Cortez Banks, and a third to a point some distance south of Cerros Island. The methods of work and some of the results obtained are recorded in the report.

Some remarkably fine skeletons of plesiosaurians from the Upper Lias of Holzmaden are described by Dr. E. Fraas, of Stuttgart, in vol. lvii. of the *Palaeontographia*. The author directs attention to the rarity of plesiosaurian remains in the German Lias as contrasting strongly with what obtains in the corresponding English formation. The latter indicates that these saurians were relatively abundant in the Liassic seas, although they did not, in all probability, congregate in such large shoals as the commoner species of ichthyosaurs. The majority of the English specimens come, however, from the Lower Lias of Lyme Regis, Street, and Charmouth, an horizon represented by a different type of strata at Holzmaden. Dr. Fraas refers his specimens to *Plesiosaurus guilelmi-imperatoris*, first named by Prof. Dames in 1895, and to a new species of Thaumatosaurus, which it is proposed to call *T. victor*. So perfect are the remains that they admit of restored figures of the skulls of both species being given. *T. victor* was about 10 feet in length, with a relatively small head, short and thick neck, very plump body, slender and nearly equal-sized paddles, and a very short and powerful tail.

In the Bulletin of the Johns Hopkins Hospital for June (xxi., No. 231) Dr. Corson contributes an interesting biography of Sir Charles Bell, who did so much to elucidate the structure and functions of the nervous system, and whose "Anatomy of Expression in Painting" has remained a classic. Dr. Walker describes glandular structures hitherto supposed to form part of the prostate gland in rats and guinea-pigs, which, however, differ entirely in structure from the latter, and the secretion of which coagulates the secretion of the seminal vesicles when mixed with it. This coagulation is produced by a very minute quantity of the secretion, 1 part to about 21,000 parts of the secretion of the seminal vesicles being sufficient to produce the reaction. The active principle presumably belongs to the class of ferments.

It is a pleasure to note the excellent manner in which the natural history of the American State of Connecticut is being worked up, and the results recorded in a series of pamphlets entitled "Bulletins of the State Geological and Natural History Survey of Connecticut." Five geological and five botanical bulletins have been issued, the last (No. 14) being devoted to a catalogue of flowering plants and ferns. A committee of six members of the Connecticut Botanical Society is responsible for the work, which has been compiled with great care. The list enumerates 1481 native and 461 introduced species, besides which 286 varieties and forms are recognised. The Cyperaceæ, Gramineæ, and Compositæ stand out as the largest families. Aster is the largest genus, and also one of the most interesting, as the native species include such useful horticultural types as *laevis, novae-angliae, novi-belgii, ericoides, longifolius*, and the rare *concinnus*; Solidago, another large genus, also provides the original types of some garden plants. The critical genera, Cratægus and Rubus, contribute to the size of the rose family, and the number of Violas is remarkable. Among the ferns, eight species of Isoetes and six of Botrychium are recorded.

The current number of the Bulletin of the Department of Agriculture, Jamaica (vol. i., No. 3), maintains the high standard set by the two previous issues. Mr. R. Newstead contributes a valuable article on the ticks and other blood-sucking Arthropoda of Jamaica, describing their life-history and the methods adopted in attempts to exterminate them. It appears that ticks are most prevalent during the dry winter months, and that relatively few are found during the rainy season. As a rule the ticks infest cattle, but one much dreaded species, Chrysomyia (Compsamyia), attacks man; a case of myiasis thus produced is mentioned. This tick often passes its larval stages in putrid carcases, and is no doubt kept in check by the scavenger work of the John Crows (*Cathartes aura*), which remove practically all traces of carrion from man's habitations. From an article by the Hon. H. E. Cox, it appears that tea is now being successfully grown on the island; the Cinchona strain is used, and yields a tea of mild character similar to the old China teas and without astringency. There is also a useful history of the economic plants of Jamaica by Mr. Harris.

The twenty-second annual report of the Agricultural Experiment Station, Lafayette, Indiana, chronicles several important events in the history of the station. The old buildings having proved insufficient, new ones were erected, and were formally opened during the course of the year. Still more important, however, was the provision of further funds, necessitated by the rapidly increasing demand from the farmers of the State for information on the lines of the work already being done. So strong was the demand that the General Assembly amended the Smith Act of 1905, whereby the station annually receives 25,000 dollars, and increased the State subvention to 75,000 dollars annually, to be expended as follows:—10,000 dollars for the general work of the station, 15,000 dollars for the improvement of the crops and soils of the State, 10,000 dollars for the advancement of the dairy interests, 10,000 dollars for the advancement of live-stock interests, 5000 dollars for the investigation of hog cholera and other diseases, 5000 dollars for poultry problems, and 10,000 dollars for extension work; and the Act concludes:—"Whereas an emergency exists for the immediate taking effect of this Act the same shall be in effect from and after its passage." The extension work includes the distribution of copiously illustrated bulletins dealing with important problems, a number of which we have also received; the provision of special trains to carry lecturers through the country, teaching as they go; attendance at shows, and so on. With such liberal support it is not surprising that much good work is done.

Mr. Robert M. Brown contributes an interesting series of diagrams to the Bulletin of the American Geographical Society (p. 107) showing the maximum, minimum, and average levels of the waters of the Mississippi system at five stations—Hannibal, on the Mississippi; Hermann, on the Missouri; St. Louis, just below the confluence of the Mississippi and Missouri; Cairo, on the Ohio; and Memphis, Tennessee. The varying influence of the different types of rainfall occurring in different parts of the drainage area is very clearly shown.

Mr. H. T. Barnes, Macdonald professor of physics, contributes an interesting paper, with excellent illustrations, to the Proceedings of the Undergraduate Society of Applied Science of McGill University, Montreal, on the problems of winter navigation on the river St. Lawrence. Experience shows that, with Lake St. Peter free of ice, a continuous open channel above that point may be safely predicted, for the river is continually struggling to free itself of its icy burden. Prof. Barnes suggests that it would be quite possible to keep the ice-bridge broken up at the foot of Lake St. Peter and at the Sorel Islands, and that the lake itself could be kept nearly free of ice. One ice-breaker could keep the river clear at the Sorel Islands as well as at Port St. Francis, and this, with one powerful ice-breaker at Quebec, would effectively keep the ship channel open. The ice-problem thus solved, Montreal would inevitably become one of the greatest seaports in the world.

We have received from the author reprints of two papers by Mr. E. A. Birge, published in the Transactions of the Wisconsin Academy of Sciences, Arts, and Letters. In the first Mr. Birge discusses a hitherto unregarded factor in lake temperatures. The heat of the sun is mostly delivered to the surface strata of a lake, and distributed to the depths by various agencies, chief of which is the wind. The efficiency of the wind as a distributing agent is opposed and limited by thermal resistance to mixture offered by the decreased density of the warmed surface water, and Mr. Birge brings forward evidence to show that the effectiveness of this thermal resistance increases as the temperature of the water departs from the temperature of maximum density, and decreases as it approaches 4° C. The second paper contains a review of the evidence adduced by Wedderburn in favour of the existence of temperature seiches in lakes, which leaves the author unconvinced.

Mr. T. S. Ellis has published a pamphlet on "The Winding Course of the River Wye" (Gloucester: Bellows, price 1*s*.), in which he expresses his views on the origin of adjacent river-systems. He regards valleys divided by cols at their heads as having originally formed a continuous channel, the two sections becoming separated when main systems tended to develop on either side. He does not seem to appreciate sufficiently the effects of rain, frost, and continual land-slide action in the cutting back of valley-heads, but represents geologists as attributing the removal of cols solely to erosion by the young streams flowing from them. On p. 9 he comes very near to the bold suggestion of Mr. A. W. Rogers, that a winding rock-ravine may record the original meanders of the river in alluvium at a higher level.

The nature of intermetallic compounds is discussed by Dr. T. Slater Price in vol. iii. of the Proceedings of the Birmingham Metallurgical Society, which has made a somewhat belated appearance. The paper in question was read in January, 1909, and contains a list of 120 of these curious compounds, more of which are described every month. Among the laws of their formation, it is claimed that the metals forming a sub-group of the periodic system do not form compounds with each other, and, further, that any particular metal either enters into combination with all the metals of a sub-group or else it does not form compounds with any of them. Those sub-groups in which there is a change from metalloid to metal, as in the case of As, Sb, Bi, form an exception to the rule. The valencies of the metals in their compounds seldom correspond with the ordinary valencies, only thirty bodies out of the 120 enumerated showing this agreement, and of these, twelve are compounds of antimony, which approaches the metalloids in its characteristics. Among the compounds there are some very remarkable formulæ, for which no explanation is offered. For example, the formulæ $NaZn_{12}$, $NaCd_5$, $FeZn_7$, $NiCd_4$, and $AuSb_2$ have a strange appearance. Among other summaries of the state of knowledge on particular subjects, there are interesting articles by Mr. A. H. Hiorns on copper-nickel alloys, and by Prof. Arnold on the testing of metals.

THE problem of determining the vertical motion of the air during a balloon ascent is complicated by the fact that the balloon itself is in motion. Measurement of the variation of the barometric pressure at the balloon has, however, proved a trustworthy means of determining the vertical motion of the balloon, and the further problem of recording the relative vertical motion of the air with respect to the balloon appears to have been satisfactorily solved by an instrument described by Mr. P. Ludevig in the *Physikalische Zeitschrift* for June 15. It consists of light anemometer vanes which can rotate about a vertical axis. The spindle carries a thin, hollow brass cylinder through which six holes are punched, each pair at opposite extremities of a diameter, two near the top, two near the middle, and two near the bottom of the cylinder. The diameters are inclined at 60° to each other. Light can pass through, say, the central pair of holes when they happen to be in the direct line between a source and a moving strip of photographic paper, and a spot is registered. According to the direction of rotation of the cylinder, the spot next registered may be the upper or lower, and the speed of rotation determines the distance between the spots. An examination of the strip allows the speed of the air with respect to the balloon at any instant to be calculated if the speed of the strip is known.

THE Ontario Government announces that the system organised for the distribution of power from the Niagara Falls will be in operation for the supply of Toronto, London, and St. Thomas by the end of the year. The most distant of these places is about 100 miles from the Falls, and the transmission will be at 100,000 volts. The electrical energy will be bought from the existing Canadian generating stations by the various municipalities, which will effect the distribution by new transmission lines extending over a wide area. By this means cheap power will be available for manufacturing and agricultural purposes, and it is hoped that a network of new tramways will be constructed which will not only improve travelling facilities, but also act as a means of bringing agricultural produce to the towns. A system of distribution of this kind should be of particular value in Canada, seeing that the supply of coal is deficient. The municipalities will not themselves own the tramways, lighting and power companies, but private companies will be formed to effect the final distribution of the power, and the control of the price charged to the consumer will rest with the municipalities in virtue of their ownership of the transmission lines. The cost of carrying out the above scheme will be defrayed by an issue by the Provincial Legislature of bonds redeemable at the end of forty years.

MESSRS. TOWNSON AND MERCER have submitted for our inspection a technical thermometer based on a novel principle. This consists of a metallic bulb containing liquid, and connected by narrow copper tubing with a pressure gauge. The gauge index responds to the variations in pressure of the contained vapour, and this depends upon the temperature of the bulb. The dial of the gauge can therefore be graduated in degrees instead of pressures, and is thus made into a direct-reading thermometer. The indications may, of course, be automatically recorded, as in the case of an ordinary aneroid barometer. The indications depend only upon the temperature of the bulb; they are independent of the temperature of the gauge, *which may be any distance away*, the air in the capillary tubing forming the connecting link which transmits the pressure of the vapour in the bulb. Damage to the bulb or capillary tube does not interfere with the accuracy of the indications; the bulb and tube may, in fact, be twisted or bent in any way which leaves them intact and does not prevent free communication of the vapour pressure. It will be seen at once that the thermometer possesses qualities which no other thermometer of the same simplicity can claim, and the result is that it is rapidly being adopted in works of all kinds where long-distance thermometry is advantageous. For example, in a single cabin of a ship may be dials indicating the temperature in any part of the hold, in powder magazines, coal-bunkers, refrigerating chambers, &c. Humidity is indicated by employing a pair, wet and dry, in the ordinary way. Its use in indicating the temperature of superheated steam has caused it to be adopted by all railways in France and by many other railways on the Continent. These thermometers are made of very various ranges, from $-25°$ C. to $+25°$ C., up to 450° C. to 700° C. This system of temperature indication is known as the "Fournier" system.

THE Journal of the Franklin Institute for June contains an article by E. E. Free on the phenomena of flocculation and deflocculation, a discussion of the mechanics of suspension, a subject of importance in the treatment of sewage, in ore separation, and many other commercial problems. The physical production of light forms the subject of a paper by E. P. Hyde, and is dealt with from the points of view of the laws of radiation and of physiological optics. There are also articles on Brennan's monorail car, the colloid nature of complex inorganic acids, and the Lumière process of colour photography.

THE *Bulletin de la Société d'Encouragement pour l'Industrie nationale* for May contains a paper by J. H. Ricard on the pine forests of the Landes. Full details are given, with numerous photographic illustrations, of the methods now employed for the extraction of the resin (*gemme*), and the extraction of essence of turpentine and rosin from the latter. Figures are given showing the yield of pine wood per hectare, and the proportions of the wood suitable for various uses. The financial aspect of the industry is dealt with fully, and the great advantages of the cultivation of the pine in these sandy districts pointed out.

THE electrolytic conductivity of non-aqueous solutions at low temperatures is the subject of a paper by P. Walden in the current number of the *Zeitschrift für physikalische Chemie* (June 17). Twelve organic solvents were used, tetraethylammonium iodide and tetrapropylammonium iodide being used for the "normal electrolytes," the observations in each case being carried down to the freezing of the solvent. The general result of the work shows that, as with aqueous solutions, the conductivity curve does not cut the temperature axis with a measurable angle; in other words, there is no definite temperature of conductivity.

THE 22,000-ton floating dock for the Brazilian Government is illustrated in the *Engineer* for July 8. This dock has been built by Messrs. Vickers, Sons and Maxim, Barrow-in-Furness, at a cost of 182,700*l.*, and is the largest dock of the kind built as yet in this country. The contract time for delivery at Rio Janeiro was eleven months. The contract was placed on October 4 last, and the dock sections were launched on June 7, 8, and 9. The designs were prepared by Messrs. Clark and Standfield, of London, who have already been responsible for sixty-seven floating docks having an aggregate lifting capacity of 486,691 tons. The present dock is surpassed by the 35,500-ton dock built last year by Blohm and Voss at Hamburg. Its lifting capacity will also be exceeded by two box-type docks now building at Portsmouth and Sheerness for the British Admiralty, which are expected to be ready for service during the autumn of next year.

THE aërial-propeller testing plant at Vickers' Works, Barrow-in-Furness, is illustrated in *Engineering* for July 8. The apparatus consists of a double cantilever, 166 feet in length, the longer arm, at the end of which the propeller under test is mounted, being 110 feet in length. The cantilever is carried on ball-bearings on a cast-iron column, and the propeller is driven from a 100 horse-power electric motor situated in a test house which is arranged on the cantilever near the supporting column. The power is conveyed to the propeller by means of a long shaft passing along the cantilever, and bevel gear. The cantilever may revolve at any speed up to 70 miles per hour at the point of attachment of the propeller. The structure is balanced by a weight on the shorter arm of the cantilever. There is a method of compensating the circular motion of the propeller so that the conditions are similar to those of a ship running in a straight line through the air. The propeller may be run at speeds from 500 to 1000 revolutions per minute, and its speed through the air can be regulated by means of resistance screens. Measurements of thrust, efficiency, &c., are recorded in the observation station. Provision has been made for attaching a gondola to the platform ahead of the propeller, so as to obtain similar conditions to those on an air-ship having the propeller astern of the gondola. With characteristic solicitude for the advancement of science generally, Messrs. Vickers will place the apparatus at the disposal of investigators, so that any type of propellers may be tested.

METEOROLOGISTS, teachers of practical geography, and others will all find Messrs. Aitchison and Co.'s catalogue, Section iv., useful and interesting. It is concerned chiefly with barometers, thermometers, rain gauges, compasses, and pedometers; and the excellent illustrations and clearly arranged letterpress make reference easy and pleasant.

A THIRD edition of Prof. Ch. Moureu's "Notions fondamentales de Chimie organique" has been published by M. Gauthier-Villars, of Paris. The first edition of the work was reviewed in our issue of January 22, 1903 (vol. lxvii., p. 269), and it is only necessary to state that the present volume has been revised and brought up to date.

"AFRICAN MIMETIC BUTTERFLIES" is the title of a monograph by Mr. H. Eltringham which the Oxford University Press is about to publish. Descriptions and illustrations are given of the principal known instances of mimetic resemblances in the Rhopalocera of the Ethiopian region, together with an explanation of the Müllerian and Batesian theories of mimicry.

A VALUABLE supplement of seventy pages, dealing with Japan in all its aspects, was published with Tuesday's *Times* (July 19). Among the numerous important articles we notice in particular those on education, seismology, and volcanoes, by Baron Kikuchi, Prof. F. Omori, and Mr. E. Bruce-Mitford respectively. The publication, as part of a daily newspaper, of such a vast amount of detail and description relating to Japan as is given in the articles and tables is a remarkable enterprise. The supplement contains more information upon the position and progress of Japan than can be found in many books.

A SECOND edition of Prof. Armstrong's book of essays, "The Teaching of Scientific Method and other Papers on Education," has been published by Messrs. Macmillan and Co., Ltd. The first edition was reviewed at length in our issue of January 28, 1904 (vol. lxix., p. 289), and it will be sufficient to direct attention to the additions made in the present volume. Prof. Armstrong has introduced a prefatory essay entitled "Twenty-five Years Later," in which he considers the changes that have taken place in the teaching of science in schools during the period to which his essays relate. He has added two contributions; one, "The Correlation of Mathematical Teaching with other Work in Schools," was part of a report presented to the British Association at its York meeting, and the other, "A Criticism of School Method, with Suggestions for its Improvement," was delivered as an address to the Portsmouth Secondary Education League.

THE following volumes of the "Fauna of British India" series are nearing completion:—Mr. G. J. Arrow's volume on the Cetoniinæ and Dynastinæ is practically ready for publication. Mr. W. L. Distant's volume, an appendix to the Rhynchota, and Canon W. W. Fowler's work on the Cicindelidæ and Paussidæ, with a general introduction to the Coleoptera, are in the press. The remaining volumes which the editor, Mr. A. E. Shipley, with the assistance of Mr. Guy A. K. Marshall, and with the sanction of the Secretary of State for India, has arranged for in this series are:—Volumes on the Orthoptera (Acridiidæ and Locustidæ), Mr. W. F. Kirby; Butterflies (Lycænidæ and Hesperidæ), Mr. H. H. Druce; the Curculionidæ, Mr. G. A. K. Marshall; the Ichneumonidæ, Mr. Claude Morley; the Longicorn Beetles, Mr. C. J. Gahan; the Blattidæ, Mr. R. Shelford; the Helicidæ, Lieut.-Colonel H. H. Godwin-Austen; the Ixodidæ and Argasidæ, Mr. C. Warburton; Leeches, Mr. W. A. Harding; Fresh-water Sponges and Polyzoa and Hydrida, Dr. N. Annandale; the Meloidæ, Mr. Creighton Wellman; the Brachyurous Crustacea, Lieut.-Colonel A. Alcock; and the Nemocera (excluding the Chironomidæ and the Culicidæ), Mr. E. Brunetti.

THE annual report of the Board of Scientific Advice for India for 1908–9 has been received. The attention of the Board has been directed to the fact that the rapid increase in the number of scientific institutions throughout the world is rendering it more difficult to obtain back numbers of the more important scientific periodicals, and that unless efforts are made now to secure complete sets of some of these for India it will be impossible at a later date to establish efficient libraries for the requirements of scientific research in India. The Board, on the advice of a sub-committee appointed to deal with the question, has recommended the Government to maintain "first-class" general reference libraries in Bengal, Bombay, Burma, Madras, the Punjab, and the United Provinces, and "second-class" libraries in large towns like Cawnpore, Mandalay, Nagpur, Simla, and so on. Lists of scientific periodicals which should be maintained in all "first-class" libraries and in "second-class" libraries accompanied the recommendations. The programmes of the various scientific departments of Government for the ensuing year were, after some revision, approved by the Board. In connection with the work of the Meteorological Department, it is proposed to make a series of balloon flights next December, the month chosen by the International Commission in Europe and America for simultaneous experiments on the conditions of the upper air. It is hoped, too, that the publication of the sixty years' records in connection with terrestrial magnetism at Colaba will be completed during the current year. The Department of Agricultural Bacteriology hopes to attack, among other problems, the determination of the chief bacteria characteristic of Indian soils, particularly those taking part in the fixation of nitrogen, the rotting of organic material, and nitrification. In other departments interesting research work is being pursued actively. Very complete reports of the work done during the year 1908–9 in each of the scientific departments is included in the volume; to name a few, that dealing with astronomy and meteorology is by Dr. G. T. Walker, F.R.S.; that in geology by Sir Thomas Holland, F.R.S.; and in geodosy and geography by Colonel S. G. Burrard, R.E., F.R.S. An appendix on the economic investigations conducted at the Imperial Institute, by Dr. W. R. Dunstan, F.R.S., completes the volume.

OUR ASTRONOMICAL COLUMN.

Photographs of Auroræ.—As an abstract from the *Comptes rendus*, we have received from the author, M. Carl Störmer, an interesting note on a photographic method of determining the altitudes of auroræ. The difficulty in obtaining such photographs is, of course, the extreme feebleness and the motion of the light, but, by using a cinematograph lens of 25 mm. diameter and 50 mm. focal length, in conjunction with Lumière's "violet" plates, M. Störmer succeeded in obtaining measurable images, some of which are reproduced in his note. By choosing two stations 4·3 km. apart and arranging for simultaneous exposures, data for determining the altitudes were secured. The four sets of photographs reproduced represent different forms of auroræ seen during March, and also show recognisable stars, so that the parallax of definite points is easily calculated. The heights determined are 166 km., between 50 and 60 km., 190 km., and 120 km. respectively.

Displacement of Spectral Lines at the Sun's Limb.—In spectroscopic determinations of the radial velocities of the various solar layers, a difficulty arises from the fact that various perturbations alter the wave-lengths of the lines considered, independently of the rotation. These subsidiary displacements have been ascribed to two causes, first, the effect of ascending currents in the solar atmosphere, and, secondly, to pressure effects. In order to decide which of these is the disturbing agent, M. A. Perot performed some delicate interferometer experiments which he describes in No. 1 (July 4) of the *Comptes rendus*. In order to determine definitely the exact point of the solar image under observation, M. Perot projected a 36 mm. image on to a copper plate ruled in millimetre squares, and having a circular hole, or a slit, 0·1 mm. broad at the centre; thus only the radiations passing through this definite aperture reached his interferometer and spectroscope. As a result of the experiments, M. Perot deduces, from the form of the curves of relative variation of wave-length obtained, that this relative variation is an effect of pressure, or density, and not of ascending currents.

The Pressure of Light on Gases.—In No. 5, vol. xxxi., of the *Astrophysical Journal*, Dr. Lebedew describes a series of very ingenious and delicate experiments by which he has been able to observe the effect of the pressure exerted by a beam of light on various gases. The apparatus is too complex to describe here, but, in effect, it consists of a small chamber in which the gas under examination is contained, and through which a beam of light can be projected in either direction. The pressure exerted by the light produces an excess of pressure in the gas at the farther end of the chamber, and this acts on a very delicate valve which is suspended on one arm of a torsion balance. From a large number of experiments, in which other variable effects were eliminated, Dr. Lebedew succeeded in establishing experimentally the existence of the translatory force exerted by light upon gases, and also in showing that these forces are directly proportional to the quantity of incident energy and to the absorption coefficients of the gas masses. As these experiments were made with gases at atmospheric pressure, the numerical values determined cannot be applied directly to such excessively tenuous masses as are involved in the case of comets' tails, but they provide a satisfactory basis on which further experimental work in this direction may be founded.

The Determination of Stellar Radial Velocities.—In No. 5, vol. xxxi., of the *Astrophysical Journal*, Prof. Frost publishes a table of corrections to be applied to the previously published list of radial velocities of certain stars of the Orion type. The corrections are necessitated by the re-determination of the wave-lengths of the three silicon lines at $\lambda\lambda$ 4553, 4568, and 4575, for which Exner and Haschek's values were previously adopted. Prof. Frost's new measures give 4552·636, 4567·897, and 4574·791 as the correct wave-lengths, and this involves positive corrections of 7·51 km., 3·48 km., and 7·14 km., respectively, to plates reduced with Exner and Haschek's values.

As Prof. Frost points out, finality in radial-velocity measures is hardly to be obtained; the values must be amended as a greater accuracy in the determination of stellar wave-lengths is attained. Further, in the case of blended lines, such as the double helium line at λ 4472, a variation in the relative intensities of the two lines will considerably modify the results. This is especially effective when the adopted blend is uncertain, as in the case of the blending of lines of different elements which may vary considerably from one stellar type to another. Prof. Frost also publishes the data establishing the variable radial-velocity of Rigel, showing a variation from +1 to +26 km., and states that on one plate a faint component to the line at λ 4472 was measured which gave a velocity of −108 km.; faint components were suspected in other instances.

The same journal also contains some further notes by Prof. R. W. Wood on the determination of radial-velocities with objective prisms. After trying several other media for producing fiducial lines, he tried peroxide of chlorine, which, contained in a suitable cell, appears to answer very well. It gives absorption bands which are very well defined on the red edge, and in his 21-foot grating photographs can be measured to within 0·02 A.U.; with such bands, he suggests, radial velocities, of suitable stars, could be determined to within 2 or 3 kms. Unfortunately, the absorption bands cover most of the hydrogen lines, so that this absorbent could not well be used for first-type stars, although it is possible that λ 4863 and λ 3837 would appear; for other types a peroxide of chlorine screen apparently answers perfectly.

Halley's Comet.—A number of observations are recorded in *Astronomische Nachrichten*, No. 4425, but, in general, they do little more than confirm others previously noted.

Herr G. Müller gives an outline of the observations made, at great altitudes, in Teneriffe, and Herr W. Münch describes the general observations at Potsdam. The spectrographic observations made on May 19, from 4h. 55m. to 5h. 10m. and from 5h. 28m. to 5h. 30m. (M.E.T.), are described by Herr v. d. Pahlen, but no modification of the normal solar spectrum was discovered. The slit covered $3\frac{1}{2}'$ of arc, and two series of six exposures on the predicted positions of the comet on the sun's disc were made, so that a large area of the solar surface was covered without revealing any trace of the comet.

An observation by Dr. Ristenpart, at Santiago de Chile, on July 1 showed the comet as a nebulous mass 1′ in diameter, with no condensation, and with a tail 2° long.

Harvard College Observatory.—In his report for the year ending September 30, 1909, Prof. E. C. Pickering deplores the diminution of 5000 dollars in the income of the Harvard College Observatory, and points out that a disproportionate decrease will have to be expected in the amount of work accomplished. As in previous years, a great number of negatives of stellar regions and stellar spectra were added to the magnificent collection now stored at Harvard, and a number of important discoveries were made from the Draper memorial photographs. Seven meteor trails were found on chart plates, and at Arequipa the spectrum of a very bright meteor was secured. At this southern station the work was sadly upset by unusually bad weather, but, among other things, the spectra of more than 400 stars of magnitudes 5–6 were secured with the 13-inch Boyden telescope.

COLOUR OF THE SEA.

APROPOS of the report (NATURE, March 10) of Lord Rayleigh's lecture dealing with the parts played by reflection and transmission of light in the production of the integral impression of colour on the eye of an observer looking at the sea from the deck of a ship, I should like to be permitted to make some observations on the proper colour of the water of the ocean, as it is a subject which has occupied my attention, off and on, during the last forty years.

During the voyage of the *Challenger* I began to log the colour of the water in February, 1874, when she was working in the neighbourhood of the Antarctic circle. My attention was there directed to it by the frequent and abrupt passage of the ship from water of the clear indigo colour of the ocean of temperate latitudes to the deep olive-green water which is a distinctive feature of these icy regions.

The colour is due to the abundance of diatoms. These are so plentiful and so preponderant that, besides putting their stamp on the surface, they furnish a distinct type of oceanic deposit, the *diatom-ooze*. The green colour of the water is due, not only to the living diatoms, but also, and perhaps to a greater extent, to the excretions of the animals for the subsistence of which the diatoms furnish the ultimate food supply. The crowds of penguins and other birds to be met with in these seas stain all the ice green where they have rested. The water, inhabited by diatoms and affected by diatomaceous débris, has a deep olive-green colour which is characteristic, and this I accepted as one colour-type of the water of the ocean. It is seen best in the water the transparency of which is not interfered with by too great a crowd of the diatoms themselves. Water belonging to this type of colour is not confined to polar latitudes; it is met with in a certain class of homologous districts of the warmer ocean, in tropical and even in equatorial latitudes.

When we quit the edge of the polar ice and steer equatorwards, the surface water assumes a pronounced indigo colour, and this persists until we pass the fortieth parallel. If we start from the equator and sail polewards, the colour of the surface water persists as a pure and brilliant ultramarine until the thirtieth parallel is passed. The passage from the ultramarine to the indigo, and *vice versa*, is usually very rapid, and the area of mixture is restricted. No one who has once sailed in the ultramarine waters of the intratropical ocean and has observed, as well as seen, its colour, can ever mistake any other colour for it. If he has doubt as to whether the water through which he is passing is ultramarine or not, he may be sure that it is not. The ultramarine and the indigo are the two great colour-types to which the mass of the surface water of the deep sea belongs, and, with the olive-green, they make the three fundamental colour-types which are required, and are sufficient for the adequate logging of the colour of the surface water of the ocean.

The water of the Mediterranean belongs to the ultramarine type, but it always appears to me to have a harder tone than the soft and brilliant ultramarine of the intratropical ocean.

With regard to the method of judging the colour of the water, much unnecessary difficulty is made. The first precaution to be observed is to take up a position where the greatest amount of light can reach the eye after passing through the water, and the smallest amount after being reflected from its surface. There is generally little difficulty in accomplishing this on one side or the other of the ship and by looking as nearly as possible vertically into the water.

The *Challenger*, like other men-of-war of her date, was fully rigged, and built for sailing as well as for steaming. When under sail the propeller causes a certain amount of retardation, and to remedy this she was fitted with a "screw-well" into which the propeller could be hoisted out of the water. This proved to be a perfect observation tube for determining the proper colour of the water. Its diameter was about 6 feet; it passed from the upper deck through the captain's cabin on the main deck and the ward-room on the lower deck into the water. Looked into from the deck, the sea water appeared to be enclosed in it as the water is in a well, but with this difference, that the water, by day, was brilliantly illuminated from below. There being no clearance between the surface of the water in the well and the structure of the ship, no light could enter except through the water. No direct sky-light could reach it down the well, because the poop awning, which was practically always spread during the day, completely excluded it. The screw-well was, in effect, an artificial and perfected *Grotto di Capri*, which was carried round the world. It was perfected, inasmuch as there is a passage for boats to penetrate into the grotto from the outside, while the screw-well is entirely shut off. During the whole of the voyage the colour of the water was under observation in this very perfect apparatus.

The statement that the blue colour of the sea is nothing but the reflection of the blue of the sky was at first frequently made, even on days when the sky was completely overcast; a visit to the screw-well, especially on overcast days, never failed to convince the doubter that the water contained in its own mass sufficient colour to account for all that was perceived. When the ship was in green water the view was never advanced that its colour was due to reflection from the sky.

As ships with screw-wells long ago disappeared from the sea, it may not be superfluous to point out that what could be observed in the screw-well was altogether different from what can be seen in the wake of the screw of a modern steamer. While the screw-well was a perfect instrument for gauging the colour of the water, the determination of its transparency was more conveniently made from a boat. Thus in mid-Pacific, with the aid of a "water-glass" to eliminate the disturbing action of ripples, a metal plate measuring only 4 by 4 inches, painted white and not masked by the suspending line, was distinctly seen at a depth of 25 fathoms (45 metres). Beyond this depth it became indistinct, and became invisible at about 27 fathoms, but this was due mainly to its smallness and to its want of steadiness, being attached to the boat, which rose and fell with the swell. At 25 fathoms the plate had a pale ultramarine colour, and its edges were sharply defined. These separated the column of water, into which I looked through the water-glass, into a central column of rectangular section having a depth of 25 fathoms, and into a column, surrounding and contiguous with it, which had a depth many times greater. These columns, being juxtaposed, were placed in the way most favourable for the comparison of their colours. The colour of the central column, 25 fathoms in length, was a pure but pale ultramarine; that of the external and uninterrupted column through which the whole unabsorbed and undissipated part of the sunlight which had penetrated into the water returned to the surface was of the same tone, but of many times greater intensity. Assuming the intensity of the colour to be proportional to the length of the column of water traversed by the light, it is to be concluded that the length of the uninterrupted column which transmitted the more intense colour was many times greater than 25 fathoms. It must be noted that the glass plate forming the bottom of the small tub, which is called a "water-glass," was during the observation completely protected from direct sky-light by my head and the brim of the panama hat which, at that time, I always wore when exposed to the sun.

It has already been said that water of as pure a green as that of the Antarctic occurs in other and warmer districts of the ocean. My attention was first directed to this during the cruise of the *Dacia*, which, although it occupied no more than three weeks, marks an epoch in deep-sea research. A short account of it is given in a paper by me—"On Oceanic Shoals discovered in SS. *Dacia* in October, 1883"—and published in the Proceedings of the Royal Society of Edinburgh, 1885, xiii., p. 748. Perhaps the most remarkable of these shoals was the one which was named the "Coral Patch," in lat. 34° 57′ N., long. 11° 57′ W., the exploration of which, along with that of the tidal currents in the open ocean (Proc. Roy. Soc., 1888, xliii., p. 356), supplied the evidence which definitively established the fact that coral islands are a product of elevation and not of subsidence.

When the survey of this shoal had been completed, in so far as the time at the disposal of a steamer engaged on a commercial mission permitted, a line of soundings was run from the "Patch" to the African coast at Mogador. Independently of the high land which is visible from the sea at a distance of many miles, the approach to the coast is indicated by a fall in the temperature of the water of the sea surface, and a remarkable change in its colour. Outside, the temperature of the surface water was 21° C., and its colour was ultramarine. After sighting the land its temperature fell, at first slowly, then rapidly, and, when at a distance of two miles from Mogador, it was only 16° C. The colour at the same time had become a pure olive-green, which maintained its transparency until close to the shore, where it became masked by the solid matter kept continually in suspension by the mechanical energy of the breaking waves.

The pure green colour of the water and its temperature, so much lower than that which could persist at the surface of the sea in the latitude of Mogador, made me for a moment think that it might be in reality Antarctic water which had found its way, at or near the bottom, into the northern hemisphere, having been diverted first to the west while in the South Atlantic, then to the east after crossing the line. But this idea could persist only for a moment, because the temperature and the density of the bottom water were found to be those characteristic of the bottom water of the eastern basin of the North Atlantic, as shown by the *Challenger* observations, and these are much higher than those of any other ocean.

The low temperature of the water showed that it could not come on the surface from the north or south or west of it, and the only source from which it could come was from below the surface. Deep water comes close to the coast, and the water at 2000 fathoms was found to have a temperature of 2·5° C., so that the supply of cold from this source was adequate, and it was available with a very small expenditure of energy. Arrived at the surface and following the south-westerly drift of the surface water, exposure to the sun raised the temperature of the water and discharged its colour *pari passu*. It was evident that there was here a case of the rising of deep water at the weather coast of an ocean, away from which the prevailing wind was continually driving the surface water.

From Mogador the *Dacia* proceeded to the "Seine Bank," in lat. 33° 47′ N., long. 14° 1′ W., and explored it thoroughly. Among the specimens brought up on the grapnel were masses of dead coral and shells, all having the same green colour. Some of these fragments were preserved in spirit, which quickly assumed the green colour, leaving the shells and coral practically decolourised. I sent the bottle, with the specimens and spirit, to my friend Prof. W. N. Hartley, in Dublin, who was good enough to subject them to spectroscopic examination. He wrote to me on February 15, 1884:—"I have made a spectroscopic examination of the colouring matter you sent me and have no doubt that it is altered chlorophyll. I have got identical wave-length measurements for the absorption band with your liquid and a specimen of very pure chlorophyll dissolved in ether"; and he adds, "there is very little real substance in even a dark green solution."

As the year 1884 belongs now to the remote past, I recalled the matter to Prof. Hartley, and, confirming his previous information, he added:—"I believe my impression at the time was that the chlorophyll was the colouring matter in a living micro-organism, and that these settled upon the shells, but when not deposited they were floating in the sea water." I am obliged to Prof. Hartley for kindly permitting me to use these private communications. Further information will be found in his paper on chlorophyll from the deep sea (Proc. Roy. Soc. Edin., 1885, xiii., 130).

Prof. Hartley's report furnished a remarkable confirmation of my first impression in so far as it showed that the green water of the Mogador coast owed its colour to the same substance as did the diatom-crowded water of the Antarctic, namely, chlorophyll.

In April and May of 1885 I made a coasting voyage from Valparaiso to San Francisco. Excepting the equatorial part, stretching from Cape Blanco to Panama and round the coast of Central America to near Mazatlan, the west coast of the American continent between the fortieth parallels is the weather shore of the Pacific Ocean. All along it cold and green water is met with, in the same way as we have seen to be the case on the Atlantic coast of Morocco. On the South American coast the green water was found to extend, with few interruptions, from Valparaiso, lat. 33° S., to Cape Blanco, lat. 4° 27′ S. As on the Morocco coast, the green colour and the low temperature of the water are found only close to the shore. At a distance of ten miles outside the colour is blue, and the temperature normal for the latitude. There can be little doubt that, as the localities where the green water occurs are geographically homologous, so the substance which produces the colour is generically the same, namely, chlorophyll.

The following particulars are taken from my unpublished journal. The only ports or anchorages where the water was blue were Huasco, lat. 28° 27′ S., temperature of the surface water 14·7° C., and Carizal, lat. 28° 5′ S., temperature 15·1° C. The occurrence in this latitude of blue water with so low a temperature is very remarkable.

At Antafogasta, lat. 23° 39′ S., the water was greenish-blue, and its temperature was 18·0° C. Between this port and Iquique the ship's course took her to a distance of nearly twenty miles from the coast, and there the colour of the water was ultramarine and its temperature 21·2° C. At Iquique the water was quite green, and its temperature 17° C. Between this port and Arica the water was quite green, even at a distance of five miles from the coast, where the temperature was 19·5° C., but on anchoring at Pisagua, lat. 19° 36′ S., the temperature of the water was only 15·2° C. At Arica, lat. 18° 28′ S., the water was equally green, but its temperature was 19·5° C. Arica lies in the angle where the trend of the coast changes from north to about north-west. From Arica the ship made a longer run to Chala, lat. 15° 49′ S., keeping at a distance of fifteen to twenty miles from the coast. Here ultramarine water was met with, its temperature rising to 23·2° C., but even at fifteen miles from this coast some green water was met with having a temperature of 18·8° C. I attributed this to the foggy state of the atmosphere which prevailed. This obscured the sun, and retarded both the heating and the bleaching of the water. In lat. 14° 8′ S., when six miles off shore, the water was quite green, and its temperature 15·1° C. Outside of Callao, lat. 12° 0′ S., the water was green, and its temperature 16·3° C.; in the harbour its temperature was 17·5° C., and its colour a dirty green, turbid and milky with sulphur, smelling strongly of sulphuretted hydrogen, and full of dead fish. Continuing northwards, off Ferrol Islands, lat. 9° 11′ S., the temperature of the water was 16·0° C., and its colour olive-green. At Payta, lat. 5° 5′ S., the temperature of the water was 17·1° C., and its colour a chalky green.

The green and cold shore water ceased abruptly at Cape Blanco, lat. 4° 27′ S., and during the passage round this cape from Payta to the entrance of the Guayaquil River, lat. 3° 9′ S., the temperature of the water rose from 17·1° to 25·2° C. From this locality a pretty straight line was followed across the equatorial current near its source to Panama, lat. 9° 0′ N. During the passage the temperature of the water varied between 25° and 27° C., and it maintained a blue colour throughout. At Panama, however, with a temperature of 27° C., the water was quite green.

A similar occurrence of cold and green water near the shore was observed on the North American coast from Cape San Lucas, at the extremity of the Californian peninsula, to San Francisco. In the equatorial waters which wash the coast from Cape Blanco, lat. 4° 27′ S., to Panama, and thence to Cape Corrientes, lat. 20° 25′ N., long. 105° 43′ W., green water is prevalent along the shore, but its temperature is very high, 28° or 29° C. Further information on this subject will be found in a paper by me on similarities in the physical geography of the great oceans (Proceedings of the Royal Geographical Society, 1886, viii., p. 753).

I will here refer to only one other locality, and that a well-known one, where the weather shore of an ocean is associated with green water of abnormally low temperature, namely, the east coast of North America from Florida to Nova Scotia. The cold and green water which is found on this coast, and lying between it and the western edge of the Gulf Stream, is usually attributed to the Labrador current, which is charged with the duty of bringing cold water from Baffin's Bay as a surface current round Newfoundland and down the coast to Cape Hatteras and even beyond it. The principle was the same as that which moved Humboldt to attribute the cold water, which we have described in connection with the Pacific coast of tropical South America, to a surface current from the Antarctic Ocean. In the paper on similarities, &c., above referred to, I showed that Humboldt's explanation postulated an impossibility. The deeper layers of the water on the coast itself are capable of supplying, as and when required, much more cold than is wanted, and that with the least expenditure of energy. The same is the case with the "cold wall." Besides the south-westerly winds of the North Atlantic, and perhaps independently of them, the Gulf Stream itself, pouring its waters in a stream of great momentum past the American coast and out into the open ocean, performs the function of a colossal jet-pump, carrying water away from the surface and leaving its place to be taken by the other water which can get there most easily. This is the cold water of the deeper layers *in situ*. It is this hydraulic cold-water service which tempers the climate of the eastern States. The labours of the U.S. Coast Survey during the last seventy years have shown that fluctuations, both regular and irregular, occur in the flow of the Gulf Stream. These necessarily react on the supply of cold water drawn from the deep and spread over the continental shelf. Such variations are probably the source of the accidents which occasionally occur and cause the extinction of life over large tracts of shoal water on that coast.

J. Y. BUCHANAN.

REMNANTS OF THE PAST.

MUCH interest attaches to a paper by Mr. R. S. Lull, published in the "Proceedings of the Seventh International Zoological Congress, Boston, 1907" (issued 1910), on the evolution of the horned dinosaurs, or Ceratopsia. Although early ancestral forms are at present unknown, it is probable that the group took origin from an iguanodont stock. The earliest known types are Monoclonius and Ceratops of the Judith River beds, the single representative of the former being the more primitive, and probably ancestral to all the rest. In Monoclonius the orbital horns are much smaller than the nasal one, but in one species of Ceratops the two have become subequal; both genera show large vacuities in the cervical flange of the skull, which was probably internal. Between the Judith River and Laramie formations occur certain marine formations yielding no dinosaurian remains, but in the basal Laramie occur Agathaumas, of which the skull is unknown. Higher up this is succeeded by Triceratops, in which the vacuities in the cervical flange are obliterated, while in the various species may be traced a gradual increase in the size of the orbital at the expense of the nasal horn, the latter becoming almost obsolete in *T. elatus*, while it has disappeared in Diceratops, which forms a side-branch by itself. The remarkable genus Torosaurus of the Upper Laramie, although having developed large orbital horns at the expense of the nasal one, retains the long, straight skull, with a large vacuity in the cervical flange, of the Judith River *Ceratops montanus*, from which it may be directly descended. Physical changes in their environment seem, in the author's opinion, the most probable cause of the extinction of these marvellous reptiles.

In the April number of the *American Journal of Science* Mr. F. Loomis describes the complete skeleton of a new species of the camel-like genus Stenomylus from the Harrison beds of Nebraska. The genus differs from other Tertiary types by the hypsodont character of the dentition. This is considered by Mr. Loomis as an indication that Stenomylus differed from its relatives in habits. The early tylopods of the Protomeryx type probably fed on a mixed diet, while the members of the long-limbed Oxydactylus group may have subsisted on leaves and shoots, both retaining the original brachyodont dentition. Stenomylus, on the other hand, seems to represent a separate branch derived from the ancestral Poëbrotherium, which developed a hypsodont dentition, and took to feeding on hard-stemmed grasses growing on open, arid plains.

Dr. A. E. Ortmann contributes to the April number of the *American Naturalist* an article on the theory that a connection between Africa and South America persisted into the Tertiary. According to the Archelenis theory, as originally proposed by Dr. von Ihering, an ancient connection between the above-named continents was the last remnant of the much greater equatorial land-mass known as Gondwanaland, an area which was broken up at various dates, and remnants of which are represented by Australia, India, Africa, and Brazil. The separation of Brazil from Africa was the final stage in the dismemberment of the old continent, and it is generally considered that this took place towards the close of the Mesozoic epoch. A study of the Tertiary flora of Patagonia has, however, induced Dr. von Ihering to believe that Archelenis persisted into the Tertiary. It is argued, however, that the facts cited by von Ihering really lead to just the opposite conclusion, while the existence of marine Eocene deposits in many parts of West Africa is likewise an indication that the connection between the two continents had ceased. Accordingly, the evidence for a Tertiary Archelenis is considered valueless.

Vol. vii., No. 2, of the University of Colorado Studies is devoted to an account, by several authors, of the results of a scientific expedition to north-western Colorado. In a paper on plant-remains from the Cretaceous of Mesa Verde, Prof. T. D. A. Cockerell describes and figures a fragment of a branch bearing a remarkable resemblance to the Palæozoic lycopods of the Ulodendron type. It really belongs to an araucarian conifer (*Geinitzia reichenbachi*), but its resemblance to lycopods of an earlier period is highly significant in view of the probability of a real relationship between the two groups.

NON-FERROUS METALS.

IN many respects the second volume of the journal of the Institute of Metals marks a decided advance on the first volume—an advance which serves as a healthy sign of the continued growth of the institute. Perhaps the best sign of this advance is the inclusion, in the second volume, of a series of abstracts of scientific and technical literature bearing upon the subjects which come within the scope of the institute. These abstracts fill what has hitherto been a decided gap in metallurgical literature; they are obviously modelled on the very excellent abstracts of the literature of iron and steel which appeared in the Journal of the Iron and Steel Institute while that journal was under the editorship of the late Mr. Bennett Brough. Perhaps the most serious criticism to be offered on these abstracts is that they are of too indiscriminate a character, mere descriptive papers of small permanent interest being accorded equal space with papers of real importance.

The original papers, which, with the discussions, occupy the greater part of the second volume, have already been referred to in these pages on the occasion of the meeting at which they were read. It is satisfactory to find that the discussions show signs of free and vigorous criticism, and that such criticism seems to be accepted by the authors in a kindly spirit, even though[1] at times the criticisms are practically destructive. Thus the first paper (Edwards and Andrew on aluminium-copper-tin alloys) is criticised on the ground that the data published do not afford sufficient insight into the facts upon which the authors base their conclusions. The paper of Prof. Turner and Mr. Murray, on the volume-changes of the copper-zinc alloys, is also challenged as regards the validity of its conclusions on the ground—apparently justified—that the mere measurement of the longitudinal contraction of a casting can give no true insight into the volume-changes which accompany the passage of the metal from the liquid to the solid state. More than eighty pages of the volume are devoted to the paper of Mr. A. C. M. Smith on the elastic breakdown of non-ferrous metals, and although the subject presents certain points of interest, it appears to occupy a good deal more than its fair share of space in a journal not specially devoted to such questions as the best means of measuring elastic constants. The paper, however, shows clearly the narrow limits within which Hooke's law is applicable to such metals as copper and aluminium; the latter appears to be particularly unsatis-

[1] The Journal of the Institute of Metals, vol. ii. Pp. 341. Vol. iii. Pp. xi + 360. Edited by G. Shaw-Scott, Secretary.

factory in this respect, and to carry this property with it into some of its alloys.

The third volume of the same Journal more than maintains the character of the earlier volume; this applies particularly to such papers as those of Bengough and Hill on copper-arsenic alloys, and of Hudson and Law on the phosphor-bronzes, together with the discussions on these papers. Such work must prove of great importance to the advancement of the technology of whole classes of important alloys.

Taken as a whole, the young Institute of Metals may well be proud of the present volumes, although we may hope that greater experience on the part of the editor and of the publication committee will lead to a more satisfactory apportionment of space. The illustrations throughout have been reproduced in a very satisfactory manner, and this applies also to the frontispiece, an excellent likeness of the first president, Sir William H. White, although the portrait of the second president (Sir G. Muntz) is not nearly so satisfactory.

THE ASSOCIATION OF TECHNICAL INSTITUTIONS.

Examinations for Evening Students.

THE summer meeting of the Association of Technical Institutions was held in Manchester last week. The question of examinations for evening students formed the basis of the discussion at the morning meeting on July 15, when Sir William Mather took the chair. At the present time examinations are held by the Board of Education in science subjects by the City and Guilds in technological subjects, and the Society of Arts in literary and commercial subjects. The London Chamber of Commerce also holds examinations which overlap both those of the Board of Education and the Society of Arts—especially the latter—and there are many other smaller examining bodies.

The Board of Education has for many years held examinations in mathematics, engineering, and building subjects, and in most of the sciences. Each examination is conducted by examiners appointed directly by the Board, and the examinations in each subject are independent, or nearly independent, of those in any other subject. The examiners have no official connection (and in most cases no connection of any kind) with those responsible for instruction in the subjects; and even those on the staff of the Board who come into contact with the teachers and the students—namely, the inspectors—are not systematically consulted, if they are consulted at all. Thus, although the examinations in any given subject may be excellent, and have been valuable in developing a higher standard of work throughout the country, it was the unanimous opinion of those present at the meeting that they are capable of great improvement.

Of late years most technical institutions have endeavoured to develop organised courses of instruction in connection with the important industries, engineering, textiles, building, chemical, &c. For these courses it is desirable that the syllabus in the individual subjects shall be modified to suit the particular course.

So far are the Board of Education examinations in many directions out of sympathy with the work that some speakers at the conference were doubtful whether the Board of Education was the best authority for conducting the examinations; but the meeting as a whole considered it desirable that the advanced work should be controlled by some national examining board in order that there should be a uniformity of standard, and thus the certificates obtained should have a common value; but it was felt that the examinations must be brought more closely into touch with the teaching, and it was resolved:—

"That it be represented to the controlling authorities of the examinations taken by evening students in technical institutions that it is desirable, for the encouragement of systematic courses of instruction and to bring the examinations into closer correlation with technical teaching, that the examining authorities should constitute advisory boards upon which representatives of teaching institutions (including teachers) and of technical and commercial interests should sit.

"That it be the function of such advisory boards to receive and consider the views of persons directly concerned in technical and commercial education, as to examination subjects, syllabuses, and methods of conducting examinations; and to advise the respective examination authorities thereon."

An examination has a two-fold object—to test knowledge and to grant a certificate—and the two are to some extent antagonistic; the first, enabling the student and his teacher to judge of his progress, is probably best attained if the teacher himself conducts the examination. A certificate, however, granted on the examination of an individual teacher, can have no public value, and can only become valuable to the extent to which it attains uniformity. In the earlier stages of instruction the former object is of the greater importance, and therefore in the earlier stages it is probably desirable that the examinations shall be conducted by the teachers. In the latter stages it is more important that the certificates shall have a uniform value, and therefore in these stages it is desirable that the examinations shall be conducted by a national body. Also, in the higher stages, the number of candidates who would be sitting for the examination in any given centre would be comparatively small, and the cost of a separate examination for individual schools in these subjects would be prohibitive except in the very large centres; so that, even if it were desirable that the examinations for the higher work should be conducted by the teachers, the financial burden would be too great in most cases. Thus the following resolutions were adopted:—

"That this association is of opinion that, in the interests of technical education, it is essential that the Board of Education or other national authority shall continue to conduct examinations above Stage 1 Board of Education, and Preliminary Grade City and Guilds."

"That examinations of an elementary character (*e.g.* Stage 1 Board of Education, Preliminary Grade City and Guilds, Elementary Stage Society of Arts) should, in the main, be conducted by provincial boards, local education authorities, or the governing bodies of the institutions; but that, pending the re-modelling of the examination system, the present examining boards should continue to hold these examinations."

Even with the establishment of advisory boards there would still remain the evils arising from the overlapping and duplication of the examinations. At the present time the examinations of evening students begin in April and last well into July, thus destroying the value of the last part of the session for teaching purposes. So long as examining bodies endeavour to arrange that any student may take any subject, it is obvious that the examinations will have to spread over a large period of time. With the establishment of the course system, it will be possible to a large extent to determine beforehand those subjects which a given student will require to be examined in, and thus to concentrate the examinations upon a much smaller number of evenings. So strongly was it felt that the whole system requires a very drastic reform that it was unanimously resolved to ask the Board of Education to appoint a committee to inquire into the working of the present examination systems, including science, technology, and commerce.

Trade Schools and Trade Preparatory Schools.

At the afternoon meeting, a report prepared by the council of the association on the above subject was discussed. The report includes accounts furnished by the organisers of many of the schools which have recently been established in various parts of the country.

It is pointed out that there are two very distinct types of school with entirely different aims; one, which in the report is termed, for want of better title, *Trade Preparatory School*, may be considered a form of secondary school in which the ordinary education is continued, but with a very distinct bias on the technical side. It is assumed that the majority of the boys, though not all necessarily, attending such a school will afterwards be engaged in some trade. The schools differ from the ordinary secondary schools in the large amount of time devoted to various forms of manual instruction. As a rule the curriculum includes English, mathematics, one language, drawing—both freehand and model—science, and workshop practice in wood or metal, or both. The course is, as a rule, intended to last three years for boys from twelve to fifteen years of age.

As so many of the technical institutes throughout the country are only used at present in the evenings, and have their rooms and equipment idle in the daytime, and the staffs of the technical schools are particularly suitable for the type of instruction required, these schools, which have proved exceedingly successful where they have so far been established, may be considerably increased in number in the near future.

Attention was directed to the very strong expressions of approval by employers, the Chamber of Commerce, and trades unions in the case of the trade preparatory school, which is now in its third session at Halifax; and as the boys from these schools pass into employment as apprentices or as improvers, the value of this kind of school is becoming more and more appreciated.

One speaker pointed out the great value of manual instruction to boys and girls right through their school course, and remarked—his remark being applauded by the meeting—that he hoped the board would do its best to encourage this work in every kind of school.

Another speaker said that there are a great many boys to whom the literary subjects of the ordinary school course do not appeal, and to whom the more technical subjects introduced in the trade preparatory schools do appeal very strongly. Thus it is educationally of real advantage to the community that schools should be provided in which boys with a turn for mechanical subjects, but no liking for literary subjects, may have a chance to learn that they have some ability, and may not leave school with the feeling that they are inferior to their fellows because they are unable to distinguish themselves at literary work.

Other speakers referred to the very small grant it is possible to obtain under the board's regulations for this type of school, which is necessarily an expensive one to run owing to the large amount of practical work in the time table. It was felt that the grant should be at least as great as that given by the board to an ordinary secondary school.

Quite distinct in aim from the Trade Preparatory School is the *Day Trade School*, only a few of which are at present in existence. In London there are day trade schools for girls which have proved most successful; a good account of these is included in the report referred to. There are two special trade schools for bakery and confectionery; there are one or two part-time trade schools for boys who are already employed in the trade, the boys being allowed to attend two or three afternoons a week by arrangement with the employers. The best example of such a school is, perhaps, that for jewellers and silversmiths at Birmingham, which is already proving of real value to the trade.

Opinions were somewhat divided as to whether local authorities could be expected to establish schools of this kind, which take the burden of preparation of apprentices off the employers, without substantial financial aid from the employers themselves. It was pointed out that, although none of these schools could decrease the unemployment, they would give boys the chance of entering a useful occupation, and would thereby tend to reduce the number of those who take up so-called "blind-alley occupations."

THE POSITION OF UNIVERSITY EDUCATION IN GREAT BRITAIN.

A BLUE-BOOK has just been published (Cd. 5246, price 2s. 6d.) containing the reports from the universities and university colleges which participated, in the year 1908–9, in the annual grant, now amounting to 100,000*l*., made by Parliament for "University Colleges in Great Britain," and from the three colleges in Wales which received a grant of 4000*l*. each.

This is the sixteenth volume of the reports, and it is by far the most useful on account of the analysis it contains of the position of university education in Great Britain. For several years we have urged in these columns that the Board of Education should bring together the statistical and other information given in the separate reports of universities and university colleges, so that a comparison could be made of the position and progress of the various institutions, and of university education in Great Britain, with that in other countries. Merely to print the reports without any attempt to sum up the particulars they contain, as was done in all volumes previous to the present one, has always seemed to us as unscientific as it would be to record a long series of observations without endeavouring to arrive at conclusions from them. This unpardonable omission has now been remedied, and we have available, for the first time, an instructive abstract of the financial resources and students under instruction of institutions which participate in the Parliamentary grant for universities and university colleges. We give below some extracts from the introductory memorandum signed by Mr. W. Runciman, President of the Board of Education, and abridgements of the tables appended to it.

In the last ten years no fewer than five new universities have been founded in England, but the progress of institutions of older date has been no less marked. In July, 1909, King Edward VII. laid the foundation stone of important new laboratories for the Imperial College of Science and Technology, a college for the highest studies in pure and applied science, which was inaugurated by Royal Charter in July, 1907, and was formed by the union under a single governing body of the Royal College of Science, the Royal School of Mines, and the City and Guilds' Central Technical College. In the following October the new buildings of the University College of South Wales and Monmouthshire were opened at Cardiff, and on that occasion the present King, as Chancellor of the University of Wales, wrote words which apply equally to all the universities of England and Wales when he said, "We must look ahead and endeavour to be ready to meet all the requirements of scientific and intellectual progress. The imperative necessity for higher education and research is becoming more and more recognised."

This encouragement to further effort has been tangibly supported by the Government. Acting upon the report of a special committee of inquiry, under the chairmanship of Sir Thomas Raleigh, K.C.S.I., the treasury, by a minute dated December 18, 1909, made an increased annual grant of 15,000*l*. to the University of Wales and its constituent colleges. Of this sum 1500*l*. has been specially allocated to the Medical School of Cardiff, and another 1500*l*. a year has been assigned to the university itself for the foundation of research fellowships.

The treasury has also made a capital grant of 20,000*l*. towards the cost of the new buildings for the University College of North Wales, Bangor.

State-aid to university teaching would, however, be of doubtful advantage if it did not stimulate private effort and induce benefactors to contribute in the present day as they did in the olden times, to give of their wealth for the support of that higher learning upon which now, more than ever, "the prosperity, even the very safety and existence, of our country depend."

The Board is glad to find that there is no evidence of the springs of private beneficence failing, but rather that the growing national sense of the vital need of universities has impressed many of those, whether individuals or corporations, who are in the position to help. The following are some of the more important gifts made during the last twelve months:—

Sir Alfred Jones, the well-known ship-owner, who died in 1909, and who during his life had founded the School of Tropical Medicine in connection with the University of Liverpool, left to his trustees the sum of more than 500,000*l*. upon trust for such charitable purposes and objects in England (or any British possession on the west coast of Africa) as they may in their absolute discretion think fit. For the guidance of his trustees, however, he made suggestions as to the purposes to which the money might be applied, and amongst them were—the advancement, benefit, or support of education or science, and original research of all kinds in the cause of disease on the west coast of Africa.

Mr. Otto Beit, in December, 1909, gave 215,000*l*. for the endowment of thirty medical research fellowships of 250*l*. a year, each tenable for three years. The fund is to be entirely devoted to the furthering of medical research work, which is to be conducted, with a few exceptions, in institutions allied to London University. The fellowships are open to any man or woman of European descent who is a graduate of any approved university within the British Empire.

The late Dr. Charles Graham, who died in November, 1909, and had been since 1889 emeritus professor of chemical technology at University College, London, bequeathed his residuary estate to London University, to be applied to the promotion of research at University College Hospital Medical School "for the prevention, cure, or alleviation of human disease or suffering." The legacy was estimated at 35,000*l.*

Still more recently, M. Albert Kahn, a well-known French philanthropist, has handed over to a board of six trustees a sum of 4140*l.* to provide for the annual award of two travelling fellowships, each of the value of 660*l.* It is expressly desired by him that the trust shall be permanently associated with the University of London. The fellows, who must travel for at least twelve months, according to an itinerary regulated and prescribed by the trustees, will be elected by the trustees on the nomination of the Vice-Chancellor or other executive head of each of the universities in the United Kingdom, the President of the Royal Society, and the president of the British Academy. M. Kahn has provided funds sufficient for a period of three years, and is prepared at the expiry of that time to endow the fellowships in perpetuity if they should prove to fulfil the objects which he desires.

TABLE I.—UNIVERSITIES AND UNIVERSITY COLLEGES IN ENGLAND AND WALES

Returns of Income, 1908–9

Mr. Alexander Elder gave, in 1909, a sum of 20,000*l.* as endowment for a chair of naval architecture in the University of Liverpool, and Mr. W. H. Lever, of the firm of Lever Brothers, Port Sunlight, in March, 1910, made a gift of 91,000*l.* to the same university for the erection of a building in which the School of House and Town Planning could be accommodated, and also the School of Architecture, and for assistance to the School of Tropical Medicine and the School of Russian Studies.

City companies and corporate bodies have also made new contributions to the support of university education during the last year. The Goldsmiths' Company, who had already been generous benefactors of university education in London, made a gift in May, 1909, of 50,000*l.* towards the cost of the new engineering buildings of the Imperial College of Science and Technology referred to above. The Drapers' Company made a further grant of 10,000*l.* to the building fund of the new college at Bangor, to be applied towards the library and museum of the college. The same company make an annual grant of 7000*l.* to the East London College, which has been admitted for the first time this year to share, subject to the fulfilment of certain conditions, in the annual treasury grant made to university colleges. The company also grants scholarships in connection with this college to the annual value of 1555*l.*

The universities have recently shown in other directions that they are conscious of a joint responsibility in their direction of equalising the standards required by the several examining bodies; but there is a general agreement as to the end desired, and the difficulties are chiefly those of means, in both senses of the word. The whole question of examinations in secondary schools is at present under consideration by the consultative committee of the board, and the board hopes that the report of the committee, when presented, will point the way to further progress.

But the national life and the national needs in higher education cannot be confined within the limits of these islands. The growth of important universities in the British dominions beyond the seas, and in the Empire of India, and the rapid improvements in the means of communication, have brought new opportunities and new responsibilities to those who are entrusted with the provision of university education. The necessity for a regular interchange of views, and for the better organisation of relations to the national life. They realise that the tests they severally impose upon students applying for admission to their courses in preparation for degrees must have a profound influence upon the curricula of secondary schools, and that, if a common policy cannot be reached, evil results must ensue to the schools, and so, indirectly, to themselves, from the confusion caused by the multiplicity of tests for which school pupils must be prepared. Important and far-reaching steps have already been taken towards the mutual recognition of their various matriculation examinations, and the northern universities of Manchester, Liverpool, Leeds, and Sheffield have, under their charters, established a Joint Matriculation Board, which conducts a single examination of all candidates for admission to any one of the four universities. Much still remains to be done in the direction of substituting a school-leaving examination based upon the school course for an external test, and in the facilities for advanced study throughout the Empire, has led the Universities of Oxford, Cambridge, and London to issue invitations to the universities of the Empire to a conference to be held in the metropolis in 1912. There can be no doubt that this is the first step towards a closer union and sympathy, which cannot but have the most far-reaching and beneficial effects.

The present volume of reports deals only with those universities and university colleges which, during the session 1908–9, were in receipt of grants from the treasury, but these grants affect, directly or indirectly, every university in England and Wales, except the two ancient foundations of Oxford and Cambridge.

It has been possible this year, thanks to the hearty cooperation of the universities and university colleges themselves, to prepare the reports upon much more uniform lines than hitherto, and to supplement the audited accounts in each case by an abstract which enables a comparison to be made for the first time of the various sources of income and the main heads of expenditure in the various institutions.

The returns under the different heads of income and expenditure are summarised in an appendix, and this is the first time that a comparative statement has been possible of the sources from which the several English universities and university colleges and the Welsh university colleges draw their income, and of the main headings of their expenditure.

From Table I. it will be seen that the actual total annual income of the English universities and university colleges under review exceeds half a million, some 26 per cent. of which comes from the exchequer, and some 16 per cent. from local education authorities, while 32 per cent. is in the nature of fees of students, and nearly 15 per cent. arises from endowments.

In the case of the Welsh colleges, the total annual income exceeds fifty thousand pounds. Of this total above 39 per cent. comes from the exchequer, and next year, when the additional grant of 13,500*l.*[1] voted for the session 1909–10 comes into account, this percentage will be considerably increased. The local education authorities in Wales contribute about 8 per cent. of the total income, while some 33 per cent. is derived from the fees of students and less than 8 per cent. from endowments.

Table II. shows how the income is expended upon administration, upkeep, and teaching. It will be seen that two-thirds of the whole expenditure is devoted to the remuneration of the teaching staff and the accessories of teaching, while 20 per cent. is expended on administration and in the maintenance of buildings; but this figure is unsatisfactory, because there is no means under the present form of the return by which expenditure upon the provision of buildings and equipment can be separated from maintenance. When this separation can be made, a comparison will be possible of the expenditure of the various institutions upon the main heads of teaching, administration, provision and maintenance of buildings, and equipment; and of each with the expenditure of all. The returns show that each English university and university college, with two exceptions, has a superannuation scheme towards which funds are allocated, and of these two exceptions, one (Armstrong College, Newcastle) has since the date of the return established a satisfactory scheme. The Welsh colleges have at present no superannuation scheme.

Table III. presents an analysis of the returns of students under instruction in England during the session 1908–9, the figures contained in the tables under the various headings being obtained from the information supplied by the authorities of the universities and university colleges concerned. It is certain that this return is not in all respects

complete. It is encouraging to note that the total number of whole-time students is increasing, and that students are more and more taking advantage of the facilities now provided for research and for work of a post-graduate type.

It will be seen that the total number of day and evening students in attendance at the universities and university colleges in England (excluding Wales) in receipt of treasury grant exceeds 18,000, but that the number of whole-time students is only some 8,300, and the number of whole-time matriculated students preparing for degrees slightly more than 4500, of whom 1230, or 27 per cent., are students in training under the regulations of the Board of Education for the training of teachers for elementary schools. If to these 4500 are added the 1052 post-graduate and research students, we have a rough measure of the amount of university education, in the strict sense of the term, which is being given by the universities and university colleges under review.

The percentage of students in training under the regulations of the Board of Education for the training of teachers for elementary schools to the number of whole-time students in the case of three of the institutions concerned exceeds 50 per cent., while there are three other institutions in which it exceeds 30 per cent.

Table III. shows that the total number of whole-time students in the Welsh colleges exceeds 1300, of whom no fewer than 1175 are whole-time matriculated students preparing for degrees. Of these, 437, or about 38 per cent., are students in training under the regulations of the Board of Education for the training of teachers for elementary schools. There are also 45 post-graduate and research students.

Further appendices are added with the view of setting out the amount of financial assistance given to university education from the exchequer. Table IV. shows the annual grants to universities and university colleges and to the colleges which form constituent parts of universities, whether from the treasury, from the Board of Education or from other Government departments.

Table V. shows the amount of the grants in aid for "University Colleges in Great Britain," given by the treasury for several years since funds were first appropriated to this purpose by the vote of 15,000*l.* set down in the Civil Service estimates for the year 1889–90.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A BILL "to require that in public elementary schools instruction shall be given in hygiene, and to girls in the care and feeding of infants," was introduced in the House of Commons on Tuesday, and read for a first time.

THE council of the Junior Institution of Engineers, in conjunction with the council of the Society of Engineers, has arranged for a course of six fortnightly lectures on "The Law relating to Engineering," to be delivered by Mr. L. W. J. Costello. The first lecture will be given on October 10.

THE annual meeting of the Midland Agricultural and Dairy College will be held on Monday, July 25, when the report on the year's work will be presented. The Right Hon. Earl Carrington, K.G., president of the Board of Agriculture and Fisheries, will address the meeting, and present the diplomas and certificates gained during last session.

IT is announced in *Science* that Cornell University has been made residuary legatee of the estate of the late Dr. Goldwin Smith. It is reported that the value of the bequest will exceed 200,000*l.* From the same source we learn that by the will of Mr. Frank W. Collendar, Tulane University will receive 13,000*l.* for the Sophie Newcomb College, and that Mrs. Ida A. Richardson, who during her lifetime gave generously to various departments of the university, has left 5000*l.* to the Medical School.

AT the summer graduation ceremony at Aberdeen University on July 13, Principal Smith announced that the Chancellor of the University, Lord Strathcona, has just given to the university a sum of 10,000*l.* towards the endowment of a chair of agriculture. The interest on this money, along with the annual revenue of the Fordyce lectureship on agriculture and rural economy, and the 450*l.* a year in the charge of the governors of the college for the same purpose, will enable the university to secure the services of a thoroughly competent authority on the subject.

THE suggestion has been made that a scholarship should be established at the Imperial College of Science and Technology as a memorial to the late Mr. C. S. Rolls. It is proposed that the scholarship should be devoted especially to the engineering side of aëronautics. It would be difficult to find a more fitting memorial than such a scholarship, which would enable properly trained young men to engage in aëronautical research, to perpetuate the memory of an engineer who devoted his life to the development of various branches of applied science.

A short vacation course on oceanography (hydrography and planktology) will be held at Port Erin Biological Station, Isle of Man, in the first half of next month. We understand that there is still room for about four more persons in the laboratory. Applications for admission should be sent to Mr. H. C. Chadwick, Curator, Biological Station, Port Erin, Isle of Man. Prof. Herdman will give an opening lecture on the history and present position of oceanographic investigation; he will also deal in one or two following lectures with quantitative plankton methods, the distribution of the plankton, and its bearing on fishery questions. Prof. Herdman will also conduct some demonstrations of methods of investigation at sea, and will discuss some of the problems and results of plankton investigation. Dr. W. J. Dakin will give lectures and demonstrations dealing with the following matters :—History of quantitative methods; hydrographical apparatus as used at sea, and general work in the laboratory; the periodicity of the plankton; the most important plankton species—phyto- and zoo-plankton—of the Irish and North Seas, and the sea as a nutrient fluid. Dr. H. E. Roaf will deal with the following :—Respiration of marine animals; metabolic processes in animals; carbon-dioxide determination; and oxygen determination.

In the course of an address at the Holborn Restaurant, London, on Monday, Mr. Haldane remarked that the Royal Commission on University Education in London, of which he is chairman, will consider the subject with reference to the Empire. There are vast possibilities of the various parts of the Empire, with their different industries, their different methods for training people for the great battle of life, coordinating their systems of university training in such a fashion that we in the metropolis may accomplish our part, and they may do their specialised parts, so that we may have an educational system in which the student may proceed from place to place, and in which we may have the sense of a unity in the great conceptions of the mind as well as in more material things. Germany has vast organising capacity, a splendid educational system, and a genius for organisation which Mr. Haldane wishes we possessed at home. If we were the equals of Germany in the kind of education which bears so closely upon commerce, and if organisation with us were developed on the same plane to which it is developed in Germany, we need not have much fear for the future. But there need not be much fear for the future, because these very things—organisation and education—are being advanced among ourselves with strides which were wholly unfamiliar a short time ago. We have added nine universities in the last twelve or thirteen years to those which we had before; we have developed our school system enormously; our technical system has gone on; and there is a life and an energy in the people which, with the individual capacity of the members of the race, gives us every prospect of holding our own.

One of the best results of the Education Act of 1902 was to place the administration of education in all its grades in the hands of one committee for each area. That this course has led to the prevention of much overlapping, the encouragement of coordination, and economical management is to be gleaned from a study of the annual report of the Education Committee of the city of Manchester for the year 1908–9. The report runs to nearly 350 pages, and constitutes a splendid record of what public spirit and persistent endeavour can accomplish in the provision of educational facilities in a great manufacturing town. It is possible to refer only to one or two of the many points of interest in the report. We notice with pleasure an increase of 110 individual students attending the day departments of the Municipal School of Technology, bringing the total, including manual training students, up to 823. The work of the principal evening departments of the school is now organised in group courses of instruction ranging over five years, and leading to the diploma of the school, with the title of associate. The work of the special day course for engineering apprentices has now entered upon its seventh year. It is designed to give instruction to selected apprentices employed in engineering works, and candidates for the course are nominated by their respective firms, and they are required to give evidence of a satisfactory knowledge of mathematics and mechanical drawing. The students attend for eight hours on one day a week for forty weeks, and it is found that they are able to obtain a more extended and satisfactory course than the evening classes are able to afford, and the evenings are left free for the preparation of home work and for necessary reading. A similar course is held for apprentice plumbers. Numerous tests have been carried out in the school during the year for manufacturing firms in the city and surrounding neighbourhood, and the staff has been able to accomplish a large amount of research work.

SOCIETIES AND ACADEMIES.

Edinburgh.

Royal Society, June 20.—Prof. Cossar Ewart, F.R.S., vice-president, in the chair.—A. D. **Ross** and R. C. **Gray**: The magnetism of the copper-manganese-tin alloys under varying thermal treatment. The alloys prepared contained 14, 16, 18, 30, 38, and 48 per cent. of tin, the remainder, copper and manganese, being in the ratio of 7 to 3. At 15° C. these alloys gave in field 100 intensities, which were equal, respectively, to 55, 77, 82, 0·4, 96, and 1. Thus the 38 per cent. alloy forms a group by itself, marked off from the group of lower percentages by the 30 per cent. alloy, which has very small susceptibility. The critical temperatures varied from 225° C. to 275° C. In the case of the 38 per cent. alloy, the critical temperature was 225°, on cooling from which the alloy regained its magnetic quality, but when heated to 330° C. it did not regain its magnetism on cooling. Many other results were detailed in connection with thermal treatment of various kinds.

July 4.—Sir William Turner, K.C.B., president, in the chair.—Sir William **Turner**: Morphology of the manus in *Platanista gangetica*, the dolphin of the Ganges. Ten specimens of the manus in this species had been examined and compared with the corresponding organ in Hyperoodon and Mesoplaton. On account of fusion, the five carpal bones typically represented in Hyperoodon were reduced to four in Platanista, the fourth and fifth corresponding to the ring and little finger being united. In some cases the radial was found fused with the first carpal bone. The paper gave a full, detailed account of the morphological similarities and dissimilarities among these related forms.—Prof. Alex. **Smith** and A. W. C. **Menzies**: A static method for determining the vapour pressures of solids and liquids, and the vapour pressures of mercury. In the former paper the authors described a modified form of their "isoteniscope," in which, by adjusting the pressure under a fixed temperature, they were able to measure vapour pressures with great accuracy. Previous determinations of the vapour pressures of mercury at different temperatures showed considerable discrepancies. They had accordingly carried out a series of measurements of the pressure of this vapour between the temperatures of 255° C. and 450° C.—J. W. **M'David**: Specific volumes of solutions of tetrapropylammonium chloride. Dilute solutions had a density less than that of water, passing through a minimum as the solution became stronger. The position of this minimum depended on the temperature, occurring, for example, with a 5 per cent. solution at 0° C., and with a 20 per cent. solution at 56° C.—Dr. A. Louise **M'Ilroy**: The development of the germ cells in the mammalian ovary, with special reference to the early phase of maturation. The research was carried out with the view of determining the maturation processes which take place in the germ cells, and also to obtain evidence of the origin of the stratum granulorum. It was found that the cells matured inwards from the periphery. The capsular epithelium on the surface of the ovary was derived from the oogonia, and was differentiated at a very early stage. It had no function other than protective. Mitosis occurred among the oogonia, and also among the primary oocytes of the reticular stage. The growth of the stroma and germ cells was mutually correlated throughout the development of the ovary. The follicle cells were derived from the oogonia, and not from the stroma, cells, the latter being only supporting and vascular. The paper contained many other important details, partly supporting, partly correcting, the conclusions of other workers.—Dr. Thomas **Muir**: The theory of wronskians, recurrents, and all other less common special forms of determinants up to 1860.

PARIS.

Academy of Sciences, July 11.—M. Émile Picard in the chair.—A. **Lacroix**: General consequences to be drawn from the study of the petrographic constitution of Tahiti. The author shows the presence of granitoid rocks in this island to be of some importance, since no analogous rock has yet been found in Polynesia.—Sir William **Ramsay** and Robert Whytlaw **Gray**: The density of the radium emanation. After two years' efforts, the authors have constructed a balance sensible to a half-millionth of a milligram, and by means of this have arrived at 220 as the mean value of the atomic weight.—Édouard **Heckel**: The action of cold and anæsthetics upon the leaves of *Angraecum fragrans* and the green husks of Vanilla. As a practical deduction from these observations, it would appear useful, in order to diminish the time necessary for the industrial extraction of vanilla, to submit it first to the vapour of sulphuric ether for 5 or 8 hours, afterwards drying by the usual processes.—P. **Puiseux**: The origin of the "cirques" and angular outline of the lunar crevasses.—G. **Millochau** and H. **Godard**: Observations on Halley's comet from the Pic du Midi Observatory.—E. **Study**: The "Géométrie des feuillets" of MM. R. de Saussure and R. Bricard.—Arnaud **Denjoy**: The continuous and the discontinuous.—L. **Amaduzzi**: The variation of the appearance of a discharge with the variation of the distance of explosion.—Ettore **Cardoso** and Georges **Baumes**: Critical constants of acetylene and cyanogen. The authors find the mean values to be: acetylene, $t_c=35{\cdot}5^\circ$ (308·5 abs.), $p_c=61{\cdot}5$ atmospheres; cyanogen, $t_c=128{\cdot}3$ (401·3 abs.), $p_c=59{\cdot}6$ atmospheres.—A. **Lafay**: The average pressures supported by a body maintained in a current of air of irregular velocity.—P. **Carré**: Researches on the fixation of trioxymethylene by magnesium derivatives of homologues of benzyl bromide.—M. **Vandernotte**: The brookite of an albitic syenite from the neighbourhood of Ernée.—E. **Gourdon**: Two deposits of zeolites in the Antarctic.—Leclerc Du **Sablon**: The ascent of sap. It is shown that the mechanism of the ascent is independent of the height of the trunk, and that water has no more difficulty in rising to the top of a tree of 300 metres than a plant of some decimetres.—M. **Radais** and M. **Sartory**: Rendering a rabbit immune from the poison of mushrooms.—A. **Magnan**: A certain law of variation of the liver and the pancreas among birds.—Marcus **Hartog**: A new force: mitokinetism.—A. **Perrier**: The combustion of acetaldehyde by lower vegetable organisms.—J. **Winter**: The quantity of secretion contained in a given gastric liquid.—M. **Doyen**: The use of thermo-electric baths without alteration of normal tissue. The author describes successful experiments based on the fact that cancerous poison cannot resist a temperature of 55° C., while normal tissue supports a temperature of 58°–60°.—M. **D'Arsonval**: Remarks on the previous paper.—A. **Briquet**: The succession of cycles of erosion in the Franco-Belgian district.—Henri **Mémery**: Remarkable coincidences between the variations of sun-spots, and the temperature variations at Paris, Bordeaux, and Pau during the winter and spring of 1910.

CAPE TOWN.

Royal Society of South Africa, March 18.—Mr. S. S. Hough, F.R.S., president, in the chair.—Dr. R. **Marloth**: Some further observations on the biology of Roridula. *Roridula dentata*, commonly called the fly-bush, is a shrub 1 to 4 feet high, growing on the mountains near Tulbagh and on the Cedar mountains. As the leaves are provided with many stalked glands, which secrete a very viscid fluid, numerous insects adhere to the leaves and perish there, hence the shrublet is universally considered to be an insectivorous plant. Experiments, however, have shown that the fluid secreted by the glands does not possess any digestive properties, and that it is quite different from the fluid secreted by droseraceous plants. The fluid is a kind of balsam, and probably affords protection to the plant against the attacks of creeping animals, such as snails, caterpillars, earwigs, &c., and the capturing of other insects is merely accidental, and of no advantage to the plant. *Roridula dentata* and *R. Gorgonias*, the only two species of this genus, are consequently to be excluded from the list of insectivorous plants.—Dr. T. **Moir**: The absorption spectrum of oxygen and a new law of spectra. The AB and *a* lines of the solar spectrum, which are due to absorption by terrestrial oxygen, have each a complicated rhythmic structure. The author has discovered an algebraical formula whereby each line can be calculated from a fundamental, the differences being directly proportional to the squares of the first fifteen or sixteen integers. The agreement is practically in all cases within the observational error. The oxygen molecule is shown to be very slightly unsymmetrical.—Dr. L. **Péringuey**: Notes on some bushmen. The small, elf-like bushman was legendary, with all the concomitants of the legend. If careful comparison of the description of the old authors such as Sparrman, Barrow, and Burchell with the remnants of that so-called bush race was made, it would be found that such physical peculiarities in male or female of which the authors spoke were most accurately described. Yet the skull of the brother of one of the females exhibited came within the measurements assigned to Hottentots. This was another proof of the conclusion arrived at by Shrubsall that the Hottentots and the so-called bush people are closely allied, whereas the akin race, "Strand Looper," show more differentiation.

THURSDAY, JULY 28, 1910.

PLANETOLOGY.

The Evolution of Worlds. By Prof. Percival Lowell. Pp. xiii+262. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1909.) Price 10*s*. 6*d*. net.

ONLY by the minutest study of that which is can finite man of a finite epoch hope to draw even the roughest sketch of the antecedent, or form the vaguest speculations as to the ultimate; the truth of the sketch and the soundness of the speculation increase or decrease in proportion to the knowledge acquired by the observer. Therefore we welcome a volume in which Prof. Lowell sets out a scheme of evolution which embodies a proper sequence of congruities and is based on the results of years of careful observation.

Planetology is defined as the astronomy

"which deals with the evolution of worlds. It treats of what is general and cosmic in that evolution, as geology treats of what is terrestrial and specific in the history of one member of the class, our own earth."

On these lines Prof. Lowell develops a scheme of evolution wherein the observational evidence wrested from what is, leads to the speculations as to what was and what will be.

The matter originally formed the subject of a university course of lectures, but a larger public demanded it, and hence the present volume.

There are seven chapfers in which the probable life-histories of a planet and of a planetary system are vividly portrayed, and a perusal of the first, "The Birth of a Solar System," impresses very forcibly the idea how finite is man, how infinite matter and time. The inception of a new system is but the death-knell of its predecessor.

The problem of the birth was solved when Goodricke, the deaf mute of York, divined the cause of Algol's demoniacal winkings—a dark sun; on this is based the whole story. The descriptions of a number of Novæ support the statement that cataclysms are not unknown, and, by several lines of reasoning, the production of spiral nebulæ—the matrices of new worlds—is shown to be the result. The planetesimal hypothesis is probably now too well known to call for further elaboration here of Prof. Lowell's story of the birth, but before proceeding to the second chapter he draws a wonderfully awful picture of the conditions which would precede and attend the incursion of a second dark body, which, by its powerful perturbative action, would once more produce chaos from our present orderly system.

In the second chapter we are given descriptions of the existing proofs of this cataclysmic birth. The existence of myriads of meteors in interplanetary space, their common motions, and their likeness to terrestrial material, are cited as evidence of a common origin in one rotating mass. The mathematics for this—mathematics being "a precise reasoning appli- usually to the discovery that a pet theory will not work," but more fruitful in this instance—are, with other more or less profound items, relegated to a series of notes at the end of the book. The physical evidence for this common origin reaches a climax with a statement of the varying densities of the planets; those torn off earlier by the tidal stress are less dense because they formed the upper layers of the parent dark body. Thus the hydrogen envelopes of Neptune and Uranus, demonstrated by Dr. Slipher's spectrograms, are evidences of primogeniture.

In the chapter on inner planets, many old "facts" are reorganised, on the evidence of the careful observations made at Flagstaff, and, as they have not yet appeared in their new forms in the ordinary text-books, their statement here is a useful addition to astronomical literature. Among others, the correction to the diameter of Mercury, so dramatically confirmed, independently, by Newcomb, is an example of the value of such careful attention to observing conditions and observations as has been paid at Flagstaff. Students of astronomy will also experience a feeling of relief that the rotation periods of Mercury and Venus now appear to be placed beyond question. The following description of Mercury is so characteristic of Prof. Lowell's graphic style as to be worth quoting:—

"Two antipodal hemispheres divide the planet, the one of which frizzles under eternal sun, the other freezes amid everlasting night."

The persistent observations at Flagstaff also dispelled the idea of a cloud-covered Venus, replacing it by a diaphanously-clad body on which the strong winds sweep up enough dust to account for the planet's high albedo. The radial streaks depicted on the accompanying drawing of the planet are supposed to be "runs" produced by winds which have consistent, and persistent, directions. An interesting suggestion is that the "earth-light" sometimes seen on Venus's dark limb is but a darkened vision of the ice which for countless æons has been hoarded up on that side of the planet which never sees the sun. "Monotony eternalised" is Prof. Lowell's apt description of the Mother of Loves.

It is with something like a shock that the reader finds but about a page and a half devoted to Mars; but the author opines that he has already treated adequately of the subject elsewhere. Phobos and Deimos are dealt with, however, and, according to Prof. Lowell's observations, they are larger than hitherto supposed; he gives 36 miles and 10 miles as their probable, respective, diameters. The dilatation of "Fear" and "Panic" by observations made at the Flagstaff Observatory may not appear to some conservative tenants of "facts" as a novelty.

Coming to the minor planets, evidence is cited to show that Olbers's theory of an exploded planet is untenable, and that this congeries of fragments represents what would have been a planet had not the giant Jove prevented the agglomeration. By plotting the major axes of their orbits in the form of a spectrum band, the wave-lengths scale being replaced by one of astronomical units, Prof. Lowell shows how commensurability of period with the period of Jupiter has determined the location of the asteroids. The variability of magnitude exhibited by minor planets is accepted as evidence of dissymmetry, and this, in turn, is taken as evidence for the initial cataclysm as described. Torn by tidal stress, the dark sun was disrupted while still solid, the dissymmetry showing that the asteroids have never been in a fluid state.

Jupiter as a semi-sun is discussed at some length, its albedo of 0·75, as compared with Muller's 0·72 for clouds, being ascribed as possibly due to intrinsic light; the same explanation is offered for Saturn's albedo of 0·78. Jupiter's independence of the sun—its belts of cloud are apparently not affected by the rotation or revolution of the planet—serves as an illustration of the earlier condition of the earth, and other planets, before the advent of the sun-sustained period.

Of Saturn and Uranus but little is related, but the story of Neptune's discovery is told at some length. Rather more stress than usual is laid on Prof. Pierce's demonstration that Galle's discovery was a lucky accident. The problem solved by Leverrier and Adams was capable of three solutions, and it was but by chance that they attacked the right one.

"Congruities" is the keynote for the chapter on the formation of planets, and Prof. Lowell urges that incongruities, discovered since Laplace's time, have killed the nebular hypothesis. He then marshals the mutually-sustaining facts in support of the planetesimal hypothesis. By curves showing the masses of the planets relative to their solar distance, and others demonstrating the analogies of satellites and primaries in their departures from the common plane, he shows that the congruities, on this hypothesis, are perfect—to-day; future discoveries may necessitate further steps.

Having thus brought us to the formation of planets as discrete bodies, the author proceeds to outline the probable history of the finished sphere. On the one hand, we have the physical development, the cracks and cataclysms which formed our geographical features along lines necessarily different from those obtaining on Mars, or any other world; on the other is the chemical development, "as universal as the universe itself." Evidence that darkness was spread over the face of the earth is gleaned from many quarters, all showing that our planet was a sunless forcing-house; this was the self-sustained age. Then the earth cooled, the dense cloud covering condensed, admitting sunlight, and we arrived at the sun-sustained epoch which we still enjoy. Here the story of evolution is exceedingly interesting, especially that dealing with the Ice age. Probably the statements will be criticised by some geologists, but the author's substitute for what he terms their "astrocomico" suggestions is none the less attractively stated. The extraordinary ellipticity of the orbit, to account for the Glacial epoch, is rejected, and is replaced by one in which excessive evaporation and precipitation, producing polar ice-sheets of great thickness, play a great part. It is also shown that the glaciation was restricted to well-marked raised areas, such as Norway, Scotland, Labrador, Keewatin, &c., and was nothing more than a natural terrestrial phenomenon; observations of Mars show that, at the present time, the polar highlands retain their covering of snow for some time after the general melting of the cap has separated them from the main body of it.

In the last chapter the "Death of a World" is discussed, and the possible modes of extinction examined. It may be by collision with a dark sun, but, failing that, it is inevitable by the action of tidal friction and the diffusion of water and atmosphere. Collating the facts gleaned from the previous study of the several planets, it is shown that there is a more or less orderly sequence culminating in the present condition of our own satellite. *Sans* season, *sans* day and night, *sans* water and *sans* atmosphere, the worlds will await the quickening which can only come by the advent of a cataclysm such as is described in the earliest chapters.

The printing and illustration of the volume are beyond criticism, although the paper is rather heavy, and with its graphic language, its sustained interest, and clear story, the book is sure to appeal to the general reader who would learn more of the past, and of the probable future, of our earth and its fraternity.

WILLIAM E. ROLSTON.

NATURE-STUDY.

(1) *The Nature-Study Idea. An Interpretation of the New School-movement to put the Young into Relation and Sympathy with Nature.* By L. H. Bailey. Third edition, revised. Pp. ix+246. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1909.) Price 4*s.* 6*d.* net.

(2) *Man and Nature on Tidal Waters.* By Arthur H. Patterson. Pp. xvi+315. (London: Methuen and Co., 1909.) Price 6*s.*

(3) *Tommy's Adventures in Natureland. A Nature Story for Boys and Girls.* By Sir Digby Pigott, C.B. Pp. xvi+180. (London: Witherby and Co., 1909.) Price 2*s.* 6*d.* net.

(4) *Animal Romances.* By Graham Renshaw. Pp. vi+206. (London: Sherratt and Hughes, 1908.) Price 7*s.* 6*d.*

(1) PROF. L. H. BAILEY is well known as a botanist who believes in the practical and educational value of his science, and he has shown himself on many occasions able to give good reasons for the faith that is in him. In the present volume he discusses, in a lively and unconventional fashion, the true inwardness of "nature-study," which is not science, nor knowledge nor facts. "It is spirit. It is an attitude of mind. It concerns itself with the child's outlook on the world." "It would be better if it were called nature-sympathy." We do not think that professional educationists will quite agree with Prof. Bailey in associating all the pædagogical virtues with nature-study (for many of them may be expressed in the study of history, for instance), but most who have any sympathy at all with studying the world around us will agree with the sound educational sense which the book expresses. In a breezy and interesting fashion he discusses how nature-study may be taught, the school-garden, the rural-school problem, the teacher's outlook on nature, and about half a

hundred particular inquiries, some of which are very quaint, *e.g.* "Now that there are so many nature-books, how shall I choose the most useful one?" or, already, "Is nature-study on the wane?"

(2) Mr. Arthur H. Patterson has added a fourth volume to his series of east-coast books, and it is welcome, for the author writes with a light touch of the business of man and beast on the tidal waters of East Anglia. He describes at first hand much that is of interest regarding punt-gunning, decoying, snipe shooting, smelt fishing, shrimping, eel catching, and so on, and gives us delightful glimpses of the bird-life in particular. There is a great deal of fisherman's gossip in the book, but it is wholesome, open-air gossip, now and then cutting into the circle of the sciences.

(3) Sir Digby Pigott's nature-story for boys and girls is a sequel to "The Changeling," in which the author worked out, in a manner that pleased many, the idea of a child who was at one time a rook, at another a bee, at one time a fox, and at another a wild goose, and in due course a swift, a mole, and a short-eared owl. The author seeks to get young folks into close quarters with the real life of wild creatures, introducing them, through "Tommy's" adventures, to fur-seals and skuas, walruses and peregrines, and even to the dodo and "Archæopterix." We find the book a little too informative, but it is kept, on the whole, commendably simple, and we doubt not that it may be useful for those children who really enjoy getting at things in this curiously circuitous fashion. The notes seem to us to be an artistic mistake.

(4) Dr. Graham Renshaw's natural-history essays are well known and justly admired, but he has excelled himself in the sequel, which deserves its title of "Animal Romances." With the help of more than a score of peculiarly interesting and artistic photographs, he has succeeded in giving us living pictures of many wild animals in their natural setting—giraffes ("the dream creatures," "the aristocrats"!) Grevy's zebras ("the Horses of the Sun"), elephants ("the giants"), hippopotamus ("Behemoth"), and so on. He stays longest in Africa, but he takes us also to the Andes, to the Antarctic ice, to Tasmania, and elsewhere, and is always a lively guide. There is plenty of science in his nature-pictures, but there is poetry, too, and his book is literature of high quality.

TECHNICAL CHEMICAL ANALYSIS.

Technical Methods of Chemical Analysis. By Prof. George Lunge. English translation, edited by Dr. C. A. Keane. Vol. i., parts i. and ii. Pp. xxiv + 996. (London: Gurney and Jackson, 1908.) Price 2*l.* 12*s.* 6*d.* net.

A BOOK which covers such a wide ground as Prof. Lunge's "Technical Methods of Chemical Analysis" is by no means easy to review. No one chemist, for example, is likely to be practically conversant with all the branches of analysis which are dealt with, and, recognising this, the author has, as is usually the case in similar works, obtained those who have specialised along certain lines to undertake the writing of such sections.

One of the difficulties to the reader of books like this is that to some extent it is a dictionary of methods, and it is sometimes a little bewildering to know which of many methods given for the analysis of one special substance is the best to employ. It is consequently not a book for the ordinary student, but one for the experienced worker, although even he will require to bring his critical faculty into play. The book is well written and is interesting to read, and those who study it will find it to contain quite an extraordinary amount of information which is by no means only analytical. The sections on clay and on clay wares, earthenware, and glazes are, for example, most interesting to read, even if one has no intention of carrying out the analysis. We like the arrangement of the section on potassium salts; first, all the methods employed are given in detail, and then the applications of these methods to special cases, such as analysis of Stassfurt salts, manures, beet ashes, and so on.

That the book is of the utmost value in the laboratory—in fact, almost indispensable—we can vouch, as since its publication it has been in constant use, and it is rarely that, within the scope of this volume, we have not obtained the information desired.

In conjunction with this volume an extremely useful little handbook of 260 pages, called "The Technical Chemist's Handbook," has also been issued. It is in limp cover, and of such a size that it can be carried in the pocket. Nearly 100 pages consist of tables, comprising, among others, factors for calculating gravimetric analysis, specific gravities, boiling points, tension of aqueous vapours, and weight of sheets of metals; there are, in fact, thirty-nine useful and valuable tables. The special part which follows deals with methods of analysis under various headings. To take an example at random, "III. Saltcake and Hydrochloric acid; A. Salt, B. Saltcake, C. Chimney-testing, D. Testing of the Gases in the Hargreaves Process, E. Hydrochloric acid." It should be mentioned that beside the thirty-nine tables referred to there are further tables in the special part, for example, the specific gravities of hydrochloric acid.

Dr. Lunge and Dr. Keane are to be congratulated on the issue of this volume, the one for writing it and the other for so ably editing the English edition. We hope that it will not be long before vols. ii. and iii. are ready.

BRITISH FOSSILS.

Palaeontographical Society. Vol. lxiii., 1909. (London: The Society, and Dulau and Co., Ltd.,

THE sixty-third volume of the Palæontographical Society's monographs contains instalments of works already in progress, and the council announces its desire, so far as possible, of completing these before commencing new monographs, for which they have received numerous proposals.

Prof. S. H. Reynolds continues his monograph of the British Pleistocene mammalia, here dealing with the Canidæ, comprising the wolf, the fox, and the Arctic fox. This part is illustrated by six plates, and there are a number of text-figures and tables of comparative measurements which should prove useful, but nothing calls for special notice except the determination of the problematic *Lycaon anglicus*, Lyd., as a somewhat abnormal wolf, a conclusion which seems justified by the evidence now available.

For our knowledge of the Palæozoic fishes of the family Palæoniscidæ we are mainly indebted to the researches of Dr. R. H. Traquair, who continues his account of the British Carboniferous members of the family, describing the genera Acrolepis, Nematoptychius, and Cycloptychius; the last three of the seven plates illustrate the genus Rhadinichthys, which will, presumably, be described in the next part. The predaceous habits of the larger Palæoniscidæ are shown by a specimen of *Nematoptychius greenocki*, with the remains of a good-sized Acanthodes in the abdominal cavity, and another point of some interest to which Dr. Traquair directs attention is that in round-scaled Palæoniscidæ (Coccolepis, Cryphiolepis, &c.), the scales on the upturned portion of the tail always preserved their original angular form, as they do even in the modern Chondrosteans. The probable explanation is that the markedly heterocercal tail of these fishes was a powerful organ of propulsion, and that no sacrifice of strength could be made to gain increased flexibility; the Palæoniscidæ were strong swimmers with wide gill-openings, differing in their manner of life from the more sluggish Crossopterygians and Dipnoans, with their restricted branchial apertures, paddle-like paired fins, and diphycercal or hetero-diphycercal tail.

In the fifth part of his monograph of the fossil fishes of the English Chalk, Dr. A. Smith Woodward concludes the Teleostomes and commences the Chimæroids. Lophiostomus and Neorhombolepis are described as highly specialised Eugnathids, but of most importance is a very full description, accompanied by a restoration, of the Cœlacanthid *Macropoma mantelli*. Our knowledge of the Crossopterygian fishes of the order Actinistia is gradually becoming more complete; it is now some years since Dr. Smith Woodward made the interesting discovery that the pectoral fin was supported by a series of four hour-glass-shaped pterygials, exactly as in typical Teleosts, and in the present case he has elucidated many details of cranial structure.

Mr. Henry Woods gives another instalment of his elaborate monograph of the Cretaceous Lamellibranchs of England, describing the Solenidæ, Saxicavidæ, Pholadidæ, Teredinidæ, Anatinidæ, Pholadomyidæ, Pleuromyidæ, Poromyacidæ, and Cuspidariidæ. Several new species are included, and the preparation of the synonymy of some of the others must have been no light task.

The Palæontographical Society spares no expense in order to ensure that its monographs are properly illustrated, and the present volume contains twenty-nine plates, ten of which are assigned to Mr. Woods's memoir; the beautifully executed reproductions of English Cretaceous fishes, drawn by Mr. A. H. Searle to illustrate Dr. Smith Woodward's monograph, call for special mention. Indices to the Cretaceous Cephalopods and the Jurassic Belemnites, described many years ago, conclude the volume. C. T. R.

COMPARATIVE PHYSIOLOGY.

Handbuch der vergleichenden Physiologie. Edited by Hans Winterstein. Band ii., Physiologie des Stoffwechsel; Physiologie der Zeugang. 1st and 2nd fasciculi, pp. 1 to 320; 3rd fasciculus, pp. 321 to 482 of the first half of the 2nd volume; 4th fasciculus, pp. 1 to 160; 5th fasciculus, pp. 161 to 304 of the 2nd half of the 2nd volume; 6th fasciculus, pp. 483 to 658. (Jena: Gustav Fischer, 1910.) Price 5 marks per fasciculus.

THERE are being published in Germany just now a number of important works of a biological nature, in which eminent investigators are collaborating to produce a more or less exhaustive presentment of their special branches of knowledge. The fasciculi are published at short intervals as they are ready, and not necessarily in the sequence in which they will ultimately be bound together. The present work is the latest example of this method of publication, and the growing science of comparative physiology is receiving its due share of attention. The editor, Prof. Hans Winterstein, has an ambitious programme before him, and hopes to complete the work in four volumes. The list of selected collaborators contains the names of some of the best known of modern investigators; the majority of these are Germans, but the names of Fredericq, of Liége, Carlson, of Chicago, Tigerstedt, of Helsingfors, Bottazzi, of Naples, and Godlewski, of Cracow, also occur upon the title-page.

The fasciculi at present to hand will all ultimately be found in one or other of the two parts into which vol. ii. is to be divided. The first three fasciculi and the sixth are occupied with a single article from the pen of Prof. W. Biedermann, of Jena, and it deals with the digestion and assimilation of nutriment in the various classes of organisms; the article includes the consideration of plant as well as of animal life, so the term comparative is used in the widest sense. The article is left to be finished in future issues.

The fourth fasciculus is devoted to an interesting monograph by Prof. Léon Fredericq on the secretion of protective substances, in which we have an account of such materials from the nematocysts of protozoa up to the more elaborate means of defence found in the vertebrata; this includes an account of toxins, antitoxins, and the numerous other substances included in a general study of the vast subject of immunity. The monograph overlaps into and nearly fills the fifth fasciculus also, which concludes with the commencement of an article by Dr. R. Burian, an authority well qualified to deal with the subject allotted to him, namely, excretion.

The enterprise of our German brethren is to be admired in the conception of such a monumental work, and the preliminary fasciculi hold out the best promise for its future successful realisation.

W. D. H.

OUR BOOK SHELF.

Light and Sound: a Text-book for Colleges and Technical Schools. By W. S. Franklin and Barry Macnutt. Pp. viii + 344. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1909.) Price 5s. net.

IN writing a text-book, an author generally chooses definitely between two methods of exposition: he either writes a small book, and confines his attention to the most elementary parts of the subject treated of; or else he writes a more pretentious work, in which most branches of the subject receive adequate attention.

The authors of the text-book now under review have followed a middle course. The fundamental principles of Sound and Light are discussed with great care, and numerous practical applications of these principles are described; for the explanation of complicated phenomena, the student is referred to more advanced text-books. The book opens with a very thoughtful exposition of the wave theory, illustrated by reference to water waves, sound waves, and waves in an elastic solid; and the subject of Light is developed wholly in accordance with the wave theory. Numerous optical instruments, including the standard forms of photographic lenses, are described and illustrated; and a clear but necessarily incomplete theory is given of the defects of lenses, and their compensation. Considerable attention is devoted to the subject of photometry and illumination; technical students should carefully study the chapter devoted to this part of the subject. The fundamental facts of polarisation are explained clearly and well.

In connection with sound, the simple phenomena, which are generally discussed in elementary text-books, are dealt with concisely. A very interesting chapter is devoted to the theory of music, and an account is given of Sabine's researches on the audibility of sound in rooms of various sizes; here, once more, technical students will find much to interest them. Altogether the book should prove very useful.

E. EDSER.

Kraft: das ist animalische, mechanische, soziale Energien und deren Bedeutung für die Machtentfaltung der Staaten. By Prof. Dr. E. Reyer. Zweite Auflage. Pp. xvi + 471. (Leipzig: W. Engelmann, 1909.) Price 8 marks.

Soziale Mächte: als Ergänzung der Arbeit über "Kraft." Same author and publisher. Pp. 111 (1908.) Price 1.60 marks.

THE first edition of Dr. Reyer's "Kraft" was noticed at length in NATURE (vol. lxxviii., p. 660) shortly after publication, and to that notice we must refer the reader for details as to the scope of the work. The present, second, edition has been somewhat extended, but does not appear to have been rewritten to any considerable extent, and it retains all the faults of the earlier issue. The same lack of orderly arrangement distracts the reader, the same lack of references renders the work almost valueless to the serious student, and the same absence of "the scales and the names of the plotted quantities" continues to characterise the diagrams. The bibliography remains remarkable both for its inclusions and its omissions, and it still contains even the two remarkable entries to which attention was directed in the notice of the first edition —"Produktion and consum. of timbre in forein countries (blue book)," and "Statesman's yearbook, Statist. Abstracts (mit statistischen Tabellen)"—the latter entry apparently confusing the "Statesman's Yearbook" with the "Statistical Abstracts."

The title of the second volume named above is, at the present date, misleading. When first published—the title-page bears the date 1908, although the cover is dated 1909—the title may have been correct, for the volume is apparently a supplement to the *first* edition of "Kraft." It is not supplementary to the second edition, but a mere reprint of pp. 339–447. In these pages Dr. Reyer considers such matters as migration, wages and conditions of labour, the struggle for better conditions of life, personal energies and their contributions to civilisation.

Notes on the Electric Smelting of Iron and Steel. By Dr. W. F. Smeeth. Bulletin No. 5, Mysore Geological Department. Pp. vii + 136; maps. (Bangalore: Government Press, 1909.) Price 2 rupees.

ELECTRIC steel melting and refining is now an established industry, but the electric smelting of pig-iron from the ore has recently entered on a new phase, namely, the commercially successful. The writer has had given to him, in confidence, figures of costs in connection with an electric furnace making charcoal pig-iron, with permission to mention the facts without the figures. It is clear that under conditions where the fuel is charcoal, and is becoming increasingly scarce and expensive, so far as can be judged from experience with a furnace of commercial size working for months, the smelting of high-grade ore into charcoal pig-iron is proving profitable. Only the balance sheet is a safe guide, but this test is about to be applied on quite a large scale.

The present bulletin embodies the technical portions of a report prepared by Dr. Smeeth at the request of the Government of the Maharajah of Mysore. A short description of the Stassano furnace is given, and details of several charges of steel made in the furnace in 1908 from pig-iron and scrap with the usual additions. Chapter iii. contains details of an attempt to make high-quality steel, carbon 0·2 to 0·3 per cent., in the Stassano furnace from very impure ore, a serious task. The author calculates that to produce steel from the ore, the electric furnace will require only about one-third of the amount of charcoal necessary for smelting with fuel furnaces, but (p. 45) "The sulphur is high (0·24 per cent.) and renders the steel quite unfit for use." Trial C showed a better analysis, but the mechanical test given by the steel was not good. In part ii. of the bulletin, materials and costs at Mysore are considered, and the opinion is expressed that the manufacture of steel castings, steel forgings, railway tyres, and even rails could be carried on successfully there, and at a profit. The author evidently has courage. A folding geological map of the Bababudan iron-ore area is enclosed in a pocket on the cover.

A. McW.

Psychism. By M. Hume. Pp. 157. (London and Felling-on-Tyne: Walter Scott Publishing Co., Ltd., n.d.) Price 2s. 6d. net.

MRS. HUME begins with a curious and rather incoherent theory respecting the "Trinity of Man" (Matter, Intelligence, Force; or, in another aspect, Reason, Intuition, and Soul), but she becomes decidedly interesting when she proceeds to describe her own experiences. These have been visions, dreams, or other phenomena by which a warning of an impending event—*e.g.* the death of a friend at a distance—has been conveyed. The agency is believed by the author to be her own subconscious self, which possesses clairvoyant and other powers. The theory propounded closely approaches that of the leading investigators in these domains, but we would suggest that the terminology of Myers is preferable to that of T. J. Hudson, who, moreover, is an unsafe guide, being apt to rear a large structure of theory on a small or insecure foundation of fact. The book is well written and nicely got up.

J. A. H.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Antarctic Pycnogons.

One of the most remarkable and unexpected zoological results of recent explorations in Antarctic seas has been the discovery of Pycnogonida (so-called "sea-spiders") having five instead of the usual four pairs of legs. Soon after the return of the *Discovery* expedition, Mr. T. V. Hodgson described *Pentanymphon antarcticum*, and a little later he had the good fortune to find, among the collections of the Scottish National Antarctic Expedition, the long-forgotten *Decolopoda australis* described by Eights more than seventy years ago. A second species of Decolopoda was added by Prof. E. L. Bouvier from the collections of the French Antarctic Expedition in the *Français*. The most surprising circumstance connected with this remarkable departure from what had been regarded as the normal structure of the Pycnogonida was that it appeared in two genera by no means closely related to each other, but, on the other hand, not dissimilar in general structure from other "normal" genera. Thus Pentanymphon is indistinguishable, except in possessing an extra pair of legs, from Nymphon, while Decolopoda is only a little more divergent from Colossendeis. From the point of view of phylogeny, two explanations of these conditions may be offered. Most authorities, for example, Prof. Bouvier and Prof. D'Arcy Thompson (in the "Cambridge Natural History"), adopt the view that the ten-legged condition is the primitive one, and has been retained by the most primitive members in two divergent branches of the group. The other explanation, first suggested by Prof. G. H. Carpenter and advocated by the present writer (*Science Progress*, April, 1909), is that the decapodous condition is a recent development, appearing independently in the two cases.

Prof. E. L. Bouvier has just announced (*C. R. Acad. Sci.*, July 4) a very important discovery which shows that the zoological possibilities of the Antarctic seas are far from being exhausted. Among the collections obtained by Dr. Charcot's recent expedition in the *Pourquoi Pas?* is a representative of a third genus of decapodous Pycnogons, and, strange to say, it appears to be quite unrelated (within the limits of the group) to the other two. *Pentapycnon charcoti* is a near relative of Pycnogonum, hitherto regarded as the most highly specialised of all Pycnogonida. Further, just as Pentanymphon is accompanied by species of Nymphon, and Decolopoda by Colossendeis, so Prof. Bouvier finds that Pycnogonum, hitherto unknown from Antarctic seas, is represented by a new species alongside of Pentapycnon at the South Shetlands.

Prof. Bouvier regards this discovery as quite in accordance with his views as to the evolution of the Pycnogonida. He believes that the group has evolved from a decapodous stage in which at least the chief divisions, represented by Pentanymphon, Decolopoda, and Pentapycnon, were already differentiated from one another, and he supposes that the suppression of the posterior legs has occurred independently at least three times with very little accompanying variation in other characters.

No doubt Prof. Bouvier will justify these views in greater detail when he comes to publish his final report on the Pycnogonida of the *Pourquoi Pas?* At first sight, however, the discovery of Pentapycnon would seem to weigh heavily on the side of Prof. Carpenter's hypothesis. While Pentanymphon is at least as primitive as Nymphon, and even Decolopoda can be admitted, without much difficulty, as a reasonably primitive form, no student of the Pycnogonida will question that Pycnogonum is one of the most highly specialised members of the group, and the only single character that Prof. Bouvier can find to place Pentapycnon on a lower level of specialisation is the presence of additional genital apertures, about which he speaks somewhat doubtfully. The fact that all three genera are found only in one restricted geographical area is also against the idea of their being survivors of a primitive group, for it can hardly be supposed that the Pycnogonida underwent practically the whole of their evolution in the Antarctic seas, and only became distributed over the rest of the globe when they had reached nearly the final stages of family, and even generic, differentiation. It seems much more probable (though the like has not yet been suggested for any other arthropods) that some mysterious influence of environment in these Antarctic regions has, so to speak, upset the stability of the octopodous condition and led to the independent appearance of an additional somite and pair of legs in several unrelated families.

It is to be hoped that the British expedition now on its way to the Antarctic may obtain material for throwing light on this problem.

W. T. Calman.

A New Italian Orchid.

The enclosed photograph represents, I believe, a species of Italian orchid which has not before been discovered. M. H. Correvon, who is, I suppose, the greatest living authority on the European orchids, considers it "seems to be out of the way of species known." When first I found it, I believed it to be *Serapias triloba*, but, having studied various authorities, I have since come to the conclusion that I was wrong. They all agree that the lip of triloba is crenulated, but in my specimen there is no sign of that Triloba is considered to be a hybrid between *Serapias lingua*

and *Orchis papilionacea*; although the ground was covered with the former, I could not find a vestige of the latter in the whole of that district.

Also, the authorities only give the Riviera as the habitat of triloba, whilst I found my plant in mid-Italy, near Florence. In my plant the sepals and petals are each very distinct and separate, not joined into a cap, as in all the other varieties of Serapias.

It may possibly be a cross between *S. lingua* and *O laxifolia*, but, even so, it differs much from that pictured in Barla's book. It is a somewhat striking plant, as the flowers are very large in comparison to the rest, both the labellum sepals and petals being a very vivid shade of colour between pink and purple, the former a little darker.

W. Herbert Cox.

Centre of Gravity of Annual Statistics.

The principle of taking the centre of gravity of annual rainfall is free from objection, but Mr. Cook's method (Nature, March 31) is mathematically incorrect. Annual statistics should not be plotted on a straight line, but round a circular ring in accordance with the probable etymology of the term (*annus, anulus*).

For rainfall in India, results of some value may be obtained by Mr. Cook's method, because practically the whole of the precipitation takes place during the summer months. Heavy falls at the beginning or end of the year would entirely throw the calculation out, as was shown by Mr. Watt in the issue of April 14. In countries such as England and Scotland, where the rain is fairly evenly distributed throughout the year, the centre of gravity, as determined by Mr. Cook, will nearly always lie between 6 and 7, although its true position may be anywhere from 0 to 12.

If the monthly rainfalls be plotted round a disc arranged like a clock-face, and then the moments be calculated about rectangular axes passing through the centre of the disc, a series of simple calculations gives the true position of the centre of gravity.

It is best defined by means of an angle, α, measured clockwise from XII, and a distance, a, expressed as a fraction of the radius. The latter is a measure of the unevenness of the distribution of the rainfall. If equally distributed throughout the year, $a=0$; if very unequally distributed, a approaches 1. If the angle α be divided by 30°, a figure is obtained corresponding to Mr. Cook's C.G. But as the true position of the monthly rainfall is at the middle and not the end of the month, 0·5 must be deducted from this figure to obtain D, the date in months corresponding to the true centre of gravity. Mr. Cook omitted to make this correction.

In the tables below this method has been applied to two stations in southern India, selected at random:—

Bangalore.

Month	Mean rainfall inches	Moment about horizontal axis	Moment about vertical axis	Moment by Cook's method
I	0·06	0·05	0·03	0·06
II	0·22	0·11	0·19	0·44
III	0·72	0	0·72	2·16
IV	1·19	−0·60	1·03	4·76
V	4·53	−3·92	2·26	22·65
VI	3·13	−3·13	0	18·78
VII	4·13	−3·58	−2·06	28·91
VIII	6·00	−3·00	−5·20	48·00
IX	7·11	0	−7·11	63·99
X	6·74	3·37	−5·84	67·74
XI	2·61	2.26	−1·30	28·71
XII	0·39	0·39	0	4·68
Year	36·83	−8·05	−17·28	290·88
a		0·513		
α		245°		
D		7·67 (August 20)		
"C.G."				7·90
"C.G." corrected				7·40

Kolar.

Month	Mean rainfall inches	Moment about horizontal axis	Moment about vertical axis	Moment by Cook's method
I	0·16	0·14	0·08	0·16
II	0·04	0·02	0·04	0·08
III	0·50	0	0·50	1·50
IV	1·32	−0·66	1·15	5·28
V	3·34	−2·90	1·67	16·70
VI	3·13	−3·13	0	18·78
VII	3·36	−2·91	−1·68	23·52
VIII	4·16	−2·08	−3·61	33·28
IX	5·10	0	−5·10	45·90
X	5·50	2 75	−4·77	55 00
XI	3·17	2·75	−1·58	34·87
XII	0·81	0·81	0	9·72
Year	30·59	−5·21	−13·30	244·79
a		0·467		
α		248°		
D		7·78 (August 23)		
"C.G."				8·00
"C.G." corrected				7·50

It will be seen that the results are not very different from those obtained by Mr. Cook's method, and the difference is constant, at any rate for these two stations (0·28, 0·27). But for English stations very different results would be obtained. The constants have also been calculated for the three imaginary cases suggested by Mr. Watt:—

	A in.	B in.	C in.
I	3	0	12
II	3	0	4
III	3	0	2
IV	3	6	0
V	3	6	0
VI	3	6	0
VII	3	6	0
VIII	3	6	0
IX	3	6	0
X	3	0	2
XI	3	0	4
XII	3	0	12
Year	36	36	36
"C.G."	6·5	6·5	6·5
D	—	6·0	0
a	0	0·644	0·830

It will be seen that D and a, together with the total rainfall for the year, entirely define the distribution, whereas the "C.G." calculated by Mr. Cook's method throws no light upon it.

This method of specific gravities can, of course, be used for other annual statistics, such as barometric pressures and temperatures. In the latter case, the figures for a would depend upon the zero of temperature selected, and would consequently be different for the Centigrade and Fahrenheit scales. It would perhaps be more satisfactory to take the mean annual temperature of the station as zero. The figures for D would not be affected by the choice of scale.

The applicability of the method is not confined to meteorology, but may be used for any phenomenon which varies with the time of the year, *e.g.* vital statistics or railway receipts. A. MARSHALL.

Waverley Cottage, Naini Tal, India, June 14.

Present Meteoric Displays.

THE Perseid shower appears to have come into play rather earlier than usual this year, for I saw four meteors presumably directed from it on the nights of July 11 to 13. These meteors were of the usual streaking class, and formed a radiant at about 16°+50°, which agrees fairly well with the correct place of radiation at the end of the second week in July. This year I found meteors decidedly rare at the epoch named, but the skies were not very favourable, and twilight very strong.

By the time these lines appear in print the moon will only slightly interfere with observation, and a clear sky will show many meteors, for at the end of July the Aquarids, as well as Perseids, are generally plentiful; and there is no danger of confusing the members of the two streams, since their radiants are widely distant from each other. The Aquarids shoot slowly upwards in long flights from a radiant low in the southern sky, while the Perseids are directed in rapid courses from a radiant in the N.N.E.

On July 29–31 an observer may generally expect to see at least twenty meteors per hour, and especially after midnight, when the number visible usually exhibits a very marked increase, the radiants of both the Perseids and Aquarids taking up a more favourable position for the distribution of their meteors as the night advances.

It is to be hoped that all the brighter meteors and bolides will be individually recorded this year. The stars of Draco, Cassiopeia, Cepheus, Andromeda, Pegasus, Cygnus, and other constellations afford a ready guide for the accurate registry of meteor-flights, and such data will possess an enduring value as a means of furthering our knowledge. W. F. DENNING.

Pwdre Ser.

THE following letter, which I received last winter, may possibly throw some light on the questions raised by Prof. Hughes in his paper on "Pwdre Ser" in NATURE of June 23:—

"*Allegheny, December* 4, 1909.

"DEAR PROFESSOR SCHLESINGER,—

"Referring to the falling meteor of which my husband made mention at your lecture last evening, the facts are as follows. One evening some years since my father, Mr. Joel Powers, while walking on Lawrence St., Lowell, Massachusetts, saw a brilliant shooting star or meteor flash downward through the atmosphere, striking the earth quite near him. He found it upon investigation to be a jelly-like mass, and almost intolerably offensive in smell. I have often heard my father allude to this event, which greatly interested him, he being a close observer and an extensive reader.

"Respectfully yours,
"ELLEN M. ADAMS."

While I am of the opinion that the mass found by Mr. Powers had no connection with the meteor that he saw, it may be well to put this piece of evidence on record in view of Prof. Hughes's paper.

FRANK SCHLESINGER.

Allegheny Observatory, July 12.

THE ETHNOLOGY, BOTANY, GEOLOGY, AND METEOROLOGY OF GERMAN AFRICA.[1]

SOME time ago, reviewing a scientific treatise on German South-west Africa and the adjoining regions I ventured to make the remark in this journal that Germany deserved to be allowed to take under her control still more of the undeveloped portions of the earth's surface, provided she continued by the direct action of her Government to enrich the world's store of knowledge as she has been doing with her African and New Guinea researches during the last ten years. The present "Mitteilungen" support this exordium; they are of high scientific value.

There is, firstly, a separate volume by Dr. Weule on his ethnographical observations in the south-east parts of German East Africa. Here, for the modest sum of three shillings (three marks), one gets a splendidly illustrated work of first-rate importance on a section of Bantu Africa. "Ergänzungsheft Nr. 2" is a dissertation by Prof. Dr. Carl Uhlig on the cartography of the German portion of the Rift Valley region of equatorial East Africa, with an appendix on the orthography of place-names in Masailand, &c., by Dr. Bernhard Struck. Part i. of Band xxii. deals with the journeys in 1905–6 of Franz Seiner in the still very little explored country between the Kalahari Desert and the Upper Zambezi (especially the valleys of the Okavango, Kwando, and Omuramba rivers); part ii., with the glaciers of Kilimanjaro, the rainfall and meteorology of the Cameroons and of German South-west Africa; part iii., likewise with the exploration of the upper parts of Kilimanjaro, the rainfall of Togoland, and the geography of Ponape Island; and part iv., with the volcanoes recently active on the Cameroons Mountains, the rainfall and meteorology of the Cameroons and of the Logone River (Shari district), the Paresis Mountains of South-west Africa, and the meteorology of the German possessions in the Pacific. The space, however, which is attributed in this collection to the German oceanic territories is so small that no further allusion to them need be made (other than to praise very cordially the extremely interesting map of Ponape Island in the Carolines Protectorate), and we might proceed at once to discuss the valuable additions to our knowledge of Africa contained in these six sections of the scientific reports attached to the Deutschen Kolonialblatte.

Dr. Weule's work in East African anthropology has already been made known to English readers by Miss Alice Werner in a translation of his more "popular" account of his travels and in various papers in the Journal of the (British) African Society. It was remarked in one or other of these publications that Dr. Weule's work was a little impaired by his apparent unacquaintance with his subject before embarking on this expedition to East Africa. Had he studied more the numerous works in German and in English dealing with the native tribes of the southern portions of German East Africa and of British Nyasaland, he would have avoided a certain *naïveté* of discovering what had already been made known and a few blunders into which he had fallen through a lack of comparative knowledge; also that his orthography of native names was a little old-fashioned (in its German rendering) and divergent from the methods of spelling adopted long ago by German and British philologists and travellers.

These criticisms are less applicable to the volume under notice, "Wissenschaftliche ergebnisse meiner ethnographischen Forschungsreise in den sudösten Deutsch-Ostafrikas"; though the orthography still irritates and the many painstaking quotations of native speech in the dialects of Yao and Makua would have been the better for careful revision with German or British experts. (They tend to incorporate too much the Swahili words of some intervening interpreter.) But the greater part of this book is interesting and valuable to the ethnologist. The illustrations which accompany it are deserving of unstinted praise. Photographically (for the most part) and by clever draughtsmanship, Dr. Weule depicts the physical types of the Wa-mwera, A-makua, Wa-yao, Wa-makonde, Wa-matambwe, and Wa-ngoni peoples of the Ruvuma basin; their costumes, ornaments, and hideous self-inflicted deformities (such as the monstrous "pelele," or lip-disc, worn by nearly all the women in this region); their houses and methods of building; their graves, fetish-huts, granaries, cooking arrangements, doors, wooden locks and keys, pottery-making, metal-work, bark-cloth felting, basket- and mat-making, salt-straining; their weaving of cotton cloth and remarkable wood carving and calabash engraving. Indeed, he reveals a new chapter in negro art by his illustrations of their statues in wood, their clay dolls, their sculptured birds, Rhynchocyon insectivores, pigs, monkeys, and dogs; their most artistic carved snuff-boxes, amulets, powder-boxes, spoons, and stools. (As regards the last it is interesting to note the striking resemblance in shape and design to those of the south-eastern basin of the Congo.) One arises from this survey (and after reading the accompanying text) convinced that with due encouragement some section of the negro race is going to astonish the world yet in design and sculpture.

Then there are the extraordinarily ingenious traps, snares, and pitfalls, all most clearly and yet picturesquely illustrated. Elephants are sometimes killed by the falling of a heavily-weighted harpoon from a lofty tree-branch or scaffold which they release by the displacing of a cord; the larger antelopes similarly discharge arrows or assagais into their own bodies; the smaller quadrupeds dislodge in their passage a heavy beam which falls and crushes them. There are springes and nooses for the capture and strangling of beasts and birds, and cages for catching them alive; rat-traps and hyena-traps. All these display an ingenuity, a neat-handedness, and an unconscious knowledge of dynamics very remarkable in people still living ostensibly as semi-savages. One realises in studying Dr. Weule's work how it was that, although the fossil remains of *Homo primigenius*—and the negro stands higher as a subspecies of *Homo sapiens*—exhibit an osteology approximating slightly to the anthropoid apes, yet the brain capacity of any type of the genus Homo is almost of necessity an average

[1] Mitteilungen aus den Deutschen Schutzgebieten, &c. Ergänzungsheften Nr. 1, pp. x+150+Tafel 63; und 2, pp. iv+63. Heften i. bis iv., Band xxii. Edited by Dr. Freiherr von Danckelmann. (Berlin: Ernst Siegfried Mittler und Sohn, 1909.) Price 3 marks each.

minimum 1100 c.c.[1] to enable anything like a man to compass the degree of thought and reflection necessary to adroit use of implements and the contriving the death or capture of their prey.

Dr. Weule goes very fully into the boy and girl initiation ceremonies among the tribes above-mentioned. He seems to have omitted none of the details of these rites, all of which, whether excessively obscene, prophylactic, or rudely moral, are yet instinct with a certain feeling of natural religion: that is to say, they are performed not for their incidental lubricity but with the intention of making the girls good wives and mothers and the boys vigorous husbands and faithful members of the clan. Still, as regards the young women, native therapeutics[2] are entirely at fault, and the missionaries are quite right in believing and teaching that these "Unyago" ceremonies are in reality detrimental to health and morals.

having long ago named all the leading features of the landscapes, Dr. Bernhard Struck (the well-known philologist) contributes an article on Masai place-names and on the correct orthography of African words. It is, indeed, a pity that all civilised nations cannot agree to adopt a uniform phonetic alphabet for such purposes. Of course, the basis for such a system is best found in the Lepsius standard alphabet, with certain slight changes. As Lepsius was a German, one would think that the Germans would agree with us in adopting his system. But no: there are two schools at present in the Fatherland: one that sticks to the old-fashioned German extravagance in consonants—the *dsch, tsch, ä* for *e*, doubled *s's*, *s* for *z* plan—still used by Dr. Weule; and the over-particular new German linguists and geographers who fatigue and dishearten the average student with their meticulousness in spelling, their accents, diacritical

FIG. 1.—Young Makonde Women. Reproduced from *Mitteilungen aus den deutschen Schutzgebieten*.

The elaborate dances and their meanings, the strange dancing masks, the birth, marriage, death, and burial ceremonies are all described in detail, and a good deal of this information is absolutely new. Altogether Dr. Weule has made an important contribution to our knowledge of the still primitive Bantu tribes of the Ruvuma country, and incidentally has supplied some charming pictures of this great East African river; first studied by Livingstone in the vain hope that it might prove to be a water-route to Central Africa.

Prof. Uhlig's cartographical information on the German end of the Rift Valley is an important addition to our geographical knowledge of this somewhat desolate part of East Africa, a region, however, which is coming into such importance for the salts, phosphates, and sodas of its evaporating lakes that the British are building a branch railway to tap its products from the north. The human population is scanty, and consists mainly of Masai; and the Masai

and elliptical marks, their circumflexes, dots, underlinings, and other cabalistic signs. Why cannot all the world agree to confine itself to such a phonetic alphabet as that adopted and used by the great German explorer in the service of the British Government—Henry Barth? In the humble opinion of the reviewer Barth's system is about perfect in accuracy and simplicity. It is, of course, founded on the alphabet devised by Lepsius.

Another important piece of African research is Herr Seiner's journey of exploration in that still little explored country bounded by the Upper Zambezi on the east, the Kunene River on the north-west, and the Kalahari desert on the south, the region separating the Bechuana peoples from the Herero stock (Ama-herero, Ovambo, &c.), and the Herero from the Zambezian peoples (Ba-luyi, Basubia, Batonga, &c.). The hydrography of this region is still an unsolved problem. There is, first of all, the isolated basin of Lake Etosa in north-east Damaraland; then come the questions of the Ngami-Botletle-Makari-kari system, the real destination of the waters of the immense

[1] The cranial capacity of the Neanderthal skull was about 1500 c.c.
[2] Such as in the artificial hypertrophy of the *labia minora*.

river system of the Kubango (Okavango)-Kuito-Omurambo and Kwando. These rivers discharge the bulk of their waters into the remains of an ancient sea, of which the Haiñoma-Selinda-Mashi swamps, the network of the Tauche streams, Lage Ngami, the Botletle River, and the Makari-kari salt-pans are the vestiges; but by two separate overflows—the Mashi-Linyanti river-swamp and the Tamalakane outlet of Ngami—the surplusage of the Okavango waters (the drainage of eastern Angola) finds its way to the Zambezi above the gorge of Kasungula. But the complete elucidation of this puzzle still awaits the results of an extremely accurate survey in which the most careful attention will be given to questions of level. Did this once huge South-west African freshwater sea, when at its fullest, discharge its waters seawards through the Limpopo; or did it pierce the hills at Kasungula (some distance above the Victoria Falls) and thus united what is now the Upper Zambezi with the Gwai and the Kafue, and so create the Zambezi as we know it to-day? Herr Seiner's journey was singularly interesting because of his careful studies of plant-distribution. In this region meet the desert flora of the Kalahari and South-west Africa, the steppe flora of so much of irregularly watered tropical Africa, and the rich forest and swamp flora of West Africa. Seiner traces the approximate limits of each phytogeographical region: the southernmost boundary of the baobab tree, of the bulging-stemmed Hyphæne palm (*H. ventricosa*), of the high-timber forests of West African affinities, and the thin, low-growing woods of Copaifera and Burkea.

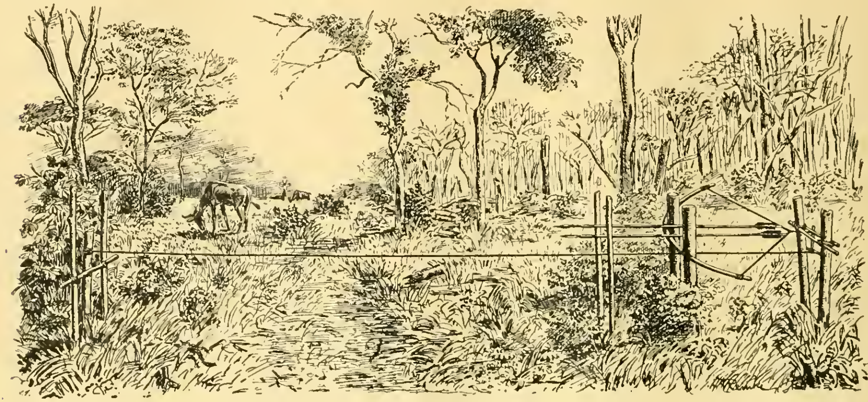

FIG. 2.—Arrows set to be discharged automatically by animals, Usagara. Reproduced from *Mitteilungen aus den deutschen Schutzgebieten.*

Another noteworthy point in this exploration was the additional light it threw on the distribution of the Bushman-Hottentot peoples. It had been known since the journeys of Serpa Pinto that a quasi-Bushman race of red-skinned hunters extended northwards from the Kalahari desert almost to the southwesternmost limits of the Congo basin; but the conclusions of Pinto were rather based on fancied physical resemblances than on language. Dr. Passarge—the German explorer who has made several journeys through the Okavango basin—added to our information, and now Seiner extends our knowledge of these people, speaking click languages, to the Kwando River and almost to the Upper Zambezi. The specimens of Bushman speech collected by Seiner and Passarge enable these travellers to divide the

FIG. 3.—The Kibo Crater of Kilimanjaro. View from the base at a distance of 3932 metres. Reproduced from *Mitteilungen aus den deutschen Schutzgebieten.*

northern Bushmen into two groups—that of the Kaukau of southern Damaraland and that of the Ngami, which would include the click-using peoples as far north as the Kwando River. Between the two groups there is very considerable linguistic difference, though there exist equally undeniable affinities. In Herr Seiner's photographs, however, only two examples of so-called Bushmen are recognisable as such, the remainder (though their language was "Bush") are obviously true negroes, and must be the result of hybrids ancient and modern with the true negro stock, as exemplified by the recent Bantu invaders (Bechuana and Zambezian) and the Berg-Damara. Seiner classifies the Zambezians as "Bantu," and the Bechuana as a class apart. There is no justification for this distinction. The Bechuana tribes are just as much "Bantu" in languages as the Zambezians, though some of them have obviously absorbed a good deal of Bushman blood during the last twelve or fifteen hundred years.

The descriptions and beautiful pictures of the Kilimanjaro glaciers (in parts ii. and iii. of Band xxii.) are of the highest interest; so also are the equally careful, illustrated reports on the "volcanelli" (if one may coin a word to describe the lesser craters which break out on the mass of a huge volcano) of the Cameroons. This article, by Dr. Otto Mann, describes the renewed activities of the Cameroons volcanic mass in 1909. H. H. JOHNSTON.

CORDITE.

THE recent discussion in Parliament on our supplies of cordite and our productive capacity for this type of smokeless powder has naturally directed public attention to these important questions. The production of a smokeless powder was ever the dream of the military strategist, and with the discovery of gun-cotton the conclusion was hastily arrived at that the ideal propellant was found, only to be rudely dissipated by numerous serious disasters. Gun-cotton for many years resisted all attempts to render its combustion sufficiently under control for it to be adopted as a propellant, yet to-day it is the basis of the smokeless powders of all nations. Its early failures were entirely due to the retention in the nitrated cotton of the physical characters of the parent cotton, for even after reduction to an extremely fine state of division during the process of manufacture, the fibrous nature of the cotton persisted. Success has only been attained by the destruction of this fibre, and the smokeless powders of all nations may be classed either as simple gelatinised gun-cottons in which soluble nitrocelluloses have been gelatinised by treatment with an ether-alcohol mixture, or as nitrocellulose-nitroglycerine colloids, in which the nitrocellulose employed may be of the soluble variety, as in ballistite, or the insoluble (true gun-cotton), as in the case of cordite.

The introduction of blasting gelatin by Nobel (1875), consisting of some 90 per cent. nitroglycerine with 10 per cent. of soluble nitrated cotton in a gelatinised form, was the first step towards the production of powders of the cordite type. The high percentage of nitroglycerine rendered blasting gelatin unsuitable for use in guns, but by incorporating the two constituents in equal quantities, Nobel gave to the world the first successful smokeless powder of this class, ballistite. Cordite was the outcome of the work of a committee presided over by the late Sir Frederick Abel, and was patented a year later than ballistite, in 1889. The essential difference between ballistite and cordite is that whilst the former contains soluble nitrocelluloses, cordite contains the insoluble or tri-nitrocellulose. This change in the character of the nitrocellulose employed entailed the introduction of acetone in the manufacture of cordite. Soluble nitrocotton and nitroglycerine can be thoroughly incorporated under proper conditions in the presence of water without the aid of any solvent, but the ingredients of cordite can only become perfectly incorporated in the presence of a mutual solvent. It is essential that the solvent shall be sufficiently volatile to permit of its removal at reasonably low temperatures from the finished powder, and acetone, which boils at 56° C., fulfils all the conditions best.

It is important to note that nitroglycerine is the only explosive containing an excess of oxygen, all nitrocelluloses being theoretically deficient in this element to give complete combustion of carbon to carbon dioxide and hydrogen to water. There are therefore admirable theoretical grounds for the incorporation of these two explosives with each other. The total change in physical characters of both nitroglycerine and nitrocellulose brought about entirely alters the character of their explosion; singly, both constituents are beyond control once combustion is started; gelatinised together, combustion is regularly progressive throughout the mass, an essential condition for a propellant.

The earlier form of cordite consisted of nitroglycerine, 68 per cent.; nitrocellulose, 37 per cent.; vaseline, 5 per cent. It was soon found that serious erosion took place in the guns, and Sir Andrew Noble showed this to be due to the rapid motion of the gaseous products at very high temperature. Since the temperature is a function of the nitroglycerine content, combustion to carbon dioxide taking place to greater extent with its accompanying higher calorific intensity, it followed that reduction of the nitroglycerine would lower the temperature of the products and lessen the erosion. This led to the introduction of modified (M.D.) cordite of the following composition:—Nitroglycerine, 30 per cent.; nitrocellulose, 65 per cent.; vaseline, 5 per cent.—practically a reversal of the former proportions of the chief ingredients. The introduction of the vaseline was made to overcome metallic fouling in the gun, arising from surfaces of metal in practically a clean condition rubbing against each other as the projectile moved outward. The vaseline decomposition products provided just the slight lubrication needed. It has performed another important office, little thought of on its introduction, in acting as a "stabiliser" in the cordite.

In the manufacture of cordite, the gun-cotton employed is thoroughly dried at a temperature of 40° C., and is then mixed by hand with the proper proportion of nitroglycerine, the mixture being finally passed through a sieve. The "paste" obtained is transferred to an incorporating machine of an exactly similar type to that employed in a machine bakery, except that temperature control is arranged for, and there worked into a thorough dough with the requisite quantity of acetone. The first kneading occupies about three and a half hours; then the vaseline is added and a further kneading for a similar period takes place. "Cordite dough," in which every trace of the fibrous character of the gun-cotton has disappeared, results, and this dough is then shaped into the finished threads, cords, or rods by pressure through suitable dies. As the thinner makes pass from the press they are wound on drums, thicker qualities being cut into suitable lengths as they pass out on an endless band. The acetone remaining must now be removed by drying in suitable rooms at a temperature of 110° F. The removal of solvent from the larger sizes of all smokeless powders offers considerable difficulty owing to their horny nature; the odour of acetone is readily detected in freshly ground cordite after long storage.

Naturally the detection of products which may indicate decomposition actually occurring or likely to occur is important, and for this purpose Abel's heat test, first introduced for gun-cotton about 1875, is employed for cordite. The test depends on the liberation of iodine from potassium iodide by the action of nitrogen peroxide, the principal decomposition gas. The ground explosive is heated to 180° F. in a tube, and the time noted for discoloration of the test paper to a certain standard tint. The question at once suggests itself, Does the test show decomposition products which were present in the explosive, or have they resulted from heating during the test, or both conditions acting together? Very divergent opinions are held as to the value of the Abel test as an indication of the stability or "life" of gelatinised explosives. Certainly a powder giving a bad test must be regarded with suspicion, but it is obviously not an easy matter to fix a time limit for a test which is subject to adverse criticism.

One of the most important considerations with any explosive is its stability. The question naturally arises, Is the molecular arrangement in such substances as nitrocellulose and nitroglycerine stable under ordinary conditions of temperature? Their explosive properties depend entirely on molecular rearrangement, which is practically instantaneous when detonation occurs. Certainly slow decomposition occurs in most nitro-compounds of the explosive class at temperatures not greatly above the normal with the production of oxides of nitrogen, and it has been shown that these oxides act catalytically on the explosive; in other words, their effect becomes cumulative and may lead to ignition. In order to avoid this catalytic action, "stabilisers" have been introduced in many explosives, substances capable of absorbing these nitrogen compounds. As already mentioned, the vaseline in cordite appears to perform this useful function.

THE SHEFFIELD MEETING OF THE BRITISH ASSOCIATION.

FOR the last few months the various committees dealing with the local arrangements for the meeting of the association have been hard at work and the general outlines are settled. The hardest task, perhaps, has fallen to the lot of the hospitality committee in finding accommodation for the large number of visitors expected, the city being notorious for its small hotel accommodation. A first list of hotels and lodgings is now ready, and members should lose no time in engaging rooms. To meet the expected demand, the committee has arranged for the two training colleges' hostels for women to receive members, the larger one for gentlemen, with a limited number of married people in an annexe, and the University Hostel for single ladies. The list may be obtained from the secretary of the hospitality committee, Mr. J. Wortley, George Street, Sheffield.

The reception-room will be at the Cutlers' Hall. Here, in addition to the various rooms and offices usually associated with the reception-room, will be a large luncheon-room, giving, close at hand, sufficient accommodation to prevent the pressure and overcrowding so prevalent in many previous meetings. The Cutlers' Hall is conveniently situated in the centre of the city, close to the tram termini, and the various section rooms are grouped round it, all within a radius of 400 yards, with the exception of that of physiology, which, for evident reasons, is better placed in the University. The president's address, and the popular lectures by Prof. Stirling (types of animal movement), Mr. Hogarth (new discoveries about the Hittites), and Mr. C. T. Heycock (the Saturday evening lecture to operatives), will be given in the Victoria Hall.

The first evening reception will be at the Town Hall, by the Lord Mayor and Countess Fitzwilliam. The Weston Park is to be the central scene of the second on Tuesday, September 6, at which about 4,000 guests are expected. The University lies along the east side of this park, and the Mappin Art Gallery is in it on the west. Advantage has been taken of this to have a combined reception by the University and the local committee. The Chancellor and the Duchess of Norfolk will receive one category of guests at the University, and the Earl and Countess Fitzwilliam another in the Art Gallery, but the two will really form a combined conversazione, with an evening garden-party in the park. One of the features of the latter will be a military tattoo with torches after dark. Afternoon garden-parties for the whole association will be given by the Lord Mayor at his seat at Wentworth, and by the local committee in the Botanical Gardens, whilst a number of smaller garden-parties will be given on other days. Arrangements have been made for visits to more than twenty works, covering the chief staple trades of the city. In the University also the various furnaces in the metallurgical department will be run on different days to illustrate that feature in the University curriculum.

Saturday, September 3, will be devoted to excursions to the Derwent Waterworks, to Chatsworth, Welbeck, and Clumber, where members will be entertained respectively by the Dukes of Devonshire, Portland, and Newcastle, also to Haddon, Roche Abbey, and Bolsover Castle. The neighbourhood is so rich in picturesque scenes that there will be ample scope for members to arrange private excursions, such as to the Peak Caverns, the limestone dales, Buxton, Matlock, Wingfield Manor, or even further afield, to York, Lincoln, or Newark Castle, and Southwell Minster.

A local handbook of 500 pages has been compiled under the editorship of Dr. Porter, with the assistance of a large number of local experts, containing a large amount of interesting matter, scientific, historic, and local. During the meeting the University will hold a congregation for the purpose of conferring honorary degrees on the president and other eminent scientific men attending the meeting.

PROVISIONAL PROGRAMMES OF SECTIONS.

SECTION A (MATHEMATICAL AND PHYSICAL SCIENCE).—The address of the president (Prof. E. W. Hobson) will be delivered at 10 a.m. on Thursday, September 1. Two discussions are under arrangement. On Monday, September 5, there will be a joint discussion with Section G on the principles of mechanical flight, to be opened by Prof. G. H. Bryan; and on Tuesday, September 6, Dr. C. Chree will open one on atmospheric electricity. The section will meet with Sections G and B on Friday, September 2, to participate in the discussion on the report of the gaseous explosions committee, and in papers to follow dealing with combustion. Several papers have been already promised to the section, but the programme is still incomplete.

SECTION B (CHEMISTRY).—The feature of the programme is the joint discussions with other sections. These are:—Friday, September 2, with Sections A and G: Subjects of general interest; in particular, combustion. Monday morning, September 5, with Sections I and K: Respiration; afternoon, with Section L: The neglect of science by commerce and industry. Reports will be presented by Prof. W. A. Bone, on combustion; Dr. J. V. Eyre, on solubility.

Papers on a fourth recalescence in steel, Prof. Arnold; the provident use of coal, Prof. H. E. Armstrong; influence of chemical composition and thermal treatment on the properties of steels, Prof. A. McWilliam; ferro-silicon, Dr. S. Monckton Copeman; corrosion of iron and steel, Dr. J. N. Friend; the crystalline structure of iron at high temperatures, Dr. Rosenhain; allotropy or transmutation? Prof. Howe; the molecular weight of radium emanation, Sir Wm. Ramsay and Mr. R. W. Gray. Papers from the Sheffield University Chemical Department: Formation of tolane derivatives from *o*- and *p*-chlorobenzylchloride, Dr. J. Kenner and E. Whitham; sulphonic derivatives of chloro- and nitrochlorotoluene, Dr. J. Kenner and Prof. W. P. Wynne; an instance illustrating the relative instabilities of the trimethylene ring as compared with the tetramethylene ring, Dr. J. F. Thorpe; three physical chemical papers dealing with viscosity and molecular association, W. E. S. Turner (in conjunction with C. L. Peddle and E. W. Merry).

Agricultural Subsection of Section B: Sugar beet growing, Sigmund Stein and G. L. Courthope, M.P.; nitrogen fixation, Prof. Bottomley and J. Golding; various: cost of a day's horse labour, A. D. Hall; cost of Danish dairy farming, Christopher Turnour; effect of town atmosphere on vegetation, Dr. Crowther; scientific problems in live stock breeding, K. J. J. Mackenzie. Joint meetings (1) with Economic and Statistical Section: The magnitude of error in agricultural experiments; scientific method in experimental work, Prof. H. E. Armstrong; experimental error in feeding trials, T. B. Wood and A. B. Bruce; experimental error in field trials, A. D. Hall and E. J. Russell; experimental error in milk analysis, S. H. Collins; experimental error in plant analysis, R. H. Berry; (2) with the Geological Section, *Soil Surveys (Agricultural)*: Survey of Kent, Surrey, and Sussex, A. D. Hall and E. J. Russell; survey of Norfolk, Mr. Newman; "Teart" land of Somerset, C. T. Gimingham; (3) with the Zoological Section: Part played by organisms other than bacteria in soil fertility, E. J. Russell and H. B. Hutchinson.

Section C (Geology).—Thursday, September 1, 10.0: The Joredale Series and its equivalents elsewhere, Cosmo Johns; the Palæozoic rocks of Cautley (Sedbergh), Dr. J. E. Marr and W. G. Fearnsides; the graptolitic zones of the Salopian rocks of the Cautley (Sedbergh) area, Miss O. R. Watney and Miss E. G. Welch; pleochroic halos, Prof. J. Joly. 11.30: Presidential address by Dr. A. P. Coleman; mountain temperatures and radium, Dr. C. H. Lees; outlines of the geology of northern Nigeria, F. D. Falconer; notes on the geology of the Gold Coast, W. Parkinson; the geological significance of the nickel-iron meteorites, Cosmo Johns. Friday, September 2, 10.0: Joint meeting with Section E (Geography): (1) Papers on local geography and geology, (*a*) the local geology, Cosmo Johns; (*b*) the local geography; (*c*) the marine bands in coal measures of south Yorkshire, H. Culpin; (*d*) the Maltby deep boring, W. H. Dyson. (2) Joint discussion on the economic products of Sheffield as affected by the structure of the district. Paper by Prof. McWilliam on the metallurgical industries in relation to the rocks of the district. (3) Regional surveys. Paper by T. Sheppard on the Humber during the human period. Monday, September 5, 10.0: Seismological report by Dr. J. Milne; thrust masses in the western districts of the Dolomites, by Mrs. W. M. Ogilvie-Gordon; on the geology of Cyrenaica, Prof. J. W. Gregory; on the geology of Natal, Dr. F. H. Hatch. 12.0: Joint discussion with subsection Agriculture on soil surveys. Tuesday, September 6, 10.0: Discussion on the concealed coalfield of Notts, Derbyshire, and Yorks. Papers by Prof. P. F. Kendall and Dr. Walcot Gibson; two papers by Ernest Dixon; (1) Kilauea and its lessons, (2) some volcanic phenomena in New Zealand, Dr. Tempest Anderson.

Section D (Zoology).—Address by the president, Prof. G. C. Bourne; mitokinetism and the electrocolloid hypothesis, Prof. Marcus Hartog; semination in *Calidris armarica*: a key to some problems regarding its migratory movements during the breeding season, Prof. C. J. Patten; some experiments and observations on the colours of insect larvæ, Prof. Garstang; a cytological study of artificial parthenogenesis, Dr. Edward Hindle; avian coccidiosis, Dr. H. B. Fantham; relation of regenerative and developmental processes, Dr. Jenkinson; first results from the Oxford anthropometrical laboratory, Dr. E. H. J. Schuster; development of the pectoral girdle in *Acanthias vulgaris*, Dr. H. W. Marett Tims; a paper dealing with some sex problems, Geoffrey Smith; Dr. Gadow will give the afternoon lecture on coral snakes and peacocks.

Section E (Geography). Presidential address, Prof. A. J. Herbertson; cotton-growing within the British Empire, J. Howard Reed; the Uganda-Congo Boundary Survey, Major R. G. T. Bright; the river systems of Nigeria, Dr. J. W. Falconer; the alluvium of the Nile, Capt. Lyons; the homeward voyage of the *Nimrod*, Capt. J. K. Davis; Prince Charles Foreland, Dr. W. S. Bruce; the geology and metallurgical industries of the Sheffield district, joint meeting with Section C.

Section G (Engineering). Presidential address, Prof. W. E. Dalby: (1) the testing of lathe tool steels, (2) a new method of testing the cutting quality of files, Prof. Ripper; experiments on aëroplanes, W. A. Scoble; accelerometers, H. S. Wimperis; optical determination of stress, Prof. Coker; laws of electro-mechanics, Prof. S. P. Thompson; the electrification of the Brighton Railway, Philip Dawson; heat insulation, F. Bacon; report of the gaseous explosions committee; joint discussion on combustion with Section B (Chemistry); joint discussion on aërial flight with Section A (Mathematics and Physics).

Section I (Physiology).—Thursday, September 1: Presidential address, Prof. A. B. Macallum; the mechanism of reflex standing and walking, Prof. C. S. Sherrington. Friday, September 2: Discussion on prevention of caisson disease, to be opened by Dr. Leonard Hill. Monday, September 5: Joint discussion with Sections of Botany and Chemistry on biochemistry of respiration. Tuesday, September 6: Joint discussion with Section of Education on speech. There will be the usual reports of committees, and the following papers have been promised:—The relation of light perception to colour perception, Dr. Edridge Green; the combination of poisons with the contractile substance of cardiac muscle, Dr. H. M. Vernon; (1) the inorganic composition of the blood of vertebrates and invertebrates and its origin, (2) the inorganic composition of the blood serum of the laboratory frog in spring, (3) further observations on the localisation of potassium salts in animal and vegetable cells, Prof. A. B. Macallum.

Section K (Botany).—A joint discussion between the Botanical, Chemical, and Physiological Sections, on the biochemistry of respiration, Dr. F. F. Blackman and others to take part; a new method of estimating the opening of stomata, Dr. F. Darwin; the paths of translocation of sugars from green leaves, S. Mangham; (1) two synthetic genera of Filicales, (2) note on *Ophioglossum palmatum*, Prof. Bower; the pollen chambers of fossil and recent seeds, Prof. F. W. Oliver; the morphology of the ovules in Gnetum and

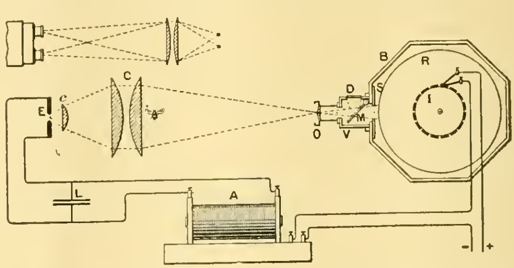
Welwitschia, Mrs. Thoday; further observations on the fossil flower, Dr. M. C. Stopes; chromosome reduction in the Hymenomycetes, Harold Wager; the sexuality of *Polystigma rubrum*, Prof. V. H. Blackman; telophases and prophases in Galtonia, Prof. Farmer and Miss Digby; a cytological paper, Dr. H. C. J. Fraser; the zoospores and trumpet-hyphæ of the Laminariaceæ, Dr. Lloyd Williams; plant distribution in the woods of north-east Kent, M. Wilson; the absorption of water by leguminous seeds, A. S. Horne. Papers are also expected by Prof. F. E. Weiss and others. The semi-popular lecture will be given this year by Prof. F. O. Bower; subject, sand dunes and golf links.

SECTION L (EDUCATIONAL SCIENCE).—The president for the meeting is Principal H. A. Miers, and his presidential address will be delivered on Thursday morning, September 1. It is intended to give up the whole of Friday, September 2, to the subject of educational research, and the meeting will be a joint one with the Anthropological Section. Prof. J. A. Green, of Sheffield, the secretary of a committee which has been investigating the mental and physical factors involved in education, will present a report on the present position of educational research at home and abroad. Dr. Gray will also present a report on behalf of a committee of the Anthropological Section on methods of observing and measuring mental characters. It is hoped that Prof. Münsterberg, of Harvard, will open the discussion, which promises to be an important one. Dr. Lucy H. Ernst, Prof. Lippmann, of Berlin, Dr. Kerr, the principal medical officer of the London County Council, and several members of his staff, Prof. C. S. Myers, Dr. T. P. Nunn, and Dr. Rivers, of Cambridge, amongst others, have signified their intention to take part, and reports will be presented, by the investigators, of serial observations on school children and others which have been conducted in London, Liverpool, Sheffield, Wolverhampton, and elsewhere. On Monday morning, September 5, Mr. J. G. Legge, Director of Education in Liverpool, will open a discussion on handwork and science in elementary schools. On Monday afternoon there will be a joint discussion with the Chemistry Section on the neglect of science in commerce and industry. Mr. R. Blair, the Education Officer of the London County Council, will open the discussion, and Prof. Bovey, Principal E. H. Griffiths, Sir William Tilden, and others have promised to take part. On Tuesday morning, September 6, the subject of open-air studies in schools of normal type will be taken up. There will be papers by Mr. J. E. Feasey, of Sheffield, Mr. G. G. Lewis, of Kentish Town, and Prof. Mark R. Wright, of Newcastle-on-Tyne, will read a paper on a training college under canvas. On Tuesday afternoon a joint meeting will be held with the Physiological Section for the discussion of voice production. Dr. A. A. Gray, Mr. H. H. Hulbert, Principal Burrell, of Isleworth, Prof. Wesley Mills, Mr. W. H. Griffiths, and others, will contribute papers.

THE ULTRA-RAPID KINEMATOGRAPH.

A RECENT number of *La Nature* (April 30) contains a very interesting account of the latest work of the Marey Institute. By means of the new instrument, the ultra-rapid kinematograph invented by M. Bull, sharp stereoscopic kinematograph views may be obtained of such extremely rapid movements as, for instance, the flight of a fly or the breaking of a soap bubble. With the ordinary kinematograph the photographic film moves discontinuously, being arrested at the moment of each exposure. While this is simple enough at moderate speeds, it would be quite impossible where the exposures are at the rate of 2000 a second, and the mean speed of the film 4000 cm. a second. These are the figures that are necessary for the study of insect flight, and these are attained in the new instrument. With such a speed the movement of the film must be continuous, and a sharp image is possible only if the exposure does not exceed 1/400,000 second, and for this the electric spark gives a light of sufficiently short duration.

The apparatus is shown diagrammatically in the figure. R is a wheel 34·5 centimetres in diameter, which may be turned at a high speed by means of an electric motor. It carries two long strips of photographic film to receive the stereoscopic images. On the same axis, but outside the octagonal light-proof case, is fastened an interrupter, I, of fifty-four strips of copper, which serve to make and break the primary circuit of an induction coil fifty-four times every turn, or 2000 times a second. The secondary of the induction coil is connected with a pair of spark-gaps, E, arranged in series, the electrodes being of magnesium to increase the light. The arrangement of the two gaps and their relation to the optical system are shown in plan (but reversed, left for right) in the upper left-hand corner of the figure. A condenser, L, is connected to the wires leading to the spark-gaps. The optical system is made clear by the figure, but the lenses are made of quartz and Iceland spar instead of glass, so as to be transparent to the actinic rays of short wavelength for which glass is opaque. A mirror, M, throws the pair of images on a ground-glass screen, D, or, on being turned up out of the way, it leaves a clear passage for them to be formed on the films. In order to prevent the photographs from being spoilt by multiple exposure, two shutters of thin steel, actuated by springs, are released electromagnetically one after the other, the interval being the duration of one turn of the wheel.



The movements photographed are determined as to time by fine wire prolongations of the prongs of a tuning-fork of 50 ~ a second, which are photographed at each successive exposure, and as to distance by a divided glass scale, which equally appears in every picture. It is, of course, necessary to ensure that the fly or other insect shall traverse the field of view just at the time that exposure is made. There is no difficulty in causing the creature to fly in the right direction, as a window is sufficient to determine the line of flight. One method by which M. Bull releases the fly at the right moment is by holding it in electromagnetically-operated forceps, which are relaxed by the same current which starts the first shutter. This works well enough with ordinary flies, but hymenoptera and some other insects hesitate and only make their flight after the exposure is completed. For such cases, M. Bull encloses them in a glass tube with a very light mica door, which is moved by the insect in its flight, and which, making a contact, sets the shutter mechanism in action.

In order to study the movements represented on the films, which in nature are far too rapid to be followed by the eye, it is merely necessary to pass them through an ordinary kinematograph, making some fifteen exposures a second instead of the 1500 or 2000 a second employed in taking the photograph, and then the movement, 100 or more times as slow, will be seen, and in many cases easily followed. Where a still greater slowing is required, M. Bull arranges to make the film appear stationary for a much larger proportion of the whole interval than is usual, and then only two or three views a second are sufficient to give an apparently continuous movement. C. V. BOYS.

THE TOTAL SOLAR ECLIPSE, MAY 9, 1910.

THE following two communications from Port Davey, dated May 7 and 9 respectively, complete the account of Mr. McClean's expedition to Tasmania. In spite of the trying weather conditions, a very complete installation of instruments was successfully erected, but, as previously reported, clouds prevented their use during the eclipse.

The photographs accompanying the report were taken by Mr. H. Winkelmann, and the three here reproduced have been selected to illustrate the setting up of some of the instruments.

Port Davey, May 7, 1910.

"The weather since April 27 was execrable until May 4, and was not good until the following afternoon. Continuous gales, heavy rains, and floods made progress absolutely impossible, and no trustworthy tests were made before May 4. The ground became a quagmire, and the instruments were covered with rust, in spite of paraffin and oil. Rain got into the concave grating slide-holder, and the cloth began to peel off. The cœlostat mirror was badly discoloured, in spite of coverings of Japara and Willesden canvas. The siderostat mirror was also permanently fogged and slightly spotted, and in the morning, on uncovering (when possible), was covered with moisture. In addition to this, the ground shook at every footstep, and everything vibrated. The barricades proved very useful in protecting the instruments from the wind, which was so strong that during the gusts it was impossible to walk against it. On several days no coverings could be taken off, and work was at a standstill. The *Wainui*, which came in on May 1, had to take refuge in Schooner Cove on the other side of the Bathurst Channel until the following day. Our boat, which had to go over to pick up Mr. Short, from Sydney, and his instruments, could not get back, and we had to cross behind Mundy Island and land : mile across country from our camp, leaving the boat in a cove until the next day.

"On May 4, however, there were a few intervals of sunshine during the afternoon, and on May 5 the afternoon was fairly bright after a drizzling morning, while May 5 was cloudless and with a gentle breeze from the east, and much progress was made. The instruments fed by the siderostat were in accurate position, and some trial photographs were taken with the concave grating spectrograph which on development proved to be good in every way.

"Mr. Short, who arrived on May 1, has decided to feed his five-foot camera from an auxiliary mirror from the siderostat, as, with the wind that is likely to occur, it would not be steady on the equatorial mount, and on this mount have been placed his telephoto and Worthington's camera, as the latter could not be run correctly with his clock.

"Considerable difficulty had been found in driving the siderostat after about 3.15 in the afternoon, and a device had been put up to help the mirror cell arm round after that time. Owing to bad weather, no complete examination had been possible until May 7, when the mirror and cell were removed, and it was found that one of the balance-arm bearings had not sufficient play to allow the rollers to continue in contact with the cell. Filing down was tried, but there was not sufficient material to do this fully, and so the bearing was reversed. This gave considerable improvement, but before the time at which eclipse would occur it was found that the rollers reached

FIG. 1.—Beginning the erection of the instruments on Hixson Point.
Figures from left to right—J. Brooks, F. K. McClean, A. Young, S. Dowsett.

the end of their slot, and greater power was required to drive them up the slope. Having no tools for continuing this groove, arrangements were made for a weight to be attached upwards to the cell arm, and this was found to answer; but considerable dangers of irregular drive are present in this method. An attempt was made to work the slow motions from the concave grating spectrograph, but, owing to the distance, no good results were obtained, and Mr. Dowsett was therefore placed in charge of the siderostat to follow instructions from the spectrograph, where the large image on the slit gives a quick idea of any movement either in right ascension or declination.

"Drills commenced on May 6 both separately and generally. The allocation of the instruments to the members of the party has been arranged as follows:—

Siderostat ... ... S. G. Dowsett

Instruments fed by siderostat.

Concave grating spectrograph ...	F. K. McClean
De la Rue coronagraph	A. Wilson
Short 5-ft. ,, ...	J. Short

Instruments fed by cœlostat.

16-ft. coronagraph	J. Brooks
42-in. spectrograph	H. Winkelmann
Telephoto	H. Winkelmann
Steward (dismounted)	E. Jeffs

FIG. 2.—Setting up the 21-inch Siderostat

Equatorial.

Short's equatorial mount carrying telephoto & Worthington camera and	J. Worthington
Time caller	A. Young

"Owing to the resilient nature of the ground, it was found advisable not to allow anyone to move about, and shutters were fitted to the 16-foot and De la Rue coronagraphs, which could be worked from the dark-slide ends. Winkelmann, who has two instruments in his charge, has only a step or two to make, and it is impossible to prevent him moving. In the following programme for the eclipse, the times mentioned are standard time (ten hours east), as given by Dr. A. M. W. Downing, F.R.S., and also local time at Pyramid Rock in the entrance to Port Davey, which is long. 145° 55′ E. and lat. 43° 22′ S. As the position of the observatory is long. 146° E. and lat. 43° 20′ S., the eclipse will start a little later, and finish a trifle earlier. The time was again checked on May 6 by Messrs. Brooks and Young, and the chronometer error found."

(Here follows a large table showing the exposures to be made in the various instruments. This is omitted here.)

"*Port Davey, May* 9, 1910.

"Rain commenced on the afternoon of May 8, and continued steadily all through May 9. No drills were possible. On the night of May 8 the dark slides were filled, and all were taken up to the observatory on the Monday afternoon, and, in spite of the rain, the instruments were made ready; but exposures were limited to one slide, which was opened at 5 seconds and closed at 200. There was a tremendous downpour during the eclipse, but it cleared a little afterwards. During totality there was a stretch of bright sky on the western horizon, and soon after sunset the clouds dispersed and a bright, starry night followed.

"Immediately after eclipse the barricades were pulled down and the ground prepared for the final packing."

Since the receipt of the above communications both Mr. McClean and Mr. Young have arrived home. They have both suffered from the effects of the hard work and inclement weather, and the former is still in the doctor's hands. While Mr. McClean has had considerable experience in roughing it, he describes his recent work in Tasmania as the most trying that he has yet had to contend with. Nevertheless, his keenness for eclipse work is by no means damped, for he is now looking forward to the eclipse of next year, which will be visible from islands in the Pacific Ocean, and is already commencing arrangements to observe it.

WILLIAM J. S. LOCKYER.

JOHN B. CARRUTHERS.

WE regret to have to record the death, at the early age of forty-one, of Mr. J. B. Carruthers, assistant director of agriculture in Trinidad. Mr. Carruthers only took up his new appointment last autumn, and with characteristic enthusiasm entered at once very energetically upon the task of making himself familiar with his fresh surroundings. The possibilities of rubber cultivation was the principal subject to occupy his attention, and to this end he visited most of the chief estates in Trinidad. Thence

FIG. 3.—Adjusting the Cœlostat.
J. Brooks on the left, F. K. McClean on the right.

he proceeded to Tobago—the dependency of the larger island—and here prosecuted his work under very adverse climatic conditions, with the result that on returning to Trinidad he was prostrated with a severe attack of malaria. After some four weeks' illness complications ensued, and he passed away on Sunday, July 17, from septic pneumonia following an operation.

John Bennett Carruthers, born in 1869, was the younger son of Mr. William Carruthers, F.R.S., until recently the keeper of the Botanical Department of the British Museum. He was educated at Dulwich College, the Royal School of Mines, and Griefswald University, Prussia. During this period appeared his first botanical contribution, "The Cystocarps of Some Species of Callophyllis and Rhodymenia" (Journal Linn. Soc., xxix., 77–86), and "The Canker of the Larch" (Journal Roy. Agr. Soc., 1891, Ser. iii., vol. ii.). A period as demonstrator in biology at the Royal Veterinary College, London, was followed by his appointment as professor of botany at Downton College, Wilts. Soon, however, he transferred his energies to the tropics, where his chief work was done.

In 1898 Carruthers went out under the joint auspices of the Ceylon Government and the Planters' Association to investigate a disease of cacao-trees. He proved successful, not only in ascertaining the cause of the disease, but in the frequently more difficult task of finding an effective remedy practicable under estate conditions. His successful work was recognised by his appointment in 1900 as mycologist to the Government of Ceylon and assistant director of the Royal Botanic Gardens.

In these days, when we regard a mycologist as necessary to any well-equipped agricultural department, it may come to many as a surprise that Carruthers's appointment, only ten years ago, was the first of its kind. He worked in Ceylon for five years, and in 1905 took up the directorship of the newly-formed Department of Agriculture for the Federated Malay States. Here he remained until he was invited to fill the Trinidad position, where it was expected that his special knowledge of cacao rubber and plant sanitation would prove of great value. These hopes have unfortunately been frustrated by his untimely death, but in the short space of time which intervened he initiated several important projects, and so recently as May contributed two papers to the Brussels International Congress on Tropical Agriculture and Colonial Development, whilst an account of rubber in Trinidad appears in the last issue of the *Trinidad Agricultural Bulletin*, of which he was joint editor.

Carruthers possessed the happy gift of "getting on well" with people, and officials and planters in many parts of the world, the members of the Royal Society of Edinburgh, the Linnean Society, the Association of Economic Biologists, the West India Committee, and a wide circle of friends unite in regretting his loss.

NOTES.

SIR E. RAY LANKESTER has been elected a foreign associate of the Paris Academy of Sciences in succession to the late Prof. Robert Koch.

THE following men of science have been elected foreign members of the Royal Society:—Dr. Svante Arrhenius, Dr. Jean Baptiste Édouard Bornet, Dr. Paul Ehrlich, Prof. Vito Volterra, and Dr. August Weismann.

A REUTER telegram from Wellington states that a new crater is in eruption near the dormant geyser of Waimangu (Rotorua), and is ejecting mud and pieces of rock. Its proximity to the volcano of Tarawera renders the outbreak significant.

MR. JOHN RAMSBOTTOM has been appointed an assistant in the Department of Botany, British Museum. Mr. Ramsbottom was lately exhibitioner of Emmanuel College, Cambridge, and Robert Platt biological research scholar, Victoria University, Manchester. He will devote himself to the fungi.

IN the course of a reply to a question asked in the House of Commons on Monday with reference to the Advisory Committee on Aërial Navigation, Mr. Asquith said that a further report of the committee will be laid before Parliament within a few days. Captain Murray Sueter, R.N., representing the Admiralty, and Mr. Mervyn O'Gorman, superintendent of the Balloon Factory, have been appointed additional members of the committee. The total approximate cost of the committee to the present date is 10,000*l*.

THE property in the centre of the Cheddar Cliffs, on which the quarry occurs that has caused much disfigurement to the gorge, has been purchased by the National Trust. Certain existing contracts, which expire in 1912, will be performed exclusively from the loose stone lying fallen in the quarry. No further blasting will take place. The National Trust hopes that by the purchase of this property the cliffs have been secured from all danger of further spoliation. The immediate and pressing danger to the finest part of the gorge arising from the vibration caused by blasting has now been stopped.

ACCORDING to a communication from Mr. J. T. Jenkins, published in the *Field* of July 23, there is reason to believe that the fur-seals on the Pribilov and other islands of the North Pacific are in imminent danger, if not of extermination, at all events of being so reduced in numbers as to be no longer of any commercial value. It will be remembered that the Anglo-American Commission of 1896 insisted upon the repression of pelagic sealing, and it was eventually agreed that, while this was to be absolutely prohibited to Americans, it would be permitted to British subjects only outside a sixty-mile limit from the Pribilovs. The Japanese were, however, no party to the arbitration by which this was arranged at Paris, and their vessels have for the last few years been actively engaged in pelagic sealing around the Pribilovs immediately outside the three-mile limit. In 1907 Canadians had fifteen vessels engaged in pelagic sealing, which took 5240 skins, while in 1908 there were eight vessels, which secured 4452 skins. On the other hand, the Japanese had thirty-six vessels in 1907 and thirty-eight in 1908, of which the respective takes were 9000 and 13,197. If the latter rate of killing be continued—especially when it is recalled that the great majority of seals killed in the open sea are females—it will not be many years before the herds will be practically annihilated. The case is one where international action is urgently demanded, and that at an early date.

AN article upon the character of King Edward VII. in the current number of the *Quarterly Review* gives much interesting information upon the early life and training of the late King. Queen Victoria and the Prince Consort appear to have considered the minutest details of the physical, intellectual, and moral training of their son, who was to become our King. The German blood and upbringing of the Prince Consort led him to attach great importance to thoroughness of educational training, while letters and notes "record the Queen's anxious solicitude that no boyish longing for excitement should interfere with the Prince's 'adherence to and perseverance in the plan both of studies and life' laid down by his father." Every hour of the young Prince's time was mapped out by his governors and preceptors; and it is not surprising that under this high-pressure system, and without the stimulus of competition, the Royal pupil did not reach the lofty standard always before the mind of the Prince Consort. Every book was placed before the boy as a task, and the subjects in which he received instruction appear to have been presented in their driest form. Had more reasonable educational methods been adopted, and the Prince's individuality been considered instead of making it subservient to scholastic ideas, there would have been no occasion for the expressions of disappointment at his want of studious reflection. He was an acute observer, and could learn better from things than words. Even in his early days his teacher said of him that he was "learning almost unconsciously from objective teaching much which, I think, could never have been taught him subjectively"; and this capacity was his characteristic through life. While at Edinburgh as a lad of eighteen, he attended Lord Playfair's lectures on the composition and working of iron ores, and he never altogether forgot them. "They imparted to him a certain liking for practical science and its votaries which he never wholly lost." His interests were practical rather than academic, and his brilliant success as Prince of Wales and King was achieved not so much by his studies with tutors as in spite of them.

We regret to announce the death of Mr. J. Ellard Gore, the well-known amateur astronomer, who did much to popularise astronomical science. While in the Public Works Department in the Punjab, he interested himself in scientific studies, and the result was the publication of "Southern Stellar Objects" (1877). From that date he was a voluminous writer on the descriptive side of astronomy, and his works have been welcomed on account of the general accuracy of his facts and the enthusiasm which his writings inspired. On double stars, variables, and planetary markings he was regarded as an authority. One of his noteworthy works was his share in the volume of astronomy which he wrote in the "Concise Knowledge" series in collaboration with Prof. Fowler and the late Miss Clerke. He was also well known for his translations of several of Flammarion's works.

The processes of pottery-making as it appears in prehistoric interments in Europe is well illustrated by two contributions in *Man* for July, in which Mr. N. W. Thomas and Capt. A. J. N. Tremearne describe the methods in vogue in South and North Nigeria respectively. In neither district is the wheel used, the vessel being built up out of flattened ribbons of soft clay over the neck and shoulders of an old broken pot. Capt. Tremearne heard of, but did not witness, a still ruder method, in which the clay is shaped for the body of the pot in a hole in the ground, the upper portion being subsequently added in the way already described.

Much discussion has arisen regarding the date of the narrow cultivation terraces known in England as lynchets, and some authorities, like Dr. Mackintosh and others, have gone so far as to deny that they are artificial, asserting that they are merely natural raised beaches. Their contiguity to Neolithic and Bronze-age camps certainly lends much support to the view that they represent a form of prehistoric agriculture. Mr. W. A. Dutt, in *Man* for July, quotes an account of similar constructions in Abyssinia from Capt. Stigand's "To Abyssinia through an Unknown Land." The close analogies presented by these to the English examples are clearly in favour of the view that they are the work of a primitive race.

An interesting phase of lacustrine culture is described in a monograph by Mr. S. A. Barnett, on the Klamath Lake and Modoc Indians of north-west California and southern Oregon, contributed to vol. v. of the Memoirs issued by the University of California. This specialised culture is largely based upon the use of the tule reed for hut-building, basketry, and other purposes. Their food is procured from the lakes on the shores of which they dwell, and for this purpose they use a peculiar duck arrow, fishing and bird nets, hooks of bone, and dug-out canoes. Stone implements, such as mullers, mortars and pestles, or mauls, are in common use. But many of these are relics of earlier Indian tribes, and their gradual disappearance before a culture based upon the use of metals is shown by the fact that they are now largely used as charms in medicine and gambling. A man, for instance, will take a large obsidian knife or spear-point, and, after reciting a charm, will place it under the mat on which a game is being played to ensure good luck. Fire is procured with a drill consisting of a piece of dry willow root twirled in a base block of cedar wood, for which purpose the canoe paddle is very commonly used.

Under the editorship of Messrs. W. M. Webb and E. S. Grew, *Knowledge* is much improved in general appearance, and, if we may judge from the July number, in the character of its contents. In one of the articles, the Rev. T. R. R. Stebbing urges that the gender of all generic names in zoology should be regarded as masculine, mainly on account of the difficulty of deciding as to the true gender of many of the terms now in use.

We have been favoured with a copy of the report of the Danish Oceanographic Expedition during the winter of 1908–9, under Dr. J. Schmidt, published in *Geografisk Tidskrift* (20, B.H. vi., 1910, pp. 243–55). The area surveyed extends from Iceland through the North Sea on the one hand, and along the eastern border of the Atlantic on the other, into the Mediterranean as far east as Greece. The report is illustrated with bathymetric tables of temperature and salinity in different parts of the area, and likewise with a chart of the isotherms and "isohalines" on the two sides of Gibraltar. The dissimilarity between the distribution of isothermal and isohalic areas in the latter region is very striking and curious.

Determinate evolution in the colour-pattern of "lady-beetles" forms the subject of an elaborately illustrated memoir by Mr. R. H. Johnson, published by the Carnegie Institution of Washington (Publication No. 122). Ladybirds, to give these beetles their ordinary name, were selected for the purpose of this investigation on account of their abundance, the facility with which they can be reared in confinement, their distribution, and the circumstance that they were recently, and perhaps still are, in an active state of evolution. Members of the leaf-eating epilachnine group were chosen for special study as being easier to rear than the aphid-eating forms. As regards the object of the colouring of the Coccinellidæ, the author accepts the view that it belongs to the warning, or aposematic, type. No single pattern can at present be recognised as forming the ancestral type, and it is evident that Eimer's laws of pattern-development are inapplicable to the present case. "Natural selection, if at all active, is principally conservative of the spotted pattern. In spite of this, determinate variation, largely actuated by the effect of the environment on the germ-plasm, and probably preponderance as well, have accomplished marked evolution of the pattern from this condition. Evolution proceeds by waves as well as by even flow and by mutation in different characteristics at different times."

IN the *Scientific American* of July 2, Mr. W. L. Beasley describes, with large-size illustrations, the method employed in the American Museum of Natural History, New York, of mounting the skins of large mammals on specially prepared models, or "manikins," which in some cases are based on clay statuettes of living specimens. After being roughly modelled, the manikins are carefully finished by artists, and the skins fitted upon them, the method being illustrated in the case of an East African zebra, or bonte-quagga, and a hippopotamus. The article specially relates to the collection of large mammals obtained by the expedition to East Africa under Mr. Roosevelt. The director of the museum, Dr. Bumpus, has planned a comprehensive and striking exhibition of African mammals, to be, in due course, displayed in the buildings under his charge. The main part of this exhibit is destined to be shown in a series of new halls about to be added to the west wing of the museum, but some specimens will be used to fill gaps in the existing series. The cost of the additions to the building is to be defrayed by Mr. Samuel Thorne, who has already done much for the museum. Unless funds are forthcoming for the addition of a new north-west wing to our own Natural History Museum, that institution will be altogether beaten by New York in the show of big-game animals.

THE July number of the *Selborne Magazine*, with which *Nature Notes* is now incorporated, contains an abbreviated report of the lecture delivered by Mr. J. Buckland on June 17, at the annual meeting of the Selborne Society, on the traffic in feathers and the need for legislation in connection with the same. To the same issue Mr. Buckland communicates an illustrated article on illegal practices in the feather-trade, dealing especially with India. It is pointed out that, in 1903, the Indian Government prohibited the exportation of the skins and feathers of birds, except those of domesticated species and ostriches, together with natural-history specimens. This prohibition, according to the author, is, however, to a great extent evaded by feathers being shipped as cow-hair, horse-hair, or silk material. One such consignment of "cow-hair" was opened by the custom-house officers at the London Docks in 1908, and found to contain more than 6000 paraquet-skins; but as these were not contraband, they were, after some delay, handed over to the consignee. Further investigation proved that, during a previous period of eight weeks, no fewer than twenty-three cases of bird-skins had been landed in London under false declarations. The author sums up as follows:—"A vast number of the feathers which are used in the millinery trade in Great Britain are able to be brought into her ports only by means of false declarations, which are a direct evasion of the law, and which declarations are made deliberately for the purpose of deceiving ship captains and the customs authorities of the countries from which the feathers are shipped."

THE fourth part of Bulletin No. 82 of the Entomological Bureau of the U.S. Department of Agriculture is devoted to an account, by Mr. W. B. Parker, of the life-history and the means of controlling the hop flea-beetle (*Psylliodes punctulata*), which has of late years done much damage to hops in British Columbia. The species, which is widely distributed over the northern United States, and ranges into southern Canada, normally feeds on rhubarb, sugar-beet, and a few other plants, and was not known as a serious pest until a few years ago, when it began to devastate the hop-gardens in certain parts of British Columbia. When hop-cultivation commenced in the Chilliwack Valley in 1894, the beetle was noticed, but did little harm until 1903, when it appeared in force. From 1904 until 1908 the numbers of these insects gradually increased, attaining their maximum in the year last named. "As soon as the hops began pushing through the ground, the beetles were observed swarming around the vines, giving the soil in the immediate vicinity a black metallic appearance. These swarms of flea-beetles devoured the hop-shoots as fast as they appeared, and in places where the vines were a foot or more on the string the attack was so severe that in a few days the field looked as if it had been burned. The infestation resulted in a loss of about 75 per cent. of the crop."

THEORIES of life we have in plenty; it is somewhat a novelty to come across a pamphlet in which we have a theory of death propounded ("Das Altern und der physiologische Tod." By M. Mühlmann. Published by G. Fischer, Jena. Price 1.20 marks). The occurrence of physiological death is comparatively rare; most human beings die of accident, under which term disease is, of course, included; very few pass unscathed from such accidents, and die of simple old age, a gradual slowing down and final stoppage of life's machinery. But when it does occur, Dr. Mühlmann's theory is that it is due primarily to changes in the nerve cells, and that the run-down of the other organs is produced secondarily by changes in the ruling system of the body, the nervous system. Moreover, this degenerative change, which becomes evident to the microscope as a formation of pigmentary and lipoid granules, begins quite early in life; from one point of view, therefore, it is a form of growth which produces death, and considerable importance is laid by the author upon granules in cells as an essential protoplasmic constituent. The *brochure* contains many interesting data, such as the rate of growth of the different organs in various periods of life, and this, together with his views on the phenomena of regeneration, will amply repay careful perusal.

A NUMBER of the *Bulletin du Jardin Impérial Botanique*, St. Petersburg (vol. ix., part ii.), is devoted to a paper on lichens by Mr. A. N. Danilov, in which he adduces morphological evidence opposed to the theory of a mutually advantageous symbiotic union of alga and fungus. In the summary the author states that his results confirm the evidence of Peirce and Schneider with regard to the close investment of the algal gonidia with a net of hyphal threads, and the complete absorption of the contents of the gonidial cells.

ARISING out of a demand from members of the Manchester Microscopical Society for specimens illustrative of marine zoology, a quarterly publication, the *Micrologist*, has been initiated by Messrs. Flatters, Milborne, and McKechnie, of Manchester, which will contain directions for manipulations of such specimens, and thereby take the place of instructions that would otherwise be required. The specimens will be issued quarterly with the journal, and mounted preparations will also be available for purchase.

A NEW volume—the fifth—of the Circulars of the Royal Botanic Gardens, Ceylon, opens with a report on the tea plots at the Peradeniya experiment station, and subsequent numbers deal with "Rubber in the Early Days" and a visit to a rubber factory. In the last named, Dr. J. C. Willis gives an account of a visit to the large factory in Hanover. With regard to the tea experiments, the chief point is the proved value of green manuring, for which purpose *Erythrina spp.* (Dadap) and *Crotalaria striata* were found to be most suitable.

The exhibition at Shepherd's Bush has naturally created an interest in the methods and craft of "Japanese gardens." Judging from an illustrated article in the July number of *Irish Gardening*, a typical and most successful example of such a garden has been laid out at the Tully nurseries, Kildare, which to those interested would certainly repay a visit. It is explained that such gardens are purely pleasure resorts, and therefore the practice displayed therein is entirely distinct from the methods adopted in ordinary and agricultural gardens, in which the Japanese are fully alive to the value of intensive cultivation.

The first three numbers of the current volume of the Bulletin of the American Geographical Society contain a detailed examination of trade routes in the economic geography of Bolivia, by Prof. Isaiah Bowman. The author deals at length with the resources and population of Bolivia in relation to the natural features of the country, and concludes that, in spite of the fact that 90 per cent. of Bolivia drains to the Atlantic and 10 per cent. is interior basin drainage with no outlet whatever to the Pacific, nevertheless, geographical position and the distribution of resources and climate are here equally powerful factors with topography. The Atlantic slope, and not the Pacific slope, is, and will long remain, the back door to Bolivia; for the section of the country in which the population is found looks to the Pacific, and the first essential of all the trade routes is a short line to the coast.

Mr. W. Joerg examines the present state of our knowledge of the tectonic lines of the northern part of the Cordillera of North America in a paper published in the Bulletin of the American Geographical Society (p. 161). Basing his discussion chiefly on the summary contained in the final volume of Suess's "Antlitz der Erde," the author suggests the recognition of the Alaskides, as a separate province of major rank, as a subdivision of the Cordillera. This would give three divisions: the northern Cordillera or Alaskides, the central Cordillera, and the southern Cordillera or Lower California and the Mexican Highland. The boundary between the first and second would be the zone of coalescence, and between the second and third the depression along Salton Sink, the Gila, and the Rio Grande.

The director-general of Indian observatories has issued a memorandum, dated June 9, on the meteorological conditions prevailing before the south-west monsoon of 1910 (June to early October). Dr. Walker has pointed out that the rainfall in India brought by this monsoon is apparently affected by previous conditions over a large part of the earth's surface, and that it is only when these are strongly favourable or otherwise that a definite forecast is justified. One of the many favourable signs is, as a rule, the prevalence of high barometric pressure in South America and of low pressure in the Indian Ocean prior to the period of the monsoon. At Buenos Aires pressure was in excess in March, April, and May last, but in the Indian Ocean conditions appeared to have been, on the whole, slightly unfavourable. From these and other factors specified in the memorandum the inferences drawn are that there appears to be no cause for expecting a large excess or defect in the total amount of monsoon rainfall. The rains are likely to be less steady than usual, especially those due to the Arabian Sea current. Rainfall due to the Bay current is likely to be, on the whole, more plentiful by comparison with the normal than that due to the Arabian Sea current.

At the international meteorological conference at Innsbruck (September, 1905) Prof. Hellmann stated that the important question of the comparison of the barometers of the various meteorological institutes had engaged the attention of several conferences, but had not been solved in a satisfactory manner. Dr. Köppen also pointed out that so long as the differences between barometric standards are unknown, discontinuities arise when isobars are drawn for large areas. The conference finally arranged that the necessary work involved by such comparisons should be subdivided among the chief institutes, and the result of the part undertaken by the Prussian Meteorological Office is contained in one of the useful papers by Dr. Hellmann in the report of that institute for 1909. The comparisons of the standards at the central offices of the various German and some foreign systems show that at some stations (especially Potsdam and Zürich) the barometers agreed closely with the Berlin instrument, while others showed ± differences of appreciable amount, the greatest being 0·246 mm. (nearly 0·01 inch). The larger differences are thought to be due to the mercury having become unclean; at all events, the results have justified the expense and care bestowed upon the somewhat laborious work.

We have received separate copies of several papers by Prof. S. Lussana, of the University of Siena, which have appeared recently in *Il Nuovo Cimento*. One of them deals with the coefficients of compressibility and of dilatation with temperature of certain pure metals and alloys. The coefficients were measured by means of a dilatometer containing the material enclosed in a metal case. The change of volume was measured by the change of resistance of a platinum wire in the capillary tube of the dilatometer as mercury was forced along the tube by the contraction of the material. The values obtained allow the difference between the specific heats at constant pressure and temperature, respectively, to be calculated. For pure metals the difference increases as the temperature rises, but for alloys it in general decreases. In nearly all cases it decreases with increase of pressure. The bearing of Prof. Lussana's work on the improvement which has been introduced into the law of Dulong and Petit by the substitution by Prof. Richarz of the specific heat at constant volume for that at constant pressure will be obvious to our readers.

In an article on the renewal of sulphated storage cells, reproduced from the *Electrical World* in the *Electrical Review* for July 1, Mr. J. O. Hamilton describes a method of dealing with such cells which has proved very successful at the Kansas State College. If on test the efficiency of a cell sinks to 50 per cent. or lower, the plates are removed and washed thoroughly with distilled water. They are then placed in a cell containing a 2 to 5 per cent. solution of caustic soda in water, and the charging current sent through the cell in the usual way. If the sulphate on the positive plate does not disappear in the time of the ordinary charge, and the solution gives an acid reaction with litmus paper, more caustic soda must be added to the solution, and the charging continued until the plate has the usual chocolate appearance. The plates should then be removed from the soda solution, well washed, replaced in the sulphuric acid solution, and the charging continued until gassing begins. Many cells have had their efficiencies raised from 25 to 75 per cent. by six hours' charge, and Mr. Hamilton considers that any cell which will still hold together will well repay treatment by this method.

Terrestrial Magnetism and Atmospheric Electricity for June contains an article by Dr. L. A. Bauer and Mr. W. J. Peters in which the complete magnetic results of the first cruise of the *Carnegie* are given. After an extensive series of tests of the vessel at Long Island, it was found that a determination of any magnetic element could be made on it with an absolute accuracy not far behind that attained by experienced observers on land. This conclusion was confirmed by further observations made at Falmouth at the end of the trip across the Atlantic. The observations made at sea show that the present charts of the Atlantic require revision, as they show compass variations which are in many cases more than 1° in error, and in some cases more than 2°. These errors appear to have been introduced by the application of a correction for secular variation at points at which no determinations of that quantity had been made. A further paper by Mr. E. Kidson deals with the observations of electrical conductivity and of radio-activity of the atmosphere made during the cruise. The conductivity was determined by means of a Gerdien apparatus, and always proved low in the neighbourhood of land, and persistently higher for positive than for negative electricity. At night the conductivity appears to be nearly constant, and about double what it is during the day. It will be seen that these observations are likely to render some modifications of the current theories of atmospheric electricity necessary. The radio-activity was determined by the negatively charged exposed wire method, the decay of activity of the wire being observed by means of an electroscope. It appears to be due to radium emanation and to be derived from the land.

A "SHORT History of the Academy of Natural Sciences of Philadelphia" has been prepared by Dr. Edward J. Nolan, recording secretary and librarian, and published by the academy. This sketch of the academy's activities is to be regarded as preliminary merely to a detailed history to be issued in connection with the proposed celebration of the centenary of the academy in 1912. The academy accomplishes its work in four departments—the library, the museum, the publication office, and the department of instruction and lectures. The library, exclusively for reference, now contains about 60,000 volumes, almost entirely on the natural sciences; in many respects it is the most important collection of the kind in America. It is claimed for the academy's museum that it is one of the most important in existence. The vertebrate animals number about 130,000 specimens, 12,000 being mammals, 60,000 birds, 20,000 reptiles, and 40,000 fishes. The insects are estimated at nearly 400,000 specimens, and the shells at a million and one-half. There are in the cases 50,000 specimens of fossils, 30,000 minerals, 20,000 pieces of archæological material, and more than 600,000 preparations of dried plants. The remaining departments are equally extensive and enterprising. The academy has twice received appropriations from the State legislature, 4000*l.* in 1905 and 30,000*l.* in 1908.

A VALUABLE supplement to the meteorological observations undertaken by the University, Manchester, has been described by Messrs. Hayhurst and Pring under the title "Examination of the Atmosphere at Various Altitudes for Oxides of Nitrogen and Ozone," in the Journal of the Chemical Society. Previous estimates of the amount of ozone have ranged from 0·01 to 31·6 milligrams per cubic metre for the minimum quantity found, and from 0·03 to 158·0 for the maximum quantity, figures which appear to indicate a range of experimental error in the ratio of 3000 to 1. The very high values found by several observers are no doubt due to the catalytic action of oxides of nitrogen upon potassium iodide solutions exposed to air, whereby a mere trace of oxide may act as a "carrier" of oxygen to an indefinitely large quantity of iodide; the similar action of sunlight in promoting oxidation of the iodide is also important as a further source of error. In the experiments now described, air was blown through bulbs containing potassium iodide either at ground-level or attached to kites or balloons; the bulbs were protected from light, and the presence of ozone was inferred, not from the mere liberation of iodine, but from the production of alkali and iodate. When this criterion was employed, it was found that whilst oxides of nitrogen were present in variable proportions, the amount of ozone at ground-level and at altitudes up to 8000 feet was less than 0·003 mg. in 1 to 10 cubic metres, or less than 1 part by volume in 4,000,000,000 parts of air. At very high altitudes, up to ten miles, small amounts of ozone were detected, the quantity found averaging 0·04 milligram in 0·1 to 0·3 cubic metre of air, or 1 part in 3,000,000 to 9,000,000 by volume. These experiments are of value as showing that the presence and merits of ozone in the fresh air of sea and country are as much a matter of fiction as the substantial excess of oxygen which was discovered by over-zealous investigators prior to the researches of Cavendish; in fact, the only method of enjoying the effects of atmospheric ozone appears to be by ascending in a free balloon, which bursts and descends as a parachute after rising to a height of several miles.

COMMENTING on the Bournemouth Aviation Meeting, *Engineering* for July 22 remarks that perhaps the most interesting feature of the meeting from the technical point of view is the fact that all the best performances were done with aëroplanes fitted with the Gnome rotary engine. In fact, it seemed as if no machine which was not fitted with this engine had any chance of success. All engines of other types appeared to give trouble, and not to be able to furnish the desired power for any long time at a stretch. In some cases the trouble was hot bearings, especially big ends. In others the engine appeared simply not to be able to maintain its power, and, after flying a short distance, it could not sustain the machine in the air. The performances of the English engines were disappointing.

A NEW book by Dr. Berry Hart, of Edinburgh, entitled "Some Phases of Evolution and Heredity," will be issued very shortly by Messrs. Rebman, Ltd.

WE have received from Messrs. Friedlaender, 11 Karlstrasse, Berlin, a copy of the third part of a catalogue of entomological books and papers, this being devoted to Lepidoptera; also a catalogue of books on natural history, sports, travel, &c., offered by Mr. B. H. Blackwell, 50 Broad Street, Oxford.

MESSRS. SWAN SONNENSCHEIN AND CO., LTD., will issue shortly a companion volume to Dr. Theal's "History of South Africa," to be entitled "The Yellow and Dark Skinned People of Africa." This will contain a summary of all that is included in Dr. Theal's "History and Ethnography of South Africa" (3 vols.), and is especially intended for the use of ethnographical students.

THE latest addition to the series of "Savants du Jour," published by M. Gauthier-Villars, of Paris, deals with the life and work of Prof. Émile Picard, of the University of Paris. Prof. Picard was born in Paris on July 24, 1856, and his biography, as here written by M. Ernest Lebon, shows a growing regard from his school-days for algebra and mathematical analysis, which eventually led in 1897 to his appointment to the chair in these subjects in the University of Paris. The list of Prof. Picard's works and papers on mathematical subjects occupies a very large part of the memoir, which also contains an appreciation of his work by Prof. Henri Poincaré, delivered in 1888 in presenting him with the grand prize of the Paris Academy of Sciences for Mathematical Science.

The first issue of a new annual, entitled "The Green Book of London Society," has been received. Its subtitle describes the volume as a directory of the Court, of society, and of the political and official world, including celebrities in art, literature, science, and sport, with many other subjects of current interest. The editors of the compilation are Mr. Douglas Sladen, who, it will be remembered, compiled "Who's Who," and Mr. W. Wigmore. Under science are given lists of some men of distinguished eminence in the London scientific world, with the researches and discoveries which have made them famous; the most important scientific and engineering institutions; and some of the chief scientific periodicals. The book runs to 487 pages, and is published by Messrs. J. Whitaker and Sons, Ltd., at 5s. net.

The sixth edition, revised, of Dr. Bernard Dyer's small handbook on "Fertilisers and Feeding Stuffs: their Properties and Uses," has just been published by Messrs. Crosby Lockwood and Son, price one shilling net. Short descriptions have been added of the two new fertilisers—nitrate of lime and calcium cyanamide—in which atmospheric nitrogen is fixed, but the practical disadvantages of their use are pointed out. Of the former Dr. Dyer remarks:—"It has a serious practical disadvantage in its deliquescent property, which makes it necessary to sow it immediately the air-tight packages in which it is sent out are opened, and it cannot be conveniently sown in moist weather." Calcium cyanamide is also unpleasant to sow. Dr. Dyer's book is a manual from which practical farmers can obtain many useful hints as to profitable procedure in fertilising the soil for different crops and feeding the stock. The text of the Act of 1906, referring to fertilisers and feeding stuffs, is printed in full, together with the regulations of the Board of Agriculture and Fisheries for the protection of farmers from the supply of adulterated materials.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in August:—

Aug. 2. 11h. 18m. Moon in conjunction with Venus. (Venus 4° 8′ S.).

8. 9h. 11m. Minimum of Algol (β Persei).

9. 6h. 26m. Moon in conjunction with Jupiter 2° 34′ S.

10. 12h. 46m. Venus and Neptune in conjunction. Venus 0° 27′ N.

11—13. Maximum of August Perseid display. Radiant 44 + 57°.

14. Venus. Illuminated portion of disc = 0·889.

16. Saturn. Major axis of outer ring = 43·21″. Minor axis = 13·51″.

25. 5h. 46m. Moon in conjunction with Saturn. Saturn 1° 18′ S.

27. 14h 11m. to 14h. 54m. Moon occults τ Tauri. (Mag. 4·3).

28. 10h. 53m. Minimum of Algol (β Persei).

30. 11h. Mercury at greatest elongation, E. 27°.

Subjective Phenomena on Mars.—In No. 4427 of the *Astronomische Nachrichten* M. Antoniadi returns to the discussion of the objective reality of the dark band seen circling the Martian snowcap. He previously directed attention to the fact that this band was not visible on photographs of the planet, and suggested that its appearance during visual observations was simply an effect of contrast. This argument was weakened by the possibility of photographic "spreading" in the sensitive film being sufficient to account for the obliteration of the dark band. But M. Antoniadi now points out that on the photographs taken with yellow screens during the last opposition, the caps are no more intense than the "continental" areas, and from this he suggests that "spreading" is negligible. Yet the dark band is not to be found on these photographs, and therefore, if the premises are true, it appears that its visibility in visual observations is only a subjective phenomenon.

The Genesis of Various Lunar Features.—In the *Comptes rendus*, No. 2 (July 11), M. Puiseux discusses the probable origins of the circles and of the angular outlines of lunar crevasses shown in the polar regions of the moon on the concluding sheets of the great photographic atlas of the moon published by the Paris Observatory. He points out that many of the circles appear in chains, of two or more, parallel or perpendicular to the meridian. Where two of these circles intersect, the point of junction is marked by a small crater or a considerable elevation, and M. Puiseux believes that this is evidence against Faye's theory that the *bourrelets* were formed by repeated periodic overflowings which filled in the circle. Such differences of level as are now revealed would be incompatible with this theory. On the same plate (lxvi.) is seen a number of circles aligned on, or across, a meridian, and joined by a high, narrow ridge, and M. Puiseux considers that these are evidence against the meteoric bombardment theory.

Near the northern pole the geometrical contours of circles are exceptional, and angular features predominate. The ridges here are found to be in echelon, and M. Puiseux considers that the sharp angles were formed where previous ejecta prevented the eruptions from following the general line of weakness to which, however, the subsequent eruptions returned, thus producing the echelon form.

Halley's Comet.—A preliminary account of the observations made by an expedition which journeyed to the Pic du Midi to observe Halley's comet is given in No. 2 of the *Comptes rendus* (July 11) by MM. G. Millochau and H. Godard.

Arrangements were made to photograph, regularly, the comet and its spectrum, but they were sadly interfered with by bad weather. No spectrograms were secured, but several good photographs were taken with a Zeiss "astroplanar" lens having a large field. The photograph secured on May 29 showed a bright condensation, detached from the nucleus, which at 2° from the head became broader, and was prolonged some 8° into the tail. The photograph of May 31 shows a secondary nucleus at a distance of 17″ from the primary.

A long summary of the numerous observations made at different places during the passage of the comet is published in the July number of the *Bulletin de la Société astronomique de France*, and is illustrated by a number of drawings and photographs.

The Gnomon in Ancient Astronomy.—All who are interested in the early days of astronomical observation will find an article by M. Jules Sagaret, published in No. 17 of the *Revue scientifique*, full of interest. M. Sagaret discusses at length the *rôle* played by the gnomon in the observations made by the ancient Chinese, Babylonians, Egyptians, &c., for the determination of time and season, especially of the solstices, and shows that in a vertical bamboo rod the Chinese of about the second century B.C. found a, comparatively, very effective astronomical instrument.

The Leeds Astronomical Society.—The Journal and Transactions of the Leeds Astronomical Society for 1909 (No. 17) shows that this society is endeavouring to popularise the study of astronomy with its wonted vigour. In addition to numerous interesting papers read by members at the meetings of the society, there are a number of reprints of popular articles contributed to various publications. Among these are articles on current phenomena contributed by Messrs. Whitmell, Scriven Bolton, and Ellison Hawks, and a series of articles by Mr. Elgie which appeared in *T.P.'s Weekly* over the pseudonym "F.R.A.S."

RECENT WORK OF GEOLOGICAL SURVEYS.[1]

IV.—THE UNITED STATES.

THE United States Geological Survey frequently assists research by publications in which definite subjects are dealt with from a comprehensive point of view. The Bibliography of North American Geology for 1906 and 1907 was issued in 1909. A bibliography of Archæan and Algonkian geology, divided up under the various States, is given in Bulletin 360 (pp. 940, 1909), in which Messrs. Van Hise and Leith review the pre-Cambrian geology of North America. As the title shows, Canada is included, and the summaries given of published work make this volume welcome in every library of scientific reference. Bulletin 364 (1909) is by Messrs. Darton and Siebenthal on the Laramie basin in south-eastern Wyoming. The name Casper formation is proposed (p. 13) for Carboniferous limestones and sandstones resting on pre-Cambrian rocks on both sides of the Laramie Range. The Laramie beds, over which much discussion has arisen, may be represented by the highest sandstones and shales of the Cretaceous Montana series, and an unconformity, now widely recognised, occurs between this series and the Cainozoic beds (pp. 35 and 43). The Laramie question, it may be observed, has been recently discussed by Mr. Whitman Cross (Proc. Washington Acad. Sci., vol. xi., 1909, p. 27), who proposes the name Shoshone Group for the beds elsewhere styled Laramie, but lying above the unconformity. The coloured geological map in the memoir, and the illustrations, show well the character of the broad valley of the Laramie, with its floor 7000 feet or more above the sea, and gneissic hills rising some 3000 feet higher on the east and west (Fig. 1). Interesting contrasts are afforded in a great variety of strata, especially where Oligocene sands form level ground in hollows of the Archæan rocks of the Laramie range.

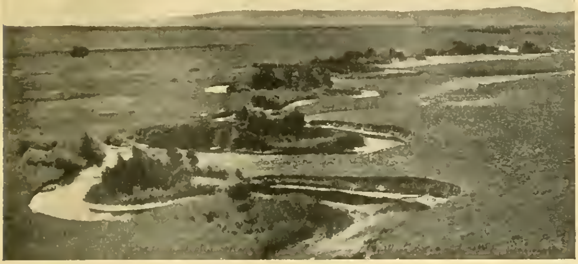

FIG. 1.—Alluvial flat of Rock Creek Valley, Laramie Basin, looking towards the Pre-Cambrian hills.

Mr. D. F. MacDonald, in Bulletin 384, carries us up to the old rocks of the Canadian border in the extreme north of Idaho, where a large series of strata exist that are presumably of pre-Cambrian age. Mr. J. S. Diller (Bulletin 353) describes the Taylorsville region at the north end of the Sierra Nevada in California, and to the south-east of the great cone of Shasta. Compression of the Jurassic and older sediments occurred here in early Cretaceous times; the present Sierra region began to rise, and the Great Basin slipped away from it along faults (p. 108). Though the sea, as happened in so many other areas, returned during the Upper Cretaceous epoch, it did not dominate the new mountains; soon after, it became excluded altogether. Elevation continued in the Eocene, and gold-bearing gravels streamed down until the end of the Pliocene, when great warping took place, accompanied by faulting. Hence (p. 110) interesting changes in the drainage-lines occurred, and old valley-floors are traceable that undulate up and down, with bulges rising 1000 feet high across the former courses of the streams. In describing the volcanic rocks, which are of various ages, from Silurian to Pliocene, the author uses the terms meta-rhyolite and meta-andesite for types much altered from their original condition (p. 81). The famous Lassen Peak volcano lies a little outside the area now described.

Mr. W. T. Lee (Bulletin 352) has explored a part of western Arizona, where the Colorado River emerges from the Grand Canyon and runs southward, forming the State boundary. Fine examples of consolidated, and probably Quaternary, conglomerates and gravels, weathered out into huge bluffs, are given in the plates. The author describes the erosion of valleys that went on in Cainozoic time (p. 58), accompanied by faulting; then followed the great uplift of the plateau, and renewed excavation by the streams, the Colorado being now driven to carve out the Grand Canyon. The gravel deposits in the broad Detrital-Sacramento valley to the south are 2000 feet thick, and are believed to have been deposited after the erosion of the canyon. The obstacle that checked the southward flow of the river down this valley may have been a barrier of comparatively modern basalt, and the formation of a nearly flat cone of deposition above it allowed the river to wander westward and to start new excavation along its present course (p. 65). During this next epoch the alluvial conglomerates were eroded into their present fantastic outlines (Fig. 2). The history of the southern valleys, here somewhat modestly presented, must clearly be taken into consideration when we review that of the more famous plateau-region to the north. The coloured geological map, inserted, according to the present useful practice, in the memoir, enables one to follow the arguments, as well as the travels, of the author. It will be noted that the excavation of the Grand Canyon is here transferred from Cainozoic to early Quaternary times.

FIG. 2.—Bluff of eroded Quaternary Conglomerate, mouth of the Virgin River, Arizona.

Mr. Lee also describes the "Manzano Group" of marine red sediments in the Rio Grande Valley of New Mexico (Bulletin 389, 1909). Mr. G. H. Girty deals with the palæontology of these strata, which are now ascribed to the Upper Carboniferous (p. 38). Red beds were deposited in the Rocky Mountain region from Lower Carboniferous to Jurassic times. There seems here a suggestion of the continuity of the bright colour conditions that influence tropical and semi-tropical strata at the present day. The

[1] Continued from vol. lxxxiii., p. 234, April 21.

fauna includes numerous new species, and a new molluscan genus, Manzanella, allied to Nucula, is established (p. 75). The stratigraphical simplicity introduced by this systematic piece of work may be realised from the previous reference of the beds to Permian, Triassic, and Jurassic series (p. 11).

Mr. L. M. Prindle's account of part of the Yukon-Tanana region in Alaska, extending nearly to the Arctic Circle (Bulletin 375, 1909), is interesting for comparison with Canadian work, and has also an economic value. The lignites of the "Kenai formation" are placed, with other "Arctic Miocene" deposits, in the Eocene (p. 26). Our old friend *Corylus MacQuarrii* appears in the flora, which may, of course, prove ultimately to be Oligocene.

Professional Paper 61 (1909), by Mr. W. W. Atwood, describes the glacial history of the Uinta and Wasatch Mountains, which lie to the east of the now desiccated area of the Great Salt Lake of Utah. Here "it is certain that there were at least two ice epochs separated by a long interglacial interval" (p. 92). Lake Bonneville sediments rest upon the earlier drift, and are overlain by the later drift, and support is given to Gilbert's conclusion that "the inter-Bonneville epoch of low water was of greater duration than the time that has elapsed since the final desiccation." The correlation of glacial advance with lake-extension is interesting in connection with the association by Messrs. Davis and Huntington of pluvial flood-gravels in Central Asia with the growth of ice upon the highlands. Mr. Lee, in his Arizona bulletin, referred to above, seeks to connect epochs of erosion in the Colorado basin with those of high water in Lake Bonneville, so that we may now realise a good deal of "the face of the earth" as it appeared soon after Pliocene times, from the Wyoming border down to the Gulf of California.

Mr. G. H. Girty's memoir on the fauna of the Caney shale of Oklahoma, in which cephalopods are prominent (Bulletin 377, 1909), will interest students of Carboniferous zoning. Professional Paper 58 (1908), a quarto of 652 pages, is by the same author, on the Guadalupian fauna of New Mexico. The Guadalupe mountains are formed of marine limestones and sandstones, the Capitan Limestone in the upper part yielding a scarp reminding one of Tyrol. A large Fusulina, *F. elongata*, is abundant in the higher beds. The fauna as a whole furnishes a localised type (p. 28), and differs from the Upper Carboniferous and Permian faunas of the eastern and most of the western States, while it is younger than beds styled Permian in Kansas. The Guadalupian series is compared most nearly with the Fusulina Limestone of Palermo (pp. 35 and 50), and it is urged that the beds may possibly be younger than the European Permian, although truly of Palæozoic age. New genera of lithistid sponges and calcisponges are described. Attention is especially directed to the bryozoan species grouped under Domopora, as indicating Mesozoic affinities, and throughout the memoir discussions arise which must be considered by workers on Permo-Carboniferous horizons. In Professional Paper 59 (1909) Mr. W. H. Dall describes the Miocene of Astoria and Coos Bay, Oregon, including some Oligocene forms from the Aturia beds. Reprints of rare papers on Cainozoic strata of the Pacific coast are usefully given as appendices. Mr. True (p. 143) contributes an account of the Miocene sea-lion, *Pontolis magnus*, which has interesting alliances with *Eumetopias jubata*, still living in the district. The plates of fossils are of exceptional beauty, and include whorl-like groups of a singularly large Crepidula.

The Survey has also issued numerous bulletins on economic geology, among which may be mentioned those on the granites of Massachusetts, New Hampshire, and Rhode Island (No. 354); on the Great Falls Coal Field of Montana (No. 356), where the Carboniferous strata contain gypsum and the Lower Cretaceous sandstones contain valuable seams of coal; on the Book Cliffs Coal Field of Colorado and Utah (No. 371), where the coal is in the higher beds of the Upper Cretaceous; on the iron ores of southern Utah (No. 338), where igneous intrusions have introduced iron salts into limestone, and where the petrographic observations of the geological surveyor (p. 86) have a special bearing on future exploration; and on magnesite in California (No. 355), from which it appears that this mineral is in special demand for refractory bricks and for the production of carbon dioxide, the residue being more valuable than lime. Bulletins 328, 335, 337, and 345 deal with mineral resources in Alaska. In the first of these (p. 151) the famous beach-placers of Nome are described, which were practically exhausted, with great profit, in two years. In No. 335 the level Bering Glacier, a companion of the Malaspina, and also in part forest-clad, is described and illustrated (p. 46). No. 337, by Mr. Prindle, should be read in connection with No. 375, by the same author, noticed above. Professional Paper 62 (1908), by Messrs. Ransome and Calkins, describes the ore deposits of the Cœur d'Alène district, Idaho. The post-Glacial gravels (p. 77) are in this case referred to the epoch of the dwindling and recession of the ice, which was here localised in cirques and valleys. Lead, silver, zinc, copper, and gold are worked, and the district produces more lead than any other in the United States. The labour-wars in the district, waged with dynamite and rifles, show that the difficulties have not been all due to geological structure. The rich lead-silver ores, ranging through 4000 feet of contorted Algonkian rock, are believed to represent emanations from a great batholite (p. 137), which is represented by its uppermost intrusions (monzonite) at various points.

The papers on water-supply issued by the United States Survey are well known by their brown covers, and usually contain matter of geological as well as of economic importance. Two of them have been recently noticed in NATURE (vol. lxxxii., p. 379). No. 223 (1909), by Mr. F. G. Clapp, on the underground waters of S. Maine, includes a coloured geological map and useful illustrations of joint-structures in granite, diorite, and slate. In No. 221 (1909) Mr. C. A. Fisher describes the Great Falls region of Montana, where the Missouri is still fresh and vigorous, and liable to considerable additions when the snow melts off the mountains to the west. The destruction of forests by fire on these high slopes has further increased the risks of flooding. The copious water-supply is now being utilised for a system of irrigation-canals in the somewhat arid plains to eastward. In No. 220 (1908) Mr. G. A. Waring records a piece of pioneer work in southern Oregon, where no good topographical map previously existed. The country reminds us of N.W. Europe in Triassic days, with its large shallow lakes, liable to dry up at times, and at others to extend their boundaries, so as to find outlets and swell the diminished streams. Goose Lake has thus been known to flow over southward into Pit River. It receives, in all probability, a considerable supply from subterranean sources (p. 42). The problem of the region, of course, lies in the alkali-lands, where sodium chloride, sulphate, and carbonate may be brought to the surface during irrigation, the carbonate being much the most injurious. Sodium carbonate not only blackens the surface of stems and roots just below the surface, whence its name "black alkali," but also deflocculates the soil. References are, of course, made to the bulletins issued by the U.S. Department of Agriculture, and this memoir shows a promising correlation between the work of the Geological Survey and of the Bureau of Soils.

No. 225 (1909), by Mr. W. C. Mendenhall, continues the history of the Salton Sea, from its disastrous formation by the drawing in of the Colorado River in 1905 (see NATURE, vol. lxxv., p. 501) to the closing of the gap by the energy of the Southern Pacific Railroad early in 1907. If the work holds, it is estimated (p. 40) that the great lake will have disappeared by evaporation in 1925, to the detriment of the users of ground-waters in the valley to the north-west. This valley, and the Colorado Desert generally, were once occupied by the head of the Gulf of California. The surface of the Salton Sea had fallen to 200 feet below sea-level early in 1907. A remarkable water-line, 40 feet above sea-level, is traceable round the bluffs, and is attributed (p. 18) to an important predecessor of the Salton Sea, formed before the Colorado took up its present course across its delta (Fig. 3). In this rainless region it is estimated that such indications, often accompanied by deposits of calcium carbonate, have lasted through a thousand years. The same author describes, in Paper 222 (1908), the conditions of the San Joaquin Valley, California, and urges the importance of small farming with individual hard work, as carried out by the Italian immigrants, in opposition to the characteristically American "desire to get rich overnight, to control large holdings, and to avoid personal labour." The warning is also true in regard to English agriculturists in South Africa, and may in time become applicable even to the enormous prairie-lands of Canada.

The Geological Survey of New Jersey, in its annual report for 1908 (1909), records its continued cooperation with the Survey of the United States. In a paper on the building-stones of New Jersey, the rocks are excellently illustrated by coloured photographs of polished surfaces, as well as by views of the buildings constructed from them.

FIG. 3.—Old water-line above west side of the present Salton Sea, California.

The annual report of the Iowa Geological Survey for 1908 has been received in 1910, and is mainly occupied (pp. 21–687) by a comprehensive series of papers on the coal-deposits of the State. The peat bogs and their flora are described in the concluding papers.

G. A. J. C.

REPORTS OF METEOROLOGICAL OBSERVATORIES.

THE *Meteorological Service of Canada* (1906).—This report extends to nearly 650 quarto pages; the geographical position, and height above sea where known, of the numerous stations in operation in that year are given, also hourly observations at Victoria, Winnipeg, Toronto, and Montreal. From a monthly chronicle of weather conditions it would appear that, generally speaking, temperature was above and rainfall below the normal. Temperatures exceeding 100° and below −50° were, as usual, recorded at many stations, the highest being 107°, at Point Clark, Ontario, and the lowest −65·5°, at Dawson City, Yukon. The absence of maps, the impracticability of comparing data contained in various tables, and the frequent practice of separating rainfall and depth of snow, render it somewhat difficult to obtain a general idea of the characteristics of the year over such a vast area beyond that given by the chronicle referred to. For this purpose the excellent summaries in the *Monthly Weather Review*, although based chiefly on telegraphic reports, are more convenient. The weather predictions were very successful; the general total percentage of fulfilment (including partial verifications) varied from 81·3 in November to 92·4 in July, the average being 86·3 per cent.

Toronto Observatory (1907).—The results of the meteorological and seismological observations for the year are interesting and valuable. In the annual summary the results are compared with the means for the last sixty-eight years. The mean temperature of 1907, 44·2°, was practically normal; mean of maxima, 51·6°, of minima, 36·7°. The absolute maximum was 88·8°, in July (highest on record, 99·2°); absolute minimum, −10·0°, in January (lowest on record, −26·5°). The highest solar radiation was 112·3° (June); lowest night radiation, −13·9° (January). The annual rainfall was 25·56 inches (normal, 26·88 inches); depth of snowfall, 52 inches (normal, 66 inches). Rain fell on 100 days and snow on forty-seven days. Bright sunshine was recorded on 1921 hours, being 43 per cent. of the possible amount.

Bombay and Alibag Observatories (1909).—The equipment of these institutions is very complete; the routine operations, which include terrestrial magnetism, meteorology, seismology, and astronomical observations, so far as these relate to time-keeping and signalling, are carried out with great minuteness and regularity. The annual rainfall was 71·22 inches, being 3·94 inches below the normal (1873–96); the mean temperature was 78·9°, 0·5° below the average. Milne's seismograph registered fifty-three earthquakes; great disturbances occurred on April 11, June 3, July 8, and October 21. The table representing the magnetic character of each day shows there were 149 calm days, 182 days of small, and 34 days of larger disturbance. The mean declination was 1° 0′ 16″ E.

Helwan Observatory (1909).—The magnetic observations made during the year have been published in pamphlet form by the Egyptian Survey Department. The tables include mean monthly values of the various elements, and hourly deviations from the mean. The mean annual results were:—westerly declination, 2° 49·2′; dip, 40° 40·4′; horizontal force, 0·30031 (C.G.S. unit); vertical force, 0·25804. A list is given of the maximum and minimum values of the elements during fifteen of the principal disturbances with a daily range of more than 100 γ in the horizontal intensity (γ=0·00001 C.G.S. unit). The greatest disturbance was recorded on September 25 (to which we have already referred as regards Kew Observatory). At Helwan the range of horizontal intensity was >585 γ (the curve extending below the limit of the photographic sheet), vertical intensity 237 γ, declination 38′. The range of horizontal intensity in most of the cases quoted was from three to four times that of the vertical intensity.

Royal Prussian Meteorological Institute (1909).—The increasing work during the year was much hampered by the loss of Dr. Sprung and Dr. Kremser, and by the consequent changes in the re-organisation of the staff. The institute has now established observations of earth temperature at some of its principal stations, and the results will be published weekly for the benefit of agriculturists. The rain stations (exclusive of ordinary meteorological stations) now number 2637, and the thunderstorm stations 1482. The Potsdam Observatory has greatly increased its activity in respect of atmospheric electricity and other useful researches. Dr. Hellmann points out that a considerable improvement has been introduced in the "Statistical Correspondence" issued for many years by the Statistical Bureau (now the Landesamt), of which the institute was formerly a department. Beginning with January, 1909, that publication has doubled its size, and includes, as an appendix, under the title of "North German Weather Report," monthly observations from forty-three stations supplied by the institute, with a chart showing the distribution of rainfall. The report contains several interesting short discussions, in continuation of the practice introduced in the previous year; we have already referred to one or two of them.

The Deutsche Seewarte (1909).—This report is divided into two parts:—(*a*) general part, containing interesting particulars relating to the staff, the agencies for the supply of instruments, &c., the observers on land and at sea, together with other details; (*b*) reports of the chiefs of the different departments. By looking through these an idea is gained of the great variety and importance of the work performed under the superintendence of the Seewarte. They include (1) oceanography and maritime meteorology; in addition to such work as sailing directions and ordinary meteorological charts, daily synoptic weather charts of the North Atlantic and adjacent coasts have for many years been issued in conjunction with the Danish Meteorological Institute, and these furnish invaluable data for studying the sequence of weather conditions over western Europe. (2) Verification of nautical, meteorological, and magnetic instruments, both at the Seewarte and at the agencies, of which there are twenty-two, and the determination of the deviation of compasses in iron ships. (3) Weather telegraphy; in addition to a very wide distribution of weather telegrams and storm warnings, this branch superintends the agricultural weather service between May and September, and conducts experiments from time to time on the possibility of making profitable use of wireless telegrams from ships in the Atlantic. (4) Other branches deal with the testing of chronometers and watches, the collection of materials referring to coasts and harbours for the benefit of navigators, the collection and publication of observations at distant stations, &c. The investigation of the upper air by means of kites is carried out daily when weather permits, and the results telegraphed at once to various services; in the summer half-year the ascents are made at 6h. a.m., and in other months at 8h. a.m.; the altitude attained generally reaches or exceeds 2000 metres.

The Sonnblick Observatory (1909).—The results of meteorological observations made at the summit of the Sonnblick, 10,187 feet above sea-level, show that the mean temperature for the year was 18·0°; the highest monthly mean was 33·6°, in August (the only month with mean above freezing point); absolute maximum, 48·2°. The month with lowest mean temperature was February, −3·1°; absolute minimum, −23·4°. The total annual precipitation amounted to 61·65 inches, on 233 days; most of this fell as snow; rain only occurred on eighteen days, and hail on three days. Fog was prevalent on 271 days, the least being in January. As in previous years, the report includes observations and interesting details relating to some other mountain observatories and to upper-air research.

Norwegian Meteorological Institute (1909).—The observations and results are published in two volumes:—(1) Meteorological Year-book: The principal tables include hourly readings for Christiania, daily observations for twelve stations, monthly and yearly summaries for sixty stations. (2) Rainfall (and Snow): Daily observations are given for 200 stations, monthly and yearly results for 476 stations, and normal values for the years 1876–1905. The volumes have appeared in the same form for many years, and contain valuable and trustworthy data for an area extending as far north as latitude 71° in the Arctic Ocean. The yearly rainfall varies considerably, according to locality; the isohyets for 1909 range from 1000–2000 mm. and upwards along the Atlantic coast, with closed areas of 3000 mm., while near the Swedish borders the lines vary from 400–800 mm. and upwards. The methods of measuring both rain and snow are explained, with illustrations of the gauges.

The Southport Meteorological Observatory (1909).—Every effort is made to render this report as interesting and complete as the important position of the establishment on the eastern shore of the Irish Sea warrants. Fifteen carefully prepared tables show the principal results obtained there and at the subsidiary stations at Marshside and Barton Moss; rainfall returns at nine other stations in the district, and a useful tabular comparison between the year's values of temperature, rainfall, and sunshine at sixty health resorts and ten large towns in Great Britain are included in the report. The outstanding feature of the year was the remarkable coldness of the summer months, due to unusual prevalence of cold polar (N.W.–N.E.) winds, while at other times the centres of depressions frequently passed to the southward of Lancashire, producing miserable, gloomy weather. The mean temperature of the year was 47·4°, 0·8° below the average; the highest shade temperature was 78·4°, on May 21, the lowest 18·0°, on December 21. The greatest daily range was 33·6°, on May 20, and the least 2·0°, on February 4. The annual rainfall amounted to 35·72 inches, 2·82 inches above the thirty-five years' average. In December precipitation amounted to 5·94 inches, which Mr. Baxendell states was unprecedented, being nearly 3 inches above the mean; but for this the annual amount would barely have equalled the normal.

Falmouth Observatory (1909).—The important meteorological and magnetical work performed by this institution has been carried out with great assiduity during the year. The observations are supplied to the Meteorological Office (from which it receives an annual grant of 250*l.*), to the National Physical Laboratory, and other organisations. An event of special interest during the year was the visit of the magnetic survey ship *Carnegie*; the scientific staff of the vessel was furnished with valuable data in connection with the proposed magnetic survey of the Atlantic and Pacific Oceans. The results of the "climatological" observations (taken for the Royal Meteorological Society) show that the mean maximum temperatures were 46·4° in February, 69·6° in August; absolute maximum 80·0°, in August (the highest in that month for twenty-eight years). Mean minimum, 36·8° in March, 55·3° in August; absolute minimum, 26·4°, in February. The annual rainfall was 37·6 inches, nearly 4½ inches below the normal. Some interesting details are given of the great magnetic storm of September 25, which disorganised the telegraphic system of this country and parts of the Continent. The mean value of magnetic declination for the year was 17° 48·4′ W.

Observatory Department of the National Physical Laboratory (1909).—This report shows that the useful work of the observatory to which it refers continues to expand; this is especially noticeable in the verification of instruments (exclusive of watches and chronometers), the total number being 41,318, nearly 11,000 more than in the previous year, and including 25,861 clinical thermometers. The meteorological observations call for no special remark; the automatic records are tabulated for each hour, and are published in detail by the Meteorological Office, as one of its principal observatories. The chief magnetic disturbances took place on January 3, 30–31; March 19, 28–29; May 14, 18; September 25, 30; and October 19; the most remarkable was that of September 25 (see NATURE, September 30, 1909). As in previous years, a table is given of the magnetic elements at a number of observatories, and reports of the results at Falmouth and Valencia. The largest seismic disturbances occurred on January 23 (earthquake in Persia), July 30 (earthquake in Mexico), and October 20–21. An account of the work at the affiliated observatory at Eskdalemuir, Dumfries, N.B., is included in the report; we note that some useful researches on atmospheric electricity and on solar radiation are being carried out there.

In our issue of June 23 we referred to the important changes that were being carried out in connection with the control of the two observatories at Richmond and Eskdalemuir.

SCIENCE AT THE JAPAN-BRITISH EXHIBITION.

THE arrangement of the British Science Section at the Japan-British Exhibition differs considerably from that of the Franco-British Exhibition. At the latter exhibition a separate annexe was set aside for science which made it comparatively easy to arrange the exhibits uniformly; but although the building was close to the entrance, the majority of the public passed it by and went straight through to the grounds. The fact is, the average man is rather afraid of anything called scientific, and unless he is brought to examine such an exhibit unawares is very apt to fight shy of it. Yet it was noticeable that those who did go into the building, even if they had no scientific knowledge, found a great deal to interest them, and frequently stayed a considerable time.

This year the Science Section is housed in the upper galleries leading from the Uxbridge Road entrance into the grounds. Consequently, all who go to the exhibition by that entrance, and the majority do, must pass through the Science Section. The exhibits are more broken up than in the Franco-British Exhibition; but this is rather an advantage than otherwise, as it takes away the museum appearance of the exhibit. Another advantage to the public is that there are two special attendants, who are able to explain the exhibits to the public in an intelligent manner. It has also been decided that certain members of the Science Committee shall give short lectures on special subjects in a portion originally intended for a bandstand, which has been curtained off; whether they will attract and keep an audience remains to be seen.

Science is so diversified, and its scope so enormous, that it is not possible to give in the space of a short article a comprehensive account of the exhibit which has been collected. Of course, it must be understood that the exhibit is not comprehensive in the sense that it covers the whole range of scientific research; but what it does do is to give to those unacquainted with scientific work an idea as to what is actually done by those engaged in scientific study. The Agricultural Section will be of interest to almost everyone; the South-eastern Agricultural College at Wye exhibits some most interesting specimens and preparations showing the various insects, mites, and eelworms which are injurious to crops and stocks, and in some cases even harmful to man. The largest section is that dealing with the enemies of fruit trees and bushes, because the damage done to these is enormous, and has received a great deal of attention. There are, for example, specimens of the various aphides, green and black fly. The insect pests of the hop are also fully illustrated, one of the aphides being the most important, or rather, from the grower's point of view, the most disastrous. It was very prevalent in 1909, and is calculated to have cost the hop-growers in England 120,000*l.* in combating the attacks of this insect.

Astronomy is well represented, the section comprising a large number of old astronomical, nautical, and horological instruments. Examples are shown of the peculiar wooden Davis quadrant employed by the navigators in the time of Elizabeth for the determination of latitude. The Royal Astronomical Society shows, among other things, a reflecting telescope made by Sir William Herschel; also a sextant, formerly the property of Captain Cook. The transparencies of photographs of the southern heavens made by Mr. Franklin-Adams seem to attract considerable attention, and are indeed worthy of it. The Solar Physics Observatory exhibits a large number of photographs of stellar spectra taken with different instruments. There are also photographs of ancient British stone monuments which Sir Norman Lockyer has investigated and shown their astronomical connection.

The history of fire-making, illustrating the gradual evolution of the match, is very interesting, and is probably one of the most complete exhibits of its kind which has ever been shown. The exhibit includes fire drills, tinder, pistol tinder-box, and a brass fire piston. In order to operate this latter a little tinder was placed in a small cavity at the end of the piston; the piston was then rapidly compressed, and the sudden compression of the air caused sufficient heat to ignite the tinder. Optical, electrical, and chemical methods are also illustrated, and one of the first friction matches, made by John Walker, of Stockton-on-Tees, is shown.

One of the largest sections is oceanography; this section is mainly designed to show the progress of oceanography within the past forty years. Before the *Challenger* expedition in 1870, very little was known as to the depths of the ocean, and there was practically nothing known about the ocean beds. Specimens of the method of sounding are shown, also recording thermometers for ascertaining the temperature of the ocean at any depth. The series of hydrographical charts shown are intended to illustrate the process of construction of a chart from a sheet of blank paper until it is printed and is ready to be issued to the fleet. There is a very complete exhibit of compasses, which comprises specimens used in H.M. ships from 1705 to the present day. In the days when very little iron was used in the construction of ships, the errors of induced and permanent magnetism were very slight, but with the construction of iron vessels alterations had to be made in the construction of the compasses, and specimens of these compasses are shown.

Biology is very well represented; there is an interesting series of photographs illustrating the origin of the domestic breeds of horses. An exhibit of particular interest is one of the parasites which cause grouse disease, also a series of charts illustrating the method of systematic research into the conditions of life in the sea, which is the only true method for any attempt to improve the fishing industry. There are also interesting specimens illustrative of the parental care of fish. One fish carries its own eggs in its mouth, while another has an abdominal pouch like that of a kangaroo, in which the young seek refuge; but there is so much to see and so many things one would like to mention that we must pass forward with the words go and see, as there is very much more of interest.

The chemistry exhibit ranges from artificial silk to sections of ships' propellers, showing the erosion produced on different alloys. There is the handsome exhibit of nickel produced by the Mond process, oils from all over the world collected by Sir Boverton Redwood; an original example of mauve, electrochemical preparations, pharmaceutical products, and preparations of dye products from the University of Leeds.

The Physics Section is very representative, and includes apparatus in connection with mechanics, heat, optics, electrical measuring instruments, and telegraphy and telephony. The electric micrometer of Dr. P. E. Shaw is shown, which, by means of a train of levers, an electrical contact, and a telephone, enables movements of 100,000,000th inch to be detected. A seismograph is shown, and in connection with it records of earthquakes taken in London and the Isle of Wight. Much attention has of late been devoted to rubber testing and its mechanical properties; in this connection the hysteresis rubber-testing machine of Prof. Schwartz is shown. Under heat, there is a model of the calorimeter used by Joule in his work on the mechanical equivalent of heat, and near by it the most recent example of the Boys calorimeter for testing the calorific value of gases. Electrical instruments make an exceedingly fine display, amongst which may be mentioned Dr. Drysdale's potentiometer for measuring alternating and direct currents, the Duddell twisted strip ammeter, and a number of X-ray apparatus.

In the Geological Section there are some specimens of volcanic rocks from Antarctica, obtained during the recent South Polar Expedition of Sir Ernest Shackleton. The rocks were collected on Ross Island by Dr. Priestley, and consist principally of lavas belonging to the type known as kenyte. The important subject of geological surveying and mapping is exhibited historically, one of William Smith's maps of nearly a century ago being exhibited by Mr. F. W. Rudler.

Under arithmetic and mathematics, models of surfaces and of crystals are shown; also the calculating machine of the late Charles Babbage, electrical machine for solving equations, and electromagnetic device for solving equations.

It has only been possible to direct attention briefly and imperfectly to the scope of the science exhibit, but this will perhaps serve to give an idea to those interested in science and cause them to visit and examine it in detail. In conclusion, mention should be made of the anthropological exhibit, an interesting feature being that a small space has been set aside for the actual taking of measurements, so that certain particulars of those attending the exhibition can be taken and data added to the large collection already obtained. F. M. P.

THE PROGRESS OF CANCER RESEARCH.

THE annual meeting of the general committee of the Imperial Cancer Research Fund was held at the Royal College of Surgeons on July 20, Mr. A. J. Balfour being in the chair. Sir William Church presented the annual report, and gave an able exposition of its most salient features.

The Duke of Bedford, who has been a strong financial supporter of the fund from its foundation, was elected president. Mr. A. J. Balfour moved a vote of thanks to the members of the various committees, and to Dr. Bashford and his staff. Mr. Balfour's remarks were mainly directed to the layman, and have received such wide publicity in the daily papers that we need not quote them in full, well as they will bear quoting. Mr. Balfour emphasised the progress made since he presided in July, 1903, and directed attention to the caution characterising the statements emanating from the laboratory, urging the need for patience upon the public, the members of which are not always able to comprehend that the slow progress made by scientific methods is the only progress that can legitimately be expected. Mr. Balfour emphasised the fact that heredity has been shown to be not of main importance, meaning thereby, we infer, that the congenital germ-theory of cancer has been discarded for good, in view of the facts elicited by the Imperial Cancer Research Fund on the association of cancer with peculiar irritants in human races practising peculiar customs, and in some animals.

Emphasis may be laid upon this point; in India, draught-cattle are liable to cancer at the root of the left horn, not of the right horn; cancer of the skin of the abdomen is only frequent in the Kashmiris who wear the "Kangri," or charcoal fire-basket; cancer of the floor of the mouth is only frequent in women who chew betel-nut. Surely these peculiar incidences of cancer are not due to a different distribution of congenital germs in the right than in the left horn of cattle, or in the abdominal skin of Kashmiris other than that in other races, any more than is betel-nut cancer due to a peculiar accumulation of congenital germs in the mouths of those women who chew betel-nut. All these forms of cancer could almost certainly be greatly diminished if the parts attacked were not irritated.

Advance in knowledge must yield information regarding other more obscure forms of cancer. Another point emphasised by Mr. Balfour was his belief in the reasonableness of expecting that the cure and prevention of the dissemination of transplanted cancer, as announced in the report, foreshadows similar achievements for original cancer, although perhaps so much may not be attained in his lifetime.

The other business was purely formal.

The report itself states that King George has consented to become Patron of the Imperial Cancer Research Fund in succession to His late Majesty King Edward VII., who was so largely responsible for its inception, as well as for inciting the modern crusade against cancer, and who in July, 1901, when opening the congress on tuberculosis, stated:—"There is still one other terrible disease which has, up till now, baffled the scientific and medical men of the world, and that is cancer. God grant that before long you may be able to find a cure or to check its course, and I think that to him who makes the discovery a statue should be erected in all the capitals of the world."

The appeal which the investigations of the Imperial Cancer Research Fund make to students throughout the world is exemplified by the number of foreign voluntary workers attracted to its laboratories. They have flocked to them from Germany, Italy, Belgium, Norway, Austria-Hungary, Roumania, the United States, Holland, and Japan, and many now hold independent appointments abroad. Thus the British national investigations on cancer may be said to have fulfilled their immediate purpose in that the English school of cancer research commands world-wide confidence, which we hope will be confirmed and extended by the director's necessarily technical report, from which we give below extracts of a few important passages. The report makes no pretence to appeal to the man in the street who wishes to know if the cause, the cure, or the means of preventing cancer have been discovered. Nevertheless, to all with "inside" knowledge, the progress made by the indirect method of attack—by the intelligent sapping and mining of hitherto unassailable citadels—must appear full of encouragement for the future.

Cancer in Vertebrates.

Much additional information has been obtained on the occurrence of cancer in lower vertebrates. It is gratifying to record that the systematic investigation of cancer in the animal kingdom has found numerous adherents both at home and abroad. Particular attention has been devoted to the incidence of the disease in cattle and in mice. While in mice the phenomena are presented in miniature even in their most advanced stages, in cattle they are demonstrated on a magnified scale as compared with man, although the universal minuteness of the early stages is independent of the size of the animal. In the course of the past six months, ninety cases of malignant new growths in cattle were obtained from a single abattoir. The histological types comprise the majority of the forms met with in man.

Breeding Experiments bearing on Heredity and Contagion.

The advantages of using short-lived animals for studying the possible influence of heredity were pointed out in 1903. The breeding experiments which have been in progress for five years have yielded a material of nearly 2000 animals of known age and ancestry. Of these, 700 females attained the age of six months or more. In them, seventy-five cases of cancer of the mamma have appeared spontaneously. This material is very complete as regards diagnosis of the disease, age, pedigree, and other important data, and it is now sufficiently large to permit of the most exact analysis of the influence of ancestral constitution on the liability of mice to spontaneous cancer of the breast. Analysed so as to bring out the liability to cancer according as the young were born before or after it appeared in the mother, the figures show a higher incidence in those born before the mother developed the disease. Since the conditions necessary for contagion were present, the opposite result would have been obtained had any analogy existed between cancer and the recognised infective diseases.

Constancy and Variability of Tumour Cells.

Tumours growing in a living animal can be protected from all outside influences, and, when propagated in large numbers of young mice of the same strain, the conditions are as constant as it is possible to provide. In these circumstances, it would not be surprising, on the one hand, if tumours showed little or no departure from the features they exhibited at the outset of propagation; on the other hand, it would not have been surprising if tumours widely different in character had tended all to approximate to a common type, in response to the unvarying nature of their environment. What has actually come out is both interesting and instructive, in that it shows that the tumour cells possess a relative constancy in their general biological properties, but, at the same time, exhibit an inherent tendency to vary in spite of the constancy of the environment, and therefore apparently for reasons independent of it. Each tumour preserves its individual features, and if there be variation, then the variations likewise are individual. The constancy may be very perfect, so that strains of the same tumour propagated separately for three and four years remain indistinguishable in all their properties. On the other hand, the variations arising may be so great and of such constancy that strains propagated separately from the same mother-material would not be suspected to have any relation to one another if submitted to one ignorant of their life-history.

In former years we have pointed out that an increase in the rate of growth, or in the percentage of successful inoculations, does not necessarily imply a fundamental biological alteration finding expression in an accelerated rate of proliferation of the tumour cells, but may be explained by the selection of particular cells adapted to the conditions of growth, and, consequently, the survival and proliferation of a larger number of such cells. That is to say, these two phenomena may be explained by an increase in the dose of the cells able to grow. The evidence for the acquirement of new properties by tumour cells is very much stronger when one observes the occurrence of morphological alterations which become of relative constancy, such as the disappearance—or latency—of their typical characteristics in the case of squamous-celled carcinoma, the disappearance of acinous structure in the case of glandular carcinoma, the derivation from cubical epithelium of epithelial cells which, if their previous history had not been known, could not have been distinguished from those of a spindle-celled sarcoma. In other cases, the change is made manifest by the alterations taking place in the supporting connective tissue and blood-vessels, so that tumours which at one time exhibited dilated blood-vessels lose this character. Biological alterations occur without evident morphological expression, *e.g.* some tumours at the commencement of propagation, after an initial exuberant growth, disappear in a large proportion of cases, whereas after the propagation is prolonged, a large percentage of the implantations grow progressively. The opposite phenomenon may also be observed, and tumour strains which grew progressively at the outset of propagation may later be found very liable to disappearance. A tumour which grows well only by the implantation of intact grafts, *i.e.* if the tissue structure is preserved, can be adapted to transplantation as a cell emulsion, and again brought back to its original condition.

Of the twenty-nine tumours of the mamma that have been propagated in the laboratory for more than two years, as many as sixteen have shown departures from the features they exhibited at the outset, these departures affecting the degree and nature of the histological differentiation, the percentage of successful inoculations, the rate of growth of the resulting tumours, the relative proportions of progressively growing tumours and of tumours which undergo spontaneous absorption after transitory growth, the susceptibility of the tumour to method of transplantation, to dose, to race, to age, and to the influence of induced immunity.

Thirteen tumours have shown a relative constancy of their structural and biological characters.

Of the sixteen variable tumours, nine have varied from the primary condition in both respects. Two have shown biological variations without histological change, and five have altered in microscopical characters without noticeable modification of their biological behaviour. On the whole, therefore, histological character is less constant than biological behaviour.

The relative constancy, but still more the variability which the tumour cells exhibit during propagation, throws indirect light of the most suggestive kind upon the nature and the manner of the development of cancer. The variability in a constant environment, during propagation, allows one to infer that corresponding variations may take place while the cells are under the influence of the particular environment provided by the animal in which the tumour developed spontaneously. The environment of the cell will depend on the individuality of the animal, and, with the progress of life, distinctions between one animal and another may become more and more marked. This inference accords with what has been said above on the ease with which auto-transplantation is effected and the difficulty with which transplantation can be effected to another individual, and therefore also with the fact that all cancerous mice do not exhibit an equally suitable soil for tumours in general.

These spontaneous variations of the parenchyma cells of tumours during propagation suggest that we have here a repetition, in a minor degree, of the cellular processes responsible for the primary transformation of non-cancerous into cancerous tissue; just as cellular changes occurring during propagation may transform within a brief space of time an acinous growth into a solid one, or a slow-growing tumour into one rapidly proliferating, so in the tissues prior to the development of a malignant new growth the responsive proliferation of cells may pass into the progressive, independent proliferation of cancer.

Experimental Sarcoma.

In this connection it may also be well to refer again to the production of sarcoma under experimental conditions from what have been the non-malignant connective tissues of carcinoma. Not the least significant aspect of the origin of sarcoma by the transformation of the stroma of transplantable carcinomata is the rarity of its occurrence. Two only of our strains have exhibited it, and the conclusion seems warranted that in these cases the parenchyma is possessed of peculiar properties. In one of our strains the change occurred only in a small number of animals, and the whole process, from the first indications of sarcomatous changes in the stroma to the substitution of the carcinomatous elements by pure sarcoma, took place slowly, and was only completed after several successive transplantations. In the other strain, the transformation was much more frequent, took place more rapidly, and the disappearance of the carcinomatous element may be complete in one transference. In spite of these differences, the parallelism between the histological pictures in the two strains is extremely close, and leaves no doubt of the essential similarity of the processes involved. The stimulus exerted by the carcinoma cells on the stroma must be different in these two strains from that exemplified by the other transplantable tumours, otherwise every transplantable carcinoma should end in sarcoma, as it has, indeed, been asserted they might do. A fairly long duration of the stimulus exerted by the carcinoma cells without cessation of their proliferation seems to be necessary, and the first steps of the process are always localised in an extremely minute area of what are often large tumours. The parallel to the circumscribed origin of squamous epitheliomata arising in areas subjected to chronic irritation in man (chimney-sweeps' cancer, paraffin cancer, Kangri cancer) does not require to be insisted on further, since it has been emphasised in previous years.

Immunisation.

It is now possible, under given experimental conditions, to prevent a secondary transplantation, *i.e.* artificial metastasis, taking place for certain tumour-strains. This result has been obtained by inserting between the primary and secondary transplantations an inoculation of a very rapidly growing tumour showing only transitory growth, as the following sample experiment shows. Of twelve mice, already bearing progressively growing tumours and treated in the manner described, the secondary inoculation was successful in three only, and then the tumours were very much smaller than in the control consisting of thirteen mice, of which ten developed new progressively growing tumours on secondary inoculation. A similar result can be obtained by the implantation of tumours growing much more slowly and liable to spontaneous absorption, as well as by an inoculation of normal mouse-tissue. By similar methods the growth of the primary transplanted tumour may be greatly hindered, can be brought to a standstill and the animal cured, in circumstances under which the disease would certainly have progressed, and where the possibility of the occurrence of spontaneous cure can almost certainly be excluded. Thus the control of *transplanted* cancer has been brought within the region of probability.

These achievements must not be confounded with successful vaccination against spontaneous cancer arising, or against infectious disease. Animals perfectly protected against the repeated inoculation of cancer may develop tumours of their own—an observation often confirmed. Still more emphatically do we warn against applying to the human subject the methods which, after long perseverance, have enabled us to arrest the growth, and even to cure, animals of transplanted tumours that were well established, and also to render animals resistant to a secondary inoculation, *i.e.* to dissemination and metastasis formation.

The immunity reactions to transplanted cancer are throughout clearer and more easily studied than are those of spontaneous cancer. The problems presented by spontaneous tumours are more delicate and elusive. The methods effectual in normal animals against primary inoculation with transplantable tumour, which, as mentioned above, also arrest the growth of growing transplanted tumours and prevent successful re-inoculation in suitable circumstances, have been without action on the continued growth of the twenty-five spontaneous tumours on which they have been tested, have failed to prevent recurrence or dissemination, and have not yet prevented a successful re-inoculation of the spontaneously affected animal with its own tumour. The investigations must go on until a higher degree of resistance can be obtained in this way, or it may be that an entirely different method must be sought. The expectation of ultimate success seems a fair inference from the results obtained with transplanted tumours which reproduce all the phenomena of growth and dissemination of spontaneous tumours, and from the rare but undoubted cases in which temporary arrest of growth or total disappearance have occurred in spontaneous tumours.

The prospect is made the more hopeful by the discovery of a method whereby an animal can be immunised by means of one of its own tissues against a primary inoculation of a tumour transplanted from another animal. This, again, is a very different matter from immunising an animal against its own tumour. Nevertheless, it illustrates how much that was previously unsuspected is being revealed, as step by step advances are made into yet unexplored regions. Inquiries into the effects which the several tissues of the body may have, either singly or in combination, in inducing protection are being made.

Chronic Irritation and Cancer.

A practical result arises out of the association of various forms of irritation with the development of cancer in sites where more obscure influences can be excluded, especially from what has been ascertained on the incidence of cancer in native races practising peculiar customs, and on the incidence of cancer in some animals. Experiment has emphasised this relation, and has thrown light upon the mechanism which makes the irritation effective, leading to similar consequences, although the irritants themselves have nothing in common. Recent legislation is thereby justified in the interest of workers employed in circumstances exposing particular parts of the body to chronic irritation of peculiar kinds. In 1903–4 the feasibility of obtaining more accurate information of the incidence of cancer in different occupations was before the Statistical Sub-committee. The progress made since renders such an investigation still more urgent to-day. It must not be supposed, however, that cancer has been proved to be always the result of irritation. The *mediate* influence of irritation has only been defined more closely than ever before.

MANGANESE MINING IN INDIA.[1]

THE many uses of manganese in the arts were known long before the metal had itself been recognised. It has been used since prehistoric times as a colouring material, and by primitive Indian smiths as a flux and as an alloy for hardening iron and bronze; and its power as an oxidiser now renders it one of the most important of disinfectants, and a valuable chemical reagent. The metal has an interesting, but uncertain, history; the origin of the name is doubtful, but it appears to have been first used in the sixteenth century as a variant of magnesium, from which it had not been separated; and even after its recognition as a distinct metal by Gahn in 1774, Bergmann still called it magnesium, though the name manganese, derived from magnésie by the reversal of two letters, had already been used.

Manganese is one of the most widely distributed of the metals. According to Mr. F. W. Clark it forms one-thousandth of the earth's crust, and is the fifteenth of the elements in quantitative importance. Mr. Fermor, accepting the number of mineral species as 1000, reports that no fewer than 130 to 140 of them contain manganese as an essential constituent. The manganese minerals are especially conspicuous, as they are mostly found in decomposed rocks upon the earth's surface; and as manganese salts are easily dissolved, the metal is a common constituent in the ash and latex of plants, and is found in the blood and tissues of many animals. According to Penrose, the proportion of manganese to iron in the human body is said to be as 1 to 20.

The increased use of manganese as an alloy has led to a more active search for its ores, with the result that the once important manganese mines of the south of England have been closed owing to the discovery of much larger supplies abroad. The manganese mines of India, according to native traditions, supplied ores to the Phœnicians, and the local smiths faced their anvils and hammers with manganese steel, which they knew as kheri. It was not, however, until 1892 that India began to produce manganese ores for export, with the small contribution of 685 tons. The ores are abundant in India, especially in the Central Provinces and in the States of Hyderabad and Mysore, and as the deposits are on the surface, and can be worked by shallow quarries, the Indian output increased rapidly until, for the years 1890–1906, it was second only to that of Russia. In 1906, and possibly some later years, India has taken the front place as a producer of manganese ores. The other countries in order of yield are Brazil, Spain, Turkey, Chile, France, Greece, the United States, and Japan, while large quantities of manganiferous iron ores are raised in the United States, Germany, and Greece.

The manganese ores of India have frequent but short references in geological literature, but little was known certainly about them until after the discovery of their economic importance. They have now been carefully investigated by Mr. L. Leigh Fermor, of the Geological Survey of India, and he has issued the result of his studies in a monograph that forms a most important addition to the geology and mineralogy of manganese. The Indian mines have added several new species of manganese minerals, amongst which the most important are hollandite, the crystalline form of psilomelane, and two new species characterised by their striking pleochroism—juddite, a manganese pyroxene, and blanfordite, the corresponding amphibole. Mr. Fermor also introduces new names for two manganese garnets, grandite, an abbreviation for grossular-andradite, and spandite, for spessart-andradite. Commercially, the most important of the Indian species are braunite and pyrolusite, which together produce 90 per cent. of the output.

Mr. Fermor's memoir includes a detailed account of the manganiferous minerals. The chemical composition of the various species is re-considered, and the complexity of many of them is shown by the elaborate general formulæ, by which alone they can be adequately represented.

The Indian manganese ores are mainly found in the pre-Cambrian rocks, though some interesting deposits of secondary economic importance occur in the laterites. The chief ores are associated with a varied series of igneous rocks, which Mr. Fermor groups as the kodurite series. They range from acid to ultra-basic varieties, all characterised by being rich in manganese and manganiferous minerals. Mr. Fermor describes in detail the petrography of this interesting rock series. The kodurites are apparently intrusive—though the evidence for this fact is described as incomplete—into two series of Archean gneisses. The first series consists of calcareous gneisses and the second of the metamorphic gneisses, which have been described by Mr. J. T. Walker as the kondalite series.

As usual with manganese deposits, the Indian mines are still shallow, and the deposits are probably very limited in depth; for they have been formed by chemical processes that only take place near the surface. They are generally due to the replacement of rocks by solutions containing manganese. Mr. Fermor reports that many of the deposits

[1] Memoirs of the Geological Survey of India. Vol. xxxvii The Manganese-Ore Deposits of India. By L. Leigh Fermor. Part i., Introduction and Mineralogy. Pp xcvii+231. Part ii., Geology. Pp. 232–405. Part iii., Economics and Mining. Pp. 406–610. (Calcutta: Geological Survey, 1909.) Price 3 rupees each.

are not more than 50 feet deep, and none has yet been proved to continue below 300 to 500 feet. The future of manganese mining is limited by some of the same factors as iron mining, owing to the limited range of the ordinary oxide ores. The mines are still open quarries, from which the ore can be very cheaply produced. Mr. Fermor's monograph concludes with a comparatively elementary statement regarding the methods of mining and the economics of the industry. More precise information as to labour costs and efficiency would have been of interest. The rates of pay are from $2\frac{1}{2}$ to 7 annas a day for men, $1\frac{1}{2}$ to 4 annas for women, and from 1 to 3 annas for children; the efficiency must be very low if it may be judged by dividing the annual output of the different mines by the number of people recorded as engaged in them. The native miners appear to insist on more holidays than Welsh colliers, without having the same excuse.

Owing to the present great activity in Indian manganese mining, the known deposits there cannot last very long. Mr. Fermor in 1907 estimated that the supplies would be worked out in from thirty to fifty years. Now, in spite of some additional discoveries of ore, he is disposed to reduce even that short limit; and he earnestly warns India that it is adopting a wasteful policy in the reckless export of manganese, which will have to be purchased from other countries for the manufacture of ferro-manganese when India works its enormous supplies of iron ores. Owing to the possibility, however, of the discovery of fresh deposits and of the invention of new processes that may supplant manganese, it is not proposed to impose legal restrictions on the export of the ore. J. W. G.

THE STRUCTURE OF CRETACEOUS PLANTS.

HITHERTO our knowledge of the structure, as distinguished from the mere external appearance, of Mesozoic plants has been for the most part limited to the older floras, in which only the earlier types, such as ferns, cycadophytes and conifers, are represented. From the Upper Cretaceous, the epoch when the now dominant angiosperms first overspread the world, little structural material has been available until lately, if we except the petrified wood of palms, which has long been known and is of the utmost interest.

At the present time new facts of great value are coming in from two principal sources—from the researches of Drs. Hollick and Jeffrey on the lignites of the eastern United States, and from the work of the authors below cited on the petrifications from northern Japan.

The specimens described in the present paper, which must be regarded as only a first instalment of the work, were among those collected by Miss Stopes on her recent expedition, undertaken with the assistance of a grant from the Royal Society, and helped in every possible way by the Government and universities of Japan. Eighteen types are described—not a large number, but quite enough to make a good beginning. The number of species with structure preserved is not very large, even in the best known fossil floras. We think, however, that the authors in their comparison somewhat underestimate the richness of the English Carboniferous flora in admitting only about seventy structural species; 100 would be nearer the mark.

The flora investigated is a mixed one, the eighteen species including one fungus, three ferns, eight gymnosperms, and six angiosperms; such proportions are quite unusual, the angiosperms commonly being dominant if they appear at all.

Only a few of the most important forms can be referred to here. Among the ferns, *Schizaeopteris mesozoica* bears the characteristic sporangia of Schizæaceæ, Aneimia being the nearest genus. Of the gymnosperms, *Niponophyllum cordaitiforme* may be either a leaf or a leaflet; if the former, it may be a belated member of the ancient Cordaiteæ; if the latter, it may be akin to the Bennettiteæ. *Yezonia vulgaris*, with a cypress-like habit, has a very peculiar structure, the small adpressed leaves containing numerous vascular bundles. If, as there is reason to suspect, the cone *Yezostrobus Oliveri* was its fruit, the plant appears to represent a type intermediate in certain respects between Cycadophyta and Coniferæ.

Cunninghamiostrobus yubariensis shows a clear affinity with the recent Cunninghamia, while *Cryptomeriopsis antiqua*, so far as vegetative characters can decide, comes near the familiar Cryptomeria of modern Japan.

Among the fossils referred to angiosperms, *Saururopsis niponensis* shows an anatomical structure similar in some ways to that of Saururus, an ally of the peppers. Some readers may perhaps ask if it is quite certain that this plant is an angiosperm, and may even think of a possible comparison with Ophioglossaceæ. In the meantime, the authors' suggestion is at any rate tenable. It is interesting that the commonest angiosperm in these rocks, *Sabiocaulis Sakuraii*, appears to show the nearest affinity with the native climbing plant *Sabia japonica*.

The most sensational discovery, however, is that of a three-celled ovary of the type of Liliaceæ, for this is the first case in which any angiospermous fructification has been found fossil with its structure preserved. A perianth or bract is adherent to the lower portion of the ovary, making it partly inferior. It is curious, if somewhat disappointing, to find that this ancient flower appears to have been already so advanced as to give no clue to its ancestry.

In many cases diagrammatic text-figures are used very advantageously to supplement the photographs (sometimes a little obscure) which form the bulk of the illustrations.

The authors' concluding remarks suitably sum up the results so far attained:—"These new fossil plants, then, seem to be an interesting community, consisting of a mixture of old and new types, of higher and lower plants mixed in nicely balanced proportions: a community, which in some respects, at any rate, one could have hardly imagined from the fossil remains hitherto available from the Epoch."[1]

[1] "Studies on the Structure and Affinities of Cretaceous Plants." By Dr. Marie C. Stopes and Prof. K. Fujii. Phil. Trans. Royal Society, Series B, vol. cci. Pp. 90; plates 9. (Royal Society, 1910.)

ARCHÆOLOGICAL AND ANTHROPOLOGICAL INVESTIGATIONS IN ARKANSAS AND LOUISIANA.[1]

MR. CLARENCE B. MOORE in 1908–9 investigated the mounds and cemeteries of the valley of the Ouachita, a river that rises in central western Arkansas and flows south-easterly into the State of Louisiana; its lower course is the Black River, which joins the Red River, a tributary of the Mississippi. The more striking remains are earthenware vessels of very varied forms and different colours. The most common form of decoration consists of the original surface of the vessel being left in scroll bands and round or oval discs, the interspaces being generally filled up with parallel lines or cross-hatching. The accompanying figure illustrates a superb bottle, $8\frac{1}{4}$ inches in height, which has a coating of red pigment of superior quality, through which is incised a beautiful combination of discs and running scrolls in a field of parallel lines which emphasise the design; possibly the incised lines were accentuated with white pigment, but no trace of this remains. The technique of some of the vessels from Glendora is superior to anything of the kind hitherto met with outside the Lower Mississippi region.

The excavations were confined almost entirely to land that was, or had been, under cultivation. When the aborigines selected dwelling sites along rivers subject to overflow, they naturally chose high ground; and later, when Europeans selected land to clear for cultivation, they were similarly influenced, especially as much of this land had been enriched by aboriginal deposits. It is needless to say that the report is illustrated in that sumptuous manner which characterises Mr. Moore's publications.

The value of the memoir is enhanced by a very careful study, by Dr. Aleš Hrdlička, of the skeletal remains discovered by Mr. Moore. This constitutes a welcome contribution to the craniology and osteology of the American Indian, and we hope it will be followed by similar studies by the same anatomist. Dr. Hrdlička, in an attempt to determine the amount of prognathism, made use of the

[1] "Antiquities of the Ouachita Valley." By Clarence B. Moore (Journal of the Academy of Natural Sciences of Philadelphia, 2nd series, vol. xiv. part i., 1909).

basi-facial angle, a measurement which was independently arrived at by Dr. Rivet (*L'Anthropologie*, xx., 1909, pp. 35, 175). The majority of the crania exhibit one of the two main forms of artificial deformation, *i.e.* occipital flattening, or cradle-board compression, and fronto-occipital flattening ("flat-head" deformation). Each variety predominates in, but is not limited to, a certain type of people, thus indicating an exchange of customs.

The predominating type is that of the brachycephals, who range in stature from moderate to well developed, with good, though not pronounced, muscular development. They were probably the people among whom prevailed, and who communicated to their neighbours, the intentional fronto-occipital deformation. The other type, less well represented, indicates Indians of stature and strength similar to those of the people just mentioned, but with oblong, mesocephalic to dolichocephalic skulls. They were, in all probability, remnants of a relatively large local strain of dolichocephals mixed with the more numerous round-headed people. The physical characters of these people approach, on the one hand, those of the more northerly tribes of Missouri, Illinois, and parts of Tennessee and Kentucky, and, on the other, those of the more westerly and south-westerly tribes, represented in northern Texas

Bottle from Glendora, Ouachita Valley, La.

and especially by the oblong-headed type among the Pueblo Indians. The prevalent occipital flattening of the skull would point likewise to a connection with the south-west and the north-east. In addition, a few crania from these two States resemble very closely the subtype of the eastern Algonquians. A. C. Haddon.

THE TABULATION OF VITAL STATISTICS.

Attention has so often been directed in these columns to the desirability of the adoption of more scientific methods in our Government departments that it gives us pleasure to notice the paper which was read by Dr. T. H. C. Stevenson before the Royal Statistical Society on June 21. Dr. Stevenson was appointed last year Superintendent of Statistics in the General Register Office for England and Wales, and his paper on suggested lines of advance in English vital statistics is, in effect, an outline of all the changes which it is proposed shortly to introduce in the mode of compilation of the vital statistics issued from that office, and of the mode in which it is proposed to compile certain tables in the census reports, more especially those relating to the new data to be obtained in 1911 (see Nature for April 7, p. 152).

That a civil servant should, with the approval of his official superiors, submit for criticism to a scientific society, before their final adoption, a statement of changes which it is proposed to introduce is, we believe, a course wholly without precedent, and deserves the warmest commendation. Taken in conjunction with the acceptance by the Registrar General, Mr. Bernard Mallet, of many of the suggestions made by the Statistical Society for the improvement of the census, the course augurs well for the thoroughly scientific spirit in which his office will be conducted.

The matter of Dr. Stevenson's paper is too detailed for abstraction in these columns, but it may be noted that it is intended in future to tabulate vital statistics by administrative instead of by registration districts, and that the data as to number of children which will be obtained at the next census will be tabulated, not only for different occupations of father, as suggested in the article in this journal to which reference is made above, but also by the number of rooms occupied or the number of servants employed, so as more clearly to distinguish the different social strata. It is also proposed to introduce the card-system for vital statistics and for census work, and to use mechanical methods for sorting and counting the cards. The frankness with which Dr. Stevenson points out difficulties and asks for suggestions is one of the most pleasing features of a paper on which he can be unreservedly congratulated.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Entrance scholarships have been awarded at Bedford College for Women (University of London), as follows:—Pfeiffer scholarship in science (value 50*l.* a year for three years) to Miss W. R. Smyth, of the North London Collegiate School; Henry Tate scholarship in science (value 50*l.* a year for three years) to Miss F. M. Lunniss, of the Cambridge and County School.

With the view of securing uniformity in the statistics concerning higher education, the Carnegie Foundation for the Advancement of Teaching has issued, as Bulletin No. 3, a series of standard forms for financial reports of colleges, universities, and technical schools. The forms as they are published are the result of a prolonged inquiry concerning the practice of universities and colleges in the United States in the rendering of public financial statements of their receipts and expenditures. The object of the forms is to make it easy for students of education and others to answer the questions, What is the total income of a given institution for the year? What is its annual expenditure? What are the assets at the end of the year? The forms may be commended to the attention of officials who are responsible for preparing balance sheets and other statistics in connection with universities and colleges in this country.

Mr. Sidney Ball, fellow and senior tutor of St. John's College, Oxford, and Prof. I. Gollancz, professor of English at King's College, London, have been elected the first fellows of the English foundation of the A.K. travelling scholarships. It may be remembered that these fellowships, each of the value of 660*l.*, were recently founded in this country by Mr. Albert Kahn, of Paris, to enable the fellows to travel round the world. The object of the founder is that persons selected from the first rank of those engaged, in whatever way, in the education of the nation may become better qualified to teach and to take part in the instruction and education of their fellow-countrymen. The trustees are the Lord Chancellor, the Lord Chief Justice, the Speaker, Lord Avebury (nominated by the founder), and the principal of the University of London (Dr. Miers), the last-mentioned being honorary secretary to the trustees. The affairs of the trust are administered at the University of London.

The current issue of the *Reading University College Review* contains several articles of interest. An editorial discusses the American faith in universities. The institution and development of universities, each of which is wholly dependent upon a particular State, is, the writer maintains, the most conspicuous activity that has of late been shown in America. The American recognises more and more that university life, under favourable conditions, can give a training in comradeship and personal character which is one of the best preparations for efficient citizenship. He wants, too, the best knowledge—useful and technical—because without it he knows he cannot have the right kind of citizens. Prof. H. N. Dickson contributes an essay on higher education and commerce, and points out that those universities and colleges which are able to provide instruction of the higher kind in commercial subjects are steadily increasing in number. An address delivered by Prof. A. L. Bowley last May on progress and leisure is also included.

IN reply to a question asked in the House of Commons, Mr. Lloyd George has informed Mr. Duncan Miller that he is not prepared to propose any additional grants to the Scottish universities during the current financial year beyond the sum of 21,000*l.* included in the Supplementary Estimate issued on July 13, but as regards the future he has expressed willingness to sanction, subject to certain conditions, a further addition to the existing grants, provided that suitable schemes of expenditure can be submitted by the authorities of the several institutions concerned. For the current financial year the total grants in aid to Scottish universities and their allocation will be :—

	Grant under Universities (Scotland) Act, 1899	Grant under Education and Local Taxation Account (Scotland) Act, 1892*	Grant from Votes, Class 4. Sub-head I.	Supplementary Estimate	Total
	£	£	£	£	£
St. Andrews	6,300	4,500	—	4,000†	14,800
Dundee University College	—	—	1,000	—	1,000
Glasgow	12,180	8,700	—	6,250	27,130
Aberdeen	8,400	6,000	—	4,500	18.900
Edinburgh	15,120	10,800	—	6.250	32,170
	£42,000	£30.000	£1,000	£21,000	£94,000

* Payable from the Local Taxation (Scotland) Account.
† Includes £1,000 for Dundee University College.

FOLLOWING an order of the House of Commons, the Board of Education has issued a return by each county council in England and Wales, except London, of the rates levied for elementary education, and of the rate levied for higher education. So far as higher education is concerned, it is interesting to notice that Glamorganshire is most highly rated for this purpose, the rate being $3\frac{1}{4}d.$ in the pound, and bringing in 43,030*l.* Eleven counties levy a rate of 2*d.* or more, but less than 3*d.* They are, in order :—

	Rate *d.*	Amount raised £
Yorks : West Riding	2·97	92,948
Cardigan	2·88	2,647
Monmouth	2·73	13,074
Denbigh	2·46	6,096
Merioneth	2·31	2,049
Herts	2·13	14,853
Cheshire	2·12	30,746
Westmorland	2·10	3,771
Flint	2·10	3,636
Pembroke	2·10	2,813
Salop	2·00	11,131

A number of counties levy a smaller rate than a halfpenny in the pound ; these are Devon, Dorset, Hereford, Lincolnshire (three divisions), Notts, East Suffolk, West Suffolk, East Sussex, and the North Riding of Yorkshire. The Holland division of Lincolnshire raises nothing for higher education ; the Kesteven division raises 10*l.* only, Hereford 35*l.*, East Suffolk 58*l.*, and Dorset 100*l.* Two counties only raise more than 50,000*l.*, namely, the West Riding, 92,948*l.*, and Lancashire, 65,082*l.*

A SCHOOL of aviation is to be established near London in memory of the late Mr. C. S. Rolls. A sub-committee of the Aërial League has had the scheme under consideration, and its cost for the first year is likely to be 2500*l.* The primary aim of the school will be to provide training in aëroplane manufacture and flight, and to obtain a class of men grounded in the subject from beginning to end, including such laboratory and theoretical work as funds and the gifts of apparatus may permit. The laboratory will be open for the use of students from technical institutions already providing elementary classes in the theory of flight, and also for public demonstrations in order to spread an interest in aëronautical science. Men who have undergone courses of training in engineering schools, and competent engineers and mechanics, will be eligible as students. The practical work of students will be directed to securing machines offering greater stability and trustworthiness, lower power and fuel consumption, diminished capital cost and expense of maintenance, and a higher factor of safety than the apparatus now used. In order that an early start may be made, two machines are to be bought at once, and the students will build all further machines, and also those of selected inventors whose ideas are judged to be worthy of construction and practical trial. The funds will be administered by an independent committee of management, including practical men of science. Mr. Patrick Y. Alexander has offered to equip the proposed laboratory with the necessary practical apparatus. The new institution will probably be called the Rolls Memorial School.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 18.—M. Émile Picard in the chair.—P. **Villard** and H. **Abraham** : The existence of two explosive potentials ; a reply to a recent note of M. Amaduzzi. The authors state that their original intention was to bring forward a theory of the silent and continuous discharge, characterised by luminescence at the anode, based in accordance with the modern hypotheses as to the passage of electricity in gases.—L. **Maquenne** and E. **Demoussy** : The toxic qualities of certain salts towards green leaves. The salts of ammonium are shown to be specially dangerous in this respect, while calcium chloride and sea salt have very little effect.—A. **Laveran** and A. **Pettit** : The forms of endogenous multiplication of *Haemogregarina sebai.* Observation in this organism shows for a given species a great variety in the multiplication cysts, both in dimensions and number of merozoites, such that it is necessary to beware of assuming the existence of different species too readily.—Joannes **Chatin** : The variations of structure of the sclerotic among vertebrates.—Ch. **Platrier** : A problem of rational mechanics and its application to the theory of propulsive helices.—Ernest **Esclangon** : The passage of the earth through the tail of Halley's comet.—M. **Schulhof** : Some remarks on the inequalities of the longitude of the moon.—Jules **Drach** : The logical problem of the integration of differential equations.—Serge **Bernstein** : The equations of the calculus of variations.—Sigismond **Janiszewski** : The geometry of cantor lines.—L. **Zoretti** : The notion of a line.—Jean **Chazy** : A differential equation of the third order which has its critical points fixed.—René **Garnier** : A class of differential equations the general integrals of which have their critical points fixed.—Witold **Jarkowski** : Some theorems on "sustainers."—A. **Tanakadate** : A photographic study of the current of air produced by the movement of a helix.—E. **Mathias** and H. Kamerlingh **Onnes** : The rectilinear diameter of oxygen. Experiments in the case of oxygen give an affirmative answer to the question whether the deformation of the surface when the critical temperature is lowered leaves intact its rectilinear form.—A. **Perot** and J. **Bosler** : The theory of the luminescence of the mercury arc *in vacuo.*—A. **Tian** : The action of ultra-violet rays on gelatine. These rays destroy jellies, causing their liquefaction or solution, thus forming a contrast to the action of the same rays in coagulating albumen.—G. A. **Hemsalech** : The relative periods of calcium rays in the spark of self-induction. Experiments of this character provide useful indications in the analysis of bodies containing unknown impurities.—

H. **Buisson** and Ch. **Fabry**: The electric arc in an atmosphere of feeble pressure.—M. **Rouch**: Observations of atmospheric electricity made on Petermann Island during the stay of the Charcot expedition.—William **Duane**: A photographic method of registering α particles.—M. **Barre**: Sulphate of thorium. The author finds that sulphate of thorium in aqueous solution shows a specific resistance and a freezing point entirely in agreement with the laws of Bouty and Raoult. Measurements also of conductivity and freezing point of solutions containing 1 per cent. of potassium sulphate show the existence of a double salt.—F. **Bodroux**: The action of some ether salts of monobasic fatty acids on the mono-sodium derivative of benzyl cyanide.—Marcel **Guichard**: The absorption of iodine by solid bodies. The fixation of iodine by the surface of a solid is a specific property, and the author gives a list of a number of substances showing this behaviour.—M. **Gard**: Binary hybrids of the first generation in the genus Cistus and Mendelian characters.—B. **Sauton**: Influence of iron on the formation of the spores of *Aspergillus niger*.—Pierre **Marty**: New observations on the fossil flora of the Cantal.—Eugène **Collin**: A determination of the nature of the wick of a Punic lamp. The author believes the fibres to have been undoubtedly of flax.—Rémy **Perrier** and Henri **Fischer**: Some particular points in the anatomy of molluscs of the genus Acera.—MM. **Jammes** and **Martin**: The *rôle* of the chitin in the development of nematode parasites.—Henry **Penau**: The cytology of *Endomyces albicans* (P. Vuillemin).—Amédée **Delcourt** and Émile **Guyénot**: The possibility of studying certain Diptera in a definite medium.—Charles **Nicolle** and E. **Conseil**: Experimental reproduction of exanthematic typhus by direct inoculation with human virus.—M. **Lucet**: The presence of Spirochetæ in a case of hæmorrhagic gastro-enteritis in a dog.

Cape Town.

Royal Society of South Africa, June 15.—Mr. S. S. Hough, F.R.S., president, in the chair.—Dr. A. **Theiler**: Note on *Anaplasma marginale*, a new genus and species of the Protozoa. This Anaplasma is transmitted by ticks, and it is a noteworthy fact that the incubation time by tick transmission is much longer than that after inoculation of the animal with blood; in the experiments carried out it varied from fifty-five to seventy-five days. Blood of an immune animal is infective; such an animal forms the reservoir of the virus. This is a peculiarity of the piroplasma diseases, to which group Anaplasmasis also belongs. Dr. Theiler's opinion is that Anaplasmasis is probably the disease which the farmer has hitherto called "gall sickness." Up to the present four different parasites are, in South Africa, found in the blood of immune cattle, and they can all be transmitted by the inoculation of the blood and by ticks.—Dr. R. **Gonder**: The development of *Piroplasma parvum* (Protozoa) in the various organs of cattle. The author suggests an explanation of the fact that the blood of animals suffering from East Coast fever injected into healthy animals does not transmit the disease. It is possible, he thinks, that the blood contains forms which can develop in the tick, and which, when injected, die. Concerning the place of the East Coast fever parasite in protozoology, he thinks the proposition justifiable to separate it from Piroplasma, and to substitute a new generic name, "Theileria," as suggested by Bettencourt.

FORTHCOMING CONGRESSES.

August 1–6.—International Congress of Entomology. Brussels. Chairman of Local Committee for Great Britain: Dr. G. B. Longstaff, Highlands, Putney Heath, S.W.

August 1–7.—French Association for the Advancement of Science. Toulouse. President: Prof. Gariel. Address of Secretary: 28 rue Serpente, Paris.

August.—International Congress of Photography. Brussels. Correspondent for United Kingdom: Mr. Chapman Jones, 11 Eaton Rise, Ealing, W.

August 2–7.—International Congress on School Hygiene. Paris. General Secretary: Dr. Dufestel, 10 Boulevard Magenta, Paris. Hon. Secretaries for Great Britain: Royal Sanitary Institute, 90 Buckingham Palace Road, S.W.

August 15–20.—International Zoological Congress. Graz (Austria). President: Prof. Ludwig von Graff. Address for inquiries: Prasidium des VIII. Internationalen Zoologen-Kongresses, Universitätsplatz 2, Graz (Österreich).

August 18–26.—International Geological Congress. Stockholm. General Secretary: Prof. J. G. Andersson, Stockholm 3.

August 29 to September 6.—International Union for Cooperation in Solar Research. Mount Wilson Solar Observatory. British Member of Executive Committee to whom inquiries should be addressed: Prof. A. Schuster, F.R.S., Victoria Park, Manchester.

August 31 to September 7.—British Association. Sheffield. President: Prof. T. G. Bonney, F.R.S. Address for inquiries: General Secretaries, Burlington House, W.

September 4–7.—Swiss Society of Natural Sciences. Bâle. Secretary: Dr. H. G. Stehlin, Museum of Natural History, Augustinergasse, Bâle.

September 8–14.—International Congress of Americanists. Mexico City. General Secretary: Sr. Lic. D. Genaro Garcia, Museo Nacional, Mexico, D.F.

September 13–15.—International Congress of Radiology and Electricity. Brussels. General Secretary: Dr. J. Daniel, 1 rue de la Prévôte, Brussels. Correspondents for United Kingdom: Prof. Rutherford and Dr. W. Makower, University of Manchester, and Dr. W. Deane Butcher, Holyrood, Ealing, W.

September 18–24.—German Association of Naturalists and Physicians. Königsberg. Secretaries: Prof. Lichtheim and Prof. F. Meyer, Drummstr. 25–29, Königsberg.

September 27–30.—International Physiological Congress. Vienna. President: Prof. S. Exner. General Secretary for United Kingdom: Prof. E. B. Starling, University College, London, W.C.

October 6–12.—Congrès International du Froid. Vienna. Correspondent for United Kingdom: Mr. R. M. Leonard, 3 Oxford Court, Cannon Street, E.C.

CHRISTIAN TOPOGRAPHY.

The Christian Topography of Cosmas Indicopleustes. Edited, with Geographical Notes, by E. O. Winstedt. Pp. x+376+xiv plates. (Cambridge: University Press, 1909.) Price *12s. 6d.* net.

THE "Christian Topography" of Kosmas Indikopleustes is a very peculiar work. As a monument of literary style it is precious, for it shows us what terrible rubbish, what wandering and discursive twaddle, people were already writing in the sixth century, when the mental degeneration of the Middle Ages (more properly called the "Dark Ages") had hardly yet set in. As a geographical landmark it is also precious, for the author, twaddlemonger as he was, went to various parts of the East beyond the ken of the ordinary man of the time, and his descriptions of the Somali coast, of Coromandel, and of Ceylon, which he apparently visited himself, in the sixth century, are in the highest degree interesting and valuable. Finally, as a work of unintentional humour, it is beyond price. Of course, the humour of it would not be apparent to all, and it is perhaps irreverent (to the sixth century, which is now somewhat venerable) to direct the reader's attention to this feature of this peculiar work. Yet, since the editor himself indulges in a hearty laugh over the poor old "Christian Topographer," perhaps the reviewer may be allowed to do so too. At any rate, he sins in the most authoritative company, and if the editor treats his subject (as Mr. Winstedt does) something after the style of Mark Twain and the Yankee at the Court of King Arthur, the reviewer must not be censured if he frivolously suspects the Syndics of the Cambridge University Press of having produced a humorous book.

For, really, Mr. Winstedt's introduction to Kosmas is pitched in rather too humorous a tone. Such a quotation as "they didn't know everything down in Judee" (p. 15) is a fault of taste, and one can imagine the bewilderment of a French or German scholar at such an unintelligible sentence as "when he can momentarily get free from the obsession of his King Charles' head—the 'great cosmographer Moses'"! (p. 9). Mr. Winstedt presumably intended this book to be of use to international science, but if so, why has he so ill-advisedly interlarded his otherwise most learned and interesting introduction with comic relief only comprehensible to Englishmen or Americans who know their Dickens and Mark Twain?

Kosmas is funny enough of himself without any editorial attempt to make him funnier by means of jarring modern jests, and Mr. Winstedt may be permitted to enjoy, as he does without spoiling things, the good man's explanation of why the Creation took six days when the Deity could *ex hypothesi* have done it at a single *coup* if He had liked; the reason is that the angels were such weak-minded creatures that if He had created everything all at once they would not have understood it at all, so He took six days about it for their sake, in order that they might fully comprehend how it was done. This, of course, in all seriousness and devoutness. But it shows how weak-minded people were themselves already becoming as early as the sixth century. To a civilised man of three centuries before, the idea would have seemed as comic as it does to us.

The stupidity of the Dark Ages is already in full blast in the mind of Kosmas the Indian-farer.

"What scholar (as the editor quotes from Marion Crawford's 'With the Immortals') has not laughed at the idea of Kosmas, the Alexandrian, that the sun retired behind a mountain to spend the night? And that the earth, the ocean, and the fabulous mountain were all included and enclosed in a luminous oblong box of the exact shape of the tabernacle of Moses?"

He undoubtedly had Moses "on the brain" (though we demur to the use of the expression "King Charles' head" in a scientific work); for him Moses was the "great cosmographer." Religious preconceptions and misunderstood texts were jumbled up in his mind with fragments of the old knowledge and the results of his own travel experiences to produce this extraordinary farrago which he called "Christian Topography," a title which, as the editor says, is excellent, "as it cannot possibly convey any particular meaning to anybody." Photius calls the book a commentary on the Octateuch. It

"might as well be called that as anything else, since Cosmas quotes and comments on a considerable portion of the Octateuch. That, however, was not the main object of his work. His intention was to refute the theory that the earth was round, and to prove that Moses' tabernacle in the wilderness was a model of the universe."

This was his theory, which he illustrated from his own travels, and it is the account of the travels that forms the serious interest of the book to us nowadays as giving a most interesting account of the East in the sixth century, and invaluable information as to the geographical ideas of the time. Kosmas observed the habits and customs of the peoples he visited, and noted the animals and plants of their countries, with care. He also drew pictures of the latter, in which undoubtedly he gave some freedom to his imagination. These pictures, copied and re-copied, have come down to us in the later MSS. of his book, no doubt, somewhat changed *en route*, but still characteristic. Several of them are reproduced by Mr. Winstedt. The picture of a man picking coco-nuts (plate xiv) is especially interesting. Pictures of his weird conception of the universe are, of course, given (plate vi), and the diagram by which he sought to throw contempt upon the horrid theory of Antipodes. The way in which the men of the Middle Ages resolutely set themselves to abjure and ban the theory of spherical worlds, which their civilised ancestors had already promulgated, is curious and characteristic. Kosmas quotes Scripture at length against the wicked pagans who believe in a round world, and his further quotation from Athanasius's "Festal Letters" in support of the current Christian view has chanced to be the means of preserving to us almost all that survives of the Greek text of that work.

Another thing of value that has been preserved in the "Christian Topography" is the text of two important historical inscriptions which he copied at Adulis, the modern Zulla. One of these was set up by officers of Ptolemy Euergetes, and commemorates that great king's conquests in the East; the other was added by a local king of the Axumite dynasty, probably in the second century A.D., to chronicle his conquests in Abyssinia. Historians have to be grateful to the "Christian Topographer" for the preservation of these two documents, and also for the valuable information which he gives us here and there as to the history of his own time. Thus he copied the Adulite inscriptions at the request of Asbas, the Axumite governor, who had been ordered to send copies of them to his master, King Ellatzbaas, who was just then about to set out on his famous expedition to Arabia against Dhu Nuwâs, king of Himyar, which was so brilliantly successful. This was about the year 525 A.D. He gives us also invaluable information as to the great spread of Christianity in the East by the sixth century, especially in Persia and India.

The book, therefore, was fully worthy of an adequate English edition, and, having made our *caveat* as to certain blemishes in dealing with the comic side of the subject, we can say that the editor has done his work well, especially, no doubt, upon the textual side.

TROPHOBLAST AND THE EARLY DEVELOPMENT OF MAMMALS.

Die Säugetierontogenese in ihrer Bedeutung für die Phylogenie der Wirbeltiere. By Prof. A. A. W. Hubrecht. Pp. v+247. (Jena: Gustav Fischer, 1909.) Price 7 marks.

IT is now twenty years since Prof. Hubrecht published, in the pages of the Quarterly Journal of *Microscopical Science*, his classic researches on the trophoblast and allantoic placenta of the hedgehog, *Erinaceus europaeus*. This work, along with the investigations of Eduard van Beneden and M. Duval, may be said to have revolutionised our knowledge of the placental phenomena in the mammalia. By it new light was thrown on the egg-cleavage, the so-called gastrulation, and, especially, on the mode of origin and the nature of the "fœtal membranes," the chorion (trophoblast), amnion, and allantoic placenta. For the Dutch investigator this was the starting-point of a long period of painstaking researches into the placental conditions of diverse mammals, and of these the present work is an author's translation of the English version, published (November, 1908) in the journal containing his earlier results.

So long ago as 1894, under the title "Spolia nemoris," an appetising account was given of the wonderful array of material of mammalian development, which, in the Dutch East Indies, had either been collected personally or obtained and sent to Utrecht by others. We do not recall any similar journey in quest of embryological material which has been attended by such remarkable success in enlisting, and retaining, the altruistic help of so many different collectors. Other embryologists remember, to their sorrow, the failure of attempts to increase their collections by the aid of others and amateurs. This vast material, much of it of rare and interesting species of mammals, has served as the basis of Prof. Hubrecht's researches, and with great generosity he has placed it at the service of other investigators in the Zoological Institute of Utrecht. The limits of space assigned to this notice allow only a general reference to the work before us.

What is *trophoblast?* The word and the thing may be described as the main theme of the work, even though it treats also of the egg-cleavage, germinal layers, allantoic placenta, and the descent of mammals. According to Hubrecht, trophoblast is a specialised portion of the outer layer, the epiblast, of the embryo, and he identifies it more particularly as equivalent to that portion of this layer which in amphibians, for example, forms the outer or covering layer. This latter, admittedly, takes no share in the formation of embryonic structures, and it, and trophoblast also, is regarded by Hubrecht as larval and transitory in character. On the other hand, another mammalian embryologist, Mr. Richard Assheton, has recently again urged the view that trophoblast is in reality a derivative of the inner layer or hypoblast. Apart from other considerations, this identification is, in our opinion, negatived by the circumstance that nowhere in the animal kingdom is the hypoblast known to be formed, as is the trophoblast, as a product of the first cleavages of the egg. Prof. Hubrecht's own recognition of its embryonic epiblastic nature (that it is really a part of "the embryo") seems to be disproved by his own researches on Tupaja. Of the eight products of the egg-cleavage here, seven are destined to become trophoblast, while out of the eighth the whole of the embryo, including presumably its epiblast, is unfolded. If the two foregoing objections be valid, the explanation of the nature of trophoblast must be sought elsewhere, for as yet no one has had the temerity to suggest the remaining alternative, the third germinal layer or mesoblast, as its source of origin.

The truth is, as so often happens in embryology, far too little account has been taken of physiological considerations. The trophoblast arises early in development, and never takes part in the formation of embryonic organs, but instead thereof it eats and erodes its way into the uterine wall, and in doing this it destroys the epithelial lining and much besides. If this happens to be in a tubal (oviducal) gestation, the erosion is finally through the oviduct, with sudden and often fatal hæmorrhage into the abdominal cavity. A mass of cells, trophoblast, which can do this, and in the absence of a normal embryo may become the most deadly form of cancer, chorio-epithelioma, can have no nutritive import for the embryo, as its name falsely implies, nor by any stretch of the imagination can it be assigned to either epiblast or hypoblast, for there is nothing in embryology to indicate that embryonic epiblast or hypoblast possesses this property of eroding and destroying maternal tissues. It is not intended as a reproach to the author, or in depreciation of the immense value of his published researches to science, when this lack of information on the physiological and biochemical side is insisted upon. In fine, like so much in embryology, these researches would appear to fall short of their object in that they ignore the foundations and principles, and even the existence, of a science of stereochemistry, founded so long ago as 1860 by Pasteur for chemists—and biologists. In his two lectures "On the Asymmetry of Naturally Occurring Organic Compounds," Pasteur wrote:—

"Who can foresee the organisation that living matter would assume if cellulose were lævo-rotatory instead of being dextro-rotatory, or if the lævo-rotatory albumens of the blood were to be replaced by dextro-rotatory bodies? These are mysteries which call for an immense amount of work in the future, and to-day bespeak consideration in the science."

Trophoblast, which, by means of its intracellular ferments, pulls down the living "lævo-rotatory albumens of the blood," cannot itself be made up of such bodies, but by all the canons of stereo-chemistry must consist of dextro-rotatory ones. B.

PLANT-LIFE IN THE BALKANS.

Die Vegetationsverhältnisse der Balkanländer (Mösische Länder). By Prof. Lujo Adamović. Pp. xvi+567; with 49 plates, 11 text-figures, and 6 maps. (Leipzig: W. Engelmann, 1909.) Price 32 marks.

THIS bulky volume on the vegetation of the Balkan district is the eleventh in the series of monographs of plant geography, edited, under the title "Die Vegetation der Erde," by Profs. A. Engler and O. Drude. The district includes Servia, Bulgaria, East Rumelia, North Thracia, and North Macedonia, and the volume therefore forms a companion one to Dr. Beck von Mannagetta's account of the vegetation of the Illyrian district, comprising the western part of the Balkan peninsula, which formed the fourth volume of the same series.

In an introductory chapter, Dr. Adamović gives a sketch of the history of the botanical exploration of the Balkan territory. This began in earnest with the work of Josef Pančić on the flora of Servia (1846–88), which has been supplemented by that of numerous other botanists, especially of Dr. Adamović himself, who has worked continuously from 1890 onwards. The bibliography includes a long list of papers.

The subject-matter of the book falls under four sections. The first is a sketch of the physical geography of the area, in which chapters are devoted to the orographic, hydrographic, geognostic, and climatic conditions respectively. Climatic conditions are regulated by the position of the area under consideration, in the interior of a broad peninsula bordered only by small seas, while in the south high mountain ranges—the Rhodope system in the south-east and the Dinaric system in the south-west—hinder the approach of warm winds, and in the north the cold northern winds find a free entrance. Three climatic zones are recognised—(1) the West Mœsic, which stretches westward from the two mountain systems just mentioned, and is characterised especially by the prevalence of northerly and easterly currents; a cold winter is followed by a cool and damp spring, a fairly warm summer, and usually a warm and fairly long autumn; (2) the East Mœsic zone, to the north of the Balkan range, characterised by easterly currents and a climate similar to that of southern Russia; and (3) a southern zone, including almost the whole of East Rumelia, Thrace, the southernmost part of "Alt Servia" and North Macedonia, which has a climate approaching that of the Mediterranean region.

The second section deals with the vegetation, and is divided into three parts, in the first of which, "Œcological Factors," the author discusses the influence on the plant-life of external influences. Such are the so-called tectonic factors—disposition of land, mountain, plain, and valley, difference of exposure and the like, composition of the soil—chalk, serpentine, volcanic sand, or salt. A good deal of matter of general biological interest is included in the chapter dealing with climatic factors and the effect of many animals and plants themselves on the vegetation. The remainder of the section is an account of the various plant-formations; these are arranged under two heads, representing the two great constituents, those characteristic respectively of the Mediterranean and Central European floras. Under the former are included the "Ornus-Mischlaubwald," the mixed deciduous forest which forms a characteristic highwood on the hilly and submontane districts of the Balkan peninsula; the diversity and abundance of its constituents render it comparable with no other European formations. Here also is the horse-chestnut-formation and the pseudo-maquis, the latter analogous to the evergreen bush-formation or maquis of the Mediterranean area, but adapted to a necessarily shorter vegetative period; the most frequent and widely distributed element of the pseudo-maquis is *Juniperus oxycedrus*, while the arborescent *Juniperus excelsa*, the box, and *Phillyrea media* are characteristic elements. These and other formations comprise the arborescent and bush vegetation, besides which is a series of steppe, rock, salt-marsh, aquatic, meadow, cultivated land, and other formations. The third and largest portion is an account of the plant-formations of a Central European type, the submontane woods of oak, sweet chestnut, and black pine, the mountain woods of fir, pine, spruce (*Picea omorica*), birch, and beech, the bush-formations, the rock, steppe, meadow, marsh, and aquatic formations, and, finally, the subalpine and alpine.

In the third section the author suggests zonal arrangements, both horizontal and vertical, of the two great type-groups of the vegetation; and in the fourth and last section attempts to trace the developmental history of the flora by a consideration of the fragmentary evidence afforded by the plant remains from successive geological strata.

A notice of Dr. Adamović's exhaustive and painstaking survey of the vegetation of the Balkan area would be incomplete without an appreciation of the plates, most of which are reproduced from photographs taken by the author. A. B. R.

MATHEMATICAL TEXT-BOOKS.

(1) *Elements of the Differential and Integral Calculus.* By Prof. A. E. H. Love, F.R.S. Pp. xiv+208. (Cambridge: University Press, 1909.) Price 5s.

(2) *Plane Trigonometry. An Elementary Text-book for the Higher Classes of Secondary Schools and for Colleges.* By Prof. H. S. Carslaw. Pp. xviii+293+xi. (London: Macmillan and Co., Ltd., 1909.) Price 4s. 6d.

(3) *Elementary Projective Geometry.* By A. G. Pickford. Pp. xii+256. (Cambridge: University Press, 1909.) Price 4s.

(4) *A First Course in Analytical Geometry, Plane and Solid, with Numerous Examples.* By C. N. Schmall. Pp. viii+318. (London: Blackie and Son, Ltd., 1909.) Price 6s. net.

(1) THIS book is founded on lectures delivered by Prof. Love at Oxford to students of applied sciences. The object, both of the book and of the lectures, is to encourage the study of the Calculus amongst a wider circle than has been commonly the case hitherto. To quote from Prof. Love's preface:—

"The principles of the Differential and Integral Calculus ought to be counted as a part of the heritage of every educated man or woman in the twentieth century, no less than the Copernican system or the Darwinian theory. In order to make a beginning no previous knowledge of mathematics is needed beyond the most elementary notions of geometry, a little algebra, including the law of indices, and the definitions of the trigonometric functions."

The more difficult theorems on limits which are needed have been proved with considerable detail, but the proofs are placed in appendices so as to avoid discouraging the beginner. The most novel of these is the very complete and satisfactory discussion of the length of an arc of a circle (App. v.); but it seems a pity that the same method was not carried on (in App. vi.) to obtain the limits of sin α/α and tan α/α (as α tends to zero) instead of following the more intuitive method which is given in most text-books.

With the aim and methods of Prof. Love's book we are in hearty sympathy; our sole criticism would refer to the difficult problem of treating the logarithmic function, about which opinions will probably always differ. In conclusion, we may refer to the welcome practice of reducing definite integrals to numbers, in suitable cases, instead of stopping at analytical formulæ; it is very instructive to beginners to compare the result of such a calculation with the value found from a graph, by estimating its area roughly.

(2) The earlier part of this book is based upon lectures delivered by Prof. Carslaw to first-year pass classes, first at Glasgow and afterwards at Sydney. Very good graphs of the trigonometrical functions, direct (pp. 60–2) and inverse (pp. 205–8), including the less familiar functions, such as sec x and sec ^{1}x, will be found in the book; and a set of four-figure tables is given at the end of the book. While welcoming the spread of these tables, it seems a pity that more modern tables (in tenths and hundredths of degrees) were not used instead of Bottomley's forms.

The second part of the book, on analytical trigonometry, is less completely handled, proofs of the more difficult theorems (such as the power-series for sin x and cos x, the product for sin x) being outlined only, without any attempt at rigorous investigations.

A few notes of difficulties may be added, in view of later editions. In discussing the limit of sin θ/θ as θ tends to zero (§ 92) it is assumed that the length of a circular arc is less than the sum of the tangents drawn at its extremities. Although this assumption is natural enough in a purely intuitive discussion, yet, after having given an arithmetic definition of length in §§ 89, 90, it would be only reasonable to deduce the theorem in question from the definition.

When discussing the solution of trigonometrical equations, it seems strange that no use is made of the substitution $t=\cos\theta+i\ \sin\ \theta$; and the more so since all the examples solved in the book (§ 136) can be more easily treated by this substitution than by any other.

In § 148 the convergence of the series $\Sigma a_n \cos n\theta$, $\Sigma a_n \sin n\theta$ is treated graphically by the aid of a spiral polygon. This method is interesting on account of its applications in physical optics, leading up to the graphical treatment of diffraction-integrals by a smooth spiral curve (such as Cornu's spiral); but it is not quite obvious where the geometrical discussion introduces the condition $a_n > a_{n+1}$. It would be helpful to give an algebraical treatment as well, following the classical methods of Abel and Dirichlet, from which the essential character of the condition $a_n > a_{n+1}$ is at once evident.

Prof. Carslaw's book may be heartily recommended to anyone wishing for a good knowledge of elementary trigonometry, together with a first introduction to more advanced methods.

(3) It is not easy to estimate the effect which a geometrical text-book will produce on a beginner; and we have had no opportunity of testing this particular book in actual teaching. But on a first reading the arrangement adopted seems less satisfactory than in several existing books: in a course on *projective* geometry, the method of *projection* should take a prominent part, and not be left until the last chapter in the book. There is a tendency also to give a variety of proofs of theorems which are really all special cases of one general theorem (such as Pascal's or Brianchon's), and this helps to make the book longer, without making it any easier to read.

Two details may perhaps be criticised: the idea of *involution* is introduced very early, before defining projective ranges on the same line; but in actual teaching it is generally found easier to define involution as a special type of homography. Also the pole-locus of a line with respect to a system of four-point conics is called the *nine-point* conic, instead of the *eleven-point* conic; the latter term is now generally adopted, and the reason for the change is not obvious.

It seems to us that there is some need for a book on projective geometry which makes occasional use of analytical methods—in fact, a book written more on the lines of the second half of Salmon's "Conics"—and a really useful addition would be some plates of drawings, on a fairly large scale, showing the actual construction of conics by means of pencil and ruler, in various ways.

(4) There is but little to distinguish the present

text-book from those in common use already. We note the usual unfortunate preference for the equation $y=mx+c$ to represent a straight line, instead of the homogeneous form $lx+my+n=0$. As a natural consequence, we find the equations $y=mx+\sqrt{(a^2m^2+b^2)}$, $y=mx+a/m$, for the tangents to an ellipse and parabola respectively; and we are still left to wonder why no teacher has the courage to write an elementary text-book which uses the tangential equations $a^2l^2+b^2m^2=n^2$, $ln-am^2=0$.

The chief innovation consists in a short chapter (xii., pp. 241–57) on higher plane curves, such as the cissoid, conchoid, lemniscate, cycloid, and some of the simpler polar curves; but as no Calculus is used, nearly all their more interesting properties have to be omitted, and it seems doubtful if the mere tracing of the curves is of sufficient interest to justify their introduction here. We should have preferred to see this space devoted to an extension of the chapters on solid geometry, which occupy only 30 pages, and are too brief to be of much service to beginners.

T. J. I'A. B.

SCHLICH'S MANUAL OF FORESTRY.

Schlich's Manual of Forestry. Vol. ii.: Silviculture. By Sir Wm. Schlich, K.C.I.E., F.R.S. Fourth edition, revised. Pp. ix+424. (London: Bradbury, Agnew and Co., Ltd., 1910.)

THIS book is a decided advance on the first edition of Schlich's "Silviculture," and a considerable amount of new matter has been added.

Probably the original intention of Schlich's "Manual" was to provide a text-book on the general principles of forestry adapted to the needs of Indian and Colonial forest officers. While this object is still met, the author has evidently made an effort (and we think successfully) to adapt the work better to British needs than was the case in earlier editions.

To accomplish this successfully is not perhaps the easy task many might imagine. It is true the principles of forestry are the same over all, but details in practice must of necessity vary, and climatic differences also tend to modify the relative silvicultural value of various species of trees for any country, or even for districts of a country.

The book is divided into four parts: part i. deals with what the author designates "The Foundations of Silviculture." Here we have a full discussion of such matters as climate, soils, effects of forest vegetation on locality; development of forest trees; character and composition of woods; advantages and disadvantages of mixed woods; and rules for forming pure and mixed woods. The various silvicultural systems are also described in detail.

Part ii. is concerning the "Formation and Regeneration of Woods." Fencing, soil preparation, sowing, planting, and tree nursing management are fully treated. Under this head also the various modern methods of natural regeneration are described.

Part iii. deals with the tending of woods throughout the various stages, from early youth to maturity.

Of part iv. ninety pages are devoted to a brief discussion of the silvicultural characters of British forest trees. Under the convenient title of "British Forest Trees" the author includes several recently introduced species, some of which are certainly of doubtful utility for British conditions, as, *e.g.*, American *Black Walnut* and *Black Cherry*. He wisely refrains, however, from definitely recommending such species for general planting.

The book is well illustrated. Although some of the illustrations are necessarily diagrammatic in character, they are none the less valuable to students on that account.

Schlich's "Silviculture" continues to hold its own as one of the chief standard works on the subject, and should be in the hands of all students of forestry.

GENERAL BIOLOGY.

General Biology: a Book of Outlines and Practical Studies for the General Student. By Prof. James G. Needham. Pp. xiv+542. (Ithaca, N.Y.: The Comstock Publishing Co., 1910.) Price 2 dollars.

WE have long felt that if biology is ever to take the place which it undoubtedly should in our educational system, there will have to be some radical reform in the manner in which it is taught, or perhaps it would be more correct to say in the selection of those portions of the subject which are to be taught. The type-system, excellent as it is in many respects, has had far too much influence on biological curricula, and the over-specialisation in zoology and botany has resulted in a general neglect of those general principles which are the life-blood of both. Fortunately, signs are not wanting of a widespread striving towards a more rational treatment of the subject, and in this respect the Americans appear to be taking the lead. The work before us, modestly described by its author as "A Book of Outlines and Practical Studies for the General Student," strikes us as being delightfully refreshing and original. Its scope is, perhaps, almost too comprehensive. There are only seven chapters, but they are very long ones. In the first, the interdependence of organisms is illustrated by the relations between flowers and insects; galls, and the relation between ants and aphids. The second deals with the simpler organisms, illustrated by typical algæ and protozoa. The third is devoted to organic evolution, with a brief account of the animal and vegetable series and the general principles of the subject. The fourth discusses inheritance; the fifth the life-cycle; the sixth the adjustment of organisms to environment; and the seventh the responsive life of organisms.

A leading feature of the book is a set of practical exercises at the end of each chapter. These are extraordinarily varied and interesting, and well calculated to impart a real vitality to the subject, though perhaps some of them, such as the observations on the internal metamorphosis of insects, are rather too specialised.

The illustrations are excellent and to a large extent novel, and the portraits of Schultze, Pasteur, Von Baer, Linnæus, Agassiz, Darwin, Leeuwenhoek, Mendel, and Aristotle help to keep the interest from flagging.

The author states in his preface that the book exists for the sake of the practical studies contained in it, and certainly any student who works conscientiously through these can hardly fail to acquire a very sound knowledge of the problems of general biology, and if his work in this direction is supplemented by an equally thorough study of the more special aspects of either zoology or botany his elementary biological training will leave little to be desired. A. D.

OUR BOOK SHELF.

Catalogue of British Hymenoptera of the Family Chalcididae. By Claude Morley. Pp. vi+74. (London: Printed by Order of the Trustees of the British Museum (Natural History); Longmans and Co., B. Quaritch, Dulau and Co., Ltd., 1910.) Price 3*s.* 6*d.*

Some years ago the Entomological Society of London commenced a "General Catalogue of the Insects of the British Isles," of which, however, only six parts were published, between the years 1870 and 1876, as follows:—Neuroptera, by R. McLachlan; the Ephemeridæ, by Rev. A. E. Eaton; Hymenoptera Aculeata, by F. Smith; Hymenoptera: Chrysididæ, Ichneumonidæ, Braconidæ, and Evaniidæ: by Rev. T. A. Marshall; Hymenoptera: Oxyura, by Rev. T. A. Marshall; and Hemiptera Heteroptera, and Homoptera, by J. W. Douglas and J. Scott. No more appeared; and, of course, those already issued are now somewhat out of date, especially those on parasitic Hymenoptera, largely through the exertions of C. Morley and F. Enock. Since then, however, the Tenthredinidæ, Siricidæ, and Cynipidæ have been monographed by P. Cameron in four volumes issued by the Ray Society; leaving only the Chalcididæ, as the last family of Hymenoptera of which we had no recent compendium of the British species.

The preparation of the present catalogue was undertaken by Mr. Claude Morley, so well known for his work on the British Ichneumonidæ, and edited by Mr. C. O. Waterhouse. Though published by the Trustees of the British Museum, it is practically uniform with the Entomological Society's catalogues already mentioned.

There is little doubt that the order Hymenoptera is the largest of all the seven great orders of insects, and the Chalcididæ, including a large number of small species, almost all parasitic (a very few, however, are believed to be plant-feeders), is by far the largest family. Mr. Morley enumerates 148 genera and 1424 species; and although many of them may probably prove to be synonymous, these will probably be far more than counterbalanced by fresh discoveries when the family is at all adequately known. A great number of species were described by Walker, both in magazines and in separate publications; and to work out his species satisfactorily would be a work of many years. But the best preparation for such an undertaking is a carefully compiled and approximately complete reference catalogue, as the work before us appears to be.

How to Keep Hens for Profit. By C. S. Valentine. Pp. ix+298. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 6*s.* 6*d* net.

This is a well illustrated volume of some three hundred pages. A portion of the material, as the preface points out, has already appeared in the *New York Farmer.* The bulk of the work, with the exception of a chapter devoted to the Indian runner duck, deals with the breeding and management of the "American hen." The reader will have gathered that the book has been produced on the "other side," but there is much that is of interest to our own countrymen. Government aid, problems of improvement, and many amusing stories of the three-hundred-egg hen, are all dealt with, and now the development grant is in sight several of the hints given might be well worthy of consideration.

The most instructive chapters for the would-be poultry-keeper are those that deal with "Handling the Chicks," "Expensive Accidents," "Diseases," and "Runner Ducks." The book is furnished with an excellent index, and in many ways may be a useful adjunct to the library of the man who keeps poultry for utility purposes only in contradistinction to the breeder of exhibition stock.

The Prince and his Ants (Ciondolino). By Vamba (Luigi Bertelli). Translated from the fourth Italian edition by S. F. Woodruff, and edited by Vernon L. Kellogg. Pp. x+275. (New York: H. Holt and Co., 1910.) Price 1.35 dollars net.

A fairy tale of three children, who wished to become insects to escape doing their lessons. The two boys wished to be an ant and a cricket, and the girl to be a butterfly. The present volume relates the adventures of the boy who became an ant, among different species of ants, and afterwards among bees. At the end of the book he meets his sister as a caterpillar, and another volume is promised giving her adventures as a butterfly. The book is well illustrated, and the account of insect life appears to be fairly accurate.

The Thames. Described by G. E. Mitton. Pp. 56. *Windsor Castle.* Described by Edward Thomas. Pp. 56. *Shakespeareland.* Described by Walter Jerrold. Pp. 63. All pictured by Ernest Haslehurst. (London: Blackie and Son, Ltd., 1910.) Price 2*s.* net each.

In noticing the first three volumes to be published in this series, the opportunity was taken to praise the beauty of the illustrations and the interest of the text. The present additions are quite up to the standard set in the earlier books. Though evidently not intended to serve any serious educational purpose, the volumes will form very acceptable gift books, and will soon become popular in this capacity.

A Manual of Geometry. By W. D. Eggar. In two parts. Part i., pp. xiii+160; part ii., pp. x+178. (London: Macmillan and Co., Ltd., 1910.) Price 2*s.* each part.

Many teachers will welcome the re-issue in two parts of Mr. Eggar's "Manual of Geometry." Part i. will prove of particular value just now, since it covers the work specified in the memorandum issued by the Board of Education on the teaching of geometry to beginners. It may be said that the first part deals with the subjects of Euclid, Book i., and the second with those of Euclid, Books ii. to vi.

The South Devon and Dorset Coast. By Sidney Heath. Pp. xvi+445. (London: T. Fisher Unwin, 1910.) Price 6*s.* net.

The latest addition to Mr. Fisher Unwin's "County Coast Series" will form a delightful companion for the visitor to the country lying between Poole on the east and Plymouth on the west. Mr. Heath's miscellany of historical, topographical, and archæological details relating to Devonshire and Dorsetshire is as informative as it is interesting, and the illustrations, which number nearly sixty, make the volume very attractive. There is little doubt that the book will become a favourite with residents in the delightful part of England with which it deals.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

X-Ray Spectra.

It was shown by Barkla and Sadler (*Phil. Mag.*, February, 1907, and October, 1908) that many elements, when subject to a suitable beam of X-rays, emit a homogeneous beam of secondary X-rays of penetrating power characteristic of the radiating element. One of the writers (Barkla, Proc. Camb. Phil. Soc., May, 1909) showed that various groups of these characteristic radiations exist, and that each element most probably emits a line spectrum of X-rays, each line moving to the more penetrating end of the spectrum, with an increase in the atomic weight of the radiating element. For no single element, however, was the homogeneity of more than one radiation proved, or the penetrating power accurately determined. As all the principal phenomena accompanying the transmission of X-rays through matter are determined by the spectra of the constituent elements, it became a matter of considerable theoretical interest to confirm the theory by demonstrating the homogeneity of various radiations from some particular element. The writers therefore chose several of those elements the characteristic radiations of which were expected to be well within the range of penetrating power comparatively easy to experiment upon.

First, by using a penetrating primary beam, a mixture of the various secondary radiations characteristic of a particular element was obtained. After absorbing the softer constituents, a homogeneous beam of the penetrating secondary X-radiation belonging to Group B was left, its homogeneity was proved, and the coefficient of absorption in aluminium determined.

In order to isolate one of the more absorbable constituents, a very "soft" primary beam was used—too "soft" to excite the radiation of Group B just referred to. After the effect of the scattered radiation was determined by separate experiment and eliminated, this secondary X-radiation was also found to be homogeneous, and its absorption was determined. This radiation belonged to Group A.

Thus two of the lines of the spectra of antimony, iodine, and barium were determined. The following values of λ/ρ are the results of the most accurate measurements so far made (λ is defined by the equation $I=I_0e^{-\lambda x}$ in transmission through aluminium of density ρ):—

Sb : (Group B) 1·21 ; (Group A) 435
I : (Group B) 0·92 ; (Group A) 306
Ba : (Group B) 0·8 ; (Group A) 224

A more absorbable radiation belonging to Group A has also been found to be emitted by silver in addition to the penetrating radiation of Group B, thus accounting for what appeared to Mr. Sadler (*Phil. Mag.*, March) to be an exception to the law connecting the emission of secondary corpuscular and secondary X-radiations emitted by an element.

There is indirect evidence of other spectral lines besides those of Groups A and B. Whether or not the radiation, more absorbable than that of Group A—in hypothetical Group X—has the properties of ordinary X-rays is a question to be decided experimentally.

C. G. BARKLA.
J. NICOL.

King's College, London, July 29.

Pwdre Ser.

In case no other reader of NATURE should do so, may I direct Prof. McKenny Hughes's attention to a paper by M. Melsheimer on "Meteorgallerte," published in the *Jahresber. d. westfäl. Provinzialver. f. Wissensch. u. Kunst* (Bd. xxxvi., 1907–8, Münster, 1908, pp. 53–5), an abstract of which appeared in the *Centralblatt f. Bakteriologie* (Abt. ii., Bd. xxvii., Nos. 10–12, p. 237), published on June 22 of this year? The author appears to have paid attention to these masses of jelly, which are to be found in winter on meadows and other open places, for a period of years, and has come to the conclusion that they are the swollen oviducts of frogs. Herons eat female frogs in winter, and the oviducts become mixed in the crop with fish remains, which may become luminous. The contents are thrown up undigested, and become gelatinous when moistened. It is also possible that the heron may, during flight, discharge the gelatinous mass in a luminous condition, and hence the idea that the jelly is of meteoric origin.

GEO. H. PETHYBRIDGE.

Royal College of Science, Dublin, July 4.

THE PRESSURE OF LIGHT.[1]

THE earliest attempts to detect the pressure of light were made in the eighteenth century. The corpuscular hypothesis was then almost universally accepted, and to the believers in that hypothesis the idea that light should exert a pressure upon a body against which it fell was perfectly natural. Regarding the atoms and molecules of a luminous surface as a battery of minute guns firing off a continuous stream of still more minute shot—the corpuscles—they inevitably supposed that any body bombarded by the shot would be pressed back. Many experiments were made to detect this bombardment by directing a powerful beam of light on to a delicately suspended disc, sometimes in air at ordinary pressures, sometimes in a vacuum, but with quite inconsistent and inconclusive results. They were met with the disturbances which still beset experiments on light forces—disturbances partly due to convection in the surrounding gas, and partly due to the radiometer action which Sir William Crookes discovered and investigated a hundred years later.

According to the corpuscular theory, the pressure sought should be equal to twice the kinetic energy of translation per unit volume in the beam used. If the earlier experimenters had known the principle of the conservation of energy and the mechanical equivalent of heat, they would no doubt have measured the energy of the beam, and would then have found that the pressure to be looked for was far too minute for detection by the apparatus which they employed.

With the abandonment of the corpuscular theory and its replacement by the wave theory, the idea of pressure of light disappeared, for the form which the wave theory took at first did not suggest a pressure, and it was not until 1874 that a definite and exact theory of light pressure was given by Clerk Maxwell. According to his theory of stresses in the medium, both electric and magnetic tubes of force press out laterally. If, then, light waves consist of electric and magnetic tubes of force transverse to the direction of propagation, these tubes should press on any surface against which they impinge, and the pressure should be equal to the energy in unit volume of the light. Maxwell calculated that the pressure which should be exerted by full sunlight amounted to about 1/23000 of a dyne per sq. cm.

Twenty-five years later Prof. Lebedew succeeded in detecting and measuring the pressure. He allowed the concentrated rays of an electric lamp to fall on a thin blackened platinum disc delicately suspended in a vacuum so high that there was probably no convection, and even the radiometer action was comparatively small. By the ingenious device of using discs of different thickness with radiometer action proportional to the thickness, he was able to calculate the force acting on an infinitely thin disc on which there would

[1] Based upon the Bakerian lecture on "The Pressure of Light against the Source; the Recoil from Light," by Prof. J. H. Poynting, F.R.S., and Dr. Guy Barlow, delivered at the Royal Society on March 17.

be no radiometer action. He measured the energy of the beam by its heating effect, and the mean of his results showed a pressure of very nearly the amount required by Maxwell's theory.

At the same time, Profs. Nichols and Hull were working at the subject. They used air pressures of one or two centimetres of mercury, that peculiar region of pressure where convection nearly ceases and where radiometer action has scarcely begun. They allowed the beam to fall on a silvered disc, thus obtaining a double pressure—that of the incident plus that of the reflected beam. To eliminate the action of the surrounding gas they made use of the fact that the light pressure has its full force the instant the beam falls on the surface, while the convection and radiometer actions only slowly develop as the disc gets heated. Nichols and Hull, therefore, only allowed the beam to fall on the disc for a short time—six seconds, a quarter period of the suspended system—and thus they eliminated the gas disturbances. They measured the energy of their beam by determining its heating effect, and the observed pressure was found to agree with Maxwell's theory to within 1 per cent.

When a beam of light, then, falls normally on an absorbing surface, it presses against it with a force per sq. cm. equal to the energy density. It is giving momentum to the surface at this rate. The beam is therefore a carrier of momentum. The waves of light carry momentum, momentum forward in the direction of propagation, just as surely as if they were material corpuscles; and on either theory the momentum given per second is equal to twice the *kinetic* energy per unit volume, since in the waves we may assume that the total energy is half kinetic and half potential.

If we trace back this momentum it must have been put into the train of waves at its source, at the luminous surface from which they issued. The waves are there acquiring forward momentum. The source is losing forward momentum, or is gaining backward momentum. That is, the source is being pressed back with a force per sq. cm. equal to the energy density in the issuing waves. Thus, if the total energy emitted by one sq. cm. in one second is R, and U is the velocity of propagation, we have the pressure given by

$$p = \frac{R}{U}.$$

It is here assumed that all the energy is emitted normally to the surface. If, however, the surface is emitting in all directions according to the cosine law, it is easily shown that the effect of the spreading round the hemisphere is to make

$$p = \tfrac{2}{3}\frac{R}{U}.$$

The pressure against the receiver is a proved experimental fact independent now of any particular hypothesis which we may adopt as to the nature of light; and it does not appear possible to avoid the conclusion that the momentum revealed in that pressure against the receiver was derived from the source.

The experiment which we now describe has been made to detect the starting of the momentum from the source. It should be manifested as a back pressure, a recoil of the emitting body from the light, or radiation, which it sends forth.

The most direct method would, no doubt, consist in suspending a disc black on one side, silvered on the other. Inside the disc should be a coil of wire, and this coil should be heated by a current introduced through the suspension. The heat would be given out as radiation by the black surface, and hardly at all by the bright surface, with the result that the black surface should be pushed back. But the experimental difficulties in the way of such a direct method appear insuperable. The disc was, therefore, heated by allowing radiation to fall upon it and to be absorbed. This heat issued again as radiation, and it is the back pressure of this issuing radiation that had to be detected.

The nature of the action to be looked for may be seen by considering an ideal case in which we allow a beam with energy P per cubic centimetre to fall normally in a perfect vacuum in turn on each of four discs, the front and back surfaces of these discs being respectively as in Fig. 1, where B represents a fully absorbing or "black" surface, and S a fully reflecting or non-radiating surface.

When the radiation falls on an absorbing face, as in the case of either of the discs (1) and (2), the temperature of the disc rises until a steady state is reached in which emission equals absorption. We may suppose that the discs are so thin that the two faces are sensibly at the same temperature. If we did not take into account the pressure due to issuing radiation, or if we only considered the initial effects before heating took place, the pressures on the first two discs would be P in each case, due to the incident beam alone, and on the last two would be 2P, due to the sum of the incident and reflected beams. We should have, therefore,

(1)	(2)	(3)	(4)
P	P	2P	2P

But when a steady state is reached, the discs (1) and (2) must be giving out as much radiant energy as they receive. The first disc gives out equal amounts

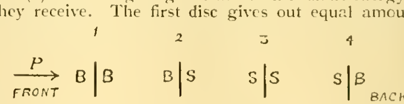

Fig. 1.

on the two sides, producing equal and opposite pressures. All the radiation from the second disc is given out at the front side, and is equal in energy to that of the incident beam. Assuming this emitted radiation is distributed according to the cosine law, the pressure resulting from it is easily shown to be $\frac{2}{3}$P, so that the total pressure on this disc is $\frac{5}{3}$P.

Since there is no absorption by discs (3) and (4), we still have the pressures 2P; hence we have now

(1)	(2)	(3)	(4)
P	$\frac{5}{3}$P	2P	2P

In a real case these results are modified in two ways:—

(1) By the possession of some small reflecting power by surface B, and of some small absorbing and radiating power by surface S.

(2) By an inequality of temperature between front and back surfaces conditioned by the energy which is carried through from front to back to be radiated thence. The vacuum is not perfect, and there is radiometer action due to the residual gas, which, owing to the inequality of temperature, is not the same on the two sides. This is probably the only way in which gas action is sensible, for the effects due to ordinary convection and conduction in the residual gas are negligible.

In the final form of the experiment each disc consisted of a pair of circular cover glasses, 1·2 cm. in diameter and about 0·1 mm. thick, between which was squeezed a layer of asphaltum also about 0·1 mm. thick, the temperature being first raised sufficiently to render the asphaltum molten. Such a compound disc appears to be perfectly opaque, and its surface is extremely black and little diffusing.

The reflecting surface was made by depositing a silver film on the outside of the compound disc by means of the discharge from a silver kathode in an exhausted receiver.

Four holes the size of the discs were cut in a plate of mica ABCD, the centres of the holes being at the corners of a 2-cm. square (Fig. 2). The discs were fixed in these holes by a minute amount of celluloid varnish. Below the mica plate were the two observing mirrors M_1, M_2. This system was suspended by a quartz fibre G, 9 cm. long, in the centre of a glass flask of 16 cm. diameter. The upper end of the quartz fibre was fixed to a brass collar H, held by friction in the neck of the flask.

The exhaustion of the flask was carried out to a very high degree, but an account of the method adopted and the precautions taken is here unnecessary. In the final stage of the process the residual gas was absorbed by a charcoal bulb kept surrounded by liquid air, which was boiled off continuously at a reduced pressure of about 2 cm. of mercury, for several hours before, and during the whole of the measurements.

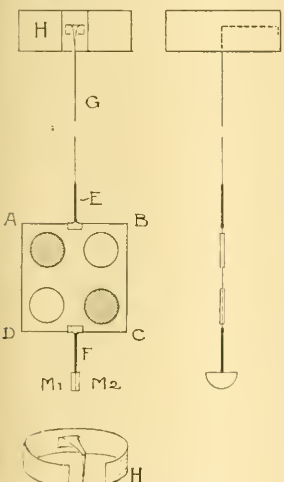

Fig. 2.

The source of light was an Ediswan 50-volt "focus lamp," which was fed from accumulators. By a suitable arrangement of achromatic lenses a uniformly illuminated image of a circular diaphragm was focussed on the disc to be worked with. The flask was mounted on a turn-table, so that by rotation through 180° experiments could be made on the reverse sides of the discs.

For reading the deflections the image of an electric lamp on a millimetre scale at a distance of 113 cm. was used, the deflection being read to 0·2 mm.

As the mean of a number of determinations we have the final values (in scale divisions) for the pressures on the four discs:—

BB	BS	SS	SB	
16·1	22·3	28·7	28·0	(Observed)

A determination of the energy of the beam was made by allowing it to fall on a blackened disc of silver and observing the initial rate of rise of temperature by means of a constantan-silver thermoelectric junction soldered to the disc. The energy was found to be 33×10^{-6} ergs per cm. length of the beam used. This would be the force in dynes on a fully absorbing surface. Had the BB disc been fully absorbing the beam should have deflected it 13·6 scale divisions. Assuming that the asphaltum disc reflects 5 per cent. and the silver 95 per cent. of the incident beam—an estimate which cannot be seriously in error—it can easily be shown that the deflections of the four discs should have been:—

BB	BS	SS	SB	
14·3	22·0	26·5	26·1	(Calculated)

The general agreement of these values with the observed values given above appears to afford satisfactory evidence for the existence of the recoil effect. In the case of the BB disc, however, there is a marked difference between the observed and calculated values, and this discrepancy is probably to be ascribed to residual radiometer action. There was reason to suspect that this action was not sufficiently reduced to make it quite negligible, and it was obvious that this disc should be more affected than the others by radiometer action, as the difference in temperature between the two sides of the disc is greatest in that case.

The forces due to light are so small, and the disturbances due to convection are relatively so great, that we cannot expect to find any effects due to light pressure here on the surface of the earth surrounded by a dense atmosphere. But out in interplanetary space, where the vacuum must be far higher than anything to which we can attain, the light forces may have uninterrupted play, and in the course of ages they may produce great effects; but even then only small bodies will be seriously affected. Take, for instance, a sphere; the pressure of sunlight upon it varies as the square of the radius, and the mass as the cube of the radius. Thus the acceleration produced is inversely as the radius for spheres of the same density. The whole pressure of sunlight upon the earth is only a forty-billionth part of the sun's gravitative pull. If we reduce the radius the pressure becomes more important in proportion, and on a sphere of one forty-billionth of the radius of the earth—or 16×10^{-6} cms. radius—and of the earth's density, if diffraction did not come into play, the pressure of sunlight would balance gravitation. Still smaller spheres would be pushed away.

But turning to the case of bodies somewhat larger than those in which gravitation is neutralised by light-pressure, bodies for which gravitation is still much greater than the light pressure, we will now consider an effect on them due to the pressure of radiation against the source. Let us suppose that a small spherical absorbing body is circling round the sun. It is receiving radiation from the sun on its bright half, transmuting it to heat, and then giving out this energy as radiation again all round. If the sphere is sufficiently small—say of 1 cm. diameter or less—it will be practically of the same temperature throughout, a small difference of temperature from front to back sufficing to carry through the energy which it radiates from the dark half. It virtually receives from the sun on its diametral plane, and it radiates out from its whole surface, which is four times as great. So that its rate of radiation per sq. cm. is one-fourth the solar radiation per sq. cm. passing the sphere. But we suppose that the sphere is moving round the sun. As it moves forward it crowds up the waves in front and opens out the waves behind it. It follows, then, that in consequence of the motion, the pressure is slightly greater against the radiation emitted in front, and slightly less against the radiation emitted behind. The negative acceleration, or retardation, works out to be

$$-\frac{S}{4a\rho}\frac{v}{U^2}$$

where S is the solar stream of radiation, a the radius of the sphere, ρ its density, v its velocity, and U the velocity of light. As the sphere moves against this resisting force its energy is gradually abstracted, and it tends to fall into the sun.

If a sphere 1 cm. in diameter, and of the density of the earth, is moving round the sun at a distance equal to that of the earth, it will fall in about one mile in the first year. If it continues to describe a nearly circular spiral, it will fall in less and less each revolution, but the revolutions take less and less time, and in equal times it will fall in more and more. Such a sphere will reach the sun in something of the order of 45,000,000 years. But the rate of falling in is inversely as the radius, so that a sphere 1/1000 cm. in diameter will fall in 1000 miles in the first year, and will reach the sun in 45,000 years.

There is no doubt that there are such bodies in our system. We have clear evidence of their existence when they perish as shooting stars in our atmosphere. Also there seems no way to avoid the conclusion that they are all spiralling in to the sun and will ultimately reach him unless their career is cut short by some intervening planet. How, then, are we to account for their existence in our system to-day? Whatever limit we may assign to the age of the earth as a habitable globe, we must assign to the sun some vast number of millions of years, vast enough to have allowed him long ago to draw to himself all the specks of dust in his system. How is the supply renewed? Is interstellar space inhabited by scattered meteorites? Are they brought in by comets which have become disintegrated? And so light pressure raises once more an old and still unsolved problem.

A NEW TRYPANOSOME PARASITIC IN HUMAN BEINGS.[1]

THE terrible mortality caused by sleeping sickness in Africa, and the knowledge that this deadly disease is caused by a species of trypanosome, has directed the attention of the general public, as well as of scientific and medical men all over the world, to these blood-parasites. The frequent occurrence of trypanosomes in the blood of vertebrate animals of all classes has long been known to zoologists, but this fact was regarded as little more than a scientific curiosity until Bruce, scarcely fifteen years ago, showed that a species of trypanosome, since named after him (*Trypanosoma brucii*), was the cause of the dreaded tsetse-fly disease of domestic animals in Africa, and followed this up by his discoveries, in the present century, with regard to the nature and transmission of sleeping sickness.

No little sensation was created, therefore, when it was announced by Chagas about a year ago[2] that he had discovered a new species of trypanosome, named by him *Trypanosoma cruzi*, in human blood in Brazil. A full account of this parasite, its development, and mode of transmission, has now been published by Chagas, with numerous illustrations, and it proves to be a form no less interesting from the purely zoological than from the medical standpoint.

The manner in which this parasite was discovered is remarkable. Chagas found that in the province of Minas Geraes the houses, especially the thatched huts of the poorer classes, were infested by bugs (Fig. 1) of the species *Conorhinus megistus*, voracious blood-suckers of large size and nocturnal habits, responsible for much loss of sleep, as well as of blood, to the unfortunate inhabitants. Some of these bugs were collected and brought to Rio de Janeiro, where they were dissected and examined in the laboratory of the Instituto Oswaldo Cruz, and were found to contain in their digestive tracts numerous flagellate organisms resembling in form and structure the genus Crithidia. When such bugs were allowed to feed on experimental animals, namely, marmosets (*Callithrix penicillata*) and guinea-pigs, they infected them with trypanosomes, to the effects of which the marmosets succumbed in about two months, the guinea-pigs in five to ten days. After this surprising result, Chagas returned to Minas Geraes and examined the blood of human beings in the zone infested by the bugs, and found several cases of human beings infected with similar trypanosomes. Thus the course of the discovery of this parasite has been the exact opposite to that of the progress of our knowledge of sleeping sickness; there the disease was thoroughly known long before it was found to be caused by a trypanosome, then the mode of transmission was discovered, and the complete life-cycle of the parasite has not yet been worked out; here the transmitting insect was first known, then the parasite itself was discovered, and, last of all, it was found to occur in human blood, with the result that the life-cycle of the trypanosome has been investigated in considerable detail, but very little is known of its effects in their clinical aspect.

The few cases of infected human beings observed by Chagas have not been followed out by him to their end as yet. He finds the effects of the parasite to be most marked, however, in children, amongst whom it appears to cause severe mortality. The chief symptoms are anæmia, œdema, general or localised, enlargement of the lymphatic glands and of the spleen, and functional disturbances, especially of the nervous system, leading in some cases to imbecility. A tendency to arrest of development, resulting in pronounced infantilism, was also noticed. According to information collected, the fatal termination of the disease was frequently attended by convulsions, regarded locally as the cause of death, and sometimes by dropsy in the last stages.

FIG. 1.—*Conorhinus megistus*, Burm., ♀.

The life-cycle of the parasite, as described by Chagas, shows some peculiarities not yet known in any other species of trypanosome. In the vertebrate host it exhibits three phases, which may be termed conveniently the adult, the multiplicative, and the growth phase respectively.

In the adult phase, the organism is free in the blood-plasma, and has the typical trypanosome-structure (Fig. 2, *a*). It shows, however, a dimorphism which Chagas regards as sexual. One form, regarded as male, is more slender, with a larger kinetonucleus and a more elongated trophonucleus; the other, regarded as female, is broader, with smaller kinetonucleus and rounded trophonucleus.

These adult trypanosomes in the peripheral blood were never observed to multiply by fission, a fact which the author seems to consider remarkable, doubtless from the standpoint of studies upon pathogenic trypanosomes, though it may be pointed out that the same is true of the common trypanosomes of vertebrate animals, especially those of birds and fishes. Chagas has discovered that the multiplication takes place by a process of multiple fission or "schizogony" in the lung. Hence he founds provisionally a new genus, Schizotrypanum, for this species. It remains to be seen how far such schizogony is peculiar to this parasite. The only salient difference between the multiple fission of *Schizotrypanum cruzi* and that of the common *Trypanosoma*

[1] "Nova tripanosomiaze humana." By C. Chagas. Memorias do Instituto Oswaldo Cruz I., 1909. Pp. 159–218; plates ix–xiii and 10 text-figures. (Portuguese and German text.)

[2] See the Bulletin of the Pasteur Institute for May 30, 1909, p. 453.

lewisi of rats, is that in the latter the flagellum is retained, as a rule, and in the former is always lost, during the process. In *S. cruzi* there appears to be an alternation between periods of multiplication with schizogony in the lungs, with adult free trypanosomes occurring sparingly in the blood, and periods in which the peripheral blood contains numerous trypanosomes. In the case of experimental animals, it was found, as a rule, that at the time of death trypanosomes were very scanty in the blood, while schizogony was proceeding actively in the lung.

The trypanosome, when about to undergo multiplication, first throws off the flagellum and undulating membrane; it may or may not lose its kinetonucleus at the same time. It then curls up (Fig. 2, *b*), and contracts into a rounded mass, the schizont (Fig. 2, *c*), after which the trophonucleus and the kinetonucleus, also, if present, divide each three times to form eight small nuclei of one or both kinds (Fig. 2, *d*). The protoplasmic body then divides up within its own skin (periplast) into as many parts, termed by Chagas merozoites (Fig. 2, *e*). Each merozoite contains either a single trophonucleus, or a kinetonucleus in addition. The generation with a persistent kinetonucleus is regarded by Chagas as male, that without

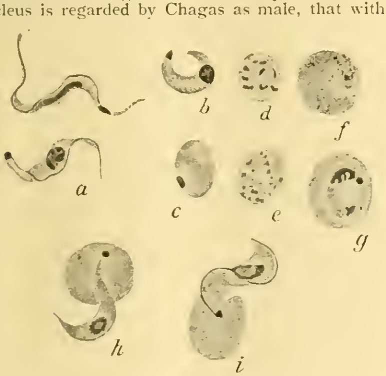

FIG. 2—*a–i*. Phases of *Schizotrypanum cruzi* in vertebrate blood. *a*, the two forms of the adult trypanosome, "male" (upper) and "female" (lower), from human blood; *b*, preparations for schizogony; *c*, schizont; *d*, division of the nucleus of the schizont; *e*, division of the schizont into eight merozoites; *f*, merozoite in a blood-corpuscle; *g*, intra-corpuscular phase in late stage of growth; *h*, similar phase escaping from the corpuscle, the flagellum not yet formed; *i*, similar phase, the flagellum in process of formation.

any such body as female. Although the author insists on interpreting these and other differences as sexual, it should be noted that no sexual behaviour has been observed in any part of the life-cycle of the parasite.

The tiny merozoites are stated to escape singly from their envelope and to penetrate into red blood-corpuscles (Fig. 2, *f*), in which they grow into the adult form (Fig. 2, *g*, *h*). In those merozoites which are without a kinetonucleus, this body arises by division of the single nucleus present. The flagellum and undulating membrance appear to be formed when the organism is full-grown, sometimes not until it has escaped from the blood-corpuscle (Fig. 2, *h*, *i*). It is remarkable, however, that Chagas does not figure any intracorpuscular phases intermediate in size between the very smallest and those which are practically full-grown; and it must be said that many of his figures of the later growth-phases are not at all convincing as to the parasite being really within the corpuscle.

With completion of growth and liberation from the corpuscle, the adult phase of the free trypanosome is reached.

On the ground that *Schizotrypanum cruzi* differs from all known trypanosomes in undergoing multiplication by schizogony, and in the possession of an intracorpuscular phase, Chagas regards it as a form connecting the trypanosomes and the Hæmosporidia (malarial parasites and allied forms), and supporting the union of these two groups in systematic classification. This view raises questions which cannot be discussed in a brief space.

By experiments on the transmission, Chagas found convincing evidence that the parasite goes through a developmental cycle, with a minimum duration of eight days, in the bug. Until this cycle is complete the bug is not infective. It is a point of great interest that, while bugs collected in human dwellings and bugs fed in the laboratory on infected marmosets transmitted the infection, he was never able to render bugs infective by feeding them on infected guinea-pigs. Chagas is of opinion that a certain condition of the parasite is necessary to produce infectivity in the bug, and that the requisite conditions are furnished by the blood of human beings or marmosets, but not by that of guinea-pigs. Experiments to prove transmission of the parasite through the egg of the bug gave entirely negative results in all cases.

Phases in the development of *Schizotrypanum cruzi* in the invertebrate host are described by Chagas from bugs bred in the laboratory and fed on infected animals. The parasites begin to undergo a change in the stomach of the bug about six hours after feeding (Fig. 3, *a*, *b*, *c*); they lose their flagellum and contract into rounded forms which multiply actively by fission (Fig. 3, *d*). After a period of multiplication, the rounded forms become pear-shaped, and develop a flagellum at the pointed end (Fig. 3, *e*, *f*); thus are produced flagellates of the Crithidia type (Fig. 3, *g*, *h*), which pass on from the stomach into the intestine, and there multiply rapidly by fission. As a result, the intestine becomes peopled by a swarm of crithidial forms, the characteristic condition of the infected bug. In a few instances Chagas found trypanosome-like flagellates in the body-cavity and the salivary glands (Fig. 3, *i*), and he regards these trypaniform individuals as the last phase in the development of the parasite in the bug, that is to say, as the form in which the parasite is inoculated into the vertebrates by the invertebrate host.

It should be noted here that the three principal forms which the parasite assumes in the bug, namely the rounded, crithidial, and trypaniform types, are found by Chagas to occur also in artificial cultures on blood-agar, and to succeed each other in the same order. This parallelism indicates that these forms represent the natural developmental cycle of the parasite in the invertebrate host; that the rounded and especially the crithidial forms represent the multiplicative phase whereby the parasite establishes itself in the bug, while the trypaniform individuals represent the propagative phase destined to infect new hosts. Chagas, however, interprets the facts observed in a different manner. He regards the crithidial forms as the end-product of an atavistic degeneration of the parasite, a mere culture-phase which does not develop further, and is of no importance for the transmission to the vertebrate host and the continued propagation of the parasite. On the other hand, he attaches great importance to two forms observed by him in the bug but not found in the artificial cultures, namely, encapsuled forms (Fig. 3, *j*), which he believes to represent zygotes, although no conjugation has been observed, and certain forms which he interprets as schizogony in the intestine of the bug. According to Chagas, the true infective cycle of the parasite in the bug is comprised in four stages:—(1) the encapsuled "zygotes"; (2) the schizogony-forms; (3) the trypaniform individuals in the body-cavity; and (4) the similar forms in the salivary glands. I feel it incumbent upon me to state that in my opinion the encapsuled forms are merely resting stages of rounded or crithidial forms, the interpretation of which as zygotes is a pure assumption, and that the so-called schizogony-forms have nothing at all to do with the life-cycle of Schizotrypanum, but appear to be merely parasitic organisms of the nature of yeasts from the intestine of the insect. In justice to the author, however, it should be mentioned that he does not regard his observations on the life-cycle in the invertebrate as in any way final, and considers that many points remain to be further investigated.

The memoir of Chagas contains a great number of very interesting observations to which space does not permit of further reference. We may direct attention especially to his experiments on the variations in the virulence of the parasite as the result of passage through different vertebrate hosts. The whole work is an exceedingly important contribution to our knowledge of the trypanosomes, and we desire to congratulate both the author and the Instituto Oswaldo Cruz on a great achievement. E. A. MINCHIN.

TIDAL RESEARCHES.[1]

THE collection of data as to high and low water at various ports and the investigation of tidal currents present arduous tasks, and amongst those who have devoted themselves to these subjects Dr. J. P. van der Stok occupies a distinguished position. It is due to him that our knowledge of the tides of the Dutch East Indies rivals that furnished by our own admirable survey of India. He is an ardent adherent of the harmonic notation, and in the paper of which we now give an account he tabulates the principal tidal constants for no fewer than 138 ports in the Dutch Indies. To the best of my belief this immense mass of data has been collected and reduced through his own personal initiative.

This pamphlet gives an account of the theory on which harmonic analysis is based, but it is to be regretted, at least by all but his own fellow-countrymen, that it should have been written in his own language. Of course, the language is immaterial as regards the tables of constants, but it may prove an obstacle to those who desire to understand the other interesting points treated by the author.

Dr. van der Stok summarises his results in the form of co-tidal charts for the tract of ocean extending from the Malay Peninsula to New Guinea. The first of these exhibits the march of the principal lunar semidiurnal tide M_2. It appears that there is a point towards the south-eastern end of Sumatra at which the wave divides, one portion travelling north-west and the other eastward along the south coast of Java. Along the north-eastern coast of Sumatra, past Singapore, the wave travels in the opposite direction, namely, towards the south-east. It is met by a wave which travels westward and south-westward along the southern and northern coasts of Borneo, and westward along the northern coast of Java. Thus, in contrast with the divergence of the tide-wave off the south of Sumatra, there is a convergence from all sides towards a point midway between Sumatra and Borneo. Eastward of Borneo, in the direction of New Guinea, the general trend of the wave is northward.

The second of these co-tidal charts is, I believe, unique in that it exhibits the progress of the diurnal tide K_1.[1] The path of this wave exhibits a considerable resemblance to that pursued by the semi-diurnal wave, but it differs in the fact that it seems to approach the south coast of Java from the south, and thus the line of advance is from the south throughout the whole tract extending from the southern extremity of Sumatra to New Guinea.

I do not think that any previous investigator has attempted to draw a diurnal co-tidal chart. In the north Atlantic the diurnal tide is insignificant in amount and imperfectly known, but I think it might be possible to construct a similar chart for the coasts of India; I am not aware, however, that any such attempt has ever been made.

At the present time there are only three tide-predicting instruments in existence, namely, those in England, France, and the United States; but I have reason to know that a fourth is being constructed for another Government. Without the aid of such an instrument, tidal prediction is notoriously very laborious, and any process which may render predictions easier is very welcome. I have myself shown how numerical predictions may be made, but the preliminary computations are very laborious and tedious, although when the requisite tables are once formed it is easy and short to make a prediction.[2] But this method does little to facilitate the computation of a tide curve for a given place and given day direct from the harmonic constants. Now Dr. van der Stok pro-

[1] "Elementaire Theorie der Getijden—Getij-Constanten in den Indische n Archipel." (K. Nederlandsch Meteorologisch Instituut, No. 102, 1910.)

[1] There is a short discussion of the diurnal tides in Harris's "Manual of Tide," part iv. A, p. 660.

[2] Phil. Trans., clxxxii. A, p. 169, or vol. i. of my "Scientific Papers."

vides just what is wanted to meet this requirement with all needful accuracy. He has computed a set of auxiliary tables from which the required results may be extracted with a fair degree of rapidity. It is in the explanation of the use of these tables that I fear the Dutch language may prove a difficulty to some would-be users of the method.[1]

I shall not try to explain the process in detail, but will only sketch the ideas on which it is founded. It is assumed that sufficient accuracy will be obtained if the phase of each of the constituent tides is specified to the nearest exact hour of mean solar time. It is easy to compute the fall and rise of any constituent tide for successive hours. For example, suppose that we consider the tide M_2, that its amplitude is, say, 174 (expressed in cm. or any other unit), and that we designate the hour of its high water as o h.; then its march would run thus:—

h.		h	
0 ...	174	3 ...	9
1 ...	152	4 ...	−76
2 ...	92	&c.	&c.

Now if at any given place, and on any given day, we find the incidence of the high water of M_2 to the nearest clock hour, it is easy to write down the successive heights from the table in a schedule numbered from o h. to 23 h. If, for example, high water of M_2 is found to occur at 13 h. of clock time on the day in question, we should write 174 opposite 13 h., 152 opposite 14 h., and so on. The same process may be carried out for each of the principal component tides, and the sum may be obtained for each hour of the twenty-four, thus furnishing the resultant height of water. Auxiliary tables are furnished by Dr. van der Stok from which it is easy to determine the incidence of each partial high water in clock time, and tables of fall and rise are given for any required amplitude.

I should guess that it would take from twenty minutes to half an hour to compute and draw a fairly accurate tide-curve for any given day. If this estimate is correct, it would take a computer a month to draw a tide-curve for a whole year. Probably the work would be quicker when the tide is to be found for a succession of days, and in any case the task would not seem to be prohibitive to compute a year's tide-table with accuracy sufficient for practical purposes.

The paper also gives an example of the synthesis from harmonic constants of the tidal currents at a place called Sembilangan. This last statement may well prove almost unintelligible even to a man versed in tidal work. For a full explanation I must refer the reader to Dr. van der Stok's "Études des Phénomènes de Marée sur les Côtes Néerlandaises."[2] Four of this series of papers have been already published by the Nederlandsch Meteorologisch Instituut. I have not seen the first, but the second and third are dated 1905, while the last is of later date than the paper which we are now reviewing. I gather that the first of the series gives a method of obtaining tidal constants from observations taken every six hours, and the subject is resumed in the last paper, which contains an immense mass of information about the constants along the whole length of the Dutch coast. But I must revert to the subject of tidal currents discussed in the second and third of the series, and explain in outline what is meant by the harmonic analysis of tidal currents.

[1] Something of the kind has been done by Harris in his "Manual of Tides," part iii., p. 183. His procedure seems to be more elaborate, and probably more accurate, but also less rapid than that devised by Dr. van der Stok.

[2] These papers ought to have been noticed in the article "Bewegung der Hydrosphäre" of the German Encyclopædia of Mathematics. My article was really written before the publication of Dr. van der Stok's first three papers, but in the subsequent and final revision for the press I carelessly took these papers merely to relate to local hydrography. References are given in them to other papers by MM. Phaff, Petit, van Heerdt, &c., on the hydrography of the Dutch coast.

The author caused a large number of observations to be made from light-ships off the Dutch coast, and then undertook to make an elaborate study of the tidal currents which had been noted. He found it possible to define the velocities and phases of the components of current by means of a notation analogous to that used in defining the rise and fall of the tide. Thus the velocities for the several kinds of tide were specified in centimetres per second, and the phases by angles analogous to the κ's in use in the more ordinary harmonic analysis. A similar investigation had been carried out at Sembilangan, in the Dutch Indies, and it is the result for that place which is given in the paper under review.

It is clear that the harmonic constants which define the horizontal motion of the water cannot claim a high degree of accuracy, but it affords a conspicuous advance that the attempt should have been made and crowned with a certain amount of success.

The vortices off the Dutch coast are very complicated, and the author refers to Airy's theory ("Tides and Waves," §§ 358–63) as affording in some measure an explanation of the facts, although he does not find the explanation by any means complete.

In No. ii. of the papers to which I now refer, Dr. van der Stok integrates, for the light-ship station of Schouwenbank, the expressions for the components of velocity, and thus finds the trajectories of a particle of water under the influences of the tides M_2, S_2, and M_4; he also determines the general drift of the water. The figures illustrative of his conclusions are very interesting, and I commend these papers to the notice of all who are interested in tidal theory.[1]

G. H. DARWIN.

[1] Similar results will be found in Helland-Hansen and Nansen's "Norwegian Sea, Report on Norwegian Fishery," vol. ii., 1909, No. 2, p. 107; and Miss Kirstine Smith's "Gezeitenstroemern," Havenundersögelser, vol. ii., No. 13, 1910.

THE LEANING TOWER OF PISA.

THE first stone of the campanile of Pisa was laid in August, 1174, by Bonanno of Pisa and William of Innsbruck, but accounts given us by various authors are very conflicting and uncertain in regard to the construction of this splendid work of art, which, after being interrupted several times, was completed nearly two centuries later.

The tower, which is entirely of white marble, is of cylindrical shape, hollow in the centre, with a spiral staircase constructed in the thickness of the outer wall which leads up to the belfry floor. The first tier is surrounded by fifteen large columns, with vaulted arches half-encased in the wall, and the six upper tiers are each decorated by an equal number of peristyles with arches, supported by altogether 192 isolated columns. The eighth and last tier, of smaller diameter, on which are placed the bells, was constructed, according to tradition, by one Tommaso, architect and sculptor, a pupil of Andrea Pisano.

As is commonly known, the tower, the height of which is about 56 metres, has a noticeable leaning on its axis, and the cause of this leaning gave rise to bitter controversy among the Pisan writers in past centuries, some of whom attributed the strange piece of architecture to the high ingenuity of the builders, while others more reasonably maintained that the explanation was to be sought in the instability of the Pisa subsoil.

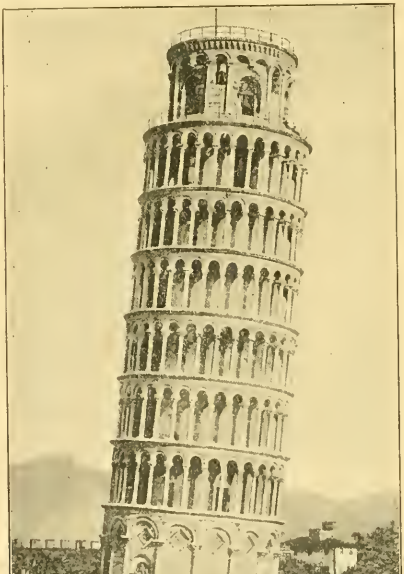
The recent investigations of a competent Government Commission, composed of Profs. Mario Canavari, Paolo Pizzetti, and Agenore Socini, and Drs. Giovanni Cuppari and Francesco Bernieri, have not only confirmed that the leaning of the tower is certainly due to a subsidence of the ground, but that this subsidence has gone on increasing in the last eighty years, and this serious conclusion has attracted the attention of competent authorities.

The investigations of the Commission have clearly brought out the following facts:—

(1) The tower does not rest on a mass of masonry extending over the whole area of the circular base, as was hitherto supposed, but is supported only by a more limited annulus of masonry corresponding to the cylindrical form of the superstructure.

(2) The foundations, hitherto supposed to be about 8 metres deep, are, on the contrary, much more superficial, and hardly sink to 3·60 metres below the level of the ground.

(3) A spring of water rises at the junction of the foundations with the surrounding permeable earth, causing serious damage to the foundations themselves.



The Leaning Tower of Pisa.

A tank excavated near the tower in 1839 for the purpose of maintaining the surrounding basin dry and preserving the base in good condition was made very deep, and much below the level of the actual edge, thus collecting other waters, which were pumped out regardless of the safety of the tower.

(4) The slope of the tower, according to the measurements made in 1829 by Messrs. Cresy and Taylor, which may be regarded as correct, was, from the first to the seventh tier, 86·5 mm. per metre of height. The slope, as now determined by optical appliances by Prof. Pizzetti, and directly by the plumb-line by the engineers, Drs. Cuppari and Bernieri, is—again from the first to the seventh tier—92 mm. per metre. The slope has therefore increased $5\frac{1}{2}$ mm. per metre, and there is thus an external displacement of 2·868 metres, and a total deviation of the axis, from the first to the seventh tier, of 3·265 metres, exceeding that found by the English observers in 1829 by nearly 20 centimetres.

The Commission has not been able to decide whether the increase in the leaning took place gradually or at intervals as the result of different causes. One such cause might be the excavation of the tank and the ill-advised pumping operations already mentioned; another might be sought in the effects of the earthquake of 1846, which was fairly violent at Pisa, and, as asserted by Leopoldo Pilla in his account of the times, caused the tower to oscillate in an alarming way. "Those people who had the opportunity of observing it during the shock," writes the great geologist, "assure me that its swaying was a terrible sight."

In spite of these serious conclusions, the Commission is nevertheless unanimously of opinion that the famous tower of Pisa still possesses good stability, and that the present condition of the same is not such as to give rise to excessive apprehension for the future.

A. BATTELLI.

RECENT BOOKS ON BOTANY.[1]

(1) MR. SCOTT ELLIOT has attempted an ambitious task, *i.e.* to give a popular and at the same time comprehensive account of modern botanical research. On the whole, he has been thoroughly successful, and has produced a readable book, which may well impress the layman or amateur botanist with the extent and scope of the botany of to-day. But (though this is perhaps inseparable from a work of this kind) one is almost bewildered by the rapidity with which the scene changes from the polar regions to the tropics, or the subject under discussion from, *e.g.*, the effect of electricity on plants to the origin of the British flora. In the preface the author states that he is particularly interested in "open-air botany, the story of the conquest of the world by green vegetation," and it is when discussing topics of this kind that he appears at his best. Such descriptions as that of the soil, with its manifold complexities of life and structure, or of a "Chroolepus Forest" are distinctly good, even if a trifle exaggerated. The chapters on bacteria, Arctic and Alpine floras, and the re-conquest of the water are amongst the best in the book. In a few cases, however, Mr. Elliot has attempted the impossible. Thus, in a chapter on the fern alliance, he condenses into three octavo pages an account of the alternation of generations, Bower's theory of the origin of the fern sporophyte, the reduction of the gametophyte in flowering plants, and a description of the pteridosperms. The result can scarcely be other than to cause confusion in the mind of the non-botanist. In describing the growth of the living crust of mosses on the top of a sphagnum bog (p. 74), the author suggests that "these moss plants may, for aught we know to the contrary, be the identical individuals which perhaps began to grow there at the close of the Glacial period." This raises the interesting metaphysical problem of how far the conception of individuality is applicable to plants. Unfortunately, Mr. Elliot does not discuss the question, though he briefly refers to it again on p. 152. It is to be expected that some inaccuracies should creep into a book of this nature. A desire for brevity is probably responsible for the statement on p. 109 that the

[1] (1) "Botany of To-day: a Popular Account of Recent Notable Discoveries." By G. F. Scott Elliot. Pp. 352. (London: Seeley and Co., Ltd., 1910.) Price 5*s.* net.

(2) "The Book of Nature Study." Vol. v. Edited by Prof. J. B. Farmer. Pp. viii+224. (London: Caxton Publishing Co., n.d.)

(3) "A Text-book of Botany for Students, with Directions for Practical Work." By Amy F. M. Johnson. Pp. viii+535. (London: Allman and Sons, Ltd., n.d.) Price 7*s.* 6*d.*

pollen grains of a flower are male sperm cells; while the somewhat astounding information (p. 132) that the leaves of *Victoria Regia* may be 60 feet across is, of course, a mere slip, and not a traveller's tale. There are a number of beautiful photographs (chiefly of plants of economic importance), some of which, however, seem to have little reference to the matters discussed in the text. Similarly, "The First Land Plants," which is the title of chapter iii., scarcely describes its contents, which deal chiefly with soil and the nitrate supply of the vegetable world. One of the photographs is here reproduced.

(2) As other volumes of "The Book of Nature Study" have been reviewed in Nature, it is unnecessary to indicate the general scope of this work. The first contribution to this volume is one by Miss C. L. Laurie, which (considering that it contains a chapter on aquatic vegetation, and another on that of meadows and pastures) bears the somewhat curious general title of "Xerophytic Vegetation." This part of the work contains a good deal of interesting information, and some useful suggestions for practical work; but, on the whole, it is rather disappointing. In many places there is a lack of clearness, both of expression and arrangement. On p. 15, for instance, it is stated that the amount of salt in the sea aster varies from 43-49 per cent. It is only incidentally mentioned in a later paragraph that this refers to ash analysis, and not to the fresh or dry weight of the plant. The editor might well have exercised a stricter supervision over these chapters.

But the remainder of the volume is on a higher level. Chapters v.-xii. are devoted to "The School Garden," the author being Mr. J. E. Hennesey. The subject is treated almost entirely from a practical point of view, gardening operations of various kinds —tillage, manuring, the propagation and treatment of plants, &c.—being clearly described. These chapters should prove invaluable to amateur gardeners, and perhaps more particularly to teachers who have the oversight of a school garden. Mr. Hennesey rightly emphasises the importance of a garden being attached to at least every rural school. It is interesting to note that such gardens are increasing in number in England, though we are still far behind Austria-Hungary, in which more than 18,000 school gardens have been established since 1870.

Distinctly the best part of the present volume has been reserved to the last chapter, which contains a really excellent account of "The Work of the Soil," by Mr. A. D. Hall. The author first deals with the origin of soils, and then with their properties. Under the latter heading clear directions are given for conducting simple soil analysis, also for experiments to show the behaviour of different soils towards water, the work performed by soil organisms, &c. Pp. 209-11 contain a graphic and convincing description of the competition of plants in nature.

Both "The Book of Nature Study" and Mr. Scott Elliot's "Botany of To-day" are worthy of a place on the bookshelves of every school library.

(3) Miss Johnson has produced a carefully and, on the whole, a clearly written text-book, but, like many other books of the kind, it is somewhat deficient in brightness and suggestiveness. In the opinion of the present writer, it is a mistake to adopt the water-tight compartment system in the teaching of elementary students. The author, however, adheres to the time-worn method of devoting entirely separate sections of her book to morphology, histology, and physiology. Thus the external characters, the structure, and the functions of a root are treated in quite different parts of the book. Further, bearing in mind the students for whom the work is intended (*vide* preface), it is somewhat overcrowded with unnecessary detail. The book is fairly free from serious errors, but perhaps it

Photo.] [*Skeen and Co., Ceylon.*

Plucking Cocoa Pods. From "Botany of To-day."

may be worth while to direct attention to the fact that the intercellular passages so frequent in the vascular bundles of monocotyledons are not *air* cavities. Again, the *chief* function of the air spaces in the stems of water plants is scarcely to "give lightness to the plant" (p. 219), though, curiously enough, this statement is also made by Miss Laurie in "The Book of Nature Study" (p. 23), reviewed above. The excellent illustrations, which are nearly all new, form the best feature of the book. These are chiefly by Miss Boys-Smith and Miss Berridge.

NOTES.

SEVERAL weeks ago the announcement was made that an Italian Government Commission, appointed to inquire into the condition of the Leaning Tower of Pisa, had reported that the structure was in danger of collapse (July 14, p. 48). We are glad to be able to print in the present issue the translation of an article by Prof. A. Battelli, professor of physics in the University of Pisa, in which the facts with reference to the tower are clearly stated. The article should serve to moderate anxiety for the safety of this famous structure.

It is stated by the Paris correspondent of the *Times* that the Government of the Republic of Ecuador has proposed to present to France the observatory at Quito, together with its apparatus and dependencies, and that the Academy of Sciences has decided provisionally to accept the gift.

WE regret to see the announcement of the death of the Rev. Robert Harley, F.R.S., on July 26, at eighty-two years of age.

THE Paris correspondent of the *Times* states, on the authority of the *Dépêche Coloniale*, that M. Louis Gentil, professor of geology at the Sorbonne, who accompanied the expedition which recently explored the Atlas region under the auspices of the Comité du Maroc, has been entrusted by the French Minister of Public Instruction with a mission to the Muluya Valley, where he will complete his scientific researches in the Algero-Moroccan frontier district.

THE famous extinct geyser of Waimangu, New Zealand, near which a volcanic eruption was reported last week as having commenced, was for a few years the most powerful geyser on record. The activity of this geyser in 1903 and 1904 created such anxiety in the North Island of New Zealand that an Auckland paper, attributing its activity to the great increase in the size of the adjacent Lake Rotomahana, proposed that the lake should be drained in order to allow the freer outlet from the hot springs of the locality. No action was taken, and the danger was removed by the bursting of the lake dam. The water of Lake Rotomahana was discharged to Lake Rotorua, and Waimangu ceased its eruptions. It will be interesting to learn from the New Zealand geologists whether the renewal of the volcanic activity along the Tarawera rift is connected with the cessation of Waimangu.

THE executive committee formed for the purpose of organising and holding a great International Horticultural Exhibition in London in the spring of 1912 is now doing everything possible to push forward the necessary arrangements. The honorary secretary of the committee is Mr. Edward White, 7 Victoria Street, Westminster, S.W. The exhibition will be held in May, and it will be open to the public on eight weekdays. Although in no way responsible for the exhibition, the Royal Horticultural Society is extending its general approval to the scheme. This society has not only agreed to forgo the holding of the usual Temple Flower Show for that year, but it has also contributed a sum of 1000*l.* towards the International Exhibition, and in addition is prepared to assist generously in the formation of a guarantee fund.

It is seldom that for the period of a whole month there is such a failure of summer weather as was experienced this year throughout July. There were in all only five days at Greenwich with a temperature of 70° or above, and this is the smallest number of warm days in any July since trustworthy records were commenced in 1841, about seventy years ago. The July with the next fewest number of warm days was in 1879, when there were eight days with the temperature above 70°, whilst there have only been four Julys during the last thirty years with fewer than twenty such warm days, and as recently as 1905 the temperature of 70° was exceeded in July on twenty-nine days. In the last nineteen years there have only been two Julys besides last month in which the shade temperature failed to touch 80°. The mean temperature for the month was 60°, which is 4° below the average of the past sixty years, and it is 1·5° below the mean for the corresponding month in 1909, when the early part of the summer was unseasonable like the present, although July last year had eighteen days with a temperature above 70°. The aggregate rainfall in the neighbourhood of London for July this year was 3·5 inches, which is 1·1 inches more than the normal, and rain fell on seventeen days. The aggregate for June and July this year is 5·6 inches, which is 1·2 inches less than for the corresponding two months last year. The duration of bright sunshine in July this year was 115 hours, which is only one-half the average, and is sixty hours less than in July last year.

THE visit of the German Association of Gas and Water Engineers to Great Britain, which was postponed on account of the death of King Edward, has now been arranged to take place during the week commencing October 2 next. The visitors are to be the guests of the Institution of Gas Engineers, the Gas Light and Coke Company, the South Metropolitan Gas Company, the Croydon Gas Company, and the Corporations of Edinburgh and Glasgow respectively, of which latter city the engineer of the gas department, Mr. Alex. Wilson, is now the president of the Institution of Gas Engineers.

AT the last meeting of the British Science Guild, held in the rooms of the Royal Geographical Society, communications were received from the Canadian and New South Wales sections of the Guild. In the case of the Canadian section, Lord Grey is resigning the presidentship on account of his departure, and it is hoped that Lord Strathcona will act as president in his place. No fewer than 120 members have joined the New South Wales section of the Guild, and important literature has been forwarded in connection with technical education and the report on open-air spaces for school children in Sydney. The agricultural memorial to the Prime Minister having received numerous signatures from representative agricultural societies and others was ordered to be submitted to the Prime Minister. The report of the committee on the synchronisation of clocks was finally approved, and it was decided to approach the Local Government Board by deputation and to ask the President to promote legislation on the subject.

ACCORDING to Miss F. Buchanan, writing in the July number of *Science Progress* on the significance of the pulse-rate in vertebrates, the relative size of the heart in different groups of animals depends on the amount of work it is called upon to perform. Thus in fishes, where it has only to pump the blood so far as the gills, the heart is always small, averaging 0·09 per cent. of the body-weight; but in the inert flat-fishes it is still smaller, being only about 0·04 per cent. of the body-weight. On the other hand, in birds, more especially migratory and vocal species, the heart has very heavy work to perform, and is consequently of great relative size, ranging from 1 to 2, or in a few cases 2·6, per cent. of the body-weight. In consequence of these differences in the amount of work the heart has to execute, its size bears no fixed relation to that of the animal to which it belongs. "The heart of a pigeon, *e.g.*, weighs twenty-five times that of a plaice of the same weight, and is about equal to that of a salmon fifteen times as heavy as the pigeon. A thrush, and a guinea-pig of six or seven times its weight, have hearts of about equal size."

In the *Psychological Bulletin* for June Dr. J. C. Hubbard describes a curious visual phenomenon resulting from stimulation of the macular region of the retina. It was first, and can be best, observed when the pupil is dilated by atropin, but it is also said to occur under ordinary conditions when any feeble source of light is viewed against a dark background. If, for example, "a patch of soft red colour, such as a ruby lamp wrapped with tissue paper, be viewed in a dark room, diffuse brushes of bluish tint are seen, apparently spreading laterally from it. With the right eye alone the brushes seem to extend to the right of the source, and with the left eye to the left." These brushes terminate at a point which is found to correspond to the position of the blind spot, for the source of light when not too large disappears if the eye be turned to the point of termination of the brushes. The brushes disappear in two or three seconds if the eye remains carefully fixed, but reappear upon slightly moving the eye. They also occur when the source of light is daylight, are brightest in orange-yellow and yellow spectral light, and are almost imperceptible in blue and violet light. Dr. Hubbard points out that the distribution of these brushes of blue light is strikingly similar to that of the bundles of optic nerve-fibres radiating from the macula to the blind spot. He suggests that certain stimuli, "passing from the macular region along these fibres to the optic nerve, are capable of inducing secondary effects in portions of the retina along which they pass."

THE preliminary announcement made in the *Times* of July 27, by Dr. Max O. Richter, of the discovery by Dr. K. Koritzky and himself of the site of the famous Cyprian temple of Aphrodite-Astarte will, if the facts are verified, rank justly as one of the most important archæological events in recent years, and a well-deserved triumph for German science. We can only express the regret that, in spite of much exploration in Cyprus by British scholars, they have failed to secure the honour of this discovery. The clue to the supposed site of the temple at Rantidi, or Randi, was gained through the examination of some inscribed stones which were smuggled out of the country, the first having been accidentally found by a shepherd. Whether this be the shrine of the Paphian Venus or not, the remains are certainly numerous and interesting. The German archæologists have taken measures to secure the rights of excavation, and Dr. Richter believes that the antiquities to be unearthed will prove to be so numerous that it will be necessary to erect a special museum for their reception, probably at Limassol. The examination of the shrine will probably solve the much debated question of the relation of the worship of the goddess to Oriental cults. In spite of the fact that the law protecting antiquities in Cyprus is severe, we regret to learn from Dr. Richter that many of the precious inscriptions have been removed from the ruins by the Government engineers and broken up for ballast for the new road from Nicosia to Limassol.

THE presidential address on "Nature and Nurture" delivered by Prof. Karl Pearson at the annual meeting of the Social and Political Education League in April last has been published by Messrs. Dulau and Co. in the Eugenics Laboratory Lecture Series. Prof. Pearson lays stress on the necessity for exact methods in the study of sociological problems, and indicates the difficulty of analysing the resultant effects of nature and nurture so as to exhibit the relative importance of each factor. A few pedigrees are given illustrating the appalling extent to which abnormalities may be propagated by a fertile degenerate stock, and conversely the persistence of intellectual eminence in superior stocks; and the strength of nature is contrasted with that of nurture by two tables, the first showing correlations between parent and offspring or between members of the same family, and the second correlations between various factors taken as inoices of environment and physical characters of children. Prof. Pearson concludes that "there is no real comparison between nature and nurture; it is essentially the man who makes his environment, and not the environment which makes the man." Not everyone will agree that the data are adequate to prove the conclusion, and from many of Prof. Pearson's *obiter dicta* the reader is likely to dissent; but the address gives a lucid and stimulating exposition, in popular language, of the lecturer's views.

No. 1746 of the Proceedings of the U.S. Nat. Mus. is devoted to an account, by Mr. G. C. Embody, of a new species of amphipod crustacean, found in abundance in a large, spring-fed pond or lake some three acres in extent near Ashland, Virginia. When first collected, in 1908, they were referred to *Eucrangonyx gracilis*, but they are now found to be distinct, and described as *Eu. serratus*. Although these amphipods formed a portion of the food of at least three species of fishes, the thick fringe of vegetation round the pond, coupled with their rather rapid propagation, prevents any very great destruction of the crustaceans.

In the July number of the *American Naturalist*, Mr. H. B. Wood discusses recent views as to the original source and spread of bubonic plague. Russian naturalists have urged that the bobac marmot (or perhaps some kindred central Asiatic species) is the sole originator of plague, and that it is permanently infected with the disease, thereby periodically re-infecting rats, and thus the human race, by means of fleas. The extermination of the bobac has, therefore, been demanded; but, as the author points out, there are probably other sources of original infection, and, in any case, certain American rodents have now become permanent centres of the disease. It is known, for instance, that a species of suslik, or ground-squirrel (*Spermophilus*, or *Citellus, beecheyi*), is plague-infected in California, and the same is the case with one of the wood-rats of the genus Neotoma, only in a less degree. Susliks may become infected *inter se* by the burrowing owl (Speotito) acting as flea-carrier, the fleas being probably carried from susliks to man by either cattle or rats, although direct transference from the former may take place. Two kinds of Californian rat-fleas will bite man, as will some suslik-fleas; and it has also been ascertained that rat-fleas will carry infection from rats to susliks, while suslik-fleas will carry it from one species of suslik to another, and likewise to rats and guinea-pigs.

AN account was given in the *Times* of July 20 of the deep-sea observations in the North Atlantic made by the *Michael Sars* expedition, which left Plymouth on April 7. It will be remembered that Sir John Murray liberally financed the expedition and took part in the cruise. The work was under the control of Dr. John Hjort, who had the assistance of Prof. Gran, Mr. Helland-Hansen, and Captain Iversen. Physical and biological investigations were made at most of the seventy-four observing stations. Upwards of 600 temperature observations at different depths were recorded. The temperature observations agree very well with those of the *Challenger*, but the determinations of the salinity and density of the water have furnished new results. The measurements of the rate of the current in the Straits of Gibraltar showed that the limit between the upper (east going) and the lower (west going) currents is situated at a depth of between 50 and 100 fathoms, varying in depth with the tide. The greatest velocities measured were about five knots. In the warm waters of the Sargasso Sea, where the tow-nets of the German Plankton Expedition obtained few plants, the centrifuging of the water gave samples showing that the plants there consist of the smallest forms, which escape through the meshes of the finest silk nets; they were found in thousands to a depth of about 50 fathoms. Prof. Gran has recorded a great number of new species, and was able to make quantitative microscopic investigations, and thereby determine the vertical distribution of the different species. The temperature section across the Gulf Stream to the south of the Great Banks showed unexpected results. Both the temperature and the plankton indicate a counter-current at the southern border of the Gulf Stream. In consequence of this the *Michael Sars* followed the course of the Gulf Stream across the Atlantic, taking observations on the way, and the results will be published later.

In No. 1749 of the Proceedings of the U.S. National Museum, Mr. A. H. Clark describes a new species of feather-star (Antedon) from the Adriatic, and discusses the relationships of the other European members of the genus. It appears that considerable differences in the size of the eggs and of their rate of development have been noted by several observers in European Antedons from different localities, although all the specimens were referred to the ordinary *A. rosacea*, the range of which was thus considered to extend from Norway to the Mediterranean. It was, however, suspected by all that the specific determination was unsatisfactory. Mr. Clark is now able to announce the existence of four European species—two from the Atlantic, for which the names of *petasus* and *bifida* (=*rosacea*) are respectively available, and two from the Mediterranean, one of which should bear the name *mediterranea*. The two Mediterranean forms have long, slender arms, and numerously segmented long cirri, while in those from the Atlantic the arms and cirri are shorter and stouter, with fewer segments to the latter; further, it is believed that neither of the Atlantic species has infrabasal plates. These are, however, present in the Mediterranean forms; but the newly named *A. adriatica* has four or five, against three in *mediterranea*. The Mediterranean forms are more primitive than those from the Atlantic, which accords with the author's view that Antedon is primarily an Indian Ocean genus, where it is now represented by the more generalised Mastigometra.

To No. 40 of the Zoological Society Bulletin, New York, July, Mr. W. T. Hornaday contributes an illustrated article on the collections of heads and horns of big game in the temporary "Administration Building" in that city. It appears that attention was recently directed to the poverty of American museums in specimens of this nature from Africa, and that this has resulted in a very gratifying effort on the part of sportsmen and collectors. We notice, however, that the specimens are exhibited on the walls of the apartments of the building without the protection of cases, and apparently exposed to strong light, which will assuredly lead to their rapid deterioration. Mr. Hornaday quotes certain pessimistic views as to the prospects of African big game, in which it is asserted that, in from ten to fifteen years, all except that in protected areas will have been practically wiped out.

The June number of the *Quarterly Journal of Microscopical Science* (vol. lv., part ii.) contains a valuable and beautifully illustrated monograph, by Mr. Cresswell Shearer, on the anatomy of *Histriobdella homari*. This very primitive segmented worm is said to be a normal inhabitant of the branchial chamber of the European lobster. The author concludes that the genus Histriobdella must be placed close to Dinophilus, but that it is more nearly related to the rotifers than the latter. Both genera show distinct relationships with Polygordius and Protodrilus, although they cannot be classed with these as true archiannelids. The same number contains Messrs. Allen and Nelson's interesting paper on the artificial culture of marine plankton organisms, already published in the Journal of the Marine Biological Association and noticed in these pages. Mr. Geoffrey Smith continues his studies in the experimental analysis of sex, and describes a case of parasitic castration in a cockerel, due to tubercle bacilli infecting the alimentary and lymphatic organs. He considers this case to be analogous to the parasitic castration of various invertebrates, such as that of the crab Inachus by the degenerate barnacle Sacculina. There are also three protozoological papers by Miss Annie Porter, Mr. C. M. Wenyon, and Mr. H. Lyndhurst Duke, all of a high standard of merit.

In the *Annals of Tropical Medicine and Parasitology* (vol. iii., No. 5), there is a memoir by A. Breinl and E. Hindle on the life-history of *Trypanosoma lewisi* in the rat-louse, *Haematopinus spinulosus*. In experiments carried on for more than a year, the authors have succeeded three times in transmitting *T. lewisi* by means of the rat-louse. Cytological changes in the trypanosomes in the gut of the louse are described and figured. Amongst other articles in the same number, one by Sir Rubert Boyce and F. C. Lewis, on "The Effect of Mosquito Larvæ upon Drinking Water," may be especially noted. It is found by experiment that "the presence of larvæ in drinking water adds very considerably to the number of bacteria present," and Cyclops appears to produce the same effect.

The eighteenth bulletin of the Sleeping Sickness Bureau contains a great deal of valuable information concerning the results of recent research upon all questions bearing directly or indirectly upon the etiology or treatment of trypanosomiases of man and animals. It begins with an editorial article upon the transmission in nature of *Trypanosoma gambiense*, the main point at issue being whether the trypanosome of sleeping sickness is disseminated, under natural conditions, by *Glossina palpalis* alone or by other species of tsetse-flies also. Recent observations tend to arouse the suspicion that *G. fusca* and *G. morsitans* may, under certain conditions in nature, serve as hosts for the human trypanosome, and if this is true, "the difficulty of prevention would be enormously aggravated. The seriousness of the problem . . . makes it imperative that skilled investigations . . . be conducted without loss of time."

The progress of palæobotany is marked by the appearance of a publication, *Die Palaeobotanische Literatur*, of which the first volume, dealing with the literature that appeared in 1908, has been issued by the firm of Gustav Fischer, Jena. The bibliography not only cites papers devoted primarily to palæobotany, but includes papers on recent botany, in which fossil plants are discussed. The greater part of the volume, which exceeds 200 pages, is taken up by the enumeration of genera and species with references to the various papers where they are mentioned. The compiler, Dr. W. J. Jongmans, of Leyden, makes an appeal for assistance in the shape of literature and papers as published.

THE systematic position of the tropical American genus Phytelephas, well known because the stone-like endosperm furnishes a cheap substitute for ivory, is discussed by Mr. O. F. Cook in vol. xiii., part v., of "Contributions from the United States National Herbarium." The author traces an affinity with Manicaria, a Central American genus, in the number of stamens and the fruit, besides noting an agreement with Attalea in the germination of the seedling. This leads to the formation of a family, Manicariaceæ, connecting the Phytelephantaceæ with the Cocaceæ. At the same time, the author controverts a family relationship between Nipa and Phytelephas.

PROF. H. MOLISCH communicates to the *Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften*, Vienna (vol. cxviii., part ix.), a note on local coloration of the cell wall in certain water plants induced by manganese compounds. The introduction of manganese salts into cultures of Elodea produces, after a few days' exposure to light, a deposition of brown matter in the outer walls of the epidermis which on continued exposure tends to mask the green pigment in the leaf. The author notes that the deposition takes place only when the plant is exposed to light, and that a similar result was obtained in leaves of Vallisneria, *Ranunculus aquatilis*, and Myriophyllum. The chief point of interest lies in the fact that it furnishes a definite instance of localised action produced by the absorption of a specific element.

DURING the coming December an exhibition is to be held at Allahabad, at which a special feature will be the display of small light machinery for use in agriculture and the allied industries. A pamphlet entitled "Northern India as a Market for Agricultural Machinery" has been issued, not only with the purpose of interesting manufacturers in the exhibition, but to give useful information to those who have in the past found it difficult to ascertain the special requirements of the vast Indian market. It should serve its purpose admirably.

THE fertilising value of seaweed has for some time past been the subject of a long arbitration case in Scotland. From the reports that have appeared in the *North British Agriculturist*, it seems that three farmers were deprived of their rights to gather seaweed when the Admiralty resumed possession of the foreshore at Rosyth for the purposes of naval construction. The facts were not contested, and the only dispute was as to the value of the seaweed. Experts and practical men were called on both sides, and the values assigned varied from 1*s.* per ton to 9*s.* 3½*d.*; in the end the arbitrator fixed 4*s.* 9*d.* and awarded compensation on this basis. As the case has been going on for eight months a considerable amount of money must have been spent, while it cannot be said that any material addition to our knowledge of the subject has been gained in consequence. The problem could only be solved by experiment, and it is reverting to the methods of the mediæval schoolmen to attempt to settle it by collecting "opinions."

THE tobacco produced in India has not hitherto been held in high repute, nor has success been attained by the introduction of American varieties and methods of curing. Mr. and Mrs. Howard have for some time been engaged in a study of the varieties already grown in the country, and have published their results in vol. iii. of the Memoirs of the Department of Agriculture in India. Perhaps no other factor in the production of high-grade tobacco is so important as uniformity in the crop, both as regards growth and also as regards the type of plant grown. Unless the crop ripens evenly the difficulties of harvesting and curing are increased, whilst a crop made up of several types of plant is not readily sorted out into uniform grades. The various types of *Nicotiana rustica* and *N. tabacum* are described in sufficient detail, and typical photographs are given. A great deal of patient work of this kind is necessary before the breeding of new varieties can usefully be begun.

PROF. A. L. ROTCH has contributed to the epitome of the *Aëronautical Annual*, 1910, a useful article on the relation of the wind to aërial navigation. After explaining the methods of investigating the upper air employed at Blue Hill Observatory and elsewhere by means of kites and sounding-balloons, he refers to the results of the upper wind observations in the eastern United States and to the recent discussion of the data by Mr. A. H. Palmer. The surface wind at Blue Hill (200 metres) has a mean annual velocity of 7·1 metres per second (15·8 miles per hour), and increases with height, as follows:—

Height in metres	550	1000	2500	3500	5400	6400
Mean velocity, m.p.s.	9·8	10·7	12·5	15·5	24·9	27·1

and the increase continues to the greatest heights; at 9500 m. it is 35·8 m.p.s. (80·8 miles per hour). The mean range from summer to winter increases very greatly with height:—

Height in metres	200—1000	1000—3000	3000—5000	5000—7000
Velocity in summer	7·5	8·2	10·6	19·1
Velocity in winter	8·8	14·7	21·6	49·3

the velocity of the upper winds in winter being more than double the rate in summer. The velocity increases nearly twice as fast at night as in the daytime up to about 500 m.; above that height there is a decrease, except in winter, up to 1000 m., and then a steady increase. The author points out that at night a suitable level for aërial navigation in summer is 1000 m.; in the daytime it is necessary to ascend above the cumulus clouds. Over the temperate regions the surface winds are obviously constantly changing their direction; above these shifting winds, the balloons sent off from St. Louis showed that the direction is generally westerly. Above the height of a mile the mean direction was from west-north-west.

THE results of a series of investigations by Messrs. de Broglie and L. Brizard, on the ionisation of gases in presence of chemical reactions, are summarised by the authors in the June number of *Le Radium*. Of the three methods adopted by the authors, that in which the ultra-microscope is used has proved the most powerful. The chemical reaction to be investigated is carried out under the microscope and between two charged plates which produce an electrical field across the line of vision. Any charged particles produced by the reaction are moved towards one or the other plate, according to the sign of the charge. A large number of reactions have been observed in this way, and the authors conclude that in none is the ionisation, if produced, due primarily to the chemical reaction, but to secondary effects, such as the bubbling of a gas through a surface of separation of two fluids, or the breaking down of crystalline structure and the projection of particles which become charged by friction with the surrounding medium, or, lastly, to the incandescence produced by the heat of reaction. It will be evident that many observations hitherto unexplained will be capable of explanation on lines suggested by these results.

In a paper entitled "Absorption and Adsorption with Reference to the Radio-active Emanations," published in the Bulletin of the Macdonald Physics Buildings of McGill University, Dr. R. W. Boyle shows that the radio-active emanations behave as all ordinary gases in obeying the laws of solution and of gaseous adsorption. In the case of thorium emanation, the experiments described show that the amount of emanation absorbed by charcoal is proportional to the concentration of the emanation in the gas in contact with it. The absorption also depends on the nature of the charcoal and the amount of surface exposed, and, as with ordinary gases, the absorption decreases with increase of temperature. On comparing the results of several experiments, it appears that thorium emanation is four times as soluble in water as radium emanation, but in petroleum the former is only half as soluble as the latter. Experiments with thorium emanation showed that this gas is less soluble in solutions such as copper sulphate and calcium chloride than in pure water, and the most powerful solvents used were petroleum and alcohol. The order of the solubilities of radium and thorium emanations in different solvents was found to be the same. The paper concludes with a brief notice of current ideas on adsorption, and there is appended a bibliography on the subjects treated.

THE University of Illinois Bulletin No. 41 contains an account of tests made on timber beams by Mr. A. N. Talbot. The tests were made with the view of adding data on the properties of timber in the form of stringers, as used in many railroad structures. The timber stringers were 8 inches by 16 inches by 15 feet to 7 inches by 12 inches by 14 feet in size. One hundred and twelve samples in all were tested, including long-leaf pine, short-leaf pine, loblolly pine, and Douglas fir. The load was applied equally at one-third points of the span length. The dimensions of the specimens were such as to bring out the strengths of timber in horizontal shear. The influence of knots, seasoning checks, and wind shakes can be traced in the results. Much of the data in existence is based on tests made on small specimens, and a valuable feature of the present series consists of the results of tests on minor specimens cut from the stringers. The flexural and shearing strengths of these smaller specimens were determined, and the relation of their properties to those of the full-sized stringers may be studied from the results given. In addition to many tables of results, the bulletin includes photographs showing characteristic fractures under the bending and shearing tests.

OUR ASTRONOMICAL COLUMN.

A CENTRAL BUREAU FOR METEOR OBSERVATIONS.—Under the auspices of the Astronomical Society of Antwerp, a central office has been established for the collection and coordination of observations of meteors. A beginning was made in 1907, and in twenty-two months 5900 observations were recorded by forty observers in thirty-six localities. This essay showed that a much wider organisation was desirable, and the new Bureau Central Meteorique hopes to receive the cooperation of all observers of meteors, amateurs and otherwise, the world over. In the Publication No. 1 is given a complete set of directions and advice, so that anyone, astronomer or not, who can observe regularly, may at once join in the international cooperative scheme. In a circular which accompanies the publication, M. Birkenstock points out that the expenses of the new organisation will be large, and asks all those interested in meteoric astronomy to assist by making an annual subscription of at least 5 francs.

THE ROTATION OF SUN-SPOTS.—To No. 4429 of the *Astronomische Nachrichten* Herr P. Kempf contributes some interesting results derived from sun-spot observations made during 1891–3.

A number of solar observers have been unable to establish any definite rotation of sun-spots, but here the observer shows from careful observations that in thirteen cases there was a distinct rotatory movement of the spot about its own centre. Seven of these occurred, in the northern, and six in the southern, hemisphere, but there appears to be no relation between the direction of the rotation and the latitude—north or south—of the spot; only in two cases in each hemisphere was the motion in the negative (*i.e.* N.W.S.E.) direction. In one case (Greenwich spot-number 2277, August 5–10, 1891) the spot rotated 139° in eleven days, while the average daily motions ranged between 7° and 37°; for the northern hemisphere the mean was 11°, and for the southern 20°.

HALLEY'S COMET.—An interesting popular summary of the phenomena presented by Halley's comet during its recent apparition is published in the July number of *The World To-day* by Prof. Frost. Discussing the "never-to-be-forgotten spectacle" presented by the 100° tail seen about the time of the comet's passage, Prof. Frost affirms that the earth probably passed through a part of the tail on the morning of May 19, and suggests that we were within the forks, or separate streamers, of it for two days following, hence the east and west tails. The strangely iridescent clouds, with a kind of horizontal "rainbow," seen at the horizon, may also have been due, at least in part, to the presence of cometary dust.

Some excellent photographs were secured by Mr. Ellerman, who led a comet expedition to the Hawaiian Islands.

LARGE METEORITES.—A description of the Guffey meteorite, discovered by two cowboys near Guffey, Park County, Colorado, in 1907, is given by Mr. Edmund O. Hovey in a reprint from the *American Museum Journal*, vol. ix., pp. 237–48.

This object is a siderite 36·5 inches long, 15 inches maximum height, and 8 inches wide. The mass is roughly pear-shaped, and weighs 682 lb. Two sides show well-developed "thumb marks" or "piëzoglyphs," but on another, which is nearly straight, these are not so well developed; the author suggests that the straight edge and lack of marks indicate that the mass split into two or more parts when near the end of its flight, and that another part may, therefore, yet be found. The mass is very homogeneous, and chemical analysis shows it to contain 88·7 per cent. Fe, 10·5 per cent. Ni, 0·5 per cent. Co, with traces of Cr, C, S, and P; the specific gravity is 7·939. It is supposed that this may be the remains of a vivid meteor which was observed to pass over the Fresh-water River region during the autumn of 1906; it now lies in the foyer of the American Museum.

Mr. Hovey also describes two other recent additions to the foyer, viz. a slice and cast of the Gibeon meteorite and the largest known portion of the Modoc meteorite. The Gibeon meteorite, weighing 562 lb., was discovered in Great Namaqua Land (lat. 25° 8′ S., long. 17° 50′ E.), and is in the possession of the Hamburg Natural History Museum. A slice of this and a plaster cast were sent to the American Museum, where it is ingeniously mounted with the slice *in situ*, the two halves of the cast being hinged so as to show the complete form with the polished surface of the slice.

The "Modoc" is the largest known portion (20 lb. 3 oz.) of a meteorite seen to fall near Modoc, Scott County, Kansas, on September 2, 1905. Twenty-five fragments have been found, and, where pieces have been broken off by the plough, the meteorite is shown to be composed of whitish stony material containing bright specks of iron.

Photographs of the Guffey and Gibeon meteorites illustrate the paper.

THE UNITED STATES NAVAL OBSERVATORY.—The report by the superintendent for the year ending June 30, 1909, shows that the Astronomical Council, consisting of the various officers and assistants at the U.S. Naval Observatory, is fulfilling a useful function in formulating the programmes of work for the various instruments. During the year, the 6-inch and 9-inch transit circles were thoroughly examined for their fitness for fundamental work, and various adjustments and modifications were made. The latitude-variation observations made with the prime vertical instrument were compared with those made with zenith telescopes at Philadelphia, Cincinnati, and Gaithersburg, and were found to give different values. The cause of this difference between the values given by the two forms of instrument was carefully looked for in the prime-vertical observations, but could not be found. Prof. Skinner was engaged until the end of the year in preparing material for the discussion of the proper motions of the 8824 stars observed by him, and published in the A.G. Zone Catalogue $-13° 50'$ to $-18° 10'$, but the work cannot be carried further until the cataloguing of the Washington zone observations, 1846–52, is completed.

Measures of Double Stars.—Prof. Burnham continues his record of double-star measures in Nos. 4426–7 of the *Astronomische Nachrichten*, where a large number of measures, made with the 40-inch telescope during 1909, are given. Particular attention was paid to doubles generally neglected or little known, also to measurements for the better determination of the proper motions of faint stars and of doubles where the motions are small or uncertain.

THE BRITISH MEDICAL ASSOCIATION IN LONDON.

The seventy-eighth annual meeting of the British Medical Association was held in London, for the first time since 1895, on July 26–30, in the buildings of the University of London. There was a very large attendance, which included a number of foreign guests and over-sea delegates and members. The Earl of Crewe and the Right Hon. Walter Long, M.P., were elected honorary members. Reference was made to Mr. Long's work, which resulted in the abolition of hydrophobia from these islands. Mr. Henry T. Butlin, the famous surgeon, was elected president. At the commencement of the proceedings he announced, amid loud cheers, that the King had signified his willingness to become patron, as his revered father was before him. The president in his address directed attention to the persevering work of the association since 1834 in placing the medical profession upon an increasingly satisfactory footing. He referred to the valuable assistance given by the association to the cause of original research. Since 1874, when scientific grants were founded, large sums have been awarded every year for research work. In 1884 two research scholarships were founded to enable men to devote their whole time to particular researches. Mr. Butlin pointed out that it was desirable to encourage research even though there were no prospect of immediate benefit from the particular line of research taken up, and he instanced cases in which an apparently unproductive investigation had led to results of vast practical importance.

At the present time the association consists of twenty-two thousand members in seventy branches. The business of the recent meeting took place in twenty-one sections dealing with particular branches of medical science, and in each section the line of inquiry which is receiving particular attention at the present time was given full discussion, foreign investigators taking a prominent part in the discussions in many of the sections. In the section of radiology and medical electricity, Sir J. J. Thomson, F.R.S., gave an address in which he pointed out that the softer rays given out from an X-ray tube were inevitably absorbed by the glass wall of the tube, and were therefore not available for application in medical treatment. He then directed attention to the researches of Prof. Barkla, of King's College, who found that substances such as metals when exposed to Röntgen radiation emitted secondary rays, the penetrating power of which was specific for the particular metal, and was independent of the penetrating power of the rays which impinged upon it. The rule was a simple one, for the hardness of the ray given out increases as the atomic weight of the metal. The only necessary condition is that the rays emitted from the X-ray tube must be harder than the specific radiation of the substance. Only substances the atomic weight of which is greater than that of calcium are found to give out these secondary rays. We have thus the power of using rays of uniform penetration for medical treatment. Thus if silver be used, the secondary rays which it gives off are about equal in penetrating power to the β radiation of radium. With iron the radiation is considerably less penetrating, while with tin it is more penetrating; with iodine, extremely penetrating radiation is given off. A large number of other papers were read bearing on Röntgen-ray diagnosis and treatment, and the great advance that has been made in Röntgen-ray diagnosis came prominently to the fore. Thus the papers of Dr. H. Orton and Dr. A. C. Jordan on phthisis showed this method to be a most valuable and trustworthy means of detecting phthisis in its early stages, and of determining the extent and position of the lung trouble. In the section of medicine, Dr. A. C. Jordan also read a paper on the Röntgen-ray appearances of thoracic aneurysm, and the lantern-slides with which it was illustrated showed very clearly the condition of the heart and great arteries in this disease. In many other sections the value of Röntgen-ray diagnosis was also evident. Thus the first session of the surgery section was devoted to a discussion of the operative treatment of simple fractures, in which Mr. Arbuthnot Lane described his method of uniting the severed fragments by means of metallic plates and screws, and in his paper, and all those that followed it, the conclusions were founded, to a very great extent, upon the Röntgen-ray appearances of the fractured part.

The discussion on chronic constipation turned very largely on the Röntgen-ray examination of the large bowel after the patient had taken a meal containing an insoluble salt of bismuth. This discussion was opened by Dr. J. F. Goodhart, who pointed out that constipation in old persons was frequently due to failure of voluntary effort. He said he held a brief for the importance and utility of the large bowel in opposition to those who, following the teaching of Metchnikoff, have come to regard the large bowel as a mere place of storage for the waste material of the food, in which poisons were generated which were very apt to be injurious. The large bowel, he stated, is meant to be full, not empty. Mr. Arbuthnot Lane said that in certain cases poisons were actually generated in the large bowel to such an extent that the patient's life was intolerable. In such cases he had removed a part or the whole of the large bowel with great benefit to his patient.

Drs. Dominici and Wickham came from Paris to discuss the subject of radium treatment. They made it clear that cancer in accessible regions can be greatly reduced in size by radium treatment, and can in certain cases be actually cured. In the case of large, deeply seated growths, a cure is not to be expected, although great diminution in size may be effected and much relief afforded. Various special forms of apparatus have been devised for applying radium to internal growths such as those of the throat, œsophagus, and stomach. Early detection of the cancer and early application of radium are the most important points.

In pathology and bacteriology, a number of important papers were read by those most fitted for the task. Thus Colonel Sir David Bruce, C.B., F.R.S., discussed human trypanosomiasis, while the paper of Prof. Wassermann, of Berlin, opened a discussion on the complement-deviation method in diagnosis—the method which he introduced for the diagnosis of syphilis, and which is now used for this purpose throughout the world. Its application to certain other diseases is now being worked out, so that it is one of the most important matters before the pathologists at the present day. A discussion on the lactic acid organisms took place, at which Prof. Hewlett was among those who took part. There was a most important discussion on the effect of digitalis on the human heart, opened by Prof. Wenckebach, of Gröningen. He was followed by Dr. James Mackenzie, Sir Lauder Brunton, and others.

The subject of dental decay was given very full discussion. It is now taught that both doctors and patients should regard decay of the teeth as a serious danger-signal, and the wholesale decay in young people and in many families so prevalent at the present time requires urgent attention. Foods that are too soft or too finely prepared are frequently causes of dental decay, and many serious illnesses, as well as cases of chronic debility, are due to poisons absorbed from the roots of decayed teeth.

The sour-milk cure, which is now in great vogue, was fully discussed from all points of view, and its benefit in suitable cases was placed beyond doubt. More practical evidence is needed, however, and the discussion will have done much to point out the directions in which this evidence should be sought.

An address on surgery was delivered by Prof. Gilbert Barling, in which he discussed the treatment of cancer. He referred in terms of praise to the work of the Imperial Cancer Research. There was evidence that the tissues resisted the inroad of cancerous growths, though little was as yet known of the nature of the resistance. We had not yet discovered the factors which heighten or lower this power of resistance. In considering the means available for the cure or relief of malignant growths, he discussed the application of X-ray and radium treatment. His conclusions were, on the whole, in agreement with those of Drs. Dominici and Wickham. He emphasised the fact that a genuine cure is not to be expected from these agents in cases of advanced cancer, and he further emphasised the great importance of early detection. Only one real opportunity for cure existed, and this was at the first operation, which should be undertaken at the earliest possible stage of the disease, and advantage of this opportunity should be pressed to its fullest extent.

Dr. J. Mitchell Bruce, in his address in medicine, gave a brief record of the most important additions to medical knowledge during the period since the association last met in London.

First came the discovery of the spirochæte of syphilis; of the part played by the mosquito in malaria and in yellow fever, and by the goat in the diffusion of Malta fever; of the connection of a trypanosome with sleeping sickness; of the Leishman-Donovan body with kala-azar; and of the *Diplococcus intracellularis meningitidis* with cerebro-spinal fever. The existence of typhoid carriers had been fully demonstrated, as well as the dangers of other typhoid products than the stools. The effects of oral sepsis had been worked out, and proved to be so widespread, so multiple, and frequently so grave, as to make us ashamed of our previous blindness to a common source of blood infection staring us in the face all those years. Autointoxication proper had attracted professional—and only too much public—attention, and led to the introduction of a great variety of dietetic and medicinal "cures." Of improved methods of observation and diagnosis, blood examination deserved first mention; and special interest and importance attached to the Widal reaction in typhoid and to the Wassermann reaction in syphilis. Radioscopy, which was coming into clinical use in 1895, had been greatly improved and extended, more particularly in its applications to the investigation of gastric and intestinal disorders and diseases; and the orthodiagraph must be mentioned in this connection. A great impetus had been given to the study of cardiac irregularity, and the sphygmomanometer was now generally employed. A real advance had been made in the introduction of lumbar puncture as a means of diagnosis in cerebro-spinal diseases.

"During these fifteen years several new methods of treatment of the first rank have been either introduced or perfected. Chief of all comes serum-therapy and vaccine-therapy. Of great importance is the employment of spinal analgesia as a substitute for general anæsthesia, the dangers of which have been closely investigated in relation to the status lymphaticus, as well as to post-anæsthetic acid intoxication. Other powerful means of treatment have been discovered in radium, in the Röntgen rays, and in the Finsen light."

A very complete medical museum formed an important part of the meeting. It included a very valuable series of microscopical preparations showing the blood parasites of malaria, sleeping sickness, and other tropical diseases. The Imperial Cancer Research showed a beautiful collection of specimens, lantern-slides, and diagrams giving a very good idea of the valuable methodical work which is being carried out by this institution under the directorship of Dr. E. F. Bashford. In the museum, the value of Röntgen-ray diagnosis was again to the fore, for many of the sections showed negatives, prints, lantern-slides, or diagrams to illustrate the Röntgen-ray appearances in various diseases. There was also a large exhibition in which numerous firms of publishers, instrument makers, chemists and druggists, and manufacturers of special foods and dietetic preparations showed their most recent work. In the electrical apparatus section, the great power of the modern generating apparatus was very obvious, each firm being able to show apparatus capable of giving so powerful a spark that a Röntgen-ray photograph could be taken by a single flash. Different contrivances were shown to accomplish this, including various forms of mercury jet interrupter, of electrolytic interrupter, and the well-known Snook apparatus, in which an alternating current is generated and transformed by means of a step-up transformer placed in a bath of oil, the secondary current being rendered unidirectional by a simple contrivance. A new apparatus was shown by Messrs. Schall for raising the internal temperature of the body by employing the thermal effect from a high-frequency apparatus. In a spark-gap where the electrodes are separated only by the thickness of a sheet of paper, undamped oscillations are generated at the rate of more than a million a second. Similar oscillations are used in wireless telegraphy for the production of continuous oscillations. The voltage of this new type of generator is less than 3000, but currents of 500 to 3000 milliamperes are used, and the patient feels nothing except the rise of temperature. The method is said to be useful in chronic cases of rheumatic and gouty origin.

The social functions included a reception by the Corporation of the City of London at the Guildhall, a garden-party at Ranelagh, receptions at the Natural History Museum and at a large number of hospitals. Special services were held in Westminster Abbey and Westminster Cathedral.

There was a large and distinguished assemblage for the annual dinner, at which Dr. Butlin presided. The Earl of Aberdeen, Lord-Lieutenant of Ireland, emphasised the good work of the British Medical Association, and expressed his opinion that those responsible for measures of social and hygienic reform should come to the association for direction as to the best means by which such reform can be carried out. As an example of a much needed reform, he dwelt on the unnecessary and noxious fumes from motor-cars. In referring to the valuable scientific papers delivered at the various sectional meetings, he selected for special note the paper by Sir J. J. Thomson, the eminent Cambridge physicist, in which he pointed out that certain substances could be made to give out a radiation which had much the same physical properties as some of the radiation given out by radium, and suggested that these radiations might be found to have the same effect upon the tissues as those at present obtained by the application of radium.

The Bishop of Kensington, speaking at a breakfast given by the National Temperance League, said that temperance owed no small debt to the British Medical Association for the new light it was constantly throwing on scientific investigation. It was to the professional men rather than the politicians that we must look for the solutions of the social problems of the day, foremost among which was that of temperance.

Thus medical progress was discussed in all its aspects at this—the greatest annual meeting by far ever held by the British Medical Association—and the discussions added new vigour to the work of observation and investigation.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE summer meeting of the Institution of Mechanical Engineers took the form of a joint meeting with the American Society of Mechanical Engineers. More than one hundred and fifty members of the latter society took part in the meeting, which opened in Birmingham on Tuesday, July 26. The reading and discussion of papers occupied the mornings of Tuesday and Wednesday, and on Thursday the party proceeded to London, where a conversazione was held at the Institution House in Westminster. On Friday morning further papers were read and discussed in the lecture hall of the Institution of Civil Engineers, kindly lent for the occasion. The institution dinner took place on Friday evening. The many excursions and visits to works were attended by large numbers of members of both societies and their lady friends.

At Birmingham, four papers on the handling of locomotives at terminals and running-shed practice were contributed by Messrs. F. H. Clark, F. M. Whyte, H. H. Vaughan, and W. Forsyth, all members of the American Society, and one on the same subject by Mr. Cecil W. Paget, member of the British Institution and general superintendent of the Midland Railway.

In the latter paper, Mr. Paget gives plans and description of two of the most recent sheds built in this country, viz. the Great Western sheds at Old Oak Common, of the centre turntable or round-house type, and the London and South-Western shed at Eastleigh, of the through straight type. Straight sheds are economical in first cost and maintenance, but unless they are of the type known as "through sheds" they are awkward to work; the latter class are necessarily draughty. The centre turntable type, though more expensive to build, possesses considerable advantages of working, because engines can be easily got in and out without moving others, and, in addition, better lighting and convenience in getting about and in bench accommodation are possible. There is, however, the disadvantage that when the turntable requires lifting for repairs it throws the whole of the pits served by it out of use whilst the repairs are going on. So far as possible, engines are allotted to and kept for the same drivers, and this is almost universally the rule in the case of passenger engines on most English railways. By this plan casualties are lessened owing to the greater care taken by the driver in working the engine and in properly reporting defects; as a result, the coal consumption is generally less.

Mr. F. M. Whyte, of New York, describes American methods of handling locomotives at terminals. To insure uninterrupted turntable service, two turntables may be supplied in a circular engine-house, the house being divided into parts, each having a turntable. Mr. Whyte deals very fully with the question of pooling locomotives, *i.e.* the system of increasing the service of the locomotive by placing any crew on any locomotive for service instead of holding it until its assigned crew could obtain the necessary rest. Extensive experiments have been made to determine the relative costs of the assigning and the pooling systems, and in some of these experiments no material difference in cost has been found. There probably is some loss in trustworthiness of service in pooling.

Some very good drawings and photographs of American engine-houses and their appliances are given by Mr. F. H. Clark, of Chicago. A common length of turntable for new installations is 80 feet. For boiler-washing, recent installations are the National, in which the steam and water blown off from the engines are used for washing out and for heating fresh water, and the Raymer system, which is of the enclosed-heater type, and performs similar functions. Mr. W. Forsyth, of Chicago, describes the arrangements of the Pennsylvania Railroad at East Altoona, Pa. The engine-house is in diameter and cross-section the largest structure ever erected for this purpose, having an exterior diameter of 395 feet and a turntable of 100 feet. There are fifty-two stalls, each 90 feet deep. Mr. Forsyth states that the reduction in boiler pressure from 225 lb. to 160 and 180 lb. has also reduced the number of boiler failures, and has permitted the more continuous use of locomotives which results from the pooling system. Mr. H. H. Vaughan, of Montreal, considers that in passenger service pooling is objectionable under any conditions, and should be avoided if possible. In freight service he considers that pooling is advisable if conditions are such that engines cannot be run with assigned crews. His experience is that where assigned crews can be used on engines, the cost of repairs, the amount of fuel consumed, and the class of service obtained will all be more satisfactory.

Other papers read at Birmingham were one on tooth gearing by Mr. J. D. Steven, of Birmingham, and another on interchangeable involute gearing by Mr. Wilfred Lewis, of Philadelphia, Pa. Mr. Steven considers the involute form of tooth only, as being that which is in most general use, and would welcome uniformity of opinion in the matters of cutting and using gearing. If a new form of tooth is desirable, it is his opinion that the stub form with 20 degrees angle of pressure would be a change in the right direction for the following reasons:—it can be used right down to twelve teeth in its true form, and cut on either a single cutter or on a generating machine; it is a stronger form than that most commonly used at present; a very large proportion of its face does useful work; the possible objections on the score of less contact and greater bearing pressure are so slight as to be nearly negligible.

Mr. Wilfred Lewis is chairman of a committee of standards for involute gears appointed about a year ago by the president of the American Society of Mechanical Engineers. Twenty-five years ago, as a result of investigations made on behalf of the firm of Wm. Sellers and Co., he recommended the adoption of a pressure angle of 20 degrees in place of 15 degrees commonly used. This practice has been since followed by the firm, and has given satisfaction in a general way. Mr. Lewis has since advocated an obliquity of 22½ degrees as giving less interference on twelve-toothed pinions. Experiments on behalf of the author's committee are being made at the Massachusetts Institute of Technology, and, although not conclusive, enough has been done to indicate that the friction loss in gear-teeth is influenced to a greater extent by the length of the addendum than by the obliquity of the system.

The papers read and discussed in London dealt entirely with problems connected with the electrification of railways. These were contributed by Messrs. F. W. Carter, of Rugby, H. M. Hobart, of London, W. B. Potter, of Schenectady, L. R. Pomeroy, of New York, and G. Westinghouse, of Pittsburg, the latter being the president of the American Society of Mechanical Engineers.

Mr. Carter directs attention to electrification as a means of recovering traffic drawn away from the railway by tramcars and motor-omnibuses, an expedient which has invariably been found successful in regaining much of the lost traffic. Modern electric railway apparatus leaves little to be desired in the matter of freedom from breakdown. There are about 200 miles of electrified route in this country, for the most part worked by motor coaches, employing a multiple-unit system of control. There appears little prospect of general electrification of the railways of this country, as no advantage is apparent which would in any way justify the expense.

Mr. Hobart draws comparison between systems employing series wound, continuous-electricity train-equipments, and the single-phase system. Continuous equipment provides, per ton of equipment, 11 horse-power at the axles (averaged over the journey), as against 6 horse-power per ton in the case of single-phase equipment. Mr. Hobart gives figures showing that 10 per cent. less of the takings are available for dividend paying in the single-phase system than in the continuous-current system.

Mr. Westinghouse is convinced that the extended distribution of electricity for industrial purposes can be secured only by the generation of alternating currents of high voltage and their conversion by static transformers into currents of various voltages, and has developed his business along these lines. He earnestly recommends to the serious consideration of railway engineers and those in authority the pressing need of determining the system which admits of the largest extension of railway electrification, and of a prompt selection of three standards of electrification which will render possible a complete interchange of traffic in order to save expense in the future and to avoid difficulties and delays certain to arise unless some common understanding is arrived at very shortly.

Mr. Potter considers that the development of apparatus for higher voltage direct-current has so far increased its scope that direct current at 600 volts or higher may be considered the most economical for city and interurban service. Single-phase and three-phase stock equipments are applicable only to exceptional conditions.

Mr. Pomeroy deals with the electrification of trunk lines, and concludes with the following paragraph, which called forth the commendation of Mr. Aspinall, the president of the Institution of Mechanical Engineers. The idea is all too prevalent with the public, and even with some of the bodies that have been given legal power of supervision over railway companies, that any expenditure which can be forced upon the railway companies is just so much gain for the public. Never was there a more absolute fallacy. In the long run, the cost of every bit of railway improvement must be paid for by those who buy tickets and ship freight. Economy in the administration of our railways is just as important in the interest of the general public as if the railways were actually under Government ownership.

THE BRITISH PHARMACEUTICAL CONFERENCE.

THE forty-seventh annual meeting of the British Pharmaceutical Conference was held at Cambridge on July 26, 27, and 28, under the presidency of Mr. F. Ransom. The presidential address dealt mainly with pharmaceutical research, and Mr. Ransom indicated certain directions in which progress may be anticipated. He deplored the fact that a better organisation did not exist to bring together the two classes of investigators—pharmacists and pharmacologists. If a joint committee consisting of medical men and pharmacists were appointed with the object of organising research work, investigations might be directed in the proper channels, and better results would be obtained. The president dealt at some length with the question of the cultivation of medicinal plants, and commented upon the attempts which had been made to obtain plants of more or less standard alkaloidal content. He suggested that a subject inviting investigation was whether the variations in the constituents of drugs were due solely to the seasons, or whether they depended upon other conditions. Referring to the subject of the standardisation of disinfectants, which has recently received much consideration, he said that neither the chemical nor bacteriological processes which had hitherto been devised seemed to be applicable in all cases, although for specific purposes comparisons of efficiency might be deduced.

In addition to the president's address, twenty-one papers were communicated, the larger number of which were of purely pharmaceutical interest. The papers which aroused the most considerable discussion were those dealing with the testing of disinfectants.

In a paper contributed by Prof. Sims Woodhead and Dr. C. Ponder, the authors made clear their position in regard to the question of standardisation of disinfectants. On analysing the Rideal-Walker drop method, they picked out and gave consideration to the following factors:—organisms to be acted upon; number of micro-organisms and amount of organic matter to be added; strength and number of dilutions; time during which the disinfectant is allowed to act; temperature. Prof. R. T. Hewlett in his paper criticised the Woodhead-Ponder method, but expressed the opinion that the use of *B. coli* instead of *B. typhosus* is perhaps a desirable change, although further investigation is necessary.

Mr. C. T. Kingzett and Mr. R. C. Woodcock contributed a paper, in the course of which it was pointed out that while the Rideal-Walker test may very well serve to determine the relative germicidal values of similarly prepared preparations of a coal-tar nature, it is not applicable for ascertaining the real or relative value of other disinfectants of a different chemical nature. Dr. D. Sommerville also read a paper. There was a long discussion on these papers, in which Dr. Rideal, Dr. E. Feilmann, Mr. J. E. Purvis, and others took part, and in the course of reply Prof. Sims Woodhead said he did not wish to doubt the value of the Rideal-Walker method, because he thought it was of extreme value, but they must not be expected to accept it as a final standard.

Another paper to which reference may be made is that by Mr. J. F. Tocher, last year's president of the conference, in which the author describes a modification of Mendeléeff's classification of the elements; the suggested new arrangement, which the author thinks may ultimately prove to have a satisfactory theoretical basis, places elements of like properties in similar positions, while elements with unlike properties are separated by distances proportional to the intensity of their differences.

In a paper on the interpretation of water analysis reports, Mr. J. E. Purvis pointed out the impossibility of fixing any standard by which waters can be judged and condemned; but, he said, there were certain rules which appeared to be necessary before a final judgment could be delivered upon any water. These were briefly as follows:—(1) the history of the water should be supplied to the analyst; (2) the rainfall before and after the analysis should be obtained, because a heavy rainfall before analysis means that the amounts of the constituents are not the same as compared with the analysis before the rainfall; (3) the method of storage and of distributing the water should also be considered; (4) the surface drainage may be a factor; (5) a bacterial analysis should go hand in hand with a chemical analysis; (6) the final judgment with regard to the quality of a water should rest with the chemist and bacteriologist in collaboration.

Mr. P. E. F. Perrédès described an insect pest in belladonna (*Epitrix atropae*, Foudras, a small beetle belonging to the tribe Halticæ of the series Phytophaga), and suggested a method of eradication.

As a result of a chemical examination of the rhizome of *Cimicifuga racemosa*, Mr. H. Finnemore found distinct reactions for alkaloids, but the amount present is very small.

The meeting, as a whole, was one of the most successful which has been held for many years. The attendance was somewhat larger than usual, and the interest taken in the papers was evidenced by the excellent discussions thereon.

ASSOCIATION OF ECONOMIC BIOLOGISTS.

THE ninth annual meeting of the Association of Economic Biologists was held on July 6, 7, and 8 in the Beyer Buildings of Owens College, Manchester. The association was indebted in particular to Profs. Hickson and Weiss for kindly hospitality, and to Mr. J. Mangan for the arrangements he had made as local secretary. Prof. G. H. Carpenter, of the Royal College of Science, succeeded Mr. A. E. Shipley, F.R.S., as president, and in the course of his address dwelt on the close interdependence of research in so-called "pure" and "applied" science. The original discovery of minute protozoal parasites in the blood of various animals was apparently perfectly "useless," yet it prepared the way to modern methods of dealing with terrible diseases of the tropics, such as malaria and sleeping sickness. Similarly, the more recent researches of workers intent primarily on alleviating these diseases have resulted in many discoveries of great theoretical significance.

Turning to another topic, Prof. Carpenter reported that a new crop—tobacco—in Ireland had brought to notice fresh pests, amongst others, a spring-tail new to science. He suggested that this was not a new introduction, but more probably an animal hitherto present in small numbers, which had multiplied under the stimulus of an ample supply of a congenial food plant.

A very interesting discussion arose out of Prof. S. J. Hickson's paper on the place of economic zoology in the modern university. The author pointed out how at present the demand for trained men capable of dealing with agricultural and other pests is in excess of the supply, especially in the colonies. He outlined a scheme for securing to students an efficient grounding in general science combined, by cooperation with experiment stations, with proper practical experience. Stress was laid on the importance of the fourth year's work, and the advisability of securing, if possible, training at a central agricultural college or experiment station, *e.g.* in India or Ceylon, for those destined for a tropical career.

Another well-discussed and important topic was the problem of wild-bird protection, introduced by Mr. W. E. Collinge, who pointed out that under the restrictions imposed by the Wild Birds' Protection Acts some birds had apparently multiplied to an excessive degree. He advocated securing definite knowledge as to which birds were harmful, and taking steps to secure their diminution, *e.g.* by placing in schools specimens of the eggs of such birds, and offering rewards for their collection. The discussion brought out prominently the difficulty of determining exactly whether certain birds, *e.g.* the rook, were beneficial or harmful in all districts and at all seasons; and practical suggestions, some of which are already being utilised, for acquiring this necessary knowledge were made.

Prof. F. E. Weiss contributed the results of observations on the garden Tropæolum, some plants of which bore flowers of different colour at different seasons of the year. These and other cases of differing flower coloration, *e.g.* in *Anagallis arvensis*, are under investigation to ascertain to what degree they are hereditary characters, and to which factors the changes are to be attributed.

Animal pests naturally received considerable attention. Dr. R. Stewart MacDougall emphasised the importance in dealing with coleopterous enemies of trees of taking account of the length of life passed in the various stages, whilst in a second paper he dealt with the sheep-maggot fly (*Lucilia sericata*) and the problems suggested by its life-history, and announced the first record in this connection of *Protocalliphora azurea*. Other pests dealt with were the warble-fly of the reindeer, by the president; a species of Rhabditis injurious to cress, by Mr. G. O. Sherrard; the horse bot-fly, by Mr. Collinge; and the larch saw-fly, by Mr. Mangan. Dr. Malden dealt with the diseases of bees, and Mr. W. G. Freeman with the economic importance of the cambium in plants.

The members of the association attended the formal opening of the Biological Experimental Laboratories at Fallowfield, when Sir Thomas Elliot, of the Board of Agriculture, spoke of the harmonious relations now in existence between practice and science, and the welcome degree to which the agriculturist is prepared to appreciate the aid of the man of science in attempting to solve difficulties. The new Manchester laboratories owe their origin to such calls for aid, and Sir Thomas indicated that the Board of Agriculture would be prepared to assist financially, so far as it could, the local efforts in providing the means for research in economic biology. W. G. F.

THE FIRST INTERNATIONAL AGRO-GEOLOGICAL CONFERENCE.[1]

SOME time ago the Royal Hungarian Geological Institute sent out letters of invitation to those interested in soils in the various countries of Europe and America asking them to attend an International Conference in Budapest, where some attempt would be made at standardising methods and objects. Some degree of uniformity is urgently needed. "Plus que partout ailleurs," says the secretary in his introduction to the present volume, "il y règne une disparité d'idées, de méthodes, de procédés, une divergence de vue sur le chemin à prendre et sur le but à atteindre, un chaos dans l'usage des termes scientifiques, des mesures, des figurés, des noms et des classifications : divergence qui se manifeste non seulement de pays à pays, de langue à langue, mais aussi entre les œuvres d'un même pays et dans la littérature d'une même langue." Some confusion is for a time inevitable in a borderland subject like the present, that joins up with geology, botany, and chemistry, and is closely connected with agriculture; indeed, even its very name has not yet been settled, for we find the subject of the conference referred to as agrogeology, agricultural geology, pedology, or simply "the science of the soil."

The results of the conference are now issued in the volume before us. Several of the papers are descriptive of the soils of the countries in which the respective writers are working, among them being accounts of the soils of European and Asiatic Russia, of Norway, of Rumania, and Bohemia. As an illustration of the method adopted, Prof. Glinka's account of the Russian soils may be noted. There are six main zones recognisable, running in belts from north-west to south-east, and corresponding fairly completely with the climatic and vegetation zones. The most northerly is the Tundra zone, practically destitute of vegetation higher than lichens and mosses. The soils have been but little investigated, but appear to be generally acid and rich in partially decomposed organic matter. South of this lies the Podzol zone, covered with forest, or in lower lying places with marshes and lakes. The typical podzols may be sands, loams, or clays; they are white when dry, acid, generally poor in mineral plant food, but contain a fair amount of organic matter, and they are porous. There is either a pan or else a good deal of concretionary matter in the subsoil, the former being usual in the sands, the latter in the loams and clays. This zone covers an enormous area in Russia and Siberia; it is not much cultivated, the method adopted usually being to clear a part of the forest, crop for a few years, then leave to run wild again, and move on to some freshly cleared ground; to the south, however, the agriculture is much more advanced. Throughout this zone the low-lying soils differ somewhat in type by reason of the accumulation of humus and the presence of reduction products such as pyrites, marcasite, and others; they are more like moorland soils.

The next zone is the famous black earth or Tschernosiom zone, but in between the two is a transition zone occupying the region of the prehistoric steppes now in forest, so that the original steppe soil has become modified. The calcium carbonate originally present may still be found lower down in the soil, and there is also more food material than in the soils further north; still, in the main, these soils are of the podzol type. The black earth proper stretches from the Carpathian to the Ural mountains, and thence across to Siberia; it covers Volhynia in the west and Perm in the east. It is characterised by a dark grey or black layer rich in humus and granular in structure, overlying a subsoil rich in calcium carbonate; this subsoil may originate either from loess, drift clay, or marine deposits. There are no forests, except in the north, as already mentioned, the whole region being steppe country now largely in cultivation producing cereals. Several other types of soil scattered as islands over the zone are described in the paper, but need not concern us here.

Southwards come the chestnut-coloured soils of laminate, and not granular, structure, where the black humus layer is thinner or absent, although calcium carbonate is found in quantity, as in the soil underlying the black earth. We are now approaching the dry steppes, a pastoral region inhabited by a nomad population. Alkali soils are not uncommon in this and the lower zones.

Below this come two others in the semi-desert region, where the rainfall is 8 to 12 inches per annum only, the northern layer being brown and the southern grey or white. They have not been much studied as yet.

We have dwelt at some length on this paper because it illustrates the difficulties in the way of introducing any uniform international system of soil classification. Any attempt to arrange British soils in zones in this way would fail; indeed, in one paper where a very broad system was used, all British soils were classed as of one type. After looking through the descriptions of the soils of the other countries we feel bound to agree with Prof. Hilgard that each region should adopt its own classification. Distinctions of colour, he points out, are not of sufficient general significance to form a basis of uniform soil classification, yet in a particular region they may be of vital importance, and would form the only basis useful in practice. Ramann has drawn up a scheme of classification, so also has Sibirtzeff, both admirable so far as they go, yet neither will fit the soils of California. Indeed, the various authors at the conference were looking at the subject from at least two different points of view: some were considering the zones of continental areas, others confined themselves to the soils of small regions. Climate reacts on soil to a marked extent. The soils of arid and of humid regions differ fundamentally, as Hilgard has shown. To take an illustration from Prof. Glinka's paper, the difference between the black earth and the chocolate-coloured or grey soils further south may arise entirely from climatic causes. Over continental areas, therefore, climatic zones will furnish a useful method of grouping soils in the first instance; but it is not complete, for marked variations occur among the soils in the same zone, necessitating a more detailed classification which would take account of the presence or absence of calcium carbonate, and the "lightness" or "heaviness" of the soil on cultivation. Probably several systems of classification would be found necessary to fit the various climatic regions. If the conference failed to come to any agreement on this subject, it at any rate did much useful work in bringing out the inherent difficulties.

Another matter was dealt with which ought to be capable of arrangement. At present no two countries adopt

[1] "Comptes rendus de la première Conference internationale agrogéologique." Publié par l'Institut géologique du Royaume de Hongrie. (1909.)

the same methods of soil analysis. This would not matter much if the methods were all absolute; unfortunately, they are mainly conventional. Thus an English analyst will say that a soil contains 0·2 per cent. of total potash, meaning by this the amount extracted by hydrochloric acid under particular conditions, although the *real* total is probably three or four times this amount. Continental and American analysts, working on the same soil, but using different methods, would reach wholly different results. The trouble is still worse in the mechanical analysis of soils. "Clay" in Great Britain means material less than 0·002 mm. in diameter, in the United States it stands for particles less than 0·005 mm. in diameter; elsewhere a widely different limit—0·01 mm.—is adopted; so with the other terms. In consequence, one can never compare mechanical analyses made in one country with those made in another; the same terms are used, but they denote different things. The confusion thus introduced into an already difficult subject is most unfortunate. One great advantage of international conferences of this sort would be to prevent such confusion arising in the future.

E. J. RUSSELL.

SCIENCE IN SOUTH AFRICA.[1]

THE Royal Society of South Africa consisted at the time of its annual report (April, 1909) of forty fellows and 160 members; it had held six meetings during the preceding year, ten papers altogether being read. Part i. of the Transactions, in which these papers appear, contains 334 pages; part ii. contains the papers read at subsequent meetings, and has expanded to 477 pages, since there were nineteen papers in place of ten. Most of the papers deal with local matters; only about half a dozen are concerned with general problems, and of these three are mathematical.

The local papers are mainly botanical. Dr. Schönland, of the Albany Museum, Grahamstown, gives a full description of *Haworthia truncata*, Schönl., the only species of Haworthia with strictly distichous arrangement of leaves. The leaves are to a large extent underground, while the exposed parts resemble small pebbles, so that the plant may be classed among the so-called "mimicry plants." Its structure is well adapted to its peculiar mode of life. The truncate apex is without chlorophyll, and thus forms a "window" through which light can pass by way of the central transparent tissue to the assimilating tissue which extends to the underground basal parts of the leaves. Dr. Marloth describes other plants possessing the same structure.

Experiments were also made to find out whether the aërial parts of plants, particularly those growing in arid regions, can absorb moisture from the air. In the Karroo there is commonly a fall of dew at night. Dr. Marloth's experiments indicate that the native plants can take sufficient moisture from this source through their leaves to satisfy their requirements. Dr. Schönland, on the other hand, is not satisfied on this point; the plants examined by him did not appear to absorb from the air anything like a sufficient quantity.

Mr. A. L. du Toit, of the Geological Survey, describes the evolution of the river system of Griqualand West. This system is very complex, but its history can be traced to a remote geological period. In Palæozoic times a continent, at a level lower than the present, extended over this area, the drainage from it being directed southwards mainly along the Kaap valley. At the close of the Carboniferous epoch this continent was intensely glaciated, and finally buried beneath the Permo-Triassic Karroo deposits; upon the surface thus formed the modern drainage system was initiated. In later periods—in late Jurassic, Cretaceous, and Tertiary times—there has been a succession of uplifts, but the rivers have been enabled to cut a peneplain. One of the most important of these surfaces extended from the Stormberg probably into Griqualand West, where it is represented by the Kaap Plateau. This surface has suffered denudation, and the rivers have cut down and laid bare the pre-Karroo floor with its drainage lines.

Dr. Broom discusses the relationship of the South African fossil reptiles to those found in other parts of the world. The Lower Karroo fauna of South Africa shows many points of resemblance to the Permian in America; it seems practically certain that both are modifications of an earlier fauna which probably inhabited a southern continent joining Brazil and South Africa. The American types are considered to be nearer the ancestral, though considerably specialised; the African, probably owing to their living in the swamps of the Karroo, developed greater length of limb and tended to become more active; but in South Africa the conditions must have been such as to promote rapid evolution, for many new types soon appeared, the most remarkable being the Anomodonts, which probably originated there. Towards the end of Permian times a land connection with Europe seems to have formed, by which the pareiasaurian fauna passed into Europe; still later—in the Upper Triassic beds of Burghersdorp—a number of European types passed into Africa without, however, any of the Cynodonts, highly characteristic of this period in Africa, passing back in return. In Lower Jurassic times land connection was well established. There is evidence of continuous land between Africa and Australia in Upper Triassic times.

The mathematical papers by Dr. Muir deal with a theorem regarding a sum of differential coefficients of principal minors of a Jacobian, an upper limit for the value of a determinant, and Borchardt's form of the eliminant of two equations of the nth degree. Other papers deal with the spectrum of the ruby, snake venom, the rainfall of South Africa, evaporation in a current of air, a list of the flora of Natal, and so on.

The *South African Journal of Science* is the organ of the South African Association for the Advancement of Science, its objects being to give a stronger impulse and a more systematic direction to scientific inquiry, to obtain a more general attention to the objects of pure and applied science, and the removal of any hindrances barring the progress of science. Instead of issuing one large annual volume, like our own association, a small journal is sent each month to the members. The numbers of the present volume (vol. vi., beginning November, 1909) contain the presidential addresses and some of the papers read before the sections; notes and articles from other sources are, however, included. The papers, nearly sixty in all, have the general merit of dealing with local phenomena, thus putting on record something that may pass away and be lost, or else attacking problems that can only be investigated on the spot.

It is eminently satisfactory to find that sufficient material exists to keep going these and the other scientific journals and societies of South Africa, including the geological, the chemical, and the engineering societies. South Africa has hitherto loomed so largely in the political and commercial worlds that it will come as a surprise to some to find that research work has been going on quietly and steadily for several years. The foundation has been laid on which a great superstructure may be raised; it has been proved that the fauna and the flora show in relation to their surroundings many features of very general interest and importance; a number of problems have thus been suggested for future workers to attack. Most important of all, however, is the fact that the spirit of research is abroad in South Africa at a time when colleges and universities are being founded and agricultural departments developed. There is, in consequence, the prospect that these new foundations may be started in the right direction at the outset, and so attain a position worthy of the vast possibilities of the country. The men who are now devoting themselves to research work are therefore making more than an examination of local problems, important as this is in a developing country where development often means extermination of species and obliteration of old records. They are creating an atmosphere in which the college and departmental staffs can do research work, in which, indeed, men will feel impelled to investigate. To do this in a busy commercial country like South Africa is no small achievement.

INDIAN PALÆONTOLOGY.

THE Geological Survey of India continues to publish well-illustrated and exhaustive memoirs on the fossil invertebrate faunas of the region with which it deals. Two more on the Himalayan Trias have lately appeared, and are of much interest for study in connection with recent work on the Triassic fossils of other areas. The first memoir (*Palaeontologia Indica*, ser. 15, vol. vi., No. 1, 1909), on the Lower Triassic Cephalopoda from Spiti, Malla Johar, and Byans, was begun several years ago by the late A. von Krafft, who collected much of the material. It has now been revised, completed, and brought up to date by Prof. C. Diener. It begins with a synopsis of the marine Lower Triassic formations of the Himalayas, which are proved to constitute a remarkably complete series. The detailed descriptions of the fossils which follow show that at least four distinct and successive faunas occur in the rocks of the district under consideration. Of these, the lowest or earliest is perhaps the most interesting, because it seems to represent the dawn of Triassic life in the sea. It is noteworthy for the complete absence of the numerous types of Palæozoic Brachiopoda, which are the predominating element in the Permian rocks of the Salt Range and the Himalayas. Both in the Alps and in the Himalayas the Permian and Trias are connected by an uninterrupted sequence of sedimentary deposits. The second memoir, by Prof. Diener (*loc. cit.*, No. 2), is more special, treating of the fauna, chiefly Cephalopoda, of the Traumatocrinus Limestone of Painkhanda. He returns to a discussion of the age of this limestone, and shows that enough of its ammonites are identical with (or closely allied to) species found in Europe to justify its correlation with the Julic horizon, or zone of *Trachyceras aonoides*.

Another memoir just received from the Geological Survey of India, though dated 1908, contains a valuable description of the Devonian faunas of the northern Shan States by Mr. F. R. Cowper Reed (*Palaeontologia Indica*, n.s., vol. ii., No. 5). The fossils are chiefly corals, bryozoa, and brachiopoda, with only few representatives of other groups, but they constitute the richest collection of Devonian age hitherto described from south-eastern Asia. Most of them were obtained from Padaukpin, and many appear to be identical with European species which characterise the lower part of the Middle Devonian. The marine faunas of Middle and Upper Devonian times prove to have been remarkably cosmopolitan, but in all cases, as at Padaukpin and other places in eastern Asia, there is also a local element giving them a special character.

DUTCH METEOROLOGICAL WORK IN THE EAST.[1]

(1) WE have to chronicle the issue of a new set of meteorological charts for the part of the Indian Ocean around Cape Guardafui. It is issued by the Meteorological Institute of the Netherlands to replace a set of similar charts published in 1888 which is now out of print. The observations are now sufficiently numerous to justify the subdivision of the restricted area under discussion into squares measuring 12′ by 12′, so as to bring out variations over short distances.

Special attention has been given to currents. Nearly 4000 observations, extending over the period 1888–1908, have been used, and these are all based on astronomical observations made at intervals of six or eight hours. The results are represented by "current roses," giving for each subsquare the mean velocity observed from each of sixteen directions. This method of representation gives an excellent idea of the varying nature of the currents; thus some of the roses quite near to Cape Guardafui are very nearly symmetrical stars, showing that currents from all directions may be encountered. We rather miss an indication of the number of observations used in computing each vector. Some must be based on very few observations, while others represent the mean of a considerable number of records, and we cannot help thinking that it would be useful both to the mariner and to the student to be in a position to weight the results.

The charts which follow give for each month and for each subsquare the averages for wind, pressure, temperature of the air, and temperature of the water. In the last the extraordinary low temperature of the surface water off the coast south of Cape Guardafui during the south-west monsoon is well shown. In July we find a reading of 18·8° C. (65·8° F.) slightly south of Ras Hafun, while in the Gulf of Aden, slightly west of Guardafui, a subsquare has a mean temperature of 30° C. (86° F.). Nevertheless, there is a caution in the introduction against relying on low surface temperatures to give warning of the proximity of land during hazy weather, for warm water is occasionally encountered south of Guardafui.

It has been found necessary to represent the monthly results for each element on a separate chart. Our first impulse when dealing with charts of this nature is to compare the results for different elements, and for this it is very laborious to have to refer to five different charts bound in different parts of the volume. We admit that there is danger of overcrowding, even if different colours are used for different elements, but it is a great advantage to be able to survey the complete data for a month with a minimum of cross-references.

(2) The rainfall volumes for the Dutch possessions in the East Indies form the thirtieth issue of the series. The first of the two volumes for 1908 gives daily observations of rainfall for 272 places. In the second volume we have statistics of the number of rain-days, greatest rainfall in a day, and comparisons with averages, and also a discussion of the records of eight autographic gauges. The publication, especially the first volume, which gives the names of all the observers for each month separately, seems at first sight unnecessarily detailed, but in a country where the rainfall is of such great economic importance such details are necessary, and do much to ensure accuracy.

PRACTICAL SPECTROSCOPY.

A NOVEL and very compact form of mounting for concave gratings is described by Mr. Albert Eagle in No. 2, vol. xxxi., of the *Astrophysical Journal*. Such a mounting has been erected, and found very satisfactory, in the spectroscopic laboratory of the Royal College of Science, and it is the experience obtained from this that has led to the publication of the details for general use.

In the Rowland form of mounting in general use there are serious disadvantages, the chief of which is that a large and darkened room must be devoted solely to the spectrograph when in use; the difficulty of efficient temperature control is also a serious one. In the new form most of the disadvantages are eliminated, and no serious new ones are introduced. The whole spectrograph for a 10-foot grating is, in the new form, contained in a box 11 feet 1 inch in length, 25 inches broad, and 22 inches deep, and the plates reproduced in the paper prove conclusively the efficiency of the apparatus under the ordinary conditions of laboratory work. On a photograph of the cyanogen band at λ 3883, taken in the fifth order with an exposure of forty minutes, lines only 0·05 Ångström are distinctly resolved. The temperature is maintained constant by lagging the double walls of the camera tube with slag wool, and the reproduction of part of a first-order iron spectrum, given four separate exposures of ten seconds at intervals of an hour, shows how efficient it is; this spectrum was taken without any special precautions whilst other work was proceeding in the well-lighted laboratory as usual, and yet the close pair of lines, separated by only 0·118 Ångström unit, at λ 4240 is resolved. Other advantages claimed for the new mounting are its comparatively low cost, its rigidity, a slightly increased dispersion, the use of higher orders than in the Rowland mounting, and the fact that the orders on either side of the normal may be employed. Against these are to be set two or three apparent disadvantages, of which, at first sight, a slight departure from normality appears to be the most serious; but, as pointed out by the author, an observer always has to construct a curve of errors when reducing observations, and such a curve would include this slight deviation from the normal, which, taken over a 3-inch range in the first-order spectrum, only amounts to 0·2 Ångström unit.

The important part played in solar and stellar spectroscopy by the H and K lines of calcium renders it essential that the absolute wave-lengths of these lines should be known with the greatest possible accuracy. For this reason Mr. C. St. John, working at the Mount Wilson Solar Observatory, has recently made a series of wave-length determinations for these lines in the arc, spark, and electric furnace, and in No. 2, vol. xxxi., of the *Astrophysical Journal* he gives his results in terms of the secondary standards of Fabry and Buisson adopted at the Meudon meeting of the International Solar Union. The mean results are 3968·476 and 3933·667 for H and K respectively, and are estimated to be certain within 0·001 Ångström. Mr. St. John also discusses the behaviour of these lines under the various conditions employed, and, from his results, concludes that the wave-lengths are identical for the absorption and the fine emission lines, and are the same in arc, spark, and furnace. The mean ratio of the width of K to H is 1·28, and the mean ratio of the respective intensities is 1·47. The experiments described were preliminary to an exhaustive comparative study of the corresponding solar lines.

PLANT DISTRIBUTION.

TWO recent papers furnish a supplement to the magnificent phytogeographical memoir on South Africa by Dr. R. Marloth. The one is an article, by Dr. L. Diels, on formations and flora-elements in the north-west of Cape Colony, published in Engler's *Botanische Jahrbucher* (vol. xliv., part i.). This is a detailed and localised account of botanical observations made in the country lying between the mouth of the Olifant River, Clanwilliam, and Calvinia. Near Clanwilliam lie sandy stretches where Compositæ and Scrophulariaceæ provide the bulk of the conspicuous vegetation. As the land rises, succulents, notably species of Euphorbia and Crassulaceæ, become predominant. At a height of 500 metres the vegetation begins to show elements natural to the true Cape flora, culminating in a "proteaceous-macchi" association on the Bokkeveld ridge. A special object of the trip was the exploration of the Hantam-berg flora, which is classed by the author with the botanical formations associated with Namaqualand.

The second paper is a contribution by Dr. H. H. W. Pearson to the Royal Geographical Society, published in the *Geographical Journal* (May), giving a general sketch of a botanical expedition through the dry western districts of Cape Colony and the adjoining German territory to Luderitzbuch, and thence from Mossamedes in Angola to Ft. Rosadas on the Kunene River. The regions of vegetation through which Dr. Pearson travelled are very clearly set out in the accompanying map. The succulent Karroo vegetation was first traversed until this gave place to a composite flora near Calvinia. Further north, floras known as the Namaqualand montane and Bushmanland were met with. The former is characterised by the presence of *Aloe dichotoma*, *Vogelia africana*, and other plants, while species of Aristida and *Parkinsonia africana* are typical of the latter type. The district lying immediately south of Mossamedes is the historic locality in which Welwitschia was discovered, and here the author found it more at home than in Damaraland, which suggests that it is a tropical species, and therefore more closely related to the genus Gnetum than to Ephedra.

Attention is frequently directed to weeds produced in new countries by exotic plants. There is, however, more interest attaching to the spread of indigenous plants caused by a disturbance of natural conditions, of which a striking instance in the case of *Celmisia spectabilis* is described by Dr. L. Cockayne in the Canterbury Agriculturists and Planters Association's Journal (April). This plant is a composite and endemic, growing naturally with other species of the genus at elevations above 3000 feet. It has a woody, creeping stem furnished with numerous cord-like roots. The end of the stem bears a rosette of thick tomentose leaves with long sheathing bases; the rosettes are crowded together, forming a circular mat or cushion. Within the shelter of the leaves lies the bud, which throws out daisy-like flowers above the leaves, and subsequently develops downy fruits. As a result of burning and overgrazing, the tussock formations at a lower level, which consist of useful grasses, are being replaced by the Celmisia. The remedy suggested is to reinstate natural conditions, when the grasses should win back the lost ground.

Captain A. A. Dorrien-Smith contributes to a recent number of the *Kew Bulletin* (No. 4) an account of his botanical excursions in Chatham Island with the primary object of collecting specimens of *Olearia semidentata*, *Aciphylla Dieffenbachii*, and other local plants for introduction into the Scilly Isles. In the south and boggiest part of the island *Olearia semidentata* covers acres of ground, and here the author discovered a pure white form of this normally purple daisy-like flower, and his companion found a pink variety. The article provides an interesting sketch of the vegetation, and is illustrated with several photographs, two of which represent bushes of the normal type and white variety of the Olearia respectively.

THE MAINTENANCE AND ADMINISTRATION OF ROADS.

AUTHORITIES having control of highways have now to consider the problem of road construction and maintenance from a new point of view in consequence of the conditions of modern traffic. The problem is an acute one everywhere, and various solutions of it have been put forward by highway engineers. Evidence of experts as to the causes of the increased wear and tear of roads and their opinions as to remedies will be found in the report of the important conference on roads, held last year at the Institution of Civil Engineers, and also in various publications of the Roads Improvement Association and the Royal Automobile Club. The subjoined extracts from these publications, and summaries of papers, provide the essence of a large amount of evidence given by road engineers before several conferences and associations upon important questions relating to roads.

A very large number of our roads, except those of recent construction, may be said to have grown, or developed, rather than to have been made. Many of them were originally mere tracks, and have arrived at their present state through the accretion of coats of ground-up stone, often of poor character, possibly faced with a thin crust of granite or some inferior material. The fact that many roads have been built up by the use of metalling, without foundations, other than the subsoil upon which the metalling is placed, accounts for the difficulties, troubles, and expensive maintenance now experienced in connection with most existing rural main roads, for where the foundation of a road is weak, the surface is always difficult and costly to maintain.

The greatest practicable improvement in the construction of macadamised roads is to be found in the use of the very hardest and toughest coating materials well consolidated by rolling, with the addition of just sufficient fine chippings during the consolidating process to fill completely the spaces between the stones. The common method (condemned by every road engineer) of binding together the aggregate of an ordinary macadam road by the use of road scrapings is productive of the greater part of the mud and dust found so objectionable. One of the resolutions referring to macadamised roads adopted by the International Road Congress held at Paris in 1908 was:—"To use as far as possible only hard and homogeneous road materials, regularly broken; to make choice of a binder suitable to the structure of the road material used, reducing, moreover, the binder to a minimum."

As to the wearing characters of various rocks used as road metals, some definite information is available. The Town Council of Hornsey possesses a machine by which the effect of wear and tear on road stones can be tested. The stones to be tested are all broken to a 2-inch gauge and placed in cast-iron cylinders, which are made to revolve 8000 times at a speed of twenty revolutions a minute. They are tested both wet and dry, and as the result of the shaking they receive a certain amount of chips and dust is produced. The percentage loss of weight experienced by the stones is then determined. As the treatment is the same in every case, the machine enables an estimate to be obtained of the relative power of road stones to withstand the wear and tear of traffic, and the rubbing action which takes place at the surface of a macadamised road. A series of tests with this machine was made a few years ago in connection with an examination of the constitution of the stones by H.M. Geological Survey, and the results were published in a work entitled "Attrition Tests of Road-making Stones." The table given below shows the average loss per cent. of a few typical rocks used for road-making:—

Stone	Quarry or Locality	Average Percentage of loss in dust
Quartzite	Wick, Glos.	4·0
Ferruginous Quartzite ...	Winford, Somerset... ...	4·4
Quartz Porphyrite	Quenast, Belgium... ...	3·7
Quartzite	Cherbourg	5·7
Biotite-hornblende Granite	Mount Sorrel, Leicestershire	6·6
Chalk Pit Flints	Grays, Essex	10·4
Gabbros	St. Sampson's Guernsey	10·7
Calcareous Sandstone ..	Liphook, Hants	17·3
Foraminiferal or Mendip Limestone	Winford, Somerset ...	19

It will be seen from this table that quartzites stood the test best, that flints came out fairly well, and that sandstones and limestones are at the bottom of the list. Though the final test of a road metal can only be known by wear and tear upon the actual road, yet the results obtained by the systematic testing of stones under precisely the same conditions serve as a guide in the selection of suitable materials. They give no indication, however, of resistance to crushing. Flints only lose a small percentage of their weight by rubbing together, but they are crushed into dust by heavy traction-engines.

There can be little doubt that poor materials, with road sidings used for binding, are largely responsible for the unsatisfactory condition of many roads. A limestone road-metal is undesirable for most districts, and flints make bad roads when they are used where heavy traction-engine traffic occurs. In the long run it is less expensive to use a good road-metal than a cheap one. It does not seem to be recognised that good material can be carted as cheaply as bad, and that, properly applied, the former lasts years longer than the latter.

Assuming that a macadamised road has been properly constructed, it is worth while to consider the chief causes of damage to it. It is often said that motor-cars are responsible for the chief part of the damage; but that is not really the case. If a newly made road be noticed, it will often be seen that the ordinary motor-car traffic scarcely wears the road at all in the tracks where the wheels go, whereas the part where the horse traffic goes is worn hollow in the middle, being dug out by the hoofs. Motor-cars probably do less damage to a good road than horses. Moreover, the damage done by a 2-ton pneumatic-tyred pleasure car is superficial compared with that done by a motor-waggon with a total weight of 12 tons. The wear and tear is caused by (1) the heavy weight per axle carried; (2) the speed at which the heavy motor-car runs. Under the Heavy Motor-car Order, a car weighing 3 tons unladen, and having a load of more than 5 tons (making a total of above 8 tons), must not exceed a speed of five miles an hour, with or without trailer; but this weight and speed are constantly exceeded. It is the combination of illegal speed with illegal weights carried that is largely responsible for much serious wear and tear of roads.

It is generally believed that ordinary motor-cars cause much damage to roads by what is described as the "sucking action" of pneumatic tyres; but this action has never been proved to exist. The action which undoubtedly does remove the small particles of the road is due to a scouring or brushing of the surface by the tyres, thus leaving the large particles to be crushed into dust by the rigid wheels of other vehicles. In the case of steel-studded pneumatic tyres the brushing action is, of course, greatly increased, and is accompanied by crushing forces. To sum up, the causes of damage due to altered conditions of traffic are:—(1) Traction engines: great weight of engine; excessive vibration, rigid and ribbed construction of tyres. (2) Heavy motors with trailers: vibration, weight, rigid tyres running over road at high speed. (3) Pleasure cars: scouring action of the pneumatic tyres of cars travelling at high speed.

The chief cause of dust, as apart from its method of production, is to be found in the use of unsuitable road material. As already stated, the horse is a serious factor in the creation of dust; and the 5-cwt. battering-ram, as each leg of the horse has been called, gives a road a succession of heavy blows, apart from the screwing or puddling action, and disintegrates the surface far more than is generally realised. The motor-car, on account of its tyres and the rapidity of its movement, though it raises and scatters dust to a greater extent than any other vehicle when going very fast, does far less to create it than is generally imagined.

The dust nuisance may be lessened greatly by using nothing but high-class road metal, reducing the quantity of binding material, and reducing the cross-fall or camber of the road, so as to ensure that the traffic spreads itself over the whole width instead of always being driven to the crown of the road; but Mr. Walker Smith, in an exhaustive book recently published on "Dustless Roads and Tar Macadam," points out that even when these conditions are satisfied no very substantial improvement can be looked for. "Even when the best material and the best methods of binding are introduced, the road will always remain a pervious road. The moisture in wet weather, which tends to hold the particles of the road together, will, on being evaporated in the dry weather, leave the surface loose and friable and a ready prey to the disintegrating forces, the shock of the horses' feet, the abrasion of the steel-studded vehicle, and the scouring action of the soft-tyred ones." Mr. Walker Smith says very strongly that the binding is undoubtedly the crux of the whole question of efficient road-making and maintenance. The binding makes or mars the macadamised road, and it is, and ever has been, the weak spot in the ordinary macadam road. The Dust and Dustless Roads Committee of the Royal Automobile Club reports that, in the opinion of the whole of the road engineers with which it has been in touch, if macadam roads are to be constructed to meet the needs of the present-day traffic, with the searching demands that the traffic makes on the road surface, a bituminous binding or matrix must be employed.

The committee states that, setting aside the temporary palliatives of watering roads with chemical preparations which keep the road damp by the absorption of moisture from the air, the treatment which has been most successful in rendering roads dustless has been the surface application of tar applied either by hand or by machine. By this method great lengths of road have been rendered dustless for a whole summer season, the mud in the winter following has been reduced in quantity, and in some cases the application has lasted for more than one season. Moreover, there is almost unanimous testimony that the whole cost of the treatment is more than saved by the increased durability of the road, and already many surveyors are able to make a strong case for the extension of the treatment solely on the ground of economy alone.

The most permanent mode of treatment is that of re-making the whole of the surface of the road with tar macadam, and when a road has to be re-surfaced this treatment is also the most economical in the end.

The use of calcium chloride to keep down dust is not recommended, one reason being that the keeping of the roads moist and soft tends to the more rapid wear of the surface.

The Roads Improvement Association has issued a report showing the extent and result of the treatment of roads by tarring. From this it appears that the road must be thoroughly cleansed before treatment; about six square yards of surface can be treated per gallon of tar; sand or granite chippings must be applied after treatment; the average cost is about 1*d.* or $1\frac{1}{4}$*d.* per square yard when a machine is used, and $1\frac{1}{4}$*d.* to $1\frac{1}{2}$*d.* when the tar is applied by hand; at least one treatment per annum is required; the road should be dry when treated. Excellent results have been obtained at the cost of about 40*l.* per mile, and with a small consumption of tar—about one-sixth to one-fifth of a gallon per square yard.

No suggestion of tarring is, however, of any use unless the road itself is constructed of good materials, so that, with the exception of some main roads, few roads in rural districts are at present in a condition for such treatment, though the changed conditions of traffic demand a change in the character of the roads. The new conditions demand increased expenditure upon maintenance both on main and secondary roads. The annual outlay in maintenance and repair of the main roads in England and Wales has steadily increased from an average of 76*l.* a mile in 1901 to more than 100*l.* a mile in 1909. Here is an average increase of 25 per cent. in eight years, and there is no prospect that the rate of increase will diminish. It would seem that a road system which requires an outlay of about 100*l.* a mile upon the 150,000 miles of road in England must be inefficient and costly. The explanation is probably to be found in the fact that the maintenance of our highways devolves upon local authorities. It is instructive to compare our system with that followed in other countries; and this comparison is made by Mr. L. W. Page, director of the U.S. Office of Public Roads, in a paper on road administration and maintenance published in the May number of the Journal of the Franklin Institute. Subjoined is a summary of a part of this paper.

Systems of Road Administration.

The basis of the French system is the School of Roads and Bridges, one of the finest technical schools in the world, and maintained at the expense of the national Government. From the graduates of this school are chosen the highway engineers who are entrusted with the building and maintenance of the roads in France. At the head of the administrative organisation is an inspector-general of bridges and highways, under whom are chief engineers in charge of the road work of single departments and communes. Single subdivisions of departments are under the direction of district engineers and assistant engineers, the latter being equal in rank to non-commissioned officers in the army. The subdivisions are under the direction of principal conductors and ordinary conductors. Next in line come the foremen of construction gangs, the clerks employed at headquarters, and finally the cantoniers or patrolmen, each having from 4 to 7 kilometres of highway under his immediate supervision. This great administrative machine, working in complete harmony with definite lines of responsibility clearly established, accomplishes results with military precision and regularity.

In England, jurisdiction over the road is vested in, first, the county boroughs; second, the county councils; third, the urban district councils; fourth, the rural district councils. In most counties the maintenance of the highways devolves upon urban councils in the urban districts and rural councils in the rural districts. The only exception to the control of the urban and rural district councils is in the case of main roads which are highways between large towns, and the maintenance of these roads devolves upon the county councils. As to skilled supervision, it may be said that no qualifications are required by law to be possessed by the men in charge of road building and maintenance, but it is the general practice, at least in important districts, to appoint experienced highway engineers for this work. It will thus be seen that the English system lacks strong central control in the counties, there being four different classes of Government units, each acting largely independently of the others.

Germany is a confederation of States, and it follows that road administration is conducted separately by each State of the Empire. The Imperial Government exercises very little control over the highways, and does not in any way contribute toward their construction or maintenance. The Kingdom of Saxony may be taken as a representative State of the German Empire. In Saxony the highways are divided into State roads, county roads, and private ways. The State roads comprise those which are built and maintained by the State. The county roads are generally termed communicating roads, and are built and maintained at the expense of the parishes through which they lead. A striking feature of the Saxony road system is the practice of planting fruit trees along the road. The fruit yields a revenue of about 8000*l.* a year from the State roads, while the amount obtained from the fruit grown on the county roads represents a much larger sum.

The State roads are cared for by a commission of engineers. The kingdom is divided into seventeen road districts, in each of which there is a road inspector. Under these inspectors are road masters, who are employed constantly throughout the year. Each road master has about thirty-seven miles of road under his direction, and a road force of about fifteen men. In the case of the minor roads, the direct responsibility is borne by the county authorities. They levy and collect the revenues necessary for maintenance and new construction. The communities engage the road employees for the continued care of the highways. The technical supervision, however, is exercised by the road masters of the State force.

The road system of Switzerland is local in character, the various cantons having jurisdiction over the roads within their respective borders. Each canton has at the head of its road system an engineer with capable assistants. In the canton of St. Gaul, which is fairly representative, there are under the control of the engineers five inspectors or road masters who are assigned to certain districts in the canton. The engineers and their assistants must have an academic education and possess a diploma from the Polytechnic Institute, while the road masters are required to have a good technical education.

It is apparent from the foregoing that while the units of administration in European countries range all the way from the localism of England to the highly centralised system of France, through varying degrees, skilled supervision is provided for by all the systems, as well as an ample cash revenue sufficient to enable the engineers to carry out the plans for improvement and maintenance. England is the most striking example of extreme localisation, and, it is a significant fact, also the most striking example of lack of uniformity in road work and of excessive expenditure in proportion to mileage. It is also significant that the most perfect road system is that of France, which is admittedly the most highly centralised of all the road systems. France, with a total mileage of about two and one-third times that of England, expends about the same amount annually for maintenance. Certainly the inference must be plain, that centralisation makes for economy and efficiency in the administration of the public roads.

When we turn to the subject of road administration in the United States, we find that about half the States are operating under practically the same road laws as prevailed in England when America was a colony. This system of road administration provides for the payment of road taxes partly in labour, and localises the work to an extreme degree. Organisation is almost entirely lacking, and no requirements are made to secure skill or knowledge on the part of the road officials. With few exceptions, no system of accounting is in force, and no definite lines of authority are established, such as would guarantee the wise and equitable conduct of the work.

The erroneous impression often prevails that when a so-called permanent road is constructed the expense has practically all been met in the first cost. An investigation of the cost of maintaining roads in the leading countries of Europe shows how incorrect is this view. In 1901 England and Wales maintained 26,598 miles of main road at a cost of 74*l.* per mile. In 1907 England and Wales maintained 27,556 miles of main road at a cost of 89*l.* per mile, or in six years the cost of maintenance had increased 15*l.* per mile, an increase of about 20 per cent. In France the increase in cost of maintaining the national roads was about 5 per cent. in the same period. The cost of maintaining main and urban roads in England and Wales in 1905 and 1906 was 88*l.* per mile. In France the cost of maintaining all roads during 1904 was 48*l.* per mile. While these last figures are not strictly comparable, one being for 1904 and one for 1905, yet the mere fact of one year's difference in time fails to explain the difference of 40*l.* per mile in cost of maintenance—the natural inference being in favour of the superiority of the French system.

These figures express most forcibly two facts: first, that even the best of improved highways are not self-maintaining, and second, that the cost of maintenance varies tremendously with the degree of centralisation of the administrative organisation which has the roads in charge.

France, with its most highly centralised organisation, is maintaining her roads at about 54 per cent. of what it costs England and Wales with her very local and loosely centralised organisation. Furthermore, the alarming increase in the cost of maintenance has been far more rapid in the countries with local and poorly organised systems of highway administration.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SHEFFIELD.—The council has appointed Mr. A. E. Findley to the newly instituted post of lecturer of applied chemistry in the University. Mr. Findley is at present assistant lecturer in chemistry at the Bradford Technical College.

THE Mercers' Company has made a donation of thirty guineas to the South-eastern Agricultural College library for the purchase of books of reference. The Fruiterers' Company has also presented a very fine copy of that scarce work, "The Herefordshire Pomona," and the Carpenters' Company a work on forestry, to the college library.

THE July issue of the *Battersea Polytechnic Magazine* shows how successfully the authorities of the polytechnic encourage an all-round development of their students. The magazine contains two general articles; one, on the house-fly, is based on the published papers of Dr. C. G. Hewitt, and the other deals with the discharge of electricity through high vacua.

AN open competitive examination for not fewer than seven situations as assistant examiner in the Patent Office will be held by the Civil Service Commissioners in September next. The examination will commence on September 26, and forms of application for admission to it are now ready for issue, and may be obtained on request addressed by letter to the Secretary, Civil Service Commission, Burlington Gardens, London, W.

ACCORDING to the *Revue scientifique*, a national office of French universities and schools has been inaugurated under the presidency of M. Paul Deschanel, of the French Academy. Prof. Paul Appell, of the University of Paris, and Prof. Georges Lyon, of the University of Lille, have been elected vice-presidents. Dr. Raoul Blondel has been appointed director. The new department is to be installed at the Sorbonne, and its object will be to make known to foreigners the educational resources of France.

AT the close of the term of the Royal Agricultural College, Cirencester, on July 27, the principal, Prof. J. R. Ainsworth-Davis, announced that the council of the University of Bristol has enacted a temporary ordinance, which will probably be made permanent in the autumn, making the college part of the University for higher teaching in agriculture and forestry. He also announced that Mr. H. J. Elwes, F.R.S., has placed a portion of his afforested land at Colesborne at the disposal of the college for research purposes.

WE are glad to receive a copy of the July number of the *Science Journal* of King's College School, Wimbledon. It is a special photographic number of twenty-four pages with several inset plates and sheets of illustrations, and is evidence that photography at Wimbledon takes a very noteworthy place among the out-of-school subjects that engage the boys' attention. Of the thirteen papers or essays, all except two seem to be by the boys themselves, and they deal with camera construction, exposure, development, printing, optics, enlarging, sports photography, and colour photography. It is gratifying to see that the greater number of the articles refer to the writers' own experiences, and are evidence of intelligent work. There may be room for different opinions as to the usefulness of a table of poisons, with the symptoms when taken and the ordinary antidotes, because it may be thought preferable for a lad to get assistance rather than to attempt to diagnose and treat a case of poisoning himself, but with reasonable care such cases of need will never arise.

THE report (Cd. 5257) has been issued of the departmental committee appointed to consider the statement of claims to additional State assistance, and estimates of the amounts needed for the respective services, which have been supplied by the Scottish universities at the request of the Government, and to report for what objects and to what extent assistance, if any, should be granted from public funds in the interests of the proper development of the work of the universities. The committee reports that a good claim has been made out for an additional grant to Scottish universities, and recommends 40,000*l.* as a fair contribution to their more pressing needs. This sum it proposes should be allocated as follows:—Edinburgh, 12,500*l.*; Glasgow, 12,500*l.*; Aberdeen, 9000*l.*; St. Andrews, 6000*l.* The grants, it is recommended, should be on condition that their administration should be in the hands of the respective University Courts, which should submit annual reports to the Treasury. Not less than 1500*l.* of the grant to St. Andrews University is to be devoted to the conjoint Medical School at Dundee. It is further recommended that, in addition to the 40,000*l.*, 3000*l.* should be paid annually to University College, Dundee, and that the grant at present received from the University Colleges (Great Britain) Grant should be discontinued.

THE antagonism which exists in England between the mathematician and the "practical man" is so deeply rooted that any attempt to break down existing prejudices will be studied with the keenest interest. In his presidential address to the Mathematical Association last January, Prof. H. H. Turner gave a remarkable account of the efficient development of the Egyptian Survey under the direction of Captain H. G. Lyons, F.R.S., in which he states:—"Now it will be readily imagined that for work of such extent and variety it is not easy to get a suitable staff of assistants. Scientific knowledge is necessary, but so also is a knowledge of Arabic and a physique which will stand the hot climate; so also is a business capacity and a faculty of detecting the truth in its Oriental disguises. It might well be that any one of these qualities was essential, while the rest, though desirable, might have to be dispensed with; or it might be that some rare combination of them must be sought with toil. It will probably be admitted that the final opinion of a man who has gone through the trying experience of getting together a staff suitable for such work, and finds himself ultimately satisfied as to the right course, is worth hearing; and hence I feel that the association will learn with peculiar pleasure that Captain Lyons's final method is to take able mathematicians from Cambridge or Oxford and trust to luck for the other qualities. The one thing he finds needful is that when some strange situation occurs, they should have a firm grasp of the fundamental principles, and not merely a knowledge of the rules deduced, which may fail to meet some unforeseen contingency. And this essential condition Captain Lyons has found to be fulfilled by mathematicians when others have failed to meet it. His faith in them has been justified in cases where a breakdown might have possibly been admitted. Even the most complete knowledge of mathematical or physical principles could scarcely be expected to inspire a man in dealing with an Arab camel-driver who was shamming sick; or with the organisation of the commissariat for a journey in the desert; or with an unexpected attack by wandering tribes which necessitated addressing them with dignity from the hump of a camel with three rifles pointed at one's chest. But it has been proved in the best possible way, viz. by actual experience, that such situations are dealt with capably by young men selected for their mathematical ability, with no special training for the contingencies of life beyond what undergraduates all pick up from life in one of our great universities. This is a lesson which we may well lay to heart."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 25.—M. Émile Picard in the chair.—H. **Deslandres** and J. **Bosler**: The phenomena presented by the tail of Halley's comet during the passage of May 19 last. From a discussion of various observations, especially those made by R. T. A. Innes at Johannesburg, it is concluded that the tail of Halley's comet was repulsed by the earth, and the evidence is in favour of this repulsion being due to electrical causes.—P. **Villard** and

H. **Abraham**: Explosive potentials. A study of the phenomena of the spark discharge. In a previous paper a description was given of the results obtained when the changes of potential were slow; the present note deals with the effects of high-voltage alternating currents.—D. **Gernez**: The colours arising in colourless solutions of coloured bodies at the moment of the solidification of the colourless solvent. Colourless solutions of mercuric iodide in various solvents (naphthalene, stearic acid, chloral hydrate, phenol, &c.) become yellow on solidification, owing to the separation of the dissolved iodide in the unstable yellow modification.—A. **Lacroix**: Some minerals formed by the action of sea-water upon Roman metallic objects found off the coast of Mahdia, Tunis. A sheet of lead gave crystals of cotunnite ($PbCl_2$); transparent brilliant crystals of phosgenite ($PbCO_3.PbCl_2$) were also found. Two copper minerals are also described, covellite (CuS) and chalcosite (Cu_2S).—L. **Mangin**: New observations on callose. This name is applied to a new substance obtained from the membrane in fungi; it is differentiated from cellulose by several reactions, especially by its insolubility in Schweitzer's reagent, and by its rapid solution and destruction by glycerol at 300°.—A. **Ladenburg**: Racemic and liquid combinations. The results of experiments on the melting points of mixtures of inactive pipecoline containing variable quantities of *d*- or of *l*-pipecoline are shown in the form of a curve. The existence of the racemic pipecoline in solution is clearly demonstrated.—A. **Calmette** and L. **Massol**: The precipitation reactions of serums from tuberculous subjects, and of the serums from animals hyperimmunised against tuberculosis in presence of the tuberculins.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the first quarter of 1910. The results are collected in three tables, giving the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—Jean **Mascart**: Photographs of Halley's comet. Reproduction of photographs taken from Mt. Guajura, Teneriffe, at an altitude of 2715 metres.—D. **Eginitis**: The physical phenomena presented by Halley's comet.—R. **Bricard**: Concerning a claim for priority by E. Study.—Paul **Dienes**: A problem of Abel.—Étienne **Mazurkiewicz**: The theory of *ensembles*.—A. **Korn**: The biharmonic problem and the fundamental problem in the theory of elasticity.—E. **Pringsheim**: The emission of gases. A reply to some remarks by M. Bauer on some experiments by the author.—Gabriel **Sizes** and G. **Massol**: The harmonics of wind instruments.—L. **Hackspill**: The electrical resistance of the alkali metals. The metals cæsium, rubidium, potassium, and sodium were distilled directly in a vacuum into the tubes used for the measurements, and the electrical resistance determined at temperatures ranging from 55° C. to the boiling point of liquid air. The figures are somewhat lower than those given by previous observers; a trace of oxide appreciably raises the resistance.—A. **de Gramont**: The place of ultimate lines in spectral series.—G. **Reboul**: Chemical reactions and ionisation. The experimental results are in general accord with those given by MM. de Broglie and Brizard.—Abel **Buguet**: The cryoscopy of the naphthylamines and addition compounds.—E. **Briner** and A. **Wroczynski**: The action of pressure and temperature upon cyanogen. Prolonged heating at 220° C. under a pressure of 3/4 atmosphere was without effect upon cyanogen; at the same temperature, under a pressure of 300 atmospheres, 10 per cent. of the gas was converted into paracyanogen in six hours. At the ordinary pressure a temperature of 310° C. is required to effect an appreciable change; under high pressures the change commences at lower temperatures, and in the latter case, in addition to *para*-cyanogen, some carbon and nitrogen are produced by the decomposition of the gas.—Henri **Bierry**, Victor **Henri**, and Albert **Ranc**: The action of the ultra-violet rays upon certain carbohydrates. Under the influence of the ultra-violet rays the molecule of *d*-fructose undergoes a profound degradation, formaldehyde and carbon monoxide being produced. Duffy **Wolk**: Aluminium nitride, its preparation and fusion. The temperature of formation of aluminium nitride from aluminium and ammonia is 820° C. to 850° C.—Miroslaw **Kernbaum**: The decomposition of steam by the brush discharge. Working at the ordinary temperature, the brush discharge converts water vapour into hydrogen and hydrogen peroxide. At higher temperatures the latter substance is decomposed, and a mixture of hydrogen and oxygen is observed.—V. **Grignard**: The decomposition of phenol ether-oxides by mixed organo-magnesium derivatives.—Gabriel **Bertrand** and G. **Weisweiller**: Researches on the constitution of vicianose. The products of the diastatic hydrolysis of vicianose have been found to be *d*-glucose and *l*-arabinose.—G. **Friedel** and F. **Grandjean**: The anisotropic liquids of Lehmann.—Leclerc **du Sablon**: The theory of periodic mutations.—M. **Hue**: The variation of the gonidia in the genus Solorina.—J. **Virieux**: The sheaths and mucilages of the fresh-water algæ.—Audebeau **Bey**: Experiments carried out in Egypt with the view of determining the influence of the level of the underground water of the Delta on the growth of cotton.—MM. de Drouin **de Bouville** and L. **Mercier**: The appearance of the *furonculose* in France. This formidable disease of the trout has appeared at Bellefontaine, near Nancy.—O. **Duboscq** and B. **Collin**: The sexual reproduction of a parasite of *Cyttarocyclis Ehrenbergii*.—J. E. **Abelous** and F. **Bardier**: An attempt at the immunisation of animals against urohypotensine: the antitoxic action of the serum of immunised animals.—E. **Tassilly** and R. **Cambier**: The abiotic action of ultra-violet rays of chemical origin. The light from a carbon bisulphide flame burning in nitric oxide possesses a distinct, though feeble, sterilising action.—E. **Gley**: The modes of extraction of secretine. A new stimulant for the pancreatic secretion.—A. **Briquet**: The genesis of relief forms in the Gallo-Belgian region.

THURSDAY, AUGUST 11, 1910.

RECENT EARTHQUAKE INVESTIGATIONS.

The California Earthquake of April 18, 1906. Report of the State Earthquake Investigation Committee (in two vols. and atlas). Vol. ii., The Mechanics of the Earthquake. By Harry F. Reid. Pp. viii + 192. (Washington: Carnegie Institution, 1910.)

ON the average a little earthquake occurs in the world every fifteen minutes. Great earthquakes occur on the average about every four days, but it is only on rare occasions that they hit populated districts. The majority of the latter originate beneath deep oceans or in uninhabited mountain regions, and as neither little fish nor wandering tribes write letters to the *Times*, all we know about their occurrence comes from the observations of enthusiastic seismologists. Nineteen hundred and six, however, was a bad year for humanity, and exhibitions of seismic relief took place in many districts. On January 31 a great disaster occurred in Colombia. On April 4 many soldiers and natives lost their lives in the Kangra Valley. On April 14 nearly 6000 houses fell in Formosa, whilst four days later San Francisco and other towns in Central California were reduced to ruins. On June 14, Kingston, in Jamaica, was badly shattered, and in the autumn, on August 17, Valparaiso and Santiago fell. In connection with the disaster at San Francisco, British shareholders in insurance companies were called upon for twelve million pounds, whilst towards the reconstruction in Kingston their contribution was two millions. What they paid for the happenings in other parts of the world I do not know, but it is quite certain that attention was directed to the fact that even the inhabitants of the British islands were not entirely beyond the pale of the vagaries of Mater Terra.

In 1906 the proprietors of newspapers, lawyers, expert witnesses, the vendors of building materials, constructors, and others may have regarded earthquakes as blessings in disguise. The charitably disposed had frequently opportunities to derive comfort from their donations, while scientific bodies saw opportunity for investigations. The International Seismological Association spent a very large sum in collecting and reproducing seismograms relating to the earth movements which had devastated Central Chile. The Carnegie Institution of Washington not only carried on similar work for the earthquake of California, but by publishing three volumes based on the material collected it has considerably extended our knowledge connected with seismological observations.

To the first two of these volumes, issued as part i. and part ii., reference has been made already (NATURE, March 4, 1909, vol. lxxx., p. 10). The second volume, by Prof. H. F. Reid, of the Johns Hopkins University, which is now before us, treats of "The Mechanics of the Earthquake." In the discussion on the origin of the shock, this is shown to have taken place from point to point along a line of fracture many miles in length and with a variable depth. There are therefore many times of origin, each of which depends upon the particular point considered. This may be a seismometrical refinement, but Prof. Reid, by his insistence on this, has done much towards the exact understanding of certain observations. In the discussion on permanent displacements of the ground we are shown that as the results of three surveys, the first of which commenced in 1851, there have been permanent displacements parallel to the length of a well-known fault. The ground on the east side of this fault has moved southwards, whilst that on the opposite side of it has gone to the north. A part of this displacement, no doubt, took place at the time of the earthquake, but there are convincing reasons for the belief that much of it took place gradually before the earthquake. The ground, in fact, was bent before it broke. By experiments with a stiff slab of jelly across which a slight cut made by a knife represented a line of fault, the nature of the strain which takes place before and after an earthquake is illustrated. The actual forces required to produce in solid rock the observed distortions, which resulted in rupture, are given in mechanical units. If the depth of the fault was 12·5 miles, its length 270 miles, and the average movement 13 feet, then the work done at the time of rupture is estimated at 13×10^{16} foot-pounds. After this energy was set free, seismographs throughout the world were set in motion.

A cause for the deforming forces which resulted in these strains is sought for in the theory of isostacy, which implies that the shifting of materials accompanying surface denudation is compensated for by a sub-surface flow. By this flow a dragging force is exerted upon the superincumbent crust, which from time to time yields suddenly. To predict tectonic earthquakes we should build a line of piers at right angles to a fault line and determine from time to time the difference in direction between these piers and their relative levels. Such observations, whether they did or did not prove of value as an assistance towards earthquake prediction, it is extremely likely that they would throw light upon certain branches of earth physics. Rotary movements are considered at some length, and the idea that they may be the result of vibrations at right angles is considered to be the one offering the simplest explanation.

A chapter of great interest, not only to the builder, but to the mathematician, relates to the influence of a foundation upon apparent intensity, this being most pronounced upon alluvium.

Part ii. of this volume is devoted to a critical description of seismograms obtained from stations in various parts of the world. This is followed by old and new explanations for the apparent increase in the duration of an earthquake as it travels. This is another good chapter, but it might easily have been extended. The discussion of the velocities with which different wave types were propagated and the paths they may have followed has been worked out with great care, and is distinctly instructive. The determination of the distance of the origin of an earthquake, as is now well known, depends upon the interval of time between the arrival of the first motion and the arrival of

 G

some other phase of motion like the large waves. This is closely examined, and observations previously made upon this point are brought more closely in accord.

Disturbances of magnetic needles at the time of the earthquake have not been overlooked. Much is said in favour of damping pendulums, and reference is made to the recently devised "dead-beat" instruments of Prince Galitzin. We have not, however, come across any reference to his method of determining the direction of an earthquake from the first of the preliminary tremors. The monograph closes with the theory of the seismograph. In this we notice the statement that the instruments designed by myself in 1892 and Dr. Schlütter about 1903, to show tilting of the ground at the time of an earthquake failed to show such a phenomenon. This is only true for the latter instrument (see British Association Report, 1893, p. 222).

Prof. Reid's memoir is a valuable contribution to the mechanics of earthquakes. He has ploughed both new ground and old, and seismologists will thank him for the material he has furnished for their consideration. JOHN MILNE.

TAR, ACID, AND ALKALI.

(1) *Coal Tar and Ammonia.* By Prof. George Lunge. Fourth and enlarged edition. Part i., pp. xix + 563; part ii., pp. xiii + 564–1178. (London: Gurney and Jackson, 1909.) Price 42*s.* net, two vols.

(2) *The Manufacture of Sulphuric Acid and Alkali, with the Collateral Branches: a Theoretical and Practical Treatise.* Third edition, enlarged. By Prof. George Lunge. Vol. ii., part i., Sulphate of Soda, Hydrochloric Acid, Leblanc Soda, pp. xx + 490; vol. ii., part ii., ditto, pp. xii + 491–1010. (London: Gurney and Jackson, 1909.) Price 42*s.* net, two parts.

THESE three terms—tar, acid, and alkali—stand for the most important of the determining factors of chemical technology. Round them may be ranged practically everything that relates to the business of applied chemistry. In its most comprehensive sense, each in turn may be regarded as the parent or genital substance from which flows a countless number of bodies, forming by their mutual actions and reactions the vast array of products which modern manufacturing chemistry has placed at the service of mankind. In the works before us, Dr. Lunge's treatment of these themes is worthy of their importance. The works themselves have already taken an assured position in the literature of chemical technology. In each successive edition their veteran author strives to make them a faithful and adequate reflection of the state of contemporary knowledge and achievement, thereby tending, so long as his ministering care is available, to make that position secure. They have long been recognised as indispensable to the technologist, and each new issue is certain of an immediate welcome.

The volume on coal-tar and ammonia is now in its fourth edition. What enormous changes have come over the industry of tar production, and of the extraction and utilisation of the innumerable substances which enter into its composition, will be evident from even the most superficial examination of the several issues. The rate of progress, indeed, transcends anything to be observed in any other branch of manufacture. Only nine years have elapsed since the third edition made its appearance, but such has been the accumulation of new material in that interval that practically the whole of the chapters—eleven in number—dealing with coal-tar and its products have had to be revised and in great part rewritten. In this section of the work Dr. Lunge has had the assistance of Dr. Kraemer, of Berlin, an acknowledged authority in this branch of chemical technology.

England is still the great tar-producing country of the world, but her supremacy in this respect is threatened by the United States. Tar is mainly obtained from gas-works, from blast furnaces, and from coke-ovens. In the United Kingdom the annual production at the present time approaches a million tons—obtained by the destructive distillation of about seventeen or eighteen million tons of coal—an amount exceeding that of the whole of Europe put together, and probably more than twice the aggregate yield of Germany and France. This country, where benzene was discovered by Faraday, where its industrial extraction was worked out by Mansfield, and where the first aniline colour was made by Perkin, has become simply as the hewer of wood and the drawer of water in this matter. We make the tar, but apparently we can do little with it except sell it to the Germans in order that they shall turn it into that astonishing array of manufactured products which their admirable system of scientific training has taught them how to produce. When in the hour of her humiliation Germany set herself to reconstruct the educational system which has culminated in her present scheme, she forged the most powerful instrument of national development which human forethought could have devised. With it has come her extraordinary commercial development and her ambition to be supreme in the world's markets, and with it, too, she thinks, has come the necessity of being able to protect that commerce, if necessary, by force of arms. What becomes of coal-tar may seem a small matter in determining the course and destiny of nations. But is is absolutely certain that if our university system had been developed, even *pari passu* with that of Germany, and that if those who were responsible for the government of this country, and those who seek to form public opinion, had paid more heed to the signs of the times, we should to-day have less talk about Tariff Reform and of the imperative necessity of more "Dreadnoughts." If Peace has her victories, no less renowned than those of War, we may well ask ourselves if we have always gone the right way to work to secure the victories of peace.

Dr. Lunge's second work—that on sulphuric acid and alkali, now in its third edition—further serves to illustrate the same text. If there was one chemical industry more than another in which Great Britain was pre-eminent, it was that to which this work relates. Upon it hangs a great number of collateral industries, and their prosperity is bound up together and is mutually dependent. We had abundant stores of most things we needed to extend and develop this industry, and whatever else we required our oversea trade enabled us to procure. That supremacy is challenged. Newer methods have undermined the position which the industry enjoyed with us for so many years, and in which such large amounts of British capital are still locked up. So long as we were concerned with the application of the simplest chemical principles we could hold our own by virtue of our natural advantages. Immediately we were confronted by new processes involving more recondite principles, questions of chemical dynamics, and abstract considerations of mass-actions, reversible reactions and the like, our manufacturers were powerless; nor were they able to find in this country the help they needed. Some of them eventually found it in imported polytechnically trained German and Swiss chemical engineers—for the most part university men with post-graduate technical training—men that the German and Swiss systems produce in abundance.

This system of fighting our industrial battles, in fact, resembles that on which decadent Rome depended for her national existence, and which eventually proved her ruin. It is true, we are beginning to wake up, and sporadic efforts are being made in various directions to rouse the country from its lethargy. Large sums of money are being spent, but whether always wisely is very doubtful. Anything like control, or action directed from outside, is resented, for there is no controlling authority armed with the necessary powers, or, even if it were armed, commands general confidence. We can only hope that "we shall worry through somehow," but if we do, it will only be, as hitherto, by the expenditure of a vast amount of fussy energy, much delay, and waste of money and means.

SOUNDING ROUND THE ANTARCTIC CONTINENT.

Deutsche Südpolar-Expedition, 1901–3. Band ii., Geographie und Geologie. Heft vi., Die Grundproben der Deutschen Südpolar-Expedition, 1901–3. By E. Philippi. Pp. 415–616+xxxi–xxxiii plates. (Berlin: Georg Reimer, 1910.)

THIS memoir forms the sixth division of the second volume—that devoted to geography and geology—of the reports on the German South Polar Expedition, under Prof. von Drygalski, in the *Gauss*. Since the issue of this important memoir, the news has arrived of the great loss which science has sustained by the death of its talented author.

During the whole of the voyage out to the Antarctic Ocean, frequent soundings were taken, directly the equator was crossed. Thirty soundings are recorded between the equator and the Cape of Good Hope, and eighteen more between the Cape and the ice-limit. In the same way, on the return voyage, eighteen soundings were obtained during the somewhat circuitous course by way of the Heard, Kerguelen, St. Paul, and New Amsterdam islands, and by the south of Madagascar back to the Cape; thence to the equator, by a different course to the outward one, thirty-nine further soundings were taken. The methods of obtaining samples of the sea-bottom, in the case of these soundings, and the subsequent treatment of the materials in the laboratory, are fully discussed in the memoir, and the careful descriptions of the specimens of the globigerina and diatomaceous oozes, and of the blue and red muds, are supplemented by mineralogical notes by Dr. R. Reinisch, and chemical analyses by Dr. J. Gebbing. On the chart, a graphic illustration is given of the nature of the sea-bottom at each of the stations, and this part of the work is of considerable value as adding fresh materials for a description of the exact character of the floors of the South Atlantic and Indian Oceans. The descriptions of the soundings and the tabular statements concerning them are very complete, and will prove of great value for purposes of comparison.

The portion of the memoir which will perhaps excite the greatest interest, however, is that which deals with the materials obtained in soundings along the margin of the Antarctic pack-ice. The thirty-three soundings in which specimens of the ocean floor were obtained are valuable as giving indications of the geological structure of that portion of the Antarctic continent lying between the meridians of 80° and 96° E. The mineral fragments, which have been very carefully examined and described, must have been brought down by glaciers from the interior of the continent. Among the larger fragments occur granitic rocks, gneisses, amphibolites, and other crystalline schists, with a red quartzitic sandstone, coarse or fine grained, and, more rarely, gabbro. Of recent volcanic rocks, fragments of basalt and of volcanic glass are recorded from a few stations only, and it is suggested that possibly these may have come, not from the continental lands, but from some island or islands lying within the limits of the ice-pack, or possibly they may be the products of submarine eruptions.

The long list of minerals given from the different soundings confirms the conclusions drawn from the study of the rock-fragments, for they nearly all belong to species characteristic of granitic rocks and the older crystalline schists. The study of the sandy or muddy materials in which these rock and mineral fragments are embedded shows that, as a rule, they are free from calcareous matter. Of the thirty-three deposits examined, only one was found to contain any considerable proportion of calcium carbonate, nearly 20 per cent.; four others contained from 1 to 5 per cent., and four others mere traces; the remaining twenty-four were perfectly free from all calcareous matter. Although the glacial muds graduate, in passing northwards towards warmer seas, into the diatomaceous ooze, the remains of the microscopic algæ are not abundant in the muds from the borders of the pack-ice. Some foraminifera occur, and glauconite was detected in five of the soundings.

The study of this very complete and suggestive memoir cannot fail to increase the regret which must be universally felt in the scientific world at the death, so early in his career, of its distinguished author.

J. W. J.

READABLE BOOKS IN NATURAL KNOWLEDGE.

Wonders of Physical Science. By E. E. Fournier. Pp. viii+201.

Tillers of the Ground. By Dr. Marion I. Newbigin. Pp. viii+224.

Threads in the Web of Life. By Margaret R. Thomson and Prof. J. Arthur Thomson. Pp. vii+198. (London: Macmillan and Co., Ltd., 1910.) Price 1s. 6d. each.

SOME years ago a new series of "Readable Books in Natural Knowledge" would have been a gift of doubtful value to the teacher. Written by the capable hands that have made the present volumes, they could not have failed to awaken here and there the genuine passion for scientific inquiry, and so would have seemed to justify their existence. But, speaking generally, the more completely such books had succeeded in "popularising" the labours of the *savant* the further they would have been held to direct the attention of the teacher from the proper aim of instruction in science. We now recognise that that aim is not so much to make the pupil acquainted with certain ranges of facts as to train him in the exercise of one of the most important forms of human activity. Thanks largely to the tireless propaganda of Prof. Armstrong, this aim is at present pursued with more or less intelligence wherever it is claimed that science is being taught. The boy learns that the essence of science consists in putting a clear question to nature and wresting from her a clear answer to it. In favourable circumstances he acquires some of the mental habits essential to success in this pursuit, or at any rate is made to see that such success comes only of faithfulness and labour.

It was natural that the training value of heuristic methods should be emphasised by their advocates since this element was almost entirely absent from the older didactic methods. But modern pedagogy, instructed by the results of psychological inquiry, has become critical of the claims of a subject to train or cultivate "faculties," and prefers to find in the nature of the subject itself the justification for teaching it. Thus the prime reason for teaching science is that, intrinsically and in its results, the scientific activity is one of the greatest and worthiest types of human effort. An education that does not give a sympathetic acquaintance with it is, therefore, necessarily incomplete. Whatever other arguments may be urged in their favour, heuristic methods in science teaching are rendered necessary by the fact that by them alone the pupil is made actually to exercise the scientific activity, and so to gain direct knowledge of one of the cardinal forms of human achievement. But when by first-hand experience he has genuine knowledge of the scientific activity, he should also have opportunities of appreciating its significance in human history. It is precisely to serve this function that the present series of "Readable Books" has been designed. To quote the publishers' note, they "aim at exalting the scientific spirit which leads men to devote their lives to the advancement of natural knowledge, and at showing how the human race eventually reaps the benefit of such research."

It may be said at once that in the first three books of the series this aim has been already admirably fulfilled. The authors have approached their task in the right temper, and have, on the whole, been remarkably happy, both in the choice and in the treatment of their topics. Mr. Fournier takes ground, a great part of which has been worked over by predecessors, but he has evidently gone himself to the works of the great physicists, and his chapters have the freshness and force derived from this direct contact. Dr. Marion Newbigin tells of the evolution and spread of food-plants with an epical directness and unity of plan. An episode in the development of Transatlantic commercialism—such as the transportation of Smyrna figs to California—becomes in her hands a wonderfully impressive illustration of the working of the scientific spirit. Mrs. and Prof. J. A. Thomson have taken a subject which hardly lends itself to the same unity of treatment. In part, their object is to exhibit the dependence of man upon deliberate or unconscious partnership with animals—such as the domesticated animals on the one hand, and earthworms on the other. They come nearer to the special aim of the series in the chapters where they show what tremendous results depend upon the scientific investigation of the life-histories of microscopic parasites. It is unnecessary to say that both parts of their programme are admirably executed.

A notable characteristic of each of the books is that they bring the tale of scientific conquests down to our own days. Thus Mr. Fournier describes Röntgen's discovery of the X-rays, and tells the story of aviation down to Blériot's flight across the Channel last year. Dr. Newbigin gives capital chapters on the work of Mendel, de Vries, and their followers. Prof. and Mrs. Thomson have a chapter on the relation between mosquitoes and malaria, as well as one on Pasteur. In short, these most interesting and stimulating little books initiate a series which will at once prove of great value as an adjunct to the systematic instruction of the class-room and laboratory, and, if continued in the same spirit and with the same ability, will become an almost indispensable part of a school equipment for science teaching.

T. P. N.

SALMON AND TROUT.

Life-history and Habits of the Salmon, Sea-trout, Trout, and other Fresh-water Fish. By P. D. Malloch. Pp. xvi+263. (London: Adam and Charles Black, 1910.) Price 10s. 6d. net.

THIS book is almost entirely devoted to the salmon of the Tay, sea-trout, and brown trout. "The other fresh-water fish" are but slightly dealt with, and the chapters allocated to them call for no particular notice, save to direct attention to the startlingly inaccurate assertion that "Prof. Grassi, of Rome, discovered the breeding grounds (of the eel) to be out in the Atlantic Ocean from Norway, Denmark, France, and Spain in some parts 1000 miles from shore."

With salmon and trout the case is different; any work upon this subject by a fisherman and fishery manager of Mr. Malloch's experience cannot fail to be of interest. Some readers will doubtless not be prepared to accept in their entirety all the views advanced, but all will be grateful to the author for recording the conclusions which he has drawn from a very wide personal experience.

The most interesting feature of the book is the really excellent series of illustrations, reproduced from photographs of Tay salmon of all ages and conditions, and of sea-trout and brown trout from various rivers and lochs. Illustrations such as these give a far better impression of the changes due to growth and condition and the variations caused by environment than any letterpress. The investigations of the Scottish Fishery Board and the Department of Agriculture in Ireland have familiarised us with the great individual difference in the period spent by salmon in the sea, and Mr. Malloch figures salmon which were marked as smolts and subsequently re-captured on their return to the river after a longer or shorter sojourn in the sea, and discusses the probable length of such sojourn. He expresses himself as "fully convinced that many (Tay) fish from 40 lb. and upwards are on their first return from the sea when they are captured in fresh water"; we could wish that some definite evidence were forthcoming in support of this conviction, for a 40-lb. salmon is presumably eight, or at least seven, years old, and Calderwood has stated that "it appears to be somewhat unusual for a fish to remain till its fourth sea year" (*i.e.* its sixth year) "without spawning."

In the Tay, salmon run at all seasons of the year, and Mr. Malloch is of opinion that the clean winter fish which run in October remain thirteen months in fresh water before spawning. We must confess to feeling sceptical on this point, more particularly as there seems to be nothing to show that such fish may not drop back again to the sea after a short sojourn in fresh water without spawning. In the case of the Blackwater (mentioned in this context as a spring river) there is some positive evidence that clean early-spring fish do drop back into the sea.

The opinion now generally held that the "bull-trout" of the Tay is a salmon is confirmed by an illustration of such a fish side by side with a salmon of the same size and weight; we understand Mr. Malloch to regard "bull-trout" as salmon which have spawned and again ascended the river as mended fish, a view which seems hardly consonant with that held by Calderwood, though not inconsistent with the results of some of the marking experiments conducted by the Scottish Fishery Board. It cannot, of course, be seriously suggested that all salmon, after once spawning, become "bull-trout."

Some space is, very properly, given to a consideration of the deductions to be drawn from an examination of the scales of salmon. While the figures given by Mr. Malloch are excellent, we find his explanations in the text rather difficult to follow; the generalisation that a salmon adds sixteen rings to its scale in each year of its life, so long as it feeds and grows, is not borne out by the scales figured or by the observations of other persons; the two years spent as a parr and smolt would, in fact, seem to account for a number of rings, varying from about twenty to twenty-seven, while from twenty to thirty rings may be added in any subsequent year spent wholly in the sea.

Such matters as the spawning and feeding of salmon in fresh water and their movements in tidal rivers are briefly discussed, and interesting figures are given of land-locked salmon up to three-quarters of a pound in weight.

Did space permit we would willingly quote freely from the chapters dealing with sea-trout and brown trout, and in particular from a most interesting discussion of the effect of environment on the latter fish, and the lessons to be drawn therefrom in the stocking and management of fisheries.

In conclusion we must deplore the entire absence of either index or detailed table of contents.

L. W. B.

NON-EUCLIDEAN GEOMETRY.

Theories of Parallelism: an Historical Critique. By W. B. Frankland. Pp. xviii + 70. (Cambridge: University Press, 1910.) Price 3*s.* net.

THE appearance of this tract is a welcome sign of the growing interest in the foundations of geometry. Those who, greatly daring, first disputed or denied Euclid's fifth postulate were treated, if not as charlatans, at least as idle speculators, whose theories, even if sound in the abstract, had no relation to actual space. It may be added that the earlier works on the non-Euclidean geometries were not very attractive to the average mathematician, because they were either so analytical that the reader was inclined to regard their geometrical interpretation as a mere *façon de parler*, or so vague and intuitive as to raise a suspicion of want of rigour.

Things have altered so much, not in substance, but in mode of presentation, that it may fairly be said that anyone with a knowledge of spherical trigonometry and elementary calculus may satisfy himself of the validity and coordinate rank of the elliptic, hyperbolic, and parabolic (or Euclidean) geometries; and he could hardly wish for a better introduction to the subject than that which Mr. Frankland has provided.

The tract falls naturally into three parts. The first, with remarkable brevity and clearness, gives the principal formulæ derived from the assumptions that the area of a polygon of n sides is proportional to the difference between the sum of its interior angles and $(n-2)\pi$, and that Euclidean geometry holds for infinitesimal figures. The second part gives, in separate paragraphs, short accounts of forty contributors to the theory, ranging from Euclid to Dodgson. This list seems fairly complete, with one noteworthy exception—Sophus Lie. In the third volume of his "Theorie der Transformationsgruppen" (section v.) Lie gives a masterly and exhaustive critique of the subject from an analytical point of view, and his discussion of Helmholtz's axioms is particularly instructive.

The third part of the tract consists of two notes—one developing the metrical formulæ of elliptic geometry, and the other dealing with planetary motion in elliptic space, with a law of attraction expressed by the formula $P=\frac{\mu}{k^2}\operatorname{cosec}^2\frac{r}{k}$, where k is the absolute constant of the space considered. The results are, in some respects, curiously analogous to the Newtonian ones; but there are also striking differences—for instance, the uniform description of areas about the centre of force does not hold good.

Mr. Frankland's critique deserves a wide circulation, and will doubtless do much to make the general public more familiar with what is, after all, a matter of great philosophical interest, that can be explained, apart from demonstration, to any intelligent person. There is no reason at all why a schoolboy, who has made some progress in geometry, should not be made acquainted with the main characteristics of the three possible systems, and realise, to some extent, the transformation so recently undergone by the oldest of the sciences.

G. B. M.

FOREST FLORA OF THE BOMBAY PRESIDENCY.

Forest Flora of the Bombay Presidency and Sind. Vol. i., Ranunculaceæ to Rosaceæ. By W. A. Talbot. Pp. vi+508+xxvi. (Poona: Printed by Government at the Photozincographic Department, 1909.)

IN 1894 Mr. W. A. Talbot issued a useful "List of the Trees, Shrubs, and Woody Climbers of the Bombay Presidency." A new and improved edition of this "List" appeared in 1902. In the present work Mr. Talbot has supplied what is essentially a more complete and considerably enlarged edition of the "List," with full accounts of all the species included, and illustrations of the more important ones. Those using the "List" will find full accounts of the species it includes in Dr. T. Cooke's "Flora of the Bombay Presidency"; the main purpose of this "Forest Flora" we may, therefore, assume to be the provision of an illustrated work of reference for Bombay comparable with the "Flora Sylvatica" which Col. Beddome prepared for Madras forty years ago. If this assumption be correct, the provision of yet another series of plant descriptions, marked as they are by all the care and accuracy which characterise Mr. Talbot's work, cannot be said to be supererogatory.

The quarto size seems to have been adopted in order to render the "Flora" uniform with the corresponding work for southern India rather than because of the nature of the illustrations, only two of which occupy the whole of a page. It seems, therefore, doubtful whether Mr. Talbot is right in thinking that the size of the work has been kept as small as possible, or justified in hoping that it may not prove too unwieldy for transport in the baggage of a forest or district officer.

The text is clearly and carefully printed, but the glazed paper used is heavy, unpleasant to handle and to look at, and does not promise to be durable in damp localities. No doubt this type of paper has been chosen on account of the process employed in the reproduction of the illustrations, which, unfortunately, as matters stand, are the least pleasing portion of the work. The drawings made use of have not lent themselves at all well to reproduction by the process adopted, a statement of fact which involves no reflection either upon the process or upon the drawings. These, indeed, one can readily imagine to have been pleasing in their original form, though they have the disadvantage of falling short of what is desirable in a work of this kind, since for the most part they do no more than display the habit of the species illustrated, and rarely include analyses of the flower.

APPLIED CHEMISTRY.

Chimica Generale e Applicata all' Industria. Vol. ii.: Chimica Organica. By Prof. Ettore Molinari. Parte i.: pp. xvi+416; parte ii.: pp. xii+417 to 979. (Milan: Ulrico Hoepli, 1908–9.) Price 21 lire the 2 vols.

THE volumes with the above title form a supplement to the treatise on inorganic chemistry by the same author, already reviewed in NATURE (vol. lxxi., p. 339). The same general plan has been followed in these later volumes as was adopted in the case of inorganic substances, the treatise differing from nearly all other smaller treatises on organic chemistry in giving very full details of industrial operations. The book is not, however, a treatise on technology in the narrower sense of the word, the theoretical side being by no means neglected. A very great deal of thoroughly up-to-date information of processes and plant is imparted, but at the same time there is due regard to the theory of the operations. The work is excellently illustrated with cuts of the latest kinds of machinery. An idea of the character of the work may be conveyed by stating that sixty-five pages of small print are devoted to the manufacture of sugar, and that the processes involved are described clearly but concisely, the illustrations being very well chosen. Such a work must necessarily prove of good service to students who intend to devote themselves to industrial chemistry and are desirous of becoming acquainted with general manufacturing operations. There are many signs that the author has spared no pains to make himself acquainted with the latest facts and processes, references in some cases being given to results brought before the recent International Congress of Applied Chemistry in 1909.

It is nowadays obviously impossible for any one individual to give an authoritative account of all the different branches into which industrial chemistry is subdivided, and in such a work as that under review it would, no doubt, be easy for specialists to detect several errors. Thus, for example, the 1898 Goldenberg process of analysis of tartaric acid material described on p. 451 was superseded by the 1907 process, and this was again modified in 1909. Certain statistical information given is, too, of doubtful correctness. Names are frequently misspelt. But putting aside minor blemishes of this kind the work is of a decidedly useful nature, and, like the inorganic portion, to be commended. It may be noted that a German translation of the whole work is in progress, so that it may shortly become more accessible to the English student.

W. A. D.

OUR BOOK SHELF.

Guide to the Crustacea, Arachnida, Onychophora, and Myriopoda exhibited in the Department of Zoology, British Museum (Natural History). Pp. 133; 90 illustrations. (London: Printed by order of the Trustees of the British Museum, 1910.) Price 1s.

THIS "Guide" admirably fulfils its functions; it is written in a clear style, and indicates tersely the main points of interest associated with the chief families and genera. The principal characters of each subdivision—class, order, tribe, family—are concisely stated, and those of its members are selected for mention which most aptly illustrate points in morphology or distribution, or show some striking habit. The section on the Crustacea opens with a short account of the lobster, its external features and appendages, internal organs, development, moulting, and the asymmetry of its chelæ. Short notes are added on the modifications caused by parasites and on adaptations to environment.

The systematic account of the Crustacea, in addition to stating the characters of each subdivision, contains a large number of interesting references to morphological and distributional points which make it valuable apart from the special purpose for which it was prepared. To give two instances—(1) the formation of a respiratory siphon which takes place in the Albuneidæ by apposition of the antennules, but in Corystes by association of the antennæ; and (2) the appearance of Apus in Scotland in 1907, which is ascribed to the introduction of the eggs, perhaps on the feet of birds, from the Continent. The Arachnida, including Limulus and the Eurypterines, and the Myriopoda are dealt with in a similarly interesting manner, and short notes are added on the Trilobita, Pycnogonida, Pentastomida, and Oncychophora. A little more space might well have been devoted to the Ixodidæ, in view of their great importance in connection with the spread of disease in man and animals. The illustrations, many of which are new and are prepared from photographs of the specimens exhibited, are excellent, and well support the text.

Popular Astronomy. By the late Prof. Simon Newcomb. Pp. xx+580+5 star maps. (London: Macmillan and Co., Ltd., 1910.) Price 8s. 6d. net.

ASTRONOMY has no doubt made progress in several directions since the late Prof. Newcomb revised his renowned work; nevertheless, if the lamented author were alive to re-write his book at the present time, by far the greater part could not be improved upon. The extensions of knowledge take place at the frontiers of a science, while the main body of fact and principle remains unaltered. While, therefore, this cheap edition of Prof. Newcomb's "Popular Astronomy" is issued without additions referring to recent developments, the volume can fairly be described as one of the most lucid and authoritative statements of the foundations of astronomical science available even now. To let such a work pass out of print would have been a misfortune, and we trust that the issue of an edition at less than half the original price will be the means of making many new readers familiar with its merits.

Naturwissenchaftliches Unterrichtswerk für höhere Mädchenschulen. Teil iv., Lehrstoff der iv. Klasse. By Dr. K. Smalian and K. Bermau. Pp. 152. (Leipzig: G. Freytag, 1910.) Price 2.50 marks.

THIS volume, one of a series graded for successive school classes, has been prepared to comply with official regulations, wherein presumably lies the reason for combining a triad admixture of botany, zoology, and mineralogy. The aim of the authors has been directed less towards a training manual and more towards providing a compendium of information on objects which are met with in daily life. The book contains an accurate but condensed collation of facts concerning cryptogamic and economic botany, the zoological groups of mollusca, vermes, and cœlenterata, and common or useful minerals. It is plentifully illustrated with good text-figures and a dozen coloured plates.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Pwdre Ser.

IN my former communication on this subject I gave all the information I had been able to collect respecting the popular belief as to the masses of white jelly found in my experience on mountain pastures, but, according to the observations of others, on different kinds of ground and at various seasons.

I recently procured a specimen of the jelly, and quoted a letter from Mr. Arber, to whom I had sent it, giving the opinion of Mr. Brookes, to whom Mr. Arber had referred it. After that was written I received the following note from Mr. Brookes, under the date April 4:—"The 'jelly' had been gathered several days before it reached me, and hence its condition was not suitable for examination, several putrefactive organisms having begun to flourish upon the jelly in the meantime. The remains of the substance which I saw seemed to be most like the zooglœa stage of some bacterial organism or the plasmodium of a myxomycete. The 'jelly' itself had no cellular structure. There was no nostoc present or any allied organism."

More recently I received a specimen which Mr. Burnett, headmaster of the Grammar School at Kirkby Lonsdale, found in the Rawthay Valley, some miles above Sedbergh. This also I sent to Mr. Brookes, who writes (July 26) that "the jelly-like mass sent from Kirkby Lonsdale is undoubtedly the plasmodium of a myxocete," and adds that he is "keeping it to see whether it will give rise to spores."

Mr. Worthington Smith, in a letter dated June 24, says:—"Perhaps you will find the substance so accurately described by you in this week's NATURE under the generic name of Zooglœa; the name as a genus may be obsolete now, but I think that in past times it was placed amongst the algæ, perhaps near Nostoc, and afterwards included in the Schizomycetes. However this may be, I know the substance very well, and I have often had it sent on to me in the past (when I used to answer correspondents for some of the horticultural papers) as a fungus—a Tremella—difficult to trace. I have heard it, as well as Nostoc, associated with fallen stars amongst rustics."

These authorities, as well as Miss Fry (NATURE, June 30), agree as to the nature of the Pwdre Ser, and I must say that whenever I have observed its manner of occurrence it has seemed to me to grow out of the sod—but I would not like to say that what I have seen has always been the same kind of matter.

The very circumstantial account given by Morton, that something of the kind is disgorged by birds, is confirmed by other later observers.

Although we must not too hastily accept what is undoubtedly a *vera causa* as the only explanation, we may feel that we are moving in the right direction to find the answer to the question, What is it?

The question why it is associated with falling stars has received a plausible explanation from Messrs. Grove and Griffiths (NATURE, July 21); but falling stars do not appear to hit the ground so that an observer can walk up to the spot where they seem to have fallen, as in the case of lightning or thunderbolts, and if we bring in possibilities of other luminous bodies we raise the difficult question of lambent fires, &c. The star-like radiating form of the jelly-fish, like that of the star-fish, is sufficient to explain the name given by Admiral Smyth (July 21, p. 73).

While our botanical friends are finding out for us what it is, may I hope that some of our literary friends will trace the belief back further than the sixteenth century, when we find it accepted as if founded upon well-known facts? T. MCKENNY HUGHES.

July 29.

The Blood-sucking Conorhinus.

IT may interest readers of NATURE to be informed that the great South American bug figured on p. 142 of the issue of August 4 punished Charles Darwin when travelling in the Pampas, happily without infecting him with its trypanosome (see "Journal of a Naturalist," ed. 1845, p. 330). J. D. H.

The Camp, near Sunningdale, August 5.

[SUBJOINED is the description to which our correspondent refers.—ED. NATURE.]

"WE slept in the village of Luxan, which is a small place surrounded by gardens, and forms the most southern cultivated district in the Province of Mendoza; it is five leagues south of the capital. At night I experienced an attack (for it deserves no less a name) of the *Benchuca*, a species of Reduvius, the great black bug of the Pampas. It is most disgusting to feel soft, wingless insects about an inch long crawling over one's body. Before sucking they are quite thin, but afterwards they become round and bloated with blood, and in this state are easily crushed. One which I caught at Iquique (for they are found in Chile and Peru) was very empty. When placed on a table, and though surrounded by people, if a finger was presented the bold insect would immediately protrude its sucker, make a charge, and, if allowed, draw blood. No pain was caused by the wound. It was curious to watch its body during the act of sucking, as in less than ten minutes it changed from being as flat as a wafer to a globular form. This one feast, for which the benchuca was indebted to one of the officers, kept it fat during four whole months; but, after the first fortnight, it was quite ready to have another suck."

The Early History of Non-Euclidean Geometry.

IN a recent number of NATURE (June 30) there appeared a review of a book by G. Mannoury on the philosophy of mathematics, and the reviewer emphasised a statement of the author to the effect that the claim for Gauss that he was the first to assert the possibility of a non-Euclidean geometry is threatened by F. K. Schweikart, who in December, 1818, sent a note to Gauss asserting the existence of a geometry in which the sum of the angles of a triangle is less than two right angles. The facts about Schweikart were made known fifteen years ago by Stäckel and Engel ("Theorie der Parallellinien," p. 243), and the actual documents were published in Gauss's "Werke," Bd. viii. (1900). It must be admitted that Schweikart arrived independently at this result, though it is not so obvious that he had forestalled the "giant mathematician." Schweikart states his hypothesis very clearly, and explains that Euclidean geometry is a special case of a more general geometry. On the other hand, Gauss was interested in the theory of parallels from at least 1799; and some time between 1808 and 1816 he arrived at the belief that non-Euclidean geometry was possibly true, for in 1808 he asserted that the idea of an *a priori* linear constant (the "space-constant") was absurd, while in 1816 he declared that, while seemingly paradoxical, this idea was in no way self-contradictory, and that Euclid's geometry might not be the true one. In his comments on Schweikart's note, he exhibits quite an extensive knowledge of non-Euclidean trigonometry.

Of course, the development of non-Euclidean geometry and trigonometry is due independently to Lobachevskij (1829), and Bolyai (1832), and even that was worked out to a large extent previously by Lambert (1786), and still earlier by the Italian Jesuit Saccheri (1733), though neither of these two conceived for a moment the possibility of non-Euclidean geometry being true.

It is interesting in this connection to recall the hesitancy of Cayley to accept non-Euclidean geometry, although he himself practically inaugurated a new epoch. He never seemed quite to appreciate the subject, and on one occasion, at least, fell into a mistake in writing about it. In his article "On the Non-Euclidean Plane Geometry," Math. Papers, vol. xiii., p. 237, he inadvertently takes the equatorial circle of the pseudosphere (the surface of revolution of the tractrix) as representing the points at infinity, whereas the absolute is only represented by a single point, viz. the point at infinity on the pseudosphere.

D. M. Y. SOMMERVILLE.

The Total Solar Eclipse of April 28, 1911.

WHILST astronomers who intend to observe this eclipse are choosing from amongst the Vavau, Tau, Nassau, and Danger Islands, the best one on which to land, it may be useful to state the totalities of the eclipse in these islands.

From the calculation of the phases obtained by the Besselian method, and with the data of the "American Ephemeris," I have found the following values:—

				m.	s.
Vavau (arch. of Tonga)	...	...	Totality	=3	36·6
Tau (arch. of Samoa)	...	...	,,	=2	13·0
Danger (arch. of Union)	...	...	,,	=3	19·4
Nassau (,,)	...	...	,,	=4	9·9

The geographical coordinates of these islands, adopted in the calculations, are respectively:—

Islands			λ		φ
			° ′		° ′
Vavau	...	...	−173 59·0	...	−18 39·0
Tau	...	...	−169 32·0	...	−14 13·5
Danger	...	...	−165 45·0	...	−10 53·0
Nassau	...	...	−165 25·0	...	−11 33·0

Rome, July 29. PIO EMANUELLI.

Mars in 1909 as seen at the Lowell Observatory.

THE accompanying prints are photographs of the globe of Mars, representing the details seen on the planet at the Lowell Observatory at the last opposition in 1909.

These maps demonstrate strikingly the development of the canals from the melting cap, shown by the number of canals visible in the southern hemisphere at the time, especially about the south pole, and by the absence of canals in the northern one, notably in the neighbourhood of the north polar cap.

The canals numbered 659 or 660 are the two great new canals, of which the account has already been published, and of which the size enabled the advent to be established with certainty. Several other examples of fresh origination are to be seen on the charts, about which the evidence is hardly less conclusive.

The white patches at some distance from the south pole mark the first frost of the autumn in the planet's southern hemisphere. These patches were photographed, as were also many of the canals.

The number of the latter photographed at Flagstaff since 1905 is between fifty and one hundred.

Treatment of Storage Cells.

IN the "Notes" of NATURE for July 28 (p. 118) reference is made to an article on the renewal of sulphated storage cells by Mr. J. O. Hamilton. Readers of NATURE may be interested in a method of treatment I have employed for a number of years, which has given most satisfactory results.

A strong (30–40 per cent.) solution of crude, commercial sodium hydroxide solution is prepared in a large iron pot and is heated to boiling. The accumulator plates, previously washed thoroughly for several days in running water, are dipped into the boiling soda solution and allowed to remain for a period of from five to fifteen minutes, depending on the extent to which "sulphating" has taken place. They are then removed and washed for several days in fresh water, after which they are placed in the jars with fresh sulphuric acid solution and thoroughly charged.

This treatment can be applied to any cells which have not undergone structural disintegration, and when properly carried out restores the cell to its full normal capacity. I have used it with complete success for treating a set of six large portable accumulators which had stood uncharged for nearly five years, during which period almost all the water had evaporated from the electrolyte, and the greater part of the sulphuric acid had combined with the plates. It is also a very effective remedy when applied to cells which show local action and continuously evolve gas from the plates after charging, with a corresponding more or less rapid loss of charge on standing. In treating such cells a more dilute solution (20 per cent.) of sodium hydroxide can be used.

I have never found a cell too completely "sulphated" to be restored by this treatment.

BERTRAM B. BOLTWOOD.

Munich, Germany, August 7.

The Sheffield Meeting of the British Association.

MAY I ask the favour of your columns to bring to the notice of intending visitors to the meeting of the British Association in Sheffield the fact that, at the reception to be given to the association by the Duke of Norfolk, the Chancellor of Sheffield University, on Tuesday evening, September 6, exhibits are being arranged of new experiments, apparatus, specimens, &c., of scientific interest? The committee of the University formed to make arrangements for the exhibition will be glad to hear from any members of the association or others who have any exhibits which they can show on this occasion. The committee will welcome cooperation, and will give every facility for demonstrations.

S. R. MILNER.

(*Secretary to the Committee.*)

The University, Sheffield, August 8.

YELLOW JACK AND THE WEST INDIES.[1]

THIS is a popularly written book, giving an account of the health of the West Indies of to-day, as compared with one hundred years ago. The motto on the title-page is "Wear a smile on your face, and a flower in your buttonhole," and, in accordance with this, the note of the book throughout is cheerful and optimistic.

The book is the outcome of a visit paid by the author, at the request of the Colonial Office, to Barbados in March, 1909, to report on an outbreak of yellow fever which threatened the colony at that time. After spending a month in Barbados, a flying visit was paid to Grenada, St. Vincent, St. Lucia, Trinidad, and British Guiana, in order to study and compare the health conditions of these colonies with those of Barbados. Further, in a series of appendices, the health progress of Martinique, Guadeloupe, Cuba, Porto Rico, Jamaica, the Bahamas, and British Honduras is summarised.

FIG. 1.—Belleville, Barbados. From "Health Progress and Administration in the West Indies."

The diseases mostly dealt with are yellow fever, malaria, filaria, plague, and ankylostoma. The medical organisation of the different islands to improve sanitary conditions, to destroy mosquitoes, to prevent the introduction of disease, and to stamp out existing diseases, is discussed at length. A large part of the book is given up to the various health ordinances and sanitary by-laws issued by the various Governments. From this it will be seen that the scope of the book is wide. It is illustrated by many fine reproductions of photographs of places and scenery in the West Indies; also by plans of the towns visited, giving the distribution of mosquitoes and the diseases due to them. There is an excellent coloured map of the region in question.

[1] "Health Progress and Administration in the West Indies." By Sir Rubert W. Boyce, F.R.S. Pp. xv+328. (London: John Murray, 1910.) Price 10s. 6d. net.

The first chapters are devoted to an historical account of the health conditions of the West Indies at the beginning of the nineteenth century. These are rather hastily and loosely written, but suffice to show that at that time these islands were veritable death-traps. It was the newcomer who was attacked, and no one felt safe until he had at least passed through an attack of yellow fever, and so become, as the saying was, acclimatised. Now, by the introduction of drainage, pipe-borne water supply, the destruction of mosquito breeding-places, and general sanitation, these diseases have almost disappeared, and the islands are becoming the sanatoria nature surely intended them to be.

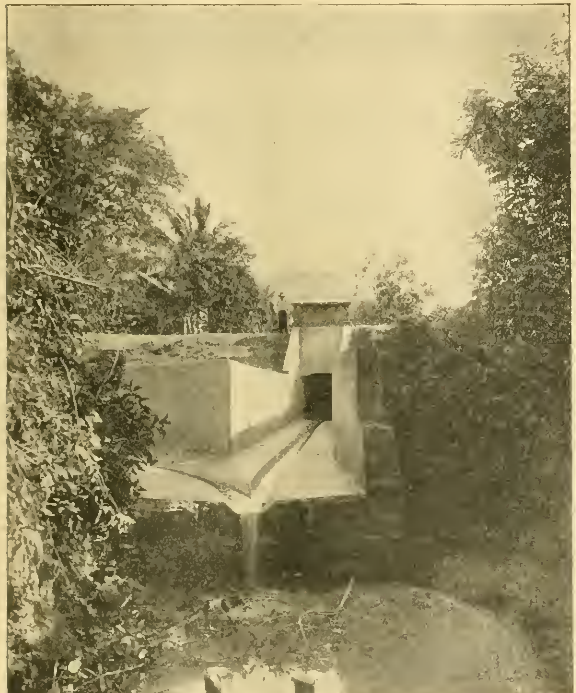

Fig. 2.—Large Concrete Drain, Port of Spain. Trinidad. From "Health Progress and Administration in the West Indies."

Truly, according to Sir Rubert, the victories of modern medicine over tropical diseases in the West Indies during the last few years have been marvellous. Owing to the discovery of the cause, and the fact of it being water-borne, cholera is now unknown. Malaria has given up its secrets, and it is now merely a matter of putting the knowledge gained into practice to stamp out that scourge of the Antilles. Yellow fever, which a hundred years ago blotted out whole regiments, is now relegated to the place of a pathological curiosity. Ankylostoma disease, one of the most potent destroyers of health and energy in the tropics, is now understood, and can be coped with. Prof. Boyce's book is full of instances of man's enlarging dominion over that unlovely domain of nature—disease.

There are some signs, as mentioned above, of haste in the production of the book, especially in the second chapter. For example, a table is given on p. 8 which is meant to show that the newly-arrived seaman was frequently attacked, but no figures are given of the total number of seamen dealt with. Again, on p. 16, the following sentence occurs:—"From 1817 to 1836, in the garrisons in Jamaica, amounting at that time to 2578 men, the deaths from intermittent and remittent fevers rose to 258 men." This probably means a yearly rate, but it is not so stated. Other awkward sentences are:—"Swooped down on every ship, war vessel, and merchantman." "These were the days which tried the nerve and endurance of our fathers and grandparents, or at least those of them who survived the deadly disease of not so long ago." "In fact, the entomological equipment of Trinidad is exceedingly good and is bearing excellent fruit." "So as to reap at once the advantages which must accrue." "In ten out of the fifteen yards larvæ were found in the barrels, and the barrels nearly always contained larvæ."

To conclude, this book, by bringing together and presenting in an easy form the efforts now being made by the various Governments in the West Indies towards the improvement of the health of their respective islands, and the brilliant results which have already rewarded their labours, will be of great use to all officials whose duty it is to look after the health and well-being of tropical populations.

THE VERTEBRATE FAUNA OF CHESHIRE.[1]

THERE are few counties in England which present a variety of natural features so favourable to a varied fauna as does Cheshire. It possesses undulating plains; heather-clad or wooded hills of considerable altitude; numerous rivers, meres, lakes, and "flashes"; tree-clad vales; forest, woods, plantations, and shrubberies; marshes and remnants of mosses, besides considerable estuarine frontages and half the broad "Sands o' Dee." The county is freer from manufactories, with their destructive smoke and fumes, and has less of its area under the plough than most of its neighbours. It is chiefly given up to sheep and dairy farming, necessitating extensive grasslands, and to large market gardens and nurseries, which are, on the whole, friendly to the increase of certain classes of animal life. Still, with all these advantages, the vertebrate fauna of Cheshire is not so rich as one might expect, nor so rich, indeed, as it once was.

1 "The Vertebrate Fauna of Cheshire and Liverpool Bay." Edited by T. A. Coward. In two volumes. Vol. i., The Mammals and Birds of Cheshire. By T. A. Coward and C. Oldham. Pp. xxxii+472; with illustrations from photographs by Thomas Baddeley. Vol. ii., The Dee as a Wildfowl Resort. By John A. Dockray. The Reptiles and Amphibians of Cheshire. By T. A. Coward and C. Oldham. The Fishes of Cheshire and Liverpool Bay. By James Johnstone. Pp. xl+210; with illustrations from photographs by Thomas Baddeley. (London: Witherby and Co., 1910.) Price 26*s.* net the 2 vols.

"During the last half-century farming has greatly improved . . . old hedgerows have been grubbed up and replaced, and waste lands and mosses have been reclaimed and cultivated; changes no doubt advantageous to the common weal, but deplorable when viewed from the standpoint of the naturalist."

That is, the increase of population and the movement and disturbance of nature due thereto, and the incessant hustling by civilisation, are in Cheshire, as everywhere else, tending to "move on" every form of life.

Although the cover bears the title of "Fauna of Cheshire," these volumes deal only with the vertebrates of the county. The editor, Mr. Coward, and his co-contributor-in-chief, Mr. Oldham, are responsible for the greater part of the fauna. Both are well known for the attention they have long devoted to the natural history of Cheshire, and theirs are, consequently, the right and proper names to appear on the title-page.

Somerford Cattle. From "The Vertebrate Fauna of Cheshire and Liverpool Bay." Edited by T. A. Coward.

The work seems to us, however, to go considerably beyond the legitimate limits of the county in including in it the marine fishes within a line "from the Great Orme's Head in Carnarvonshire to Formby Point in Lancashire." We believe that the editor would have been well advised if he had restricted his observations to the land, fresh-water, and estuarine life, and thus rendered a second volume unnecessary, which would have been a great advantage in many ways. By omitting such quite unnecessary matter as the Wild Birds' Protection Act, set out verbatim at the expense of more than six pages; by judiciously squeezing the migration section; circumspectly condensing the interesting yet somewhat disproportionately long account of Dee as a wildfowl resort, and excising the repetitions in the bibliography, room could have been made for the contents of the second volume within the first. The map, which, under the present arrangement of the book, is relegated to the second volume, where it is very inconvenient, would have then been found in the volume the contents of which necessitate its more frequent consultation. The portrait of J. Fell, Esq., the estimable former chairman of the Lancashire Sea Fisheries, seems dragged into a work dealing exclusively with Cheshire, especially as he ceased to occupy that position in 1894, and his name does not, apparently, occur in the book.

Following a short introduction, in which the extinct and fossil species of the county are enumerated, full descriptive notices are given of each of the forty-six mammals which "occur or have occurred within recent years in Cheshire and its territorial waters." We read that the Scotch white hare which was introduced into Yorkshire has spread largely into Cheshire, and it will be interesting to watch how the rodent will be affected by this change to a locality where the warmer climate disperses the snow before the time for changing its protective winter-coat arrives. An interesting *résumé*, chiefly from the British Association report on the subject in 1887, is given of the herd of white cattle at Somerford Park, where it has existed for two centuries, and still consists of twenty-five head, and that now extinct at Lyme Park. As to the birds, the authors admit the title to a place on the list "during the present and last centuries" of 231 species, of which 112 breed, or "bred till recently," in the county, and among which the nightingale is included, "as there is no doubt that the bird has bred on some, at any rate, of the occasions when it has been observed"; but, as neither eggs nor nestlings have been seen, we may be permitted to continue to doubt the accuracy of the statement until better evidence be forthcoming. With regard to the pose of the kingfisher when hovering over a stream in quest of food, the authors assert that the long axis of its body is placed almost at right angles to the plane of the water. The bird no doubt adopts any attitude which it considers most appropriate to the occasion, but it is not by any means, in the writer's experience, the usual one, which is to hover hawk-like a score or so of feet above the stream, and like it remain perfectly stationary, just as it is represented in the figure by Harting in his "Recreations of a Naturalist," reproduced in NATURE of May 24, 1906. It is pleasant to read that the great crested grebe, one of our handsomest birds, is more numerous in Cheshire than in any other county, from which we may infer that, temptation notwithstanding, plumassiers' agents leave it unmolested. It is well known that this bird covers its eggs on leaving the nest during incubation with a mass of rotting and fermenting nesting material, and our authors seem to assent to the suggestion (of Seebohm) that the material is so placed that through the heat thereby generated incubation during the bird's absence may not be retarded. This idea is rather discounted by the fact that the material used is often neither rotting nor fermenting, and therefore without heat, but consists of fibres of reeds cut off from those within reach of the breeding bird's beak, and freshly teased out by it. The most remarkable bird in the list is Schlegel's petrel (*Œstrelata neglecta*), a wanderer from the antipodes, found dead in a field near Chester. Whence it arrived and how its dead body came where it was found are unexplained mysteries. Cheshire reckons in its reptilian and amphibian fauna the usual small number of forms common to nearly every other county in the country.

Mr. Johnstone's introduction to the section of the fishes, extending to thirty-nine pages, enters into many subjects valuable in another relation which seem to us foreign to the subject of this book, and which few would look for in an inland fauna. The majority of the fishes enumerated can hardly be claimed as belonging to Cheshire, which has only a snout of seaboard less than ten miles in extent, faced, besides, with a sandbank stretching seaward almost as far as the limits of its territorial waters. Of the 107 species enumerated, fifty-five are "very rare," and many are included on the scantiest authority. The list, for instance, opens with the sunfish, "once recorded from local waters," thereby meaning Southport! Other notes are:—"No occurrence of the mature fish in strictly Cheshire waters"; "on Welsh side of Dee"; "does not occur in territorial waters of Liverpool Bay." Then why insert these species? Those taken "once in Queen's Channel" and in "Crosby Channel" are surely game poached from Lancashire. By what right can species from "off the Mersey banks," "off the estuaries," or "mouth of Dee" be ascribed to Cheshire's "territorial waters"? And if "drifted eggs" of pelagic species detected in water of the bay be sufficient evidence for adding them to the Cheshire fauna, why not include the whole marine fauna of the Irish Sea? This shortcoming, except as we have indicated, detracts little from the unquestionable value of the major part of Mr. Coward's book.

Messrs. Witherby and Co. are to be highly congratulated upon the excellence of the work as a commercial product. A special word of praise is also due to the illustrations, the majority of them separate plates on fine-surfaced paper, every one excellent, several of quite charming bits of scenery, all admirably photographed and reproduced. By the courtesy of the publishers we are enabled to present "Somerford Cattle" as an example.

ACROSS YUNNAN.[1]

IN the present work the author gives an account of his last journey from the Yangtse to Yunnan-fu, and onward to Haipong and Hong Kong. It is edited by Mrs. Archibald Little, who accompanied him in his travels, and whose personal experiences among the Chinese have been recorded in her published works. The main interest of the volume lies in its bearing upon the great railway just completed, which links up the capital of Yunnan with the French colonial possessions in Cochin-China. The author, in following the route, points out the engineering difficulties that had to be overcome in building the line. It traverses a rough, mountainous region, alternating with rivers, low-lying, malarious swamps, and stony, sterile wastes, places where work had to be suspended owing to outbreaks of fever that thinned the ranks of the labourers.

The line from Tonking, in a distance of 263 miles, rises 8000 feet to the level of Yunnan-fu, by gradients of 2·51 feet in 100. It was to be opened officially on April 1, 1910, and the issue of the book was designed to be coeval with this event "as a tribute to

Lofty Stone Column, such as are common in Yunnan, and recall Cornish Crosses. Near Chao-tung-fu. From "Across Yunnan."

the French enterprise" on which the author touches so often with warm admiration in his pages. While the project of building a British line of communication to Yunnan-fu from Kunlung ferry remained in abeyance, M. Dormer, the energetic Governor of Cochin-China, pushed forward his scheme, which was at once passed by the French Chamber in 1905, and carried through with a promptitude deserving of all praise.

The completion of this trade-route involves a new factor in the problems of international commercial intercourse with western China, the advantages which may accrue falling at present to France. There are other existing lines of communication with Yunnan, but no railways, as the west river route, by which, after tedious marches, produce reaches Canton and Hong Kong. There is also that by the Yangtse. Some

[1] "Across Yunnan." A Journey of Surprises, including an Account of the Remarkable French Railway Line now completed to Yunnan-fu. By Archibald Little. Pp. 164. (London: Sampson Low, Marston and Co., Ltd., 1910.) Price 3s. net.

idea of the difficulties encountered by this route may be gathered from the author's experiences. Were it possible to construct a railway from Ichang, at the lower entrance of the Yangtse gorges, through to Yunnan-fu, produce would readily find markets at the treaty ports on the lower river. In 1872 the present writer ascended the gorges, and concluded from his survey that it would be impossible to utilise this section of the river for steam navigation. The late Mr. Archibald Little appeared to have confirmed this view when he made his memorable ascent in 1887.

The story of this journey is admirably told, and rendered all the more attractive by a series of well-chosen photographs. J. T.

DOES THE INDIAN CLIMATE CHANGE?[1]

ANYONE who has examined carefully the meteorological elements of any country, whether they deal with pressure or rainfall, will have noticed that the curves formed by plotting the values for consecutive winter or summer seasons, or even for whole years, present a very wavy appearance. A closer inspection of such curves brings out the fact that they are really of a composite nature, and are made up by the superposition of waves of long and short lengths.

Such curves indicate that the meteorological elements not only oscillate, about a mean value, rapidly and to a considerable extent in magnitude, in a short period of time of about three or four years, but that, in addition to these variations, there is another oscillation, or perhaps several others, occurring over very much longer periods.

It is the presence of the long oscillations which has given rise to the idea that climates are permanently changing. This is due to the fact that in many cases meteorological observations made in a homogeneous manner do not extend over a sufficiently long period of time to exhibit a complete wave or oscillation, and the conclusion of climate change is drawn incorrectly from the portion of the wave which is indicated.

The main difficulty met with in dealing with a long series of observations is that those made in the early days are not so accurate as those made more recently with modern instruments and methods. Thus while the data may show a change in the meteorological elements, such a variation may be purely fictitious, and due to either the instruments, the methods, the observers, or a combination of all three.

In the volume under notice attention is directed to the fact that since the year 1894 the monsoon in north-west India has indicated a very marked weakness, and the suggestion has been made that a permanent change in the climate of that region has taken place, due, as some believe, to increased irrigation or diminution in forests.

The question of the strength of the monsoons in India is of such great importance to the inhabitants of that country—for it means drought or plenty, according as the monsoon is weak or strong—that Dr. Walker, the director-general of Indian observatories, discusses the subject in considerable detail in this memoir. In the first portion of this work he describes the care he has taken to use only data, extending over a great number of years, which can be thoroughly trusted, the records being obtained from the same stations throughout the whole period of time considered. Each province is separately dealt with, and the rainfall tabulations and curves begin at the earliest year possible and end at 1908.

Without entering into the results from each area, the broad conclusions need here alone be summarised. Thus Dr. Walker states that

> "although there is no proof of any permanent climatic change, there has been a tendency over a large part of north-west and central India for rainfall during the past thirty years (*a*) to increase to a maximum between 1892 and 1894; (*b*) to sink to a minimum in 1889; and (*c*) to improve slowly since that time. Over the remainder of India there do not appear to have been any progressive changes of importance."

Dr. Walker, in seeking the causes of this variation, remarks, in the first instance, that (*a*) and (*b*) negative any explanation which has irrigation as a basis, and that as the destruction of the forests on a large scale ceased about twenty years ago, the expected improvement in the rainfall during the last fifteen or twenty years does not agree with the actual facts.

Failing local causes for variation, he shows that the true explanation is to be found in the extra-Indian area. Thus he finds that in the Nile there was a rise to a maximum in 1892 to 1894, followed by a rapid fall to 1899, from which time until 1906 a deficiency has prevailed, while in 1908 a very great improvement occurred.

This comparison shows the close association between the monsoon rainfall and the height of the Nile, and suggests that they are both dependent on the Arabian Sea current.

He, however, goes still further afield, and utilises, in a practical manner, some of the results of the investigations which have been made in recent years at the Solar Physics Observatory, South Kensington. In the researches just mentioned, it was demonstrated that when in any year the pressure over South America was in excess, that over India was deficient, and *vice versa*. As low pressure over India means a good monsoon, and high pressure a weak monsoon, the close meteorological relationship between these two very distant countries becomes of great importance.

Dr. Walker states:—

> "Further, it is an established fact that the monsoon rainfall in India tends to be abundant when pressure is high in the Argentine Republic and Chili, and low in the Indian Ocean: it shows a fairly close correspondence, therefore, with the excess of pressure in South America above the pressure at Mauritius."

Using the data for these countries, he shows that the favourable character of the extra-Indian conditions rose to a maximum in 1892, fell to a minimum in 1899, and has on the whole recovered since that time. Thus he writes:—

> "There are valid reasons, therefore, for regarding these extra-Indian conditions as having largely determined the general character of the Indian rains."

The discussion of the question as to whether the climate of India changes leads him finally to the following inferences:—

> (*a*) "The recent deficiency of monsoon rainfall in a large part of central and north-western India must be attributed to something abnormal in the larger movements of the atmosphere and not to human agency in India; (*b*) the deficiency has not lasted long enough to justify the conclusion that there has been a permanent change of climate; and (*c*) there are marked indications of a return to good seasons."

WILLIAM J. S. LOCKYER.

[1] Memoirs of the Indian Meteorological Department, vol. xxi., part i. "On the Meteorological Evidence for supposed Changes of Climate in India" By Dr. Gilbert T. Walker, F.R.S. (Simla, 1910.)

NOTES.

THE Physical Society of London announces that the Montefiore Electrotechnic Institute at Liége has instituted a "George Montefiore Levi" prize, which will be awarded every three years, the first award being in 1911. The value of the prize in 1911 will be 20,000 francs (800*l*.). It will be awarded for the best original work presented upon the scientific advance and on the progress of technical applications of electricity in every field. Popular works and simple compilations will be excluded. Works must be in English or French. The jury will consist of ten electrical engineers, five being Belgian and five from other countries. The latest date for receipt is March 31, 1911. Further particulars are obtainable from the secretary, Association des Ingénieurs Electriciens sortis de l'Institut Electrotechnique Montefiore, rue Saint Giles 31, Liége.

THE *Morning Post* of August 9 gives prominence to an account of experiments made by Mr. Armbrecht, of Duke Street, on the change of colour of sapphires and other precious stones by the action of radium. The observations are interesting, but the results obtained are by no means new. Nearly three years ago Prof. F. Bordas read before the Paris Academy of Sciences a series of papers in which he described investigations of the effect of radium and other rays upon various forms of crystallised alumina from clear sapphire to brown and opaque corundum and other precious stones. Colourless corundum was transformed into topaz by the action of radium bromide; the depth of colour of natural topazes was increased, and a similar effect was produced with faintly coloured rubies. Short abstracts of Prof. Borda's papers will be found in the seventy-seventh volume of NATURE, November, 1908, to April, 1908.

THE tenth International Geographical Congress is to be held in Rome during the week beginning October 15, 1911. The congress will be under the patronage of the King of Italy. An organising committee of a representative character is already at work under the presidency of the Marquis Raffaele Cappelli, president of the Italian Geographical Society. Commander Giovanni Roncagli, secretary of the Italian Geographical Society, is acting as general secretary of the committee. The work of the congress will be carried on in eight sections, namely:—(1) mathematical geography; (2) physical geography; (3) biogeography; (4) anthropogeography and ethnography; (5) economic geography; (6) chorography; (7) historical geography and history of geography; (8) methodology and didactics.

WE are glad to notice that the useful work of the extension section of the Manchester Microscopical Society is to be continued during the coming winter session. The purpose of this section is to bring scientific knowledge, in a popular form, before societies unable to pay large fees for lectures. In some cases a small fee is charged, but all money thus obtained is devoted to the expenses of the section. The work of lecturing and demonstrating is entirely voluntary and gratuitous on the part of the members of the society. The list of lectures from which secretaries of societies may choose includes some sixty-one subjects and the names of seventeen lecturers. Application for lectures should be made to the honorary secretary of the section, Mr. R. Howarth, 90 George Street, Cheetham Hill, Manchester, who will send a list of the lectures on application.

MR. OSCAR GUTTMANN, whose death occurred in Brussels last week from injuries received in a taxi-cab collision, was known both as a consulting engineer and a technical chemist. He took frequent part in discussions upon chemical and manufacturing topics at the meetings of the Society of Chemical Industry, and contributed occasional papers. The titles of some of these—*e.g.* "Novelties in the Explosives Industry," "The Manufacture of Smokeless Powder," and "The Chemical Stability of Nitrocompound Explosives"—illustrate the fact that Mr. Guttmann was an authority upon explosives. Other contributions dealt with the manufacture of sulphuric and nitric acids, and the author was the patentee of several devices for use in this and other industrial operations. In an interesting note upon the oldest document in the history of gunpowder, Mr. Guttmann directs attention to the use of this explosive as described in an illuminated MS., "De Officiis Regum," contained in the library of Christ Church, Oxford; and papers upon the early phases and progress of the sulphuric-acid industry also indicate that he was interested in the historical aspects as well as the practice of his professions. As an engineer, Mr. Guttmann had been charged with the design and construction of many large chemical and explosives works at home and abroad. His experience in the two branches of his calling was probably unique, and well qualified him to speak, as he did in an address delivered some three years ago, upon "The Works Chemist as Engineer." Mr. Guttmann was born in 1855, and became naturalised here in 1894. He was a member of the Institution of Civil Engineers, a Fellow of the Chemical Society, a Fellow and sometime vice-president of the Institute of Chemistry, and a member of the council of the Society of Chemical Industry. At the time of his death he was acting as one of the British jurors at the Brussels Exhibition.

THE arrangements for Section H (Anthropology) at the forthcoming meeting of the British Association have just been communicated to us. The preliminary programmes of other sections were stated in NATURE of July 28. In general ethnography, Mr. E. Torday will describe in Section H some of the tribes encountered in his recent exploration of the Congo area; Mr. Beech will deal with the Sok, of whose language he has made a special study during his residence in Africa; Mr. A. K. Newman, of Wellington, New Zealand, will discuss the origin and racial affinities of the Maori; and Miss Fletcher, of Washington, in an important communication, will deal with certain points connected with exogamy. Miss Fletcher will also contribute an account of recent developments in the study of anthropology in American universities. The archæology of the Mediterranean area will be dealt with by members of the British School at Athens. Dr. T. Ashby, director of the British School at Rome, will describe his excavations at Hagiar Kim and Mnaidra in Malta, and Messrs. Woodward and Ormerod a primitive site in Asia Minor. Prof. W. M. Flinders Petrie will give an account of his excavations at Memphis, and Dr. Seligmann will describe a Neolithic site in the Sudan. An important communication by Prof. Elliot Smith, which summarises the results of ten years' work, will discuss the racial affinities of the Egyptians from the earliest times. Among other archæological papers may be mentioned an account of the work of the Liverpool Committee for Excavation and Research in Wales, by Prof. R. C. Bosanquet, and a report on recent excavations at Caerwent, by Dr. Ashby; a communication from Mr. H. D. Acland will describe prehistoric monuments in the Scilly Isles, and Mr. Alexander Sutherland will give an account of the exploration of a Broch at Watten, Caithness. Friday, September 3, will be devoted to a joint meeting with Section L (Education), in which intelligence tests in school children will be discussed. Among those who have promised papers written from the special point of view of the anthropological section are Dr. Lippmann, of Berlin, Dr. C. S. Myers, of Cambridge, Mr. W. Brown, of King's College, London, Mr. Burt, of the Liverpool Psychological Laboratory, and Mr. J. Gray. Dr. Kerr, medical officer (education) of the London County Council, Dr. W. H. R. Rivers, and others will take part in the discussion.

IN the Long Vacation number of the *Oxford and Cambridge Review* Dr. A. Smythe-Palmer begins an elaborate study of the luck of the horse-shoe, "a veritable fetish, maintaining its reputation for magical potency with unabated influence into the twentieth century." He agrees that the belief in its power is largely based upon the mystical respect for iron, dating from its introduction as an innovation at the close of the Neolithic period; but he also supposes that in shape it is "only a rough-and-ready substitute for the old and long venerated symbol of the crescent," the use of which as a protection against the evil eye and other demoniacal influence is illustrated by numerous examples. He postpones to another article the further question of the mode in which the crescent acquired its magical significance.

IN *Travel and Exploration* for August Mr. W. J. Clutterbuck publishes an interesting and well-illustrated account of the little known Great Lu-Chu Island, or, as the Japanese, who now occupy it, call it, Okinawa, the most important of the Lu-Chu group. He considers the islanders to be a finer race than their conquerors; the shape of the eye is different, being wide open and seldom oblique at the corners, while the women reminded him of southern Europeans. The distinguishing feature of the landscape is the tombs; and at a funeral he noticed the professional female mourners wailing as they marched along enveloped in sackcloth bags, the intention obviously being to conceal them, and thus avoid the unwelcome attentions of the ghost. The corpse is deposited in a tomb for three years, after which the bones are removed, washed, and placed in a highly ornamented earthenware urn, which has a curious resemblance to the house-shaped funeral urns found in other parts of the world, the intention in all cases being to provide a home for the spirit resembling that which the deceased occupied in this life.

Naturen for July and August (Nos. 7 and 8 of vol. xxxiv.) contains a well-illustrated account of the recent eruption of Etna, by Mr. A. Hoel.

WE have to acknowledge the receipt of vol. xxxiii., No. 1, of Notes from the Leyden Museum, which, in addition to other articles, contains a continuation, illustrated by two coloured plates, of Mr. C. J. H. Biermann's account of the Homoptera of the Dutch East Indies.

THE amphipod crustaceans of Bermuda and the West Indies, according to a memoir of 115 pages by Dr. W. B. Kunkel, published in vol. xvi. of the Transactions of the Connecticut Academy of Arts and Sciences, have apparently received but scant attention at the hands of naturalists. Recent collecting in Bermuda—by Prof. Verrill and others—has enabled the author to put matters on a very different footing. The most striking peculiarity of the amphipod fauna of Bermuda is its close affinity to that of the Mediterranean. Of forty-five Bermuda species, nineteen, or possibly twenty, are common to the Mediterranean. Eighteen out of the forty-five are peculiar to Bermuda, and only seven which are not endemic are unknown in the Mediterranean. In contrast to this abundance of European types, the presence of only nine species common to South and Central America is remarkable, especially in view of the fact that 93 per cent. of Bermuda decapods have been recorded from the West Indies and Florida Keys. "This paucity of forms from Central and South America probably has little significance, however, and is due simply to the small amount of collecting of Crustacea from these waters."

THE difficult, if not indeed unanswerable, question as to the limitations of species and races is again raised by Mr. G. Dalgliesh in the case of the yellow-necked field-mouse. In this instance the writer maintains that this mouse ought to be regarded as specifically distinct from the ordinary long-tailed field-mouse (*Mus sylvaticus*) under the name of *M. flavicollis*, basing his arguments, not only on the physical differences between the two forms, but likewise on their distribution and their divergence in habits and disposition. It may be remarked in this connection that naturalists are by no means in accord as to the proper name for the yellow-necked form. Mr. Dalgliesh uses Melchior's *flavicollis*; but in his recently published "Faune des Mammifères d'Europe" Dr. Trouessart regards this term as a synonym of the true *sylvaticus*, and employs *wintoni* for the British form. On the other hand, Mr. Millais, as quoted by Mr. Dalgliesh, regards the British yellow-neck as a distinct local form of the Continental *flavicollis*, under the name of *M. f. wintoni*. Mr. Pycraft, again, in his "Guide to the British Vertebrates in the British Museum (Natural History)," alludes to the one form as *Apodemus sylvaticus* and to the other as *A. flavicollis*. The question of species or race is of infinitesimal importance, but the eccentricities in nomenclature are perplexing.

MUCH interest attaches to an article by Dr. Felix Oswald in the July number of *Science Progress* on the area termed by Dr. Sven Hedin the Trans-Himalaya, an area bounded on the north by the chain of lakes first discovered by the explorer Nain Sing, and on the south by the Indus-Tsan-po valleys. Throughout the area the trend of the mountains, as shown by a map, is quite distinct from the north-west and south-east direction of the Himalaya proper, this alone being held sufficient to justify Dr. Hedin's proposal of the term Trans-Himalaya. There is, however, much more than this, for, in the author's opinion, the Trans-Himalaya represents a block of ancient rocks thrown into folds at a very remote epoch, but at the date of the folding of the Tibetan plateau so intractable that they yielded to mountain-making force by first becoming fractured and then uptilted. If this be granted, "it follows that the natural continuation of the parallel ranges of the block now lies sunk beneath the Brahmaputra Valley, at the base of the great fault-scarp, to which the river flows in parallel alignment. Accordingly, this valley must be of the nature of a rift-valley or sunken trench, especially since the opposite (southern) wall of the valley lies parallel to the northern wall, and in like manner possesses an average height of 23,000 feet." In conclusion, Dr. Oswald traces a curious parallelism—which he believes to be more than accidental—between the structure of the Arabian-Armenian-Caucasian area on the one hand, and the Indian, Tian Shan, and Siberian region on the other, each having an anterior and posterior table-land separated by three systems of "waves."

THE ninety-fifth volume of the *Zeitschrift für wissenschaftliche Zoologie* is completed by the number published on June 21. The papers which this volume contains deal, as usual, with a great variety of subjects, from pure descriptive anatomy, as in the case of the elaborate memoir by Albert Bauer on the musculature of the water-beetle, *Dytiscus marginalis*, to the most minute investigations in cytology and protozoology. Heinrich Stauffacher's "Beiträge zur Kenntniss der Kernstrukturen" affords a beautiful example of the results to be obtained by modern cytological methods. Its chief interest, perhaps, lies in the demonstration of "nuclear bridges" (Kernbrücken) in the form of threads which connect the protoplasm of the nucleus with that of the cell body. W. Knoll, in the next memoir, deals critically with the question of the existence of such connections between karyoplasm and cytoplasm, and demonstrates their existence in the leucocytes of the human body. Amongst the other papers we have only space to mention the first part of C. Janicki's studies on parasitic flagellates, dealing with two species of Lophomonas found in the cockroach. The application of modern technique to the investigation of the Protozoa, as we hardly need point out, marks the commencement of a new era in the study of these organisms, revealing complexities of structure previously unsuspected, as the plates illustrating the remarkable genus dealt with by Janicki abundantly testify.

In the *Bio-chemical Journal* for June (vol. v., No. 4) Prof. Benjamin Moore and Dr. Stenhouse Williams detail experiments on the effect of an increased percentage of oxygen on the vitality and growth of bacteria. Of twenty-six organisms tested, two may be termed oxyphobic. These are the tubercle bacillus, which is not only arrested in growth, but is actually killed by a high percentage of oxygen, and the plague bacillus, which, though not killed, uniformly refused to grow in percentages of oxygen from 60 to 91. The staphylococcic group was also adversely affected, but the remainder, including the typhoid, dysentery, glanders, diphtheria, anthrax, and cholera organisms, was unaffected.

In the Bulletin of the Johns Hopkins Hospital for July (xxi., No. 232) Dr. John L. Todd contributes an excellent review of the recent advances in our knowledge of tropical diseases. He summarises the most striking additions to our knowledge of tropical medicine during 1909 as being (1) the discovery of infantile kala-azar in northern Africa; (2) the discovery of a new human trypanosome in South America; (3) the researches which have made it almost certain that the parasite of sleeping sickness undergoes a developmental cycle in the tsetse-fly which conveys it; and (4) the transmission of typhus fever to monkeys by the bites of body lice.

Important information with regard to the thyroid body and related structures is supplied in a paper by Mr. F. D. Thompson, just published in the Phil. Trans. A thyroid, thymus, and post-branchial body are developed in the gill-slits of elasmobranch fishes; but parathyroid and carotid glandules have not been observed. In teleostomous fishes, on the other hand, the only organs of this nature are the thyroid and thymus; but parathyroids make their appearance in amphibians and reptiles, in the former of which the post-branchial body is retained. In these groups the structure of the various glands of the thyroid type differs considerably; but in mammals such structural differences tend to disappear, and in certain circumstances the parathyroids may develop colloid vesicles, and thus become practically identical with the thyroid. The thyroid and parathyroids may accordingly be regarded as structures of diverse embryological origin, which remain distinct in lower vertebrates, but in mammals become intimately related and constitute a single apparatus.

So closely are fungi and bacteria often associated in their destructive action on plant tissues, that it is extremely difficult to determine which organism is taking the lead. Some botanists, including De Bary, Hartig, and A. Fischer, have expressed themselves very sceptical as to the possibility of bacteria penetrating living plant tissues; others, notably E. F. Smith in the United States and Prof. M. C. Potter, have offered results of experiments as proof that bacteria do pass into the living plant and penetrate through cell walls. The subject is fairly discussed by Prof. Potter in his presidential address delivered before the British Mycological Society, and published in their Transactions. In addition to other arguments, the author refers to his experiments upon the white rot of turnips, when the bacterium *Pseudomonas destructans* was not only isolated and re-inoculated on the host, but it was demonstrated that oxalic acid was produced by the bacterium, which acts as a toxin in plasmolysing and killing the protoplasm; he also states that subsequently penetration of the cell wall by bacteria was observed.

We have received from Mr. E. Reinders a copy of his paper on the "Sap-raising Forces in Living Wood," read before the Royal Academy of Sciences of Amsterdam, January 29. After a short discussion of the available evidence on the problem of the ascent of water in trees, he gives an account of his own experiments. His results are of interest, as supporting the view that water is raised by a pumping action of the living elements of the wood (a theory generally connected with the name of Godlewski), and the detailed description of Mr. Reinders's work will be expected with interest. Mr. Reinders proceeds from the fact "that manometers placed at different heights up the trunk behave quite independently of one another. Sometimes one shows a lower pressure, sometimes the other." This irregularity is assumed by Reinders to be due to the pumping action of the living elements in the wood, and he proceeds to test his view by killing the stem either by steam or by an induction shock. He found that "as soon as the trunk was dead the difference of pressure followed the same rule as would be expected to apply to a glass tube." In one striking case the stem was not killed, but so seriously injured that five days elapsed before the behaviour of the manometers became once more "as irregular as in living trees." It should be added that Mr. Reinders assumes that in dead trunks which can no longer act as pumps, water ascends "through other causes, *e.g.* with the help of cohesion."

In the June number of the *Agricultural Journal of the Cape of Good Hope* is an article on the dried fruit and raisin industry recently established in Cape Colony. Although no great amount of produce has yet been raised it appears that the local conditions are suitable for success, and when certain improvements are effected there is the prospect of supplying the needs of the colony and even perhaps of establishing an export trade.

We have received from the University of Wisconsin Agricultural Experiment Station several "Research Bulletins" devoted to subjects of scientific interest. A study was made of the physiological effect on the cow of the milking machine which is now threatening to supplant the cowman and the milkmaid. No bad effects on the general health of the animal or the state of the udder could be found, and for an ordinary dairy herd the machine worked very well. Whether it would give equal results in a high-class herd is not certain; but here the economic problem is rather different. There still remain, however, a number of details in which improvements must be effected before the machine can be widely used. In another bulletin a description is given of an organism producing acidity in milk which appears to be closely related to *B. bulgaricus*, the characteristic organism of Yogurt, and to be widely distributed. Messrs. Hart, McCullum, and Humphrey continue their work on the functions of the mineral constituents of foods on metabolism in the animal, and show that the skeletal tissues can, if necessary, make good any deficiency of calcium and phosphorus in the ration. A low phosphorus intake was accompanied by a high calcium output in the urine.

THE use of more exact statistical methods in the investigation of agricultural problems has already led to interesting results, and is likely to prove of great benefit. Mr. Vigor recently discussed the relation between the reduction in area of wheat in England and the increased yield; his paper is published in the Journal of the Royal Statistical Society (part iv.). The reduction of the wheat area has been accompanied by a rise of the yield per acre in England as a whole, and improvements of the yield often appear to be greatest in those countries where the proportionate reductions of area have been greatest. Counties of low yields do not, however, appear to have been specially selected for a reduction of area. The yields of the various counties have shown a slight tendency to level up. By applying somewhat similar methods, H. Arctowski has, in Bulletin No. 7 of the American Geographical Society, mapped out the variations in the harvest in the United States during the decade 1891–1900. In general, very bad years in one region of the globe are years of excellent yield in another region, but the centres of compensation are not always found in the same regions nor is the compensation always exact; otherwise the supply would be constant.

THE Scotch Education Department has issued in connection with the Royal Scottish Museum, Edinburgh, two useful guide-books, "An Introduction to Petrography and Guide to the Collections of Rocks," published in 1909, and "A Guide to the Scottish Mineral Collection," published in 1910. Both are from the pen of Dr. S. J. Shand, who is in charge of the geological department of the museum, and both are sold for the modest sum of one penny. The guides have been specially compiled from the point of view of Scottish minerals and rocks, and are written in simple and, so far as possible, untechnical language, so as to appeal to the ordinary visitor unversed in these subjects. A few pages of the rock guide are devoted to a description of the collection of rocks of the Christiania district, which has, owing to Prof. Brögger's exhaustive studies, become classical in the science of petrology. Copious indices add to the usefulness of the books.

THE Tanami goldfield in Central Australia was discovered in the year 1900, but its development has been delayed by the scarcity of water and its situation in a remote part of the continent on the eastern frontier of Westralia. The general geographical and geological conditions of the goldfield are described in a short report by Mr. H. Y. L. Brown, the Government geologist of South Australia. (Government Geologist's Report on the Tanami Gold Country, Northern Territory of South Australia. Pp. 12; three maps. Adelaide: 1909.) Mr. Brown shows that the oldest rocks of the district belong to a series of slates, quartzites, and schists which, though pre-Cambrian, are stratified sediments. They have been invaded by plutonic rocks, including diorite and felsite, and covered by a series of limestones and dolomites, which he identifies as Lower Cambrian, and by quartzites, sandstones, and boulder beds, which he regards as probably Permo-carboniferous. There are widespread volcanic rocks, mainly basalts and volcanic ashes, which Mr. Brown assigns to eruptions ranging from Mesozoic to Cainozoic. His description of extinct craters suggests that some of the eruptions are of recent age. The gold occurs in lodes numerous in the pre-Cambrian sediments near the junction with the intrusive diorites, and also in "lode formations" in the igneous rocks. The mines are at present little more than prospecting shafts. The gold in the quartz is coarse, and where it occurs in the altered igneous rocks it is finely diffused. The widespread limestones and basalts produce a rich soil, and if adequate water can be obtained, the district will be valuable for pastoral purposes, while Mr. Brown regards the gold discoveries as promising and important.

IN a short article in the *Physikalische Zeitschrift* for August 1, Messrs. R. A. Houstoun and J. Logie direct attention to the fact that aqueous solutions of ferrous ammonium sulphate form a good filter for stopping heat rays. Alum solutions are, it is now known, no better than water in this respect. A glass cell, of inside thickness 3 cm., filled with a solution of ferrous ammonium sulphate, transmitted 75 per cent. of the light and 5·1 per cent. of the total radiation from a carbon glow-lamp; when filled with water it transmitted 90 per cent. of the light and 11·1 per cent. of the total radiation. The light, it should be stated, forms about 3 per cent. of the total radiation.

THE *Physikalische Zeitschrift* reproduces in its number for July 15 a communication made recently by Dr. F. Ehrenhaft to the Academy of Sciences of Vienna on an ultra-microscopic method of measuring the electric charges carried by small particles. The particles investigated were of the noble metals, and were produced by means of an electric arc between electrodes of the metal concerned. The air containing the particles in suspension was drawn into an ebonite enclosure in front of the objective of a Zeiss ultra-microscope placed with its axis horizontal, and illuminated from the side in the usual way. The enclosure contained the plates of a small condenser the axis of which was adjusted to be vertical. With the condenser uncharged, the time of fall of a particle through a measured distance in the field of view was observed; the condenser was then charged in such a direction that the particle ascended, and its speed again observed. Finally, the condenser was short-circuited, and the speed of fall again determined. Assuming that Stokes's formula for the resistance to the motion of a sphere in a viscous fluid holds for the particles investigated, the magnitudes of the electric charges carried by the particles come out smaller than 1×10^{-10} electrostatic units, a conclusion which does not accord with the view so generally held at present that the "atom" of electricity is $4{\cdot}6 \times 10^{-10}$ electrostatic units.

THE "Metzograph Grained Screen" takes the place of the ordinary cross-lined screen in photo-block making, and differs from it in giving an irregular grain and in requiring a shorter exposure. It does not produce its effect by stopping a large proportion of the light, as the cross-lined screen does, but by the lens-like action of the irregularities of its surface. It is produced by obtaining by sublimation a reticulated film on the surface of a glass plate, and then etching with hydrofluoric acid, the film acting as a resist. The screen was invented by Mr. James Wheeler about thirteen years ago, and as the little differences in its manipulation, as compared with the lined screen, appear to have hindered its adoption in those cases where it offers especial advantages, Messrs. Penrose and Co., of 109 Farringdon Road, have just issued a booklet of instructions for its use. The pamphlet includes specimens of each of the ten degrees of fineness, suitable for work from large posters to the finest photogravure. The impressions show what fine results the screen yields, the chief peculiarity being the entire absence of the regular grain that some persons find so objectionable in the usual type of photo-block.

THE report of the senior analyst, Cape of Good Hope Government Laboratories, for the year 1909, contains some interesting reading. About three-fourths of the samples examined (3154 out of 3820) consisted of foodstuffs, beverages, and drugs; these call for no special comment except, perhaps, to question the utility of giving much analytical detail in a publication of this kind. The remainder of the samples reflect the character of the country: they are mainly mineral, agricultural, and toxicological articles. Gold assays are the most numerous amongst the mineral analyses, which include also the testing of coals, supposed platiniferous rocks, copper, iron, manganese, and tin ores, and supposed diamonds. Amongst the toxicological cases, one is especially noteworthy. A native woman had been poisoned with an indigenous bulb administered by a Kaffir "doctor," and it took four months to obtain proof that such bulbs (Hæmanthus) could produce the fatal effects in question. This delay was due to lack of knowledge concerning the local poisons, and the senior analyst urges that a research into the properties of the vegetable drugs and poisons of South Africa should be carried out systematically. At present, any such investigations are merely casual and incidental upon legal proceedings. The production of barley suitable for brewing purposes, and an investigation into the agricultural soils of the colony, are some of the other topics mentioned in a report which everywhere bears evidence of useful activity.

WE learn from the *Engineer* for August 5 that the first of the large caissons for the new foundations of the Quebec Bridge was launched at the works yard, near the bridge site, on July 8. This particular caisson is for the new north pier, and will be situated clear of the old pier, its centre being 57 feet further out from the shore. The new centre line of the bridge has been decided upon 15 feet west, or upstream, from the old centre, this alteration enabling the new superstructure to be 30 feet wider than the old. The new south pier will be 15 feet nearer the river centre, consequently the span will be 1758 feet instead of 1800 feet, as before. The rebuilding of the south pier presents many more difficulties than the north. The new south pier will occupy very nearly the site of the old, necessitating the placing of a caisson at the side of the existing one, and another across the end of the pair. Upon the three a new caisson, 79 feet by 180 feet, will be sunk. It is thought that the latter will be the largest ever constructed for this class of work.

A DESCRIPTION of the hydroplane *Miranda IV.*, built by Sir John Thornycroft, appears in *Engineering* for August 5. This boat is 26 feet long by 6 feet beam, and 2 feet 6 inches deep. In general outline she approaches very much to the shape of an ordinary boat, but the bottom is specially adapted to make her skim at high speeds. This arrangement gets over the difficulties of the original type of hydroplane, for at moderate speeds she goes through the water in a similar manner to an ordinary boat, and the variation of form necessary to make her skim is so small as not materially to affect her performance. When skimming, a small portion of the length amidships carries the weight, the rest of the boat being entirely clear of the water with the exception of a small length aft, which may have enough weight on it to make the boat stable longitudinally. The greater part of the bottom being thus clear of the water, frictional and other resistances are very greatly reduced. It is remarkable how small the disturbance of the water is considering the speed of the boat, which has exceeded 31 knots under somewhat unfavourable conditions. If the speed development of hydroplanes is found to follow the same law as that of torpedo boats, a hydroplane 52 feet long, 10 tons displacement, with a brake-horse-power of 950, should do 45 knots, and a speed of 60 knots might be obtained from a boat 110 feet long. Such development depends on the progress made with petrol motors of large power, and in a matter of this kind it is not wise to be in too great a hurry.

MR. WERNER LAURIE will publish shortly "The Black Bear," by Mr. W. H. Wright, author of "The Grizzly Bear."

MESSRS. D. APPLETON AND COMPANY are publishing immediately a new work entitled "Up the Orinoco and down the Magdalena," in which Mr. H. J. Mozans relates his travels to South American countries and across the Andes.

OUR ASTRONOMICAL COLUMN.

PHOTOGRAPHS OF NEBULÆ.—Among the recent additions to the Royal Astronomical Society's collection of celestial objects are three of surpassing excellence taken by Dr. Ritchey with the new 60-inch reflector at Mount Wilson. The objects are the spiral nebulæ M. 51, M. 81, and M. 101, and these photographs bring out remarkable details as to their structure; the spirals of M. 101 are shown as broken up into soft, star-like condensations, like nebulous stars.

Dr. Ritchey has made a number of important improvements to his camera, and now uses two guiding eye-pieces, one on each side of the centre, in order to allow for any possible slight rotation of the field; a power of 800 is employed in the eye-piece. By using a smaller plate, only $3\frac{1}{4}$ inches square, the guiding star comes much nearer the centre of the field, that is, nearer the object under observation. He also has the plate carrier easily detachable, so that it may be taken off, and accurately replaced, *every half-hour* or so, to allow of re-focussing; this is done by using a knife-edge in the focal plane, and by such frequent re-focussing he keeps in the true focal plane within 1 or $1\frac{1}{2}$ thousandths of an inch. With an exposure of 7·5 hours, the photograph of M. 101 shows practically perfect star images, of which the smallest are only 1·6 seconds of arc in diameter, and Dr. Ritchey states that an exposure of $3\frac{1}{2}$ hours on the globular cluster M. 3 shows tens of thousands of star images which are only 1·15 seconds in diameter.

Photographs of parts of the Great Andromeda nebula, the Ring nebula in Lyra, and the Crab nebula were also sent, and are strikingly beautiful; much new light is likely to be thrown on the structure of these objects from the careful study of the negatives. A preliminary study shows that while in some (*e.g.* M. 101) the spirals are broken up into "nebulous stars," in others (*e.g.* M. 64, Comæ Berenices) they are apparently smooth; in M. 101 more than 1000 of these condensations have been counted. In the Andromeda nebula the central parts are apparently regular, with complicated dark rifts, and the spiral extends practically to the nucleus, but the outer branches contain great numbers of the "nebulous stars" (Monthly Notices R.A.S., vol. lxx., No. 8).

HALLEY'S COMET.—The Journal of the Royal Astronomical Society of Canada (vol. iv., No. 3) contains reproductions of fifteen photographs of Halley's comet, taken at the Dominion Observatory, Ottawa, by Mr. Motherwell, during the period May 3 to June 9, also reproductions from two photographs taken by Prof. Barnard, at Yerkes, on May 5, the former of which shows a tail 20 million miles long.

Some extraordinary phenomena were observed at Victoria (B.C.) at about 7 p.m. (local M.T.) on May 18. The sun appeared to be in a state of rotation, emitting bright flashes of light at frequent intervals. These were probably unusual refraction phenomena, possibly produced by the interposition of cometary matter, and are recorded by an octogenarian, Mr. Helmcken, who has never seen similar phenomena before.

In No. 8, vol. lxx., of the Monthly Notices there are more than a dozen papers dealing with observations of the comet's position, its physical characteristics, and its spectrum.

The *Rivista di Astronomia*, No. 6, contains some ancient records of the comet, reproduced by Father Stein, one of which shows that Halley's comet was observed in Italy for about fifty days in 1066; it became lost in the solar rays on April 19, and reappeared, as an evening star, on April 24.

The Accurate Measurement of Photographs.—In all photographic astronomical researches the results are more or less vitiated by errors introduced by the optical apparatus, including the eye and brain of the observer, employed in their reduction. To eliminate these errors, Prof. E. C. Pickering proposes, in Harvard College Observatory Circular No. 155, the employment of an automatic registering apparatus. Briefly, he suggests that the negative to be measured be passed between a constant illumination and the two balanced arms of a bolometer. As the star image, or spectral line, comes in between the heat source and the bolometer, some heat would be cut off, and the galvanometer in the circuit would show a deviation, which could be registered automatically. The galvanometer curve would thus become a record of the positions and intensities of the star images or the lines in the spectrum, and the method, especially for spectrum work, should certainly be tried by someone having the necessary bolometric apparatus or selenium cells at their disposal.

Observations of Perseids in 1909.—In No. 31, vol. iii., of the *Mitteilungen der Nikolai-Hauptsternwarte zu Pulkowo*, Herr S. Beljawsky describes the observations of Perseids made at Simëis on August 10, 11, and 12, 1909. The horary rates of the meteors observed on these three dates were 21, 60, and 17 respectively, and the positions of the radiants were $49°$, $+60°$ (5 obs.); $45°$, $+56°$ (15 obs.); and $43°$, $+55°$ (8 obs.), respectively. On August 11 there appeared to be another radiant at $62°$, $+16°$, from which four meteors appeared to emanate, but the determination is uncertain.

Results from the Micrometric Observations of Eros, 1900.—During the opposition of Eros in 1900, a number of observers made micrometric comparisons between the planet and neighbouring stars. The results from a number of observatories have been reduced at Cambridge, and Mr. Hinks now discusses them in No. 8 of the Monthly Notices. The individual results agree generally, and give as the most probable value for the solar parallax $8{\cdot}806'' \pm 0{\cdot}004$.

WILD PLANTS ON WASTE LAND IN LONDON.

THE waste ground between Aldwych and the Strand has been colonised by a variety of plants, most of which show luxuriant growth. Many of the colonists have fruits or seeds adapted to wind distribution, as in the case of the winged fruit of the sorrel (*Rumex acetosa*), and of the plumed seeds of the hairy willow herb (*Epilobium hirsutum*) and French willow, or rose bay (*E. angustifolium*), by far the most conspicuous plant on the ground. It is of interest that *E. angustifolium*, which is absent in many of the waste places of London, occurs in the garden of Fountain Court, near the Strand. Among wind-distributed forms are also numerous Compositæ, the fruits of which are furnished with a pappus; these include the spear thistle (*Cirsum lanceolatum*), the groundsel (*Senecio vulgaris*) and its ally *S. viscosus*, the dandelion (*Taraxacem vulgare*), the butter bur (*Tussilago petastes*), and the Canadian fleabane (*Erigeron canadense*). Fruits and seeds of these various types might be blown with some readiness from neighbouring districts, or from one part of London to another.

To a varying extent, wind may be also efficient in carrying the seeds of hedge mustard (*Sisymbrium officinale*), London rocket (*S. irio*), which appeared in quantity after the Great Fire of 1666, and shepherd's purse (*Capsella bursa pastoris*); and the same is the case with chickweed (*Stelloria media*), white campion (*Lychius alba*), opium poppy (*Papaver somniferum*), a garden escape, frequently established in waste places, great plantain (*Plantago major*), pale persicaria (*Polygonum lapathifolium*), and scentless mayweed (*Matricaria inodorata*). In several of the above the seed is small or flattened, but it is not elaborately adapted to wind dispersal, and it may be questioned whether wind alone will account for the presence of these plants. A probable auxiliary exists in the sparrow, through the alimentary canal of which various seeds and fruits no doubt pass, and it is not unlikely that others become attached to its feet by means of the sticky London mud. It will be remembered that Darwin in the "Origin of Species" describes eighty-two plants as springing from the earth obtained from the feet of a single partridge. This method of distribution no doubt accounts for the presence of Dutch or white clover (*Trifolium repens*) and of two balsams, the pink-flowered *Impatiens glandulifera* and a white variety. The explosive fruit characteristic of this genus could certainly not shoot its seeds across the traffic of a London street. Possibly cats may be effective as agents of distribution in this case, and they may also account for the presence of cleavers (*Galium Aparine*), the hooked fruits of which would readily cling to their fur.

Among garden escapes, the marigold, nasturtium (=Tropæolum), wallflower, and a species of Prunus can be observed, as well as the opium poppy mentioned above; in connection with these, and with many of the wild species also, the neighbourhood of Covent Garden must be recalled.

The above list is by no means exhaustive, none of the grasses, for instance, having been mentioned; in one or two cases the identification had to be made from a distance and through the fence surrounding the waste ground.

AGRICULTURAL INVESTIGATIONS IN EGYPT.[1]

SEVERAL important events are chronicled in the current "Year-book of the Khedivial Agricultural Society." The scope of the society has recently been extended by the formation of a section dealing with farm animals, the object of which is to effect as much improvement as possible in the livestock of the country. Twenty stallions have already been distributed over the country, a number of selected cows have been acquired from which good stud bulls can in time be sent out, and a herd of buffaloes has been purchased with a view to the establishment of a heavy milking strain. In addition, an experimental farm of about 160 acres has been acquired near Cairo, and an arrangement has been effected with the State Domains Administration whereby a considerable tract of land is to be set aside for the raising of cotton or wheat seed of good quality. Finally, the society has directed attention to the diminished yield of cotton in proportion to the area sown. A committee was appointed to investigate the matter, and has already issued a report.

A considerable proportion of the year-book is taken up by Mr. Lawrence Balls's studies of Egyptian cotton. A detailed account is given of the results of a single cross made in 1905 between Afifi and Truitt Big Boll. The fourth generation is now growing, and, although the cross has no special economic value, and the results are in some ways incomplete, the record is a very valuable one, and throws much light on production of cotton varieties on Mendelian lines. The synthesis of a commercially useful cotton is a tedious business. Desirable characters are mostly dominant over undesirables, except where the

[1] The Year-Book of the Khedivial Agricultural Society, Cairo, 1909. Pp. xv+239. (Glasgow: The University Press, 1910.)
The Cairo Scientific Journal. Vol. iv., No. 43.

heterozygote is intermediate. Experimental difficulties are considerable. The plants are large, the flowers are not entirely self-fertilised, and some of the characters fluctuate considerably. Numerous pests attack the plants, including aphides, boll worm, and the cotton stainer bug, while two fungi, the "sooty mould" and "sore-shin," do great damage. An advantage, however, is that the cotton plant can be grown as perennial by simply cutting it back; in this way a further supply of seed from a particular plant can always be obtained if necessary.

Bees appear to be the chief agents in effecting cross-pollination, and they have to be excluded by mosquito nets covering the whole plant; there appears to be no wind-fertilisation. Before these nets were used, the preparation of self-fertilised seed was laborious and uncertain. Tissue-paper bags were employed for separate flowers, but a large proportion of the bagged flowers were shed. Now the operation is simplified. The flowers are castrated at 4 a.m. and cross-pollinated at 9 a.m. No bags are necessary if the other open flowers under the net are removed, except, of course, to cover the flower from the plant which is to be employed as the male parent.

The results are worked out in detail for a number of unit characters, and are plotted on curves. The data thus obtained are not only interesting in themselves as a study of a Mendelian problem, but are of distinct practical value for the cotton breeder.

Mr. Balls also writes on the general position of the cotton crop in Egypt, and gives a number of interesting historical details. It is not certain how or when cotton was first cultivated in Egypt. The old mummy cloths are of flax. Apparently no distinct allusion to cotton occurs until the time of Pliny, and there is nothing to show that cotton was cultivated before 200 B.C. No definite historical account can be given until the time of Jumel, a French engineer who, in the early years of the last century, recognised the possibilities of Egyptian cotton and made plans for extending and improving its cultivation. Importation of Sea Island cotton began in 1822 and went on for many years; Mr. Balls's view is that the present Egyptian cottons are hybrids between the brown-linted tree types associated with Jumel and Sea Island cotton. He further thinks that, for the future, it is necessary to evolve strains which mature early and are therefore not likely to suffer from the boll-worm, and which yield heavily, so as to compensate for the decreased production per acre which is now setting in.

This falling off in productivity makes a very pretty problem unlike any we know of elsewhere. Fifteen years ago the yields ran about 5·5 cantars per feddan; of late years they are only 4·5. There are, of course, many conceivable explanations duly set out in the report of the commission in the present volume and meriting further examination, but it is suggested that part of the trouble arises from a rise in the subsoil water following on the rise brought about in the Nile by the barrage schemes. On this question Mr. Lucas has something to say in the *Cairo Scientific Journal*. He tabulates the minimum water-level in certain wells, and shows that in these cases there has been a rise of more than 1 metre since 1894. Other factors have to be taken into consideration, and many further measurements will be required, but the scientific interest and practical importance of the problem can hardly be overrated.

Mr. Hughes gives an account of manurial trials on cotton, and we are pleased to see that he gives full mechanical and chemical analyses of the soils on lines accepted in Great Britain. A considerable amount of trouble is involved, but the results are of much wider value in consequence. Mr. Willcocks describes the insects injurious to stored grains, seeds, &c. In the *Cairo Scientific Journal* Mr. Fletcher describes an experiment in which maize was grown for ten days in soils heated, respectively, to 95° C. and 170° C., and which he considers inconsistent with the work of Russell and Hutchinson. Mr. Fletcher accepts Whitney's hypothesis that soils contain a toxin injurious to plants, but put out of action by heat, an hypothesis much too controversial to be discussed here. No account appears to have been taken of the marked chemical decomposition of soil substances at the high temperature of the experiment.

SCIENCE IN BENGAL.

THE Journal and Proceedings (new series) of the Asiatic Society of Bengal has become a veritable miscellany—a very doubtful improvement upon the old arrangement followed by the Society, of publishing papers on philology and archæology, natural science, and ethnology, in three distinct and independent "parts," and of relegating matters of domestic and colloquial interest to the Proceedings.

The latest issues (Nos. 5–11 of vol. iv.) include thirty papers, in which Hindu mythology, numismatics, natural history both of the formal and of the discursive kind, archæology, geography, higher mathematics, lists of Oriental MSS., botany, epigraphy, and Indian history keep the strangest and most bewildering company with fragments of chemistry, philology, and geology, and with obituary notices and other domestic records.

Many of the papers deal with speculations rather than with matters of verifiable fact, and of these one of the most reasonable and most generally interesting is that by Mr. G. R. Kaye, on the use of the abacus in ancient India. The author examines, and expresses himself far from satisfied with, the evidence offered in support of the belief that the abacus was used in India in ancient times; and he is not at all disposed to accept without question the view that the Arabs borrowed their notation, which forms the basis of the science of arithmetic, from the Hindus.

The noteworthy papers on natural science are three in number. In one, Dr. N. Annandale describes a recent Himalayan species of a Psychodid fly of the genus Diplonema, a genus that "appears to have been known hitherto from three Tertiary species which occur in Baltic amber and from one Quaternary form in fossil copal." Another paper, by Mr. P. Bruhl, on recent plant immigrants into Bengal and Bihar, is a laborious compilation of considerable value, although, as the author includes cultivated plants as well as weeds, the title is a little disappointing; 234 phanerogams are enumerated and classified according to their systematic position and their land of origin, the result showing that 54·7 per cent. of them have been derived from America. Of these 234 species, however, only thirty-seven are entirely wild, and so are true, unassisted (or, at any rate, not deliberately introduced) immigrants; all the others are either cultivated or can be traced to cultivation. A third paper, by Colonel Prain and Mr. Burkill, describes seventeen new species of yams from China and neighbouring countries to the south, the descriptions, which are in Latin, being models of clearness and conciseness.

The twenty-first instalment of the late Sir George King's "Materials for a Flora of the Malayan Peninsula" is happily distinguished by appearing as an independent "extra number" of the old series of the Society's journal. It treats of the Gesneraceæ and Verbenaceæ. Of the former order, 131 species, distributed in twenty genera, are described by Mr. H. N. Ridley; of the latter order, seventy-two species, belonging to fifteen genera, are dealt with by Mr. J. S. Gamble.

We have also received Nos. 5–9 of the second volume of the new Memoirs of this society.

No. 5 of these is a most learned and interesting treatise (which is to be continued) on Mundari poetry, by Father J. Hoffmann. The Mundas are one of the aboriginal tribes of Central India, and a large remnant of them is isolated in the hills of Chota Nagpur. "Their world is a narrow circle of villages hidden away in forest-clad mountains . . . and they are quite content to leave . . . its wonders to such races as may care for them. Their only desire . . . is to be left alone." They are entirely illiterate, and know nothing about any alphabet. If they did, one would suggest that the sixteenth ode of the second book of Horace might be translated into their language as a good reflection of their views of life; but their own poetry, which is meant to be sung, does not touch the skirts of divine philosophy: it deals with the simplest of perennial themes, such as first love, friendship, maiden vanity, the pleasures of the chase, and the goodness of the good old customs, or, on the other hand, blighted affection, the pangs of hunger, and the terrors of the jungle. According to Father Hoffmann, their simple lyrics are unrhymed, and have no pronounced rhythm, except such as is imparted by the singer; and they consist for the most part of repetitions of some simple idea, but are saved from monotony by a tricky use of synonym and metaphor. As the vocabulary is limited, the Munda poet uses the utmost freedom in detaching a required word from its associations; for instance, in order to harp upon the idea of the perfume of flowers, the word that in ordinary conversation implies an ancient and fish-like smell may be used as a synonym with perfect propriety. But this poetic licence never breaks the bounds of decorum: "Of the hundreds of songs which, after the day's work, resound over the whole country, evening after evening, not one is defiled by a lewd expression, or even by an indecent allusion."

No. 8 of these Memoirs is entitled "A Monograph of Sea-snakes," and its author would have done better had he considered that in this very fallible world nothing is ever gained by labouring to expose the mistakes—or supposed mistakes—of fellow-workers. To read this pretentious "monograph," one might suppose that the British Museum Catalogue of Snakes, the author of which is persistently gleeked and galled at throughout, was hardly worth the paper it is printed on. No doubt there may be errors in the catalogue, as there are in all the works of mortal men; but even were the errors great and manifold—and no one who uses the catalogue considers this to be the case—the work would still stand out as a comprehensive and critical account of our knowledge of the Ophidia, and a well-arranged storehouse of fact, to which all after-workers must be indebted, whether they choose to acknowledge their debt or not. So that when the author of this monograph states that his "views are substantially different from those held by 'Professor' Boulenger" (the distinguished begetter of the British Museum Catalogue), and further solemnly announces that "there are discrepancies between Mr. Boulenger's work and mine affecting questions of actual fact," the most easy-going critic is roused to attention.

The shattering "discrepancy of fact" turns in the main upon the question whether the posterior maxillary teeth of certain sea-snakes are grooved or not. The British Museum Catalogue recognises the genus Hydrophis as distinct from the genus Distira, because in the former genus the posterior maxillary teeth are not grooved as they are in the latter genus; but to the author of this monograph, using "a new lens of the very highest power and quality specially recommended for this work," it "became clearly revealed" that the posterior maxillary teeth in Hydrophis are "all grooved." In any case, the matter is of no very great importance, as every naturalist understands that the limits between species and genera are often not very sharply defined; but to test the case we removed the poison-fang and one of the posterior maxillary teeth of a well-preserved and authentic spirit-specimen of *Hydrophis latifasciatus*, and examined them side by side, not indeed with any "patent double million magnifyin' gas microscopes of hextra power" such as Mr. Sam Weller demanded in order to see through a flight of stairs and a deal door, but with an ordinary microscope. In the poison-fang the poison-canal is as plain as a diagram; in the small posterior tooth there is no trace whatever of any groove.

If, instead of holding up the British Museum Catalogue to reprobation, and adding grievous burdens to terminology, the author had given us some facts about the anatomy of sea-snakes, and had summarised what is known about the habits, food, and enemies of these animals, and the nature and mode of action of their venom, his work might have approached the standard of a monograph. As it stands, it is merely what is known as a revision of the subfamily—and an incomplete revision, because, among other things, the several genera are not fully defined, and are not properly referred to their respective authors.

We cannot leave these Memoirs without a short reference to No. 9, which contains a "Polyglot List of Birds in Turki, Manchu, and Chinese," by Dr. E. D. Ross. The author disclaims any acquaintance with ornithology, and apologises for undertaking such work "with nothing but linguistic equipment." The paper, which, with indices, occupies more than 100 pages, is divided into "Part i., Large Birds," for which the "generic" name is Qus, and "Section ii., Small Birds," for which the general name is Qucqac; 360 birds are included; some of them are specifically identified, others are identified in a general way, while others are merely treated after the manner of the commentator. An illustration of each of the three methods will show how far this dish of literary minutalia is likely to be of service to an ornithologist.

"30. *Qu:* ? The Cormorant: Manchu, *Kotan*; Chinese, *Tao Ho.* The 'Mirror' says: 'It somewhat resembles the wild swan and is grey in colour. Its beak is wide and its crop large. It fills its crop with water which it pours into rat-holes, and having thus driven out the rats eats them.' I am in doubt whether the swan or cormorant is intended here. *Qu* is the common Turki name for a swan."

"179. *Aqis Cikdaci:* The Chough: *Pyrrhocorax graculus*: Manchu, *Cinjiri*; Chinese, *Liao ko* [Giles's Dict., the blue grackle]. The 'Mirror' says: 'Colouration violet; red beak parting on the top of the head. A skilful singer with a very clear voice.'"

"336. *Ding-ding Qucqac:* A species of wagtail: Manchu, *Tukiyeri cecike*; Chinese, *Yao t'un ch'iao.* The 'Mirror' says: 'Over the eyelids are long ash-coloured feathers looking like eyebrows; short tail; always struts when walking.'"

Many other fearful wildfowl are exhibited, and all are fitted with tags of comment and reference, some of which call to mind the notes to Thackeray's delightful parody "Timbuctoo."

AUSTRALIAN AND ARGENTINE BIOLOGY.

THE third number of the Memoirs of the National Museum of Melbourne is devoted to descriptions by Messrs. Baldwin Spencer and J. A. Kershaw of remains of subfossil emeus and marsupials from King Island, Bass Strait, and, in a second paper, to a review of the existing species of wombat. As regards emeus, the authors find that Kangaroo Island, King Island, and Tasmania were severally inhabited by species distinct from *Dromaeus novae-hollandiae* of the mainland. Both the Kangaroo Island *D. peroni* (*ater*) and the King Island *D. minor* were darker than the mainland bird, the first being distinguished from the second by its less robust build. The Tasmanian emeu, which survived in numbers until at least as late as 1840, is still insufficiently described, but appears to have differed in colour from each of the other three species, and also laid eggs of a distinctive character.

With the exception of a Dasyurus, the marsupials from King Island are identified with existing species.

Turning to wombats, the authors state that the first specimen known to Europeans was secured on Clarke Island, Bass Strait, in 1797 (not by Bass), and taken alive to Sydney, this forming the type of Shaw's *Didelphys ursina.* All the early examples of wombats came, in fact, from the islands in Bass Strait, and the identification of the Tasmanian animal with the Bass Strait *Phascolomys ursinus* is shown to be erroneous. In addition to skulls and bones, it appears to be now represented in collections only by a couple of skins recently secured on Flinders Island, where it still survives. The Tasmanian species, for which the authors propose the name *P. tasmaniensis*, is intermediate in size between the large *mitchelli* and the smaller *ursinus*, but agrees in shape with the former; its general colour is grizzled grey, with light hairs inside the ears.

In the course of a long paper on the birds of the East Murchison district, published in the April number (vol. ix., part iv.) of the *Emu*, Mr. F. L. Whitlock gives an account of his discovery of the playing-grounds and nests of the yellow-spotted bower-bird (*Chlamydodera guttata*), illustrated by photographs. A peculiar feature of the species is that at the commencement of the breeding season several individuals sometimes resort to the same play-ground, where the adult males make a nuptial display. The dimensions of one play-ground were 7 by 5 feet. The foundation was a mass of twigs, which raised the floor of the inverted arch about 6 or 8 inches above the general level of the ground, the walls of the arch being some

18 inches in height and 6 inches in thickness, while the total length of the intervening run was approximately 25 inches. In this run were placed thirteen flakes of limestone, together with about the same number of small green pods and a few beans, but no feathers or shells. The nests, which were built of twigs and placed in casuarina trees near the run, each contained a pair of heavily scribbled eggs.

For several years past Messrs. Baldwin Spencer and J. J. Fletcher have been studying and describing a large collection of Australian earth-worms, but in many instances it has been found impossible to decide on the proper generic position of the species. Before the classification can be considered final, a large amount of anatomical investigation is essential, and this work is being undertaken by the scientific staff of Melbourne University. Four papers, two by Miss G. Buchanan, the third by Miss F. Bage, and the fourth by Miss J. W. Ruff, embodying some of the results of this work are published in vol. xxii., part ii., of the Proceedings of the Royal Society of Victoria. Miss Bage, who treats of the structure and arrangement of the nephridea, states that these organs are subject to great variation in the different groups, and will probably be found of great value for systematic purposes.

Among other articles on local natural history in the March issue (vol. i., No. 5) of the *Queensland Naturalist*, special interest attaches to one describing a visit paid by Mr. G. H. Barker in September, 1909, to the reserve at Gold Creek, where numerous kinds of birds were observed.

The writer of these notes has been favoured with a cutting from the Argentine journal *La Nacion* of April 15 containing an account of a newly discovered skull of the gigantic glyptodont Dædicurus, with the previously unknown dermal head-shield in position. The skull appears to have been found in association with the skeleton, thus making the fourth more or less nearly complete example of the bony framework of this gigantic species.

RAINFALL OF RHODESIA AND AUSTRALIA.

TO the Proceedings of the Rhodesia Scientific Association (vol. viii., part iii., 1909) the Rev. E. Goetz, S.J., contributes a very valuable discussion of the rainfall of Rhodesia, based upon observations at sixty-three stations. Fifty of these are in southern Rhodesia; the conclusions therefore apply more particularly to the country between the Zambezi and the Limpopo (long. 27°–33° E.). The tables contain monthly and yearly amounts from the actual observations. The longest series is for Hopefountain (nineteen years), and the averages at most of the other stations have also been reduced to this normal by the usual method. An annual rainfall map shows clearly that the amounts near the Portuguese territory vary from 45 to 30 inches, and decrease westwards to 20 inches; but to the north-west (north of the Zambezi) the unreduced averages increase to 30 inches and above. There are some closed areas of high rainfall in southern Rhodesia which, the author assumes, will probably disappear with the returns of a larger number of stations. The rainfall for seasons, and for short periods at some selected stations, is dealt with in considerable detail. There is also an interesting discussion of rain and drought cycles; the nineteen-year cycle, based on the periodic movement of the high-pressure belt, recently proposed by Colonel H. E. Rawson, seems (the author thinks) to promise good results.

Bulletin No. 4, issued by the Australian Commonwealth Bureau of Meteorology, includes, *inter alia*, tables of percentages and mean monthly and annual average rainfall for each colony and for Tasmania. These values are transferred to a map consisting of miniature "graphs," showing very clearly the mean monthly percentages and other details. One of the several useful appendices shows the hourly distribution of rainfall and frequency of showers in most of the capital towns for a year ending June 30, 1909. The text of the bulletin gives an interesting account of the broad features shown by the maps, viz. that nearly the whole of tropical Australia receives the bulk of its rains during the period of the year when the convectional action in the interior of the continent is at its maximum. In the central latitudes, although the monsoonal influence still predominates, the colder months are under the influence of V-shaped depressions which skirt the southern shores during the winter and spring seasons. In Western Australia the maxima occur in the early and mid-winter months over the whole of the western and southern districts. In the agricultural areas of South Australia the winter and spring maxima are very marked, but in the far north the monthly values are very erratic. The pronounced feature of winter rains over South Australia and the western part of Western Australia is maintained in the western slope districts of New South Wales, but is obscured over the Victorian areas south and east of the mountain ranges by the disturbing character of the country. The same peculiarities affect the central, western, and northern interior of New South Wales.

THE CHEMICAL SIGNIFICANCE OF CRYSTAL STRUCTURE.[1]

LARGE numbers of chemical substances occur on the earth's surface as definite geometrical forms bounded by plane faces; these polyhedral shapes are called crystals. Inspection of the crystal forms assumed by mineral substances shows that, roughly speaking, each crystalline substance affects some specific geometrical shape which is characteristic for the material; further that, whilst crystals of any particular mineral attain vastly different dimensions and are bounded by planes which vary greatly in relative area, one geometrical feature remains constant. The angles between corresponding pairs of faces on any two crystals of the same substance are the same, notwithstanding the existence of difference in size or in relative face magnitude between the two crystals. The constancy of interfacial angle amongst crystals of the same substance is a law of nature, and has been amply demonstrated by the very careful crystallographic measurements made by Tutton during the last twenty years.

It is, however, not essential to study mineral substances alone in order to obtain a knowledge of the laws governing crystal growth. Great numbers of laboratory products can be caused to crystallise by condensation from some fluid condition; thus the crystals of various alums exhibited were obtained by slow evaporation of aqueous solutions of these salts.

The examination of a crystal shows that many of its physical properties differ according to the direction in the crystal in which the property is determined; the hardness of crystals, the speed at which light travels through them, and many other properties, are commonly dependent on the direction in which the material is examined.

The dependence of crystal properties on direction indicates the most essential feature of the crystal to be a definite and orderly arrangement of its ultimate particles; this arrangement is referred to as the crystal structure. Further evidence that crystals possess an arranged structure is furnished by the observation that crystallisation is not necessarily a spontaneous process. Thus, on melting benzophenone and rapidly cooling the clear molten mass, the liquid state is retained for many hours at a temperature far below the normal melting point of the compound. But on inoculating the liquid with a trace of crystalline benzophenone, crystallisation immediately commences and rapidly becomes complete. The introduction of a small particle of crystalline or arranged material into the liquid mass provides a nucleus upon which the molecules are able to deposit themselves in a similar crystalline arrangement; the process thus started quickly becomes propagated throughout the entire mass. The lack of spontaneity in the process of crystallisation leads occasionally to quite unexpected results. Thus tetrahydroquinaldine has been known for many years, and has been prepared by numbers of chemists. It has always been obtained as a liquid, and has never been supposed capable of existing in the crystalline state at ordinary temperatures; even when cooled in liquid air it merely becomes a thick resin, and does not crystallise. But on dissolving a few drops of it in a little light petroleum, and cooling the solution thus obtained in liquid air, the tetrahydroquinaldine crystallises out; on transferring a trace of the crystalline material obtained to

[1] Discourse delivered at the Royal Institution on Friday, April 15, by Prof. William J. Pope, F.R.S.

the liquid substance at the ordinary temperature, the liquid mass is seen to immediately crystallise. This well-known substance, hitherto known only in the liquid state at ordinary temperatures, really exists in a more stable condition as a crystalline solid.

Many substances are capable of crystallising in two or more distinct crystalline forms, of which one is, in general, the more stable at any particular temperature. The physical properties of the several crystalline modifications of any one substance are quite distinct and characteristic for the particular crystalline form, and in many instances even the colours of the several modifications are different. An example of this is afforded by pouring boiling water into a beaker coated with cuprous mercuric iodide; the brilliant scarlet crystalline form, stable at ordinary temperatures when heated in this way, becomes converted into another crystalline modification which is nearly black. The change is a reversible one, and the differences between the properties of the two crystalline modifications are to be attributed to differences in the mode of arrangement of the molecules in the two cases; the two modifications, in fact, possess different crystalline structures.

Although vast numbers of observations, such as the preceding, lead to the conclusion that crystals are arranged structures, it is not essential that the crystal should be a solid substance; during recent years large numbers of crystalline liquids have been discovered. On allowing melted cholesteryl chloride to cool rapidly, a brilliant display of interference colours is seen, owing to the particles of the substance assuming crystalline or orderly arrangement, whilst still retaining the liquid condition.

Having very briefly reviewed some of the many reasons for concluding that crystals are structured edifices, the nature of the architecture which they exhibit may now be considered. All the properties of crystalline solids harmonise with one simple assumption as to the manner in which the parts of the structure are arranged; this assumption is that the structure is a geometrically "homogeneous" one, that is, a structure the parts of which are uniformly repeated throughout, corresponding points having a similar environment everywhere within the edifice. The assumption of geometrical homogeneity as the characteristic of crystalline solids leads at once to the great problem solved by the crystallographers of the nineteenth century. This consisted in the inquiry as to how many types of homogeneous arrangement of points in space are possible, to the study of those types and to their identification, in symmetry and other respects, with the known systems into which crystalline solids fall. This work was commenced by the German crystallographer Frankenheim in 1830, and completed by the English geometrician Barlow in 1894. Briefly stated, the final conclusion has been attained that 230 geometrically homogeneous modes exist of distributing material, or points representing material throughout space, and that these 230 homogeneous types of structure, the so-called homogeneous "point-systems," fall into the thirty-two types of symmetry exhibited by crystalline solids. Models of a number of homogeneous point-systems illustrating some of these types are exhibited.

It is, however, obvious that the limitation of the possibilities of solid crystalline arrangement to 230 types marks but one stage in the determination of the nature of crystal structure, and throws no direct light on the relation between crystal structure and chemical constitution. Although by the end of the nineteenth century we had learnt that corresponding points of the units of crystalline structures form homogeneous point-systems, the great problem still remained of determining what are the entities which become homogeneously arranged, for what reason they become so arranged, and in what way the conclusions drawn by modern chemistry are reflected in crystal structure. This problem was a legacy to the twentieth century, and it now remains to indicate briefly the extent to which it has been solved and the results of chemical importance which have accrued during its investigation.

The problem may be most easily visualised in connection with some comparatively simple case, that, for instance, presented by the crystalline forms assumed by the elements themselves. It is generally admitted that an elementary substance consists of identical atoms, each of which acts as a centre of operation of attractive and repulsive forces. In a solid crystalline structure the atoms are obiously not free to travel through the mass, each, if not indeed fixed to a particular spot, being retained within a certain minute domain; each of these domains must be regarded as possessing a centre which marks the mean position of the atom.

The crystalline condition of an element may consequently be defined as one of equilibrium between forces of attraction and repulsion emanating from or referable to a flock of points homogeneously arranged in space, that is to say, conditions, the space occupied by a crystalline element, a homogeneous assemblage of identically similar atoms, may be partitioned into identically similar cells in such a manner that the boundaries of a single cell shall enclose the entire domain throughout which a particular atom exercises predominant influence. Since it is postulated that every point in the space is subject to the dominating influence of some next neighbouring atomic centre, it follows that the cells fit together so as to occupy the whole available space without interstices. Nothing is here said about the shape of the cells; but since, in the case of an elementary substance, the atomic centres are all alike, so too will be the cells. Before proceeding to discuss the actual shapes of the cells referred to, it will be convenient to illustrate

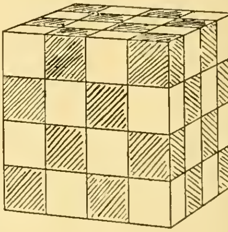

FIG. 1.

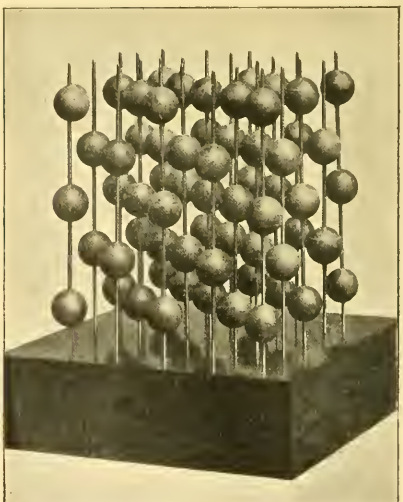

FIG. 2.

more graphically the mode of treating the problem which is here introduced with the aid of a particular point-system connected with the crystalline structure of elementary substances.

The point-system in question may be derived in the following manner. Space is first partitioned into cubes by three sets of parallel planes at right angles to one another (Fig. 1); a point is then placed at each cube corner and at the centre of each cube face. The cubes of the partitioning, having served their purpose, may now be removed, leaving one of the 230 types of homogeneous point-systems (Fig. 2). Imagine, next, that each point of the system expands uniformly in all directions until it touches its neighbours; a system of spheres packed together in contact is thus obtained (Fig. 3), and, on examination, it is found that no way exists of packing these equal spheres more closely together than the one thus derived. The system is therefore termed the cubic closest-packed assemblage of equal spheres, and, being derived in the manner described, still retains the high symmetry of the cube; the fragment shown, in fact, outlines a cube. Three directions at right angles in it, those which are parallel to the three cube edges, are seen to be identical in kind; this identity in kind in the three rectangular directions a, b, and c is conveniently expressed by the ratio $a:b:c=1:1:1$.

On removing spheres from one corner of the cubic closest-packed assemblage of equal spheres a close triangularly arranged layer is disclosed, and, by similarly treating each corner of the fragment of assemblage, the cube outline gives place to one of octahedral form. The assemblage is now seen to be built up by the superposition of the disclosed triangularly arranged layers, the hollows in one layer serving to accommodate the projecting parts of the spheres in adjacent layers. When this operation is performed it is perceived, however, that two ways of stacking the layers homogeneously are possible. The first of these, in which the fourth layer lies immediately over the first, the fifth over the second, and so on, yields the cubic closest-packed assemblage. The alternative mode of stacking, in which the third layer lies immediately over the first, the fourth over the second, and so on, exhibits the same closeness of packing as the first, but possesses the symmetry of the hexagonal crystal system; it is accordingly termed the hexagonal closest-packed assemblage of equal spheres (Fig. 4). Examination of the hexagonal assemblage shows that the horizontal directions, in the planes of the layers, are not identical in kind with vertical directions perpendicular to the planes of the layers. Corresponding dimensions in these two directions, a and c, are in the ratio of

$$a:c=1:\sqrt{(\tfrac{2}{3})}=1:0{\cdot}8165.$$

The final step in the treatment of the closest-packed assemblages of equal spheres consists in converting them into the corresponding assemblages of cells fitting together without interstices which have been already mentioned; it may be carried out in these, and in all other cases, by causing the component spheres to expand uniformly in all directions until expansion is checked by contact with the expanding parts of neighbouring spheres. The cubic closest-packed assemblage then becomes a stack of twelve-sided polyhedra, rhombic dodecahedra, which are so fitted together as to fill space without interstices. It is now seen that the even rate of expansion from each point of the original point-system which gives rise to the closely packed stack of rhombic dodecahedra symbolises an even radiation in all directions of the forces of which the atom is the centre of emanation. On applying the same operation of expansion to the spheres present in hexagonal closest-packing, each becomes converted into a dodecahedron, although of symmetry different from that of the rhombic dodecahedron. In each of the two cases the system exhibits the important property that, with a given density of distribution of the centres, a maximum distance prevails between nearest centres; these two systems thus represent the equilibrium arrangements of the postulated forces of repulsion exerted between near centres, the repulsions between more distant ones being neglected.

It will be sufficiently evident from what has been said that the function of the spherical surfaces in the closest-packed assemblages of spheres, as representing crystal structures, is merely a geometrical one; these surfaces are employed only as so much scaffolding by the aid of which may be derived arrangements exhibiting a maximum number of equal distances between neighbouring centres, and no physical distinction is to be made between portions of space lying within the spheres and portions forming part of the interstices between them. Insistence on this point is necessary, because many investigators have made use, quite illegitimately, of spheres for the representation of atomic domains, piling the spheres together in what they have termed open packing; this term seems to imply that some physical difference can subsist between the portions of space lying within the spheres and those lying without. The one kind of space is apparently regarded as susceptible to atomic influence in some sense not exhibited by the other. To state this view in any definite manner probably suffices to demonstrate its superficiality; the question of ascertaining what proportion of the total space is available for atomic occupation by the use of assemblages of spheres does not arise, because the spheres used are solely the geometrical instruments for producing equality amongst the atomic distances, and so determining the prevailing equilibrium conditions.

So far as the inquiry has been carried, it would seem that the elements should crystallise either in the cubic or the hexagonal system, and that in the latter case corresponding dimensions in the horizontal and vertical directions should be in the ratio of $a:c=1:0{\cdot}8165$. The facts are summarised in Table I.

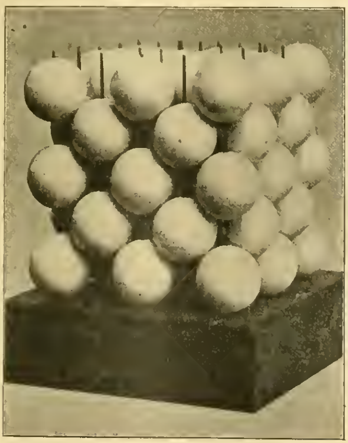

FIG. 3.

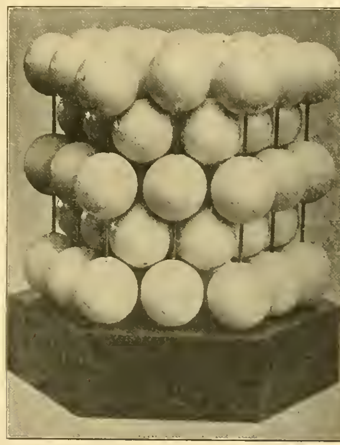

FIG. 4.

TABLE I.—*Relation between Crystal Form and Molecular Complexity.*

Crystal system	Elements	Number of atoms in molecules of compound inorganic substances					Organic compounds
		2	3	4	5	More than 5	
Cubic	50	68·5	42	5	12	5·8	2·5
Hexagonal	35	19·5	11	35	38	14·6	4·0
Tetragonal	5	4·5	19	5	6	7	5·0
Orthorhombic	5	3·0	23·5	50	36	27·3	34·0
Monosymmetric ...	5	4·5	3	5	6	37·3	47·5
Anorthic	0	0	1·5	0	2	8	7·0
Number of cases summarised in each vertical column ...	40	67	63	20	50	673	585

The proportion of substances crystallising in each system is stated above as a percentage.

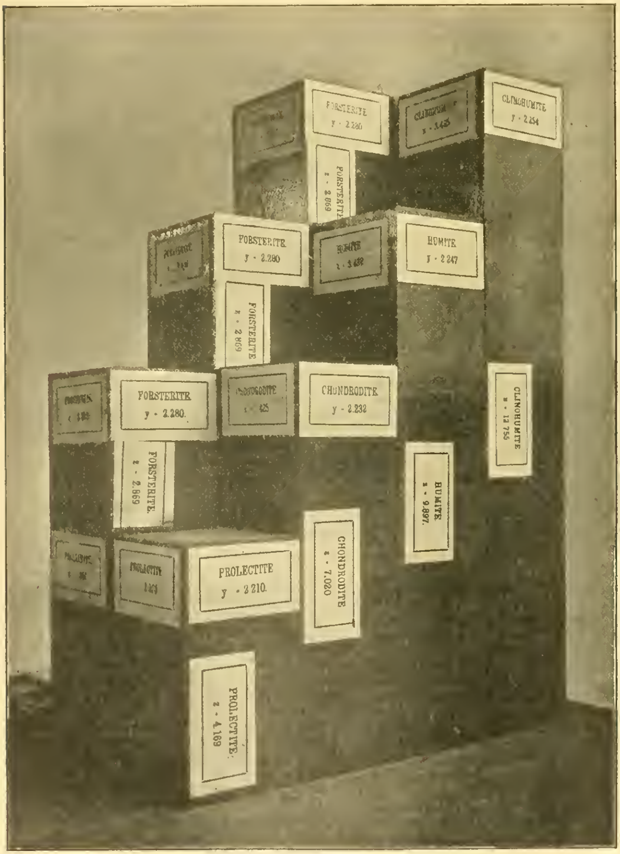

FIG. 5.

Of the elements which have been crystallographically examined, 50 per cent. are cubic; their crystal structure is simulated by the cubic closest-packed assemblage of equal spheres. Another 35 per cent. belong to the hexagonal system, and that these are correctly represented by the hexagonal closest-packed assemblage of equal spheres is indicated by the fact that for the hexagonal elements the ratio of corresponding dimensions in the horizontal and vertical directions approximates to the value $a:c=1:0{\cdot}8165$, deduced for the model assemblage.

The task of accounting for the 15 per cent. of the crystalline elements which have been examined and found to crystallise in systems other than the cubic or hexagonal still remains. A little inspection shows that the crystal forms of these elements in every case approach very closely to one or other of the two of highest symmetry, namely, the cubic or the hexagonal; one example of this will now suffice. The values of corresponding dimensions in three directions in space for the monosymmetric form of the element sulphur are given by the axial ratios $a:b:c=0{\cdot}9958:1:0{\cdot}9998$, $\beta=95^\circ\ 46'$. The slight departure of these dimensions from the corresponding values for the cubic closest-packed assemblage, in which $a:b:c=1:1:1$, $\beta=90^\circ$, at once suggests that the monosymmetric modification of sulphur is derived from the latter assemblage by some minute distortion. Such a distortion indicates a very trifling departure from uniformity in the influence exerted in different directions from each atomic centre, and may either arise from some want of symmetry in the individual atoms or in a reduction of the symmetry caused by some grouping of the atoms; two or more atoms might thus be more closely connected in some way with one another than with other next neighbouring atoms.

Having shown that the crystalline forms of the elements are in complete harmony with the conception that crystal structures can be homogeneously divided into similar cells of polyhedral shapes approximating closely to the spherical, reference may now be made to some simple compounds, those, namely, in which the molecule consists of two dissimilar atoms.

The conception of the equilibrium of centred forces which has been shown fertile in the case of the crystalline elements can be immediately applied to the binary compounds; as before, each atom will be represented by forces emanating from a centre, and equilibrium will demand closest packing of the spheres used, just as in the previous case. The atomic centres will now, however, be of two kinds, and the question arises as to whether the domains of atomic influence to be described about them will be all of the same magnitude or whether two magnitudes of spheres must be employed, one for each element present. This question is difficult to answer by reference to the facts already reviewed above; probably the only indication which the latter afford in this connection is that closest packing of a considerable variety of different magnitudes would certainly be most unlikely to lead to the close similarity of crystal form observed as between the elements and the binary compounds. A direct answer is, however, provided as the result of investigating the crystalline forms of organic substances, to which reference will presently be made; this investigation has led to the discovery of a definite law which governs the magnitudes of the several kinds of atomic domain concerned in any crystalline compound substance. It is found that the magnitudes of the atomic domains in any crystalline compound are very approximately in the ratio indicated by the fundamental valencies of the corresponding elements. Since the molecules of nearly all the binary compounds which have been crystallographically examined contain in the molecule one atom each of two elements of the same valency, the polyhedral cells from which a crystalline binary compound must be supposed built up are all, in general, of approximately the same magnitude. The fact that most binary compounds, like most elements, crystallise in either the cubic or the hexagonal system, represents one of the simple results of this law of valency volumes.

The binary compounds thus, in general, affect crystalline structures which are derived from the cubic or the hexagonal closest-packed assemblage of equal spheres; one-half of the spheres, selected homogeneously, represent atoms of the one element and the remainder atoms of the second element. The mode in which the necessary homogeneous selection may be made in the cubic assemblage, without altering the values of corresponding dimensions in three rectangular directions, is shown in a model.

The crystalline forms of the binary compounds are in accordance with what has been above foreshadowed. Table I. indicates that in geometrical respects the crystalline binary compounds closely resemble the elements; 68·5 per cent. of those examined are cubic and 19·5 per cent. hexagonal, the remaining 12 per cent. crystallising in systems of lower symmetry than these. The axial ratios, $a:c$, of all the hexagonal binary compounds known are stated in Table II.; all approximate closely to the value, $a:c=1:0{\cdot}8165$, for the model hexagonal closest-packed assemblage of equal spheres.

TABLE II.—*Hexagonal Binary Compounds.*

		$a:c$			$a:c$
Beryllium oxide	BeO	1 : 0·8153	Cadmium sulphide	CdS	1 : 0·8109
Zinc oxide ...	ZnO	1 : 0·8039	Silver iodide.	AgI	1 : 0·8166
Zinc sulphide..	ZnS	1 : 0·8175	The ratio, $1:\sqrt{(\frac{2}{3})}$		1 : 0·8165

In connection with the elements and binary compounds, it is noteworthy that the mode of treatment described appears practically to eliminate molecular aggregation of the atoms as a factor in determining the crystalline structure; that is to say, the distance separating two neighbouring atom centres is the same whether those atoms belong to the same or to different molecules. Another interesting fact is that, whilst the elements and binary compounds for the most part crystallise in the cubic or hexagonal systems, substances of greater molecular complexity rarely crystallise in these highly symmetrical systems; thus, of a great number of organic compounds examined, 2·5 and 4·0 per cent. only belong to the cubic and hexagonal crystalline systems respectively (Table I.). This observation is important as one of many indications that the cells into which the crystal structure of a complex compound are partitionable are not, in general, all of the same volume. Further investigation shows that the volumes of the polyhedral cells representing the atomic domains of the several elements present in a complex crystalline compound are governed by the law of valency volumes, to which reference has already been made. The correctness of this conclusion concerning the proportionality between the numbers expressing the fundamental valencies of the elements and the volumes of the corresponding spheres of atomic influence has been abundantly verified, not only by the laborious process of working out a large number of cases, but in several other ways which may be more rapidly indicated. The following are illustrations of the latter kind of verification.

Table III. states the composition and axial ratios, $a:b:c$, of a series of four crystalline minerals which differ in composition by the increment, Mg_2SiO_4; the sums of the valencies of the atoms composing the different molecular aggregates are stated under the heading W. The increment, Mg_2SiO_4, also occurs as the crystalline mineral forsterite, of which the axial ratios have been determined. It is evident that the ratio a/b has approximately the same value of 1·08 for all four members of the series, and that practically all differences in relative dimensions are expressed by the ratio c/b. On dividing the valency volume, W, by the corresponding value for c/b in each case, the quotients 11·7, 12·1, 12·3, 12·4, and 12·7 are obtained respectively for the substances prolectite, chondrodite, humite, clinohumite, and forsterite. The relative dimension, c/b, is thus roughly proportional to the sum of the valencies in this set of minerals. The comparison may, however, be made more accurately by including the changes in both relative dimensions, a/b and c/b, in the calculation, in the following manner. The "equivalence parameters" are the rectangular dimensions, x, y, and z, of a rectangular block having the volume W, and are in the ratio of the axial ratios $a:b:c$. The parameters x and y preserve almost constant values throughout the series, and addition of the increment, Mg_2SiO_4, leads to a practically constant increase of about 2·86 in the dimension z on passing from one mineral to the next in the series. The mineral forsterite also gives nearly the same x and y values as before, and its z value, 2·87, is equal to the differences between consecutive pairs of z values in the main series; these differences vary between 2·85 and 2·88. The axial ratios and equivalence parameters of forsterite can, indeed, be calculated with considerable accuracy from the data available for the series of four minerals.

TABLE III.—*The Humite Minerals.*

Prolectite ...	$MgSiO_4$	$2Mg(F,OH)$ ...	W = 22
Chondrodite ...	$Mg_3(SiO_4)_2$.	$2Mg(F,OH)$ ...	W = 38
Humite	$Mg_5(SiO_4)_3$.	$2Mg(F,OH)$ ...	W = 54
Clinohumite ...	$Mg_7(SiO_4)_4$.	$2Mg(F,OH)$ ..	W = 70

The increment is Mg_2SiO_4, namely, forsterite, with W = 16.

	Axial Ratios $a:b:c$	Equivalence Parameters $x:y:z$
Prolectite	1·0803 : 1 : 1·8862	2·389 : 2·210 : 4·169
		Diff. = 2·851
Chondrodite ...	1·0863 : 1 : 3·1447	2·425 : 2·232 : 7·020
		Diff. = 2·877
Humite	1·0802 : 1 : 4·4033	2·428 : 2·247 : 9·897
		Diff. = 2·858
Clinohumite ...	1·0803 : 1 : 5·6588	2·435 : 2·254 : 12·755
Values for the increment, forsterite.		
Oberved	1·0757 : 1 : 1·2601	2·449 : 2·277 : 2·869
Calculated	1·0823 : 1 : 1·2775	2·429 : 2·245 : 2·869

The relations here displayed may be rendered more obvious by a series of models (Fig. 5). Rectangular blocks having as the horizontal dimensions the x and y values, and as vertical dimension the z value, for forsterite, when superposed upon a similar set of blocks having the corresponding dimensions for prolectite, form a stack exhibiting the equivalence parameters of chondrodite; superposing on this a second set of forsterite blocks leads to a stack showing the equivalence parameters of humite, and on again repeating the operation, a stack with the dimensions of clinohumite results. From the numerical data and the models exhibited, it must be regarded as definitely proved that, in this series, the volumes appropriated by the constituent atoms are, in any one member, directly proportional to the valency numbers of the corresponding elements.

Another set of observations of a very convincing character, although of a totally different kind, is laid out in Table IV. Experimental determinations of the mole-

TABLE IV.—*Molecular Volumes of the Normal Paraffins at their Melting Points.*

Mean value of S = 2·970.

cular volumes of a long series of normal paraffins, made on the liquid substances at temperatures at which the materials are in physically similar conditions, are stated in column 4. Since the valency of carbon is four times that of hydrogen, it would be anticipated from the crystallographic conclusions previously drawn that each carbon atom should appropriate four times as large a space for occupation as one hydrogen atom; the quotient of the molecular volume by the valency sum or valency volume, W, should consequently lead to the same value, S, in the case of all the hydrocarbons. The mean value of S, namely, the atomic volume of hydrogen, is thus calculated as 2·970, and that it is constant within very narrow limits is seen on comparing columns 4 and 5, the latter of which states the product of the valency volume, W, by the value 2·970. The simple relation between the atomic volumes of carbon and hydrogen in the liquid normal paraffins indicated in the above table was recently pointed out by Lebas, and is abundantly confirmed by numerous series of determinations in addition to that now quoted. It is thus definitely proved that the law of valency volumes, first enunciated on the ground of the crystallographic evidence, holds rigidly in the case of these liquid substances.

Sufficient has been said to demonstrate that a method has now been devised by means of which the vast stores of accurate goniometric measurements collected by crystallographers during the past century can be interpreted, and that the requisite interpretation has in many cases already been given. Prof. Liveing, in a discourse delivered in this room nineteen years ago, suggested that crystalline forms are the outcome of the accepted principles of mechanics; the aid of these, and of these alone, has been invoked to show that crystalline structures result from the equilibrium of the attractive and repulsive forces radiating from the atomic centres.

RESULTS OF SOME RECENT INVESTIGATIONS ON MAGNETIC DISTURBANCES.[1]

AN examination of the times of beginning of the magnetic disturbance which occurred on May 8, 1902, as coincidently with the Mont Pelée eruption as can be determined, revealed the interesting fact that they were not the same all over the globe, being, in general, earliest at European stations. The times next progressed going around the earth eastwardly, the complete circuit being made by the disturbance in about $3\frac{1}{2}$ minutes. This fact led to an examination of other similar disturbances, such as the one of January 26, 1903, and it was again seen that this one also progressed around the earth eastwardly, the time for the complete circuit being about 4 minutes.

Mathematical analyses were next made, and it was found that for both disturbances (May 8, 1902, and January 26, 1903) the systems of disturbance forces which it would be necessary to superpose upon the earth's own magnetic field were precisely of the same character as the earth's. In other words, were we to assume electric currents as constituting the disturbance systems, then, as is the case for the earth's field, the currents would have to circulate around the earth from east to west if they are positive ones, and in the contrary direction—from west to east—if they are negative or such as would be produced by moving negative charges. Furthermore, for both disturbances the electric currents would have to circulate chiefly in the regions above the earth.[2]

For the disturbance of May 8, 1902, there were a sufficient number of trustworthy determinations of the effect on the vertical intensity, and accordingly it was possible, by means of the analysis, to separate the external system of currents from the internal (below the surface) one; and then the surprising result revealed itself that the internal currents went in the same direction as the external ones, the latter being about three times the strength of the former. Hence, were we to suppose that the disturbance is caused by the motion of negative charges around the earth eastwardly, then the internal negative currents also go in the same direction, and accordingly they are not currents induced in the earth by the outer system.

If the earth's own magnetic field is likewise separated into an internal system and an external one, it is also found that for both systems the negative electric currents go in the same direction around the earth, viz. from west to east. The disturbance systems found above are therefore precisely similar in character to the earth's field. It should also be noted that the negative currents of the disturbance progress around the earth in the same way as did the times of beginning referred to above.

We have now become acquainted with the fundamental facts of observation pertaining to the simplest class of magnetic disturbances experienced by the earth—the sudden beginnings of magnetic perturbations, which, in accordance with van Bemmelen's suggestion, we will term for brevity "S" storms. Let us see what hypotheses are necessary for a *physical* explanation of the observed facts.

Prof. Kr. Birkeland, of Christiania, was the first to have attempted a definite physical theory to account for this class of disturbances, which he termed "equatorial perturbations," since they are most strongly developed in the equatorial regions, as judged alone from the size of the disturbance effect on the horizontal intensity. If the latter element suffered an increase, the disturbance was called a "positive equatorial perturbation," and if, on the other hand, the horizontal intensity was decreased, the disturbance was termed a "negative equatorial perturbation." The theory for these particular disturbances is only a part of the general "kathode-ray theory" developed by Birkeland and Störmer to account for all classes of magnetic disturbances and of polar lights, as set forth in their various papers, and especially in Birkeland's recent publication, "The Norwegian Aurora Polaris Expedition, 1902–3," vol. i., "On the Cause of Magnetic Storms and the Origin of Terrestrial Magnetism." It will be noted that it is even hoped to build up a general theory of terrestrial magnetism, and there is an intimation that the earth's magnetic periodic variations may likewise be among the consequences of kathode rays coming from the sun and entering the earth's field.

Without question, these important contributions of Birkeland and Störmer mark a distinct advance, and the student of magnetic science will find not only incentive, but also a wealth of material and many suggestive facts by looking over these very valuable researches. At present, however, their theoretical results and deductions must be regarded chiefly as *qualitative*. While it is made very plausible that the cause of our magnetic storms is to be referred principally to kathode rays originating in the sun and coming within reach of the earth's magnetic field, there are a great many questions left open which will require answering before full acceptance can be given to the theory in all its details. How the earth's own magnetic system is affected by a magnetic disturbance—whether the intensity of magnetisation is increased or decreased, if there are any after-effects, whether the currents within the earth are induced ones or are the same in direction as those outside, &c.—are but a few of the interesting and important questions to be solved.

It seemed very desirable, therefore, that someone should take up the investigation from an *analytical* point of view, viz. to take a typical magnetic storm and analyse the observed effects into spherical harmonic terms, so as to determine just how much is due to outside currents and how much to currents within the earth itself.

Birkeland concluded, from a general consideration of the effects of a magnetic disturbance on the vertical intensity, that all storms originate from without, and it is quite possible that, in the main, he may be right, but the conclusion cannot be accepted as invariably true without a detailed mathematical analysis of each particular case. In his first volume he accordingly proceeds on the assumption

[1] A summary of two papers presented respectively at the meeting of the Washington Academy of Sciences, February 17, 1910, and at the meeting of the Philosophical Society of Washington, April 9, 1910.

[2] See *Terrestrial Magnetism and Atmospheric Electricity*, vol. xv., pp. 9–30. In this connection it is also well to record that Dr. W. van Bemmelen, in his recent investigations on "The Starting Impulse of Magnetic Disturbances" (Proceedings of the Amsterdam Academy of Sciences, April 24, 1908), found the following important fact as applying to the Batavia magnetic observatory records, 1882–99:—"Taking no consideration of the slight introductory movement, 124 cases furnished for the duration of the impulse: in horizontal intensity, 4·5 min.; declination, 3·2 min; vertical intensity, 12·0 min. The duration of the vertical intensity movement is in general difficult to determine, as the decrease in this element keeps on mostly much longer. It is important to notice that the initial movement of D stops or is inverted, whilst of H the increasing movement keeps on."

that by far the greater part of a disturbance is due to upper electric currents, though quite likely, in a subsequent volume, he will consider the subterranean currents also. Since the observed quantities actually to be operated with appear to be resultant effects of both external and internal forces, it is very desirable that we should know just what proportion must be referred to one cause or the other. For this separation we require, however, a knowledge of the disturbances in the vertical intensity, and these are either difficult to determine with sufficient accuracy or are not to be had always at a sufficient number of stations, so that Birkeland was perforce compelled in his first treatment to assume chiefly external currents.

It was for these reasons deemed desirable to make known promptly the deductions derived from the mathematical analysis of certain typical cases of the class of "S" storms. We have now the means of applying the first decisive tests as to how far the Birkeland-Störmer theory will account for the facts.

There is a distinct advantage in treating, for the present, simply these sudden beginnings of magnetic disturbances for the reason that not only the time of beginning can be sharply determined, but, what is equally important, the actual magnitude and direction of the disturbance effect on any particular element can be most accurately determined. As the effects we are here especially considering do not extend, in general, over five minutes, we may readily scale off on the magnetogram the disturbance effect, being, without essential error, simply the difference between the ordinate to the curve at the point of beginning of the disturbance and the ordinate to the particular point of the disturbance considered. When, however, a magnetic storm extends over many hours, and even days, and one wishes to know the magnitude and direction of the disturbance at stated times, for example, every hour or half-hour, then what is called a "normal curve" must be drawn from which the disturbance ordinate is to be measured. This "normal curve" is supposed to represent the curve of magnetic variations which would have resulted had there been no disturbance; but to determine such a curve is far more difficult than is generally realised, and usually an arbitrary assumption of some kind must be made to derive it. Of such assumptions we are practically free in the disturbances considered.

Application of Tests.

The first fact of importance found from the analysis of the disturbance of May 8, 1902, was that the direction of flow of the negative electric currents, which could account for the external and internal magnetic disturbance systems, was the same for both systems. While the strength of the external system was about three times that of the internal, nevertheless, the internal currents were not the direct consequence of the outside moving negative charges, *i.e. they were not induced currents.* Instead, for both systems—outside and inside the earth—the flow of electricity was eastwardly around the earth for negative charges and westwardly for positive charges.

Having fixed the direction of flow of negative electricity, let us inquire now whether kathode rays coming from the sun will give the required direction. Birkeland, in his experiments on a magnetised terrella when placed in a Crookes's tube and subjected to a bombardment of kathode rays, observed, among other interesting phenomena, the formation, under certain conditions, of a ring of kathode particles which encircled the terrella in the magnetic equatorial regions. For an unmagnetised terrella there was no such ring. Störmer, from his mathematical investigations, found under what conditions a similar ring would be formed when kathode rays from the sun came within the deflecting influence of the earth's magnetic field. The ring results when electric charges enter a magnetic field perpendicularly to the lines of magnetic force, *e.g.* in the magnetic equatorial regions. It was on account of the possible formation of such an equatorial ring that Birkeland was apparently led to the adoption of his term "equatorial magnetic perturbation," and to refer its cause to such a ring.

If we apply, however, the well-known law according to which a negative charge would be deflected if entering the earth's magnetic field from without at right angles to the lines of magnetic force, it is unfortunately found that the deflection is to the west, and the moving negative electric charges would accordingly encircle the earth from east to west, hence opposite to what our mathematical analysis of the disturbance of May 8, 1902, and January 26, 1903, have shown must be the case to account for the observed disturbances.

Were we to assume, on the other hand, that the corpuscles are shot up into the earth's field instead of downwards, then those which struck the lines of magnetic force perpendicularly would, after successive deflections, circulate around the earth from west to east or eastwardly, and hence harmonise with the observed facts. Thus far, then, we should have to conclude that if the disturbances considered are to be referred to kathode rays deflected by the earth's field into more or less circular paths, the source of the kathode rays would have to be within the earth itself, and not without.

But if the radius of the ring of moving corpuscles is computed to conform with the time of propagation of the disturbance around the earth (about $3\frac{3}{4}$ minutes), it is found that the orbit would have to be distant from the earth's centre 580 times the earth's radius, or 3,700,000 kilometres, or 2,300,000 miles, and thus the possibility of a terrestrial origin of the kathode rays is likewise eliminated. Furthermore, if we calculate the intensity of the current which at that distance could produce the observed effects of the disturbances of May 8, 1902, and January 26, 1903, it is found to be 5,900,000 amperes. Now Birkeland says on p. 311 of his book:—"In the case of the greater storms, we found current-strengths that varied between 500,000 and 1,000,000 amperes, or even considerably more." Hence, to produce the comparatively insignificant magnetic disturbance effects here considered, by supposing a band of kathode particles circulating around the earth, would require a current at least six times stronger than that which Birkeland finds sufficient to account for the much larger storm effects!

The hypothesis was next briefly examined on which the disturbance effects considered might be referred to alterations in the electrical conductivity of the atmosphere and of the earth, either brought about by the secondary effects from bombarding kathode particles, viz. the formation of Röntgen rays, or, say, by the entrance into the earth's field of the penetrating radiation (γ rays of radium). The ionising effect and resultant alteration of electrical conductivity of the regions involved might either be due to the penetrating radiation from the sun or from the earth, if only *qualitative* results are considered. It is therefore at present not possible to state definitely whether the initial cause of the disturbance of May 8, 1902, was due to a terrestrial eruption or a solar one. First, further examinations will have to be made of the disturbances of May 20 and July 9, 1902, which were again closely coincident with the Mont Pelée eruptions. The electric-conduction hypothesis appears to satisfy, in general, the observed phenomena, and accordingly it is to be subjected to a further rigid examination. It seems also to explain why some of the disturbances take a westward path, although the majority of them go eastward.

Were we to suppose that the generated currents lie on a sphere of radius approximately equal to that of the earth, a velocity of the moving negative charges of 180 kilometres, or 110 miles per second, results, hence a quantity of the order of that for metallic conduction, or as found for the kathode rays from glowing electrolytes.

In conclusion, it should be stated that while it has been shown that the class of simple disturbances discussed in this paper cannot be referred to kathode rays in the way Birkeland and Störmer have supposed, it should be distinctly understood that this in no wise vitiates other portions of their theory, especially with reference to the larger and more complicated magnetic disturbances and to the origin and formation of polar lights. Before anything definite can be said as to the validity of these portions of their theory, it will be necessary to await the completion of a similar analytical treatment to that made for the "S" disturbances.

Such an analytical examination the writer has had under way for more than a year, and a preliminary statement of results was made at the meetings of the American Philosophical Society and of the American Pnysical Society in April, 1909. Instead of drawing curves showing the variations in the diurnal ranges of the magnetic elements with solar activity, as is most frequently done, curves were constructed showing the effects of the magnetic disturbances experienced by the earth during the period April, 1906, to December, 1909, at the Coast and Geodetic Survey magnetic observatories, on the absolute values of the magnetic elements, and especially upon the intensity of magnetisation. This latter curve had been drawn for the first time; when it was compared with the curves showing the variation in solar activity, during the same period, as manifested by sun-spot frequency, sun-spot area, and calcium flocculi area, then the interesting result was obtained that "the intensity of magnetisation of the earth in general decreases with increase in solar activity."

In other words, the average or residual effect of magnetic disturbances, in general, is equivalent to that which would result by the superposition of a magnetic system opposite to the earth's own field, *i.e.* a demagnetising or induction system of magnetic forces. The north magnetic pole of this superposed system is, in general, in high south latitude instead of high north latitude, as is the case generally for the small "S" disturbances already discussed.

Hence for the larger *disturbance systems*, the electric currents which we may suppose to cause the effects would circulate around the earth, for negative ions, from east to west, *i.e.* contrary to the negative currents for the "S" disturbances, but this time in strict accordance with the direction in which a kathode ray coming from the sun would be deflected by the earth's magnetic field.

For these big disturbances, accordingly, the times of beginning, if they can be accurately obtained, will show an increase going round the earth westwardly. A good example is the most remarkable disturbance of which there is any record, viz. that of September 25 last. Here are the times for two sudden deflections at the beginning of the storm, as scaled by Mr. R. L. Faris, of the U.S. Coast and Geodetic Survey, from the horizontal intensity magnetograms of the five Coast and Geodetic Survey magnetic observatories:—

No.	Station	Greenwich mean civil time Sept. 25, 1909 Impulse		
		First h. m.	Second h. m.	I.–II.
(1)	Porto Rico	8 37·7 ...	11 39·8 ...	−2·1
(2)	Cheltenham	8 40·9 ...	11 43·3 ...	−2·4

(4)	Sitka	8 39·5 ...	11 39·8 ...	−0·3
(5)	Honolulu	8 42·7	11 45·4 ...	−2·7
(6)	Mean of all	8 39·9 ...	11 41·9 ...	−2·0
(7)	Mean of Nos. 1, 2, 3.	8 39·10 ..	11 41·37 ...	−2·27
(8)	,, ,, 2, 4 ..	8 41·10 ...	11 42·60 ..	1·50
	Difference No. 7–No. 8	−2·00	−1·23	
	Mean Difference ...		−1·62	

The average latitude for the two groups Nos. 7 and 8 is, respectively, 32° N. and 39° N., and the average longitude 79° W. and 147° W. It is accordingly found that this particular disturbance was propagated from stations in the eastern part of the United States to stations in the eastern Pacific Ocean about two and a half times slower than was found for the simple "S" disturbances, hence roughly at the rate of 2600 miles per minute, against 6700 miles for the latter cases. It is not to be assumed at present, however, that the big disturbances progress over the whole earth at a uniform rate. Their motions appear much more complicated than for the "S" cases.

Accordingly, so far as the big disturbances in general are concerned, the kathode-ray theory of Birkeland and Störmer fulfils the test regarding direction of progression of the disturbance over portions of the earth, and as far as the direction in which the negative electric currents must, in general, go, as found from the preliminary analyses above mentioned. Whether the theory will bear the application of quantitative tests cannot be discussed now. The main thing is to have working hypotheses to which rigid tests can be applied.

Should the electric-conduction theory above proposed to account for the disturbances there considered find further confirmation, the way is opened to a possible corpuscular theory of terrestrial magnetism. On the basis of such a theory, a number of the puzzling features of the distribution of the earth's magnetism and of its variations can readily be explained.

L. A. BAUER.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

WE have received a copy of the "Livingstone College Year Book" for 1910. It contains college news, letters from old students detailing their experiences, a review of a year's progress in tropical medicine, &c. The training given at Livingstone College (a nine months' course) is designed to educate missionaries going to tropical countries in the elements of medicine, so far as they are required for the prevention of disease and the recognition and treatment of common accidents and diseases.

INDIANA UNIVERSITY, says *Science*, owns an experimental cave farm near Mitchell, Indiana, and has established a small laboratory there primarily for cave work. Cement pools have been placed inside and outside the caves, and give opportunities for breeding cave animals in the light and outside forms in the dark. The University offers a 100*l*. fellowship, in addition to a furnished cottage, to anyone who has had sufficient training to take up such work. Applications should be sent to Mr. F. Payne, Winona Lake, Indiana.

WE have received a copy of the handbook of the faculty of engineering at University College, London, for next session. The faculty includes the departments of mechanical, electrical, civil, and municipal engineering, and is intended to provide a systematic training for students who wish to devote themselves to engineering. It has been recognised by the Board of Trade as providing suitable technical training for marine engineers, and its courses also meet the needs of students who intend to enter for engineering appointments in the various public services. Prof. J. A. Fleming, F.R.S., is the dean, and Prof. J. D. Cormack the vice-dean, of the faculty.

THE governing body of the Imperial College of Science and Technology at South Kensington last year awarded two scholarships for research in connection with aëronautics. The students have held their scholarships at the National Physical Laboratory at Teddington. We learn from the *Times* of August 5 that an additional scholarship is now being offered for award at an early date by the governors of the college. The scholarship will be tenable for one year, and will consist of exemption from fees, together with a maintenance allowance at rates fixed with regard to the circumstances of the case, the value of the scholarship being not less than 50*l*. and not more than 150*l*. a year. It is open to any properly qualified individual, irrespective of residence or place of education. At Regent Street Polytechnic, too, the courses in aëro-engineering are to be developed. A second-year course of aërodynamics is being arranged for students who have qualified in the first year's work in aëro-engineering inaugurated during last session. The course will be open to other persons who can provide evidence that they possess the requisite knowledge of applied mathematics. Special instruction in workshop practice relating to aëroplanes and airships will be given, and students will receive help in making gliders and working models of different types of aërial craft they may be interested in.

THE calendar of the Edinburgh and East of Scotland College of Agriculture for 1910–11 provides full information as to the courses of instruction offered to pupils for the coming session. The college was founded in 1901 with the object of providing for agricultural education and research in the central and south-eastern counties of Scotland. Its classes are arranged in conjunction with certain classes in the science faculty of Edinburgh University. Courses for the diploma of the college and for the science degree of the University are concurrent. A short course, specially arranged to suit those who are actively engaged in farm work, is held at the college annually. The college also maintains a comprehensive scheme of extension work in the neighbouring counties, and the services of its staff are placed at the disposal of farmers investigating new conditions or special points arising out of their farming operations. Under the regulations of the Scotch Education Department, the college is recognised as a central institution to which students may be sent by burgh and county education committees. Instruction in poultry-keeping has been considerably developed. The interest in school gardening grows, and seventy-three gardens have been laid out with the assistance of the college staff. The experiments and demonstrations carried on throughout the neighbouring district are described in the calendar, and give proof of the practical nature of the work undertaken.

SOCIETIES AND ACADEMIES.

London.

Physical Society, July 8.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Prof. H. L. **Callendar**: The radio-balance: a thermoelectric balance for the absolute measurement of radiation; with applications to radium and its emanation. In this apparatus, which was first constructed in 1905, and was briefly described in an article on radiation contributed to the "Encyclopædia Britannica," heat supplied by radiation is directly compensated by the Peltier absorption of heat in a thermo-junction through which a measured electric current is passed. In the simplest form of the instrument, radiation admitted through a measured aperture, 2 mm. diam., falls on a small copper disc 3 mm. diam. by 0·5 mm. thick, to which two thermo-junctions are attached, forming a Peltier cross. One couple is connected to a sensitive galvanometer for indicating changes of temperature. The other is connected to a battery and rheostat in series with a millammeter or potentiometer for measuring the current required to reduce the deflection of the galvanometer to zero. In practice, two similar discs with similar connections are mounted side by side in a thick copper box, and are balanced against each other in order to avoid changes of zero due to exposure to sunshine, or rapid variations of temperature. The advantages of the disc radio-balance are that it is very simple to construct and easy to reproduce without material variation in the reduction constants. It is very suitable for measurements of solar radiation, or strong sources, but is insufficiently sensitive for weak sources; and the absorption coefficient a must be determined by comparison with a standard. In the cup radio-balance, the radiation is received in a copper cup 3 mm. diam. by 10 mm. deep, so that the absorption coefficient is practically equal to unity. Greater sensitiveness is secured by employing a pile of several couples, insulated from the cup, in place of the single balancing couple. External disturbances are eliminated by employing a pair of cups, similarly mounted but oppositely connected, enclosed in a thick copper cylinder. The Joule effect, represented by the C^2R term in the equation, is automatically eliminated by passing the same current in series through the opposing Peltier junctions soldered to the bottom of the cups. The cup exposed to radiation is cooled, and the cup screened from radiation is heated, by the Peltier effect, while both are equally heated by the Joule effect. A complete observation involves reversing the current and switching over the radiation screen, in order to eliminate any difference of sensitiveness of the two piles. By observing the neutral current, each cup can be used separately, as with the disc balance, but the disc balance cannot be used with the Peltier couples connected in opposition unless the balancing couples are insulated from the discs. The cup radio-balance is sensitive to less than a tenth of a micro-watt, and is very suitable for measuring the heat evolved by small quantities of radio-active substances. It was applied to radium at Prof. Strutt's suggestion, and Prof. Rutherford has kindly supplied samples of emanation, and has determined the value of the radium sample employed by comparison with his own standards. The second sample of emanation had only just come to hand, and the absolute values had not been finally reduced at the time the paper was read; but it appeared from the preliminary reductions that the heat evolution of radium in terms of Prof. Rutherford's standards was much greater than that given by previous observers.—Dr. A. **Russell**: The convection of heat from a body cooled by a stream of fluid. Attention is directed to certain deductions made by Boussinesq from the mathematical theory of the conduction of heat in liquids. Complete proofs are given of Boussinesq's formulæ, stress being laid on their limitations, and some of their practical applications are pointed out. It is proved that when a hot body is immersed in a stream of liquid flowing with constant velocity, the cooling is proportional to the difference of temperature between the body and the liquid. Newton proved experimentally in 1701 that this law was true for the case of a hot body being cooled by a draught of air. He enunciated his law with reference to the forced convection of heat from a body, and not, as is often stated, to the natural free convection from it. Lorenz has shown that in special cases the natural convection of heat will vary as the 1·25th power of the difference of temperature. Provided that the velocity of the cooling draught is kept constant between certain limits, Compan has shown that Newton's law is very approximately true even when the difference of temperature is as high as 300° C. Another deduction from the formulæ proved in the paper is that the cooling is very approximately proportional to the square root of the velocity of the convection current. The author gives the solution of the problem of the heating of a liquid flowing steadily, with a velocity less than the critical velocity, through a cylindrical tube which is maintained at constant temperature. It is shown that, in many practical cases, the heating power of the tube varies as $R\theta\sqrt{s\sigma k V l}$, where R is the radius of the tube, θ the difference of temperature between the tube and the liquid, s the specific heat, σ the density, k the conductivity, V the velocity of flow, and l the length of the tube. It is proved that if a wire be immersed in a stream of liquid with its length at right angles to the direction of flow, the electric current which will fuse the wire varies as the 1·25th power of the diameter of the wire. Finally, the effect on the cooling of an electrically heated cylinder by a stream of liquid, of putting an insulating wrapping round it, is considered. It is shown that in certain cases the effect of this procedure is to lower the temperature of the cylinder, an effect which can be easily demonstrated experimentally. In order to simplify the mathematical work, only the case of incompressible fluids is considered. Experimental results, however, obtained by various physicists are quoted to show that some of the formulæ are approximately true for the cooling of heated bodies by convection with currents of air.—Prof. S. P. **Thompson**: Hysteresis loops and Lissajous's figures, and on the energy wasted in a hysteresis loop. Attempts have been made to find an explanation of the forms of the looped curves which express the hysteresis exhibited by iron and steel when subjected to cycles of magnetisation. Physical explanations to account for their general shape have been given by Ewing and Hopkinson, and M. Pierre Weiss has put forward an electronic theory to account for the principal features. The author shows that any hysteresis loop can be analysed into a harmonic series of closed curves corresponding to the various terms in the analysis of the current wave, and their constituents are examined in the paper. A number of examples of hysteresis loops were chosen and subjected to analysis. The loops chosen related to various kinds of iron and steel, hard and soft, solid and laminated, and taken by various methods. In carrying out the analysis, the simple approximate method described by the author (Proc. Phys. Soc., vol. xiv.) was used. Details are given of the analysis of various loops, the effect of eddy currents on the size and form of the loops is discussed, and an account is given of the effect of the higher sine and cosine constituents of the current wave.—Dr. W. H. **Eccles**: The energy relations of certain detectors used in wireless telegraphy. The paper is a record of the results of an experimental examination into the physical properties of the electrolytic detector, the zincite rectifier, the carborundum rectifier, and a thermoelectric detector consisting of a light contact between graphite and galena. The conditions of the experiments have been generally identical with those arising in the ordinary employment of the detectors, and, in particular, the quantities of energy given to the instruments, in the form of electrical oscillations, have been of the same order in these experiments as in actual practice. The chief fact brought to light is that the power curves of all the detectors are straight lines, which suggests that all the detectors are fundamentally thermal in their action.

PARIS.

Academy of Sciences, August 1.—M. Émile Picard in the chair.—M. **Bassot**: The geodesic expedition to the equator. A description of the first two volumes dealing with the results of the expedition under Col. Bourgeois for measuring the arc of the meridian at Quito.—A. **Gautier** and P. **Clausmann**: The action of mixtures of carbon monoxide and hydrogen, or of carbon dioxide and hydrogen, upon the oxides of iron. Carbon monoxide and hydrogen with Fe_3O_4 at 500° C. gave a mixture of ferrous oxide and a carbide of iron, the latter corresponding to the composition $Fe_{12}C$. The bearing of the results on the composition of the gases issuing from fumerolles is discussed.—Paul **Sabatier** and A. **Mailhe**: The catalytic preparation of alkyl-aryl ethers. A mixture of methyl alcohol and phenol vapours passed over thoria at 390°–420° gives a good yield of anisol, $C_6H_5.O.CH_3$. If the phenol is replaced by its higher homologues, the corresponding homologues of anisol are obtained, and the substitution of ethyl alcohol for the methyl alcohol gives $C_6H_5.O.C_2H_5$ and its homologues, some unsaturated hydrocarbon being produced by a secondary reaction between the ethyl alcohol and the thoria.—M. **Schwœrer**: The thermal phenomena of the atmosphere.—G. **Gaiffe**: A method of stereoscopic and kinematographic radiography.—E. M. **Antoniadi**, F. **Baldet**, and F. **Quénisset**: The occultation of η Gemini by the planet Venus. Observations made at the Juvisy Observatory on July 26. The duration of the occultation was 3m. 30s. ± 2·5s. The variations in the luminosity of the star when approaching contact lead to 80 to 110 kilometres as the height of the atmosphere of Venus.—José Comas **Solà**: The discovery of a small planet, presumably new. This was found on a photograph of Halley's comet, taken on June 6 last.—José Comas **Solà**: Study of Halley's comet.—M. **Coggia**: The occultation of η Gemini by Venus, observed at Marseilles.—Th. **de Donder**: Poisson's theorem and the differential invariants of Lie.—Paul **Lévy**: Some equations defining line functions.—Harald **Bohr**: The convergence of Dirichlet's series.—A. **Sainte-Laguë**: Proportional representation and the method of least squares.—William **Duane**: The evolution of heat in a mixture of radium and a phosphorescent salt. The rate of evolution of heat by a radium salt is not affected by admixture with a phosphorescent substance.—Pierre **Jolibois**: The relations between white phosphorus, red phosphorus, and pyromorphic phosphorus. By a study of the vapour pressures, the author concludes that these three varieties of phosphorus are distinct, and criticises the theory recently proposed by Cohen and Olie.—Henri **Leroux**: The heats of combustion of some hydronaphthalene derivatives.—Ed. **Chauvenet**: The combinations of thorium chloride with ammonia.—Georges **Charpy**: Behaviour of steel analogous to the "tin disease." A study of the conditions leading to an increase of the velocity of crystallisation in steel on annealing.—J. B. **Senderens**: Catalytic reactions in the wet way based on the use of aluminium sulphate. In the preparation of ethylene by the interaction of alcohol and sulphuric acid, the presence of aluminium sulphate lowers the temperature of the reaction and increases the velocity of evolution of the gas. The same salt also possesses a favourable catalytic effect in the preparation of ether.—Daniel **Berthelot** and Henry **Gaudechon**: The mechanism of photochemical reactions and the formation of plant principles: the decomposition of sugar solutions. The mechanism of the reactions caused by exposure to ultra-violet rays is analogous to that in living plants. Exposed to these rays, solutions of glucose give carbon monoxide, dioxide, methane, and hydrogen. Levulose, maltose, and saccharose behave similarly, but the proportions of the gases are different in each case.—André **Piedallu**: A new mould in oil tanning.—Henri **Labbé**: Contribution to the study of nitrogenous exchanges.—Gabriel **Bertrand** and A. **Compton**: The individuality of cellase and emulsin. Comparative experiments on the hydrolysis of cellose by cellase and of amygdalin by emulsin show that these two diastases are quite distinct.—N. A. **Barbieri**: The non-existence of free or combined lecithins in yolk of egg.—Etienne **Sergent** and Edmond **Sergent**: Immunity against malaria in birds. Conservation *in vitro* of the sporozoïtes of *Plasmodium relictum*. Relative immunity obtained by inoculation with these sporozoïtes.—B. **Brunhes**: Telluric currents.

NEW SOUTH WALES.

Linnean Society, June 29.—Mr. C. Hedley, president, in the chair.—R. J. **Tillyard**: Monograph of the genus Synthemis (Neuroptera: Odonata). The most important points discussed are:—(1) The position of the genus in the subfamily Corduliinæ. The view is put forward that it should be separated from the Macromina, so as to constitute a subgroup Synthemina. (2) Subdivision of the genus itself.—T. G. **Sloane**: Studies in Australian entomology. No. 16. New species of Carabidæ. A new genus, Stichonotus, referable to the subfamily Carabinæ, and eighteen species belonging to the subfamily Harpalinæ, are described as new, including a species of the Asiatic genus Holcoderus, now first recorded from Australia.—W. W. **Froggatt**: The entomological fauna of Narru Island, of the Ocean Island group.—A. H. **Hamilton**: Description of a new species of Lepidosperma (Cyperaceæ) from the Port Jackson district, with some miscellaneous botanical notes.

INTERNAL-COMBUSTION ENGINES.

The Design and Construction of Internal Combustion Engines. A Handbook for Designers and Builders of Gas and Oil Engines. By Hugo Güldner. Translated from the second revised edition, with additions on American engines, by Prof. H. Diederichs. Pp. xix+672. (London: Constable and Co., Ltd., 1910.) Price 42*s.* net.

THIS work is the most complete and elaborate treatise on the gas-engine which has ever been published, as will be realised when it is stated that there are 664 pages of comparatively small-type letterpress, 728 figures, and 36 folding plates. There is a certain amount of the usual padding, namely, photographic reproductions of large and small gas-engines of various makes, as well as records of tests, but there is also a large amount of original work and practical information which, owing to the position of the author, viz., chief engineer and director of the Güldner Motoren Gesellschaft, must be regarded as of great value. In the preface to the first edition, the author states:—

"Germany's gas-engine industry justly enjoys an international reputation . . . everything that has served to lay the foundation of the industry and that has helped to make it vital and important is either the product of German thought, or was first practically realised on German soil."

It is not surprising, therefore, that the work reflects German practice.

The book is translated into English by Prof. H. Diederichs, of Cornell University, and he has entirely omitted the first part of the German edition, which treats of the history of the gas-engine, and has substituted therefor descriptions of, and information relating to, American gas-engines. The author says that his principal object in writing this book was to make it "serve as an every-day working guide to the designer and constructor," and to follow out this object he has adopted the somewhat unusual feature of giving dimensioned drawings, not only of complete engines or producers, but of various parts. These drawings will undoubtedly be found to be of the greatest use to many designers and also to purchasers of engines who may wish to verify whether a proposed engine is correctly designed or not.

The work is divided into four parts and an appendix. The first part deals with the various methods of operating gas-engines and the gas-engine cycles; the second part with the design and construction of internal-combustion engines; the third with the erection and tests of modern internal-combustion engines; the fourth with gas-engine fuels and combustion in gas-engines; and the appendix with various theoretical matters relating to thermodynamics and thermochemistry, as well as with certain details derived from practice.

In dealing with the constant-volume cycle, the author investigates the question of the maximum compression that should be practically adopted, taking into consideration the theoretical thermal efficiency based on comparatively recent data of the variation of specific heat with temperature, as well as the efficiency ratio and mechanical efficiency, and finds that the economic limit of maximum compression lies between 210lb. and 280lb. per square inch, a conclusion which, although these pressures are somewhat higher, is substantially in agreement with the experimental work of Prof. Burstall.

A critical comparison of the four-cycle and two-cycle engines is made, and the author comes to the conclusion that the four-cycle engine can only be considered "as a makeshift until an efficient and trustworthy two-cycle machine appears on the market"; he also discusses the question of compounding, and states that "it will remain without promise in gas-engine construction." The design of the various parts of gas-engines is gone into in the very fullest manner, and numerical examples are worked out in great detail; some interesting photographs are given showing the effect of weak frame construction and of imperfectly designed crank-shafts. A great deal of information respecting the type of material to use for the various parts of gas-engines is given, and in the matter of connecting-rods, while stating that soft steel is usually employed, the author says that the use of cast-steel is on the increase. The design of inlet and exhaust valves is given in great detail, and the various methods of water-cooling are described. Amongst the latter is an interesting arrangement designed by Pawlikowsky, in which the water-pipe is stationary and the water is led through the valve spindle, which is large enough to be bored out to admit the inlet pipe with a space around it through which the hot water can find its way back. The design of fly-wheels is discussed at considerable length, and numerous tangential effort diagrams for various types and designs of gas-engines are given, and the results of various calculations are embodied in a series of curves by which the required weight of rim of a fly-wheel can be ascertained under various conditions occurring in practice.

In respect of gas-producers, the author appears to favour the suction-producer in preference to pressure-producers, and says that the former have almost entirely displaced the older form. This statement is made without any reference to the size of the engine to be supplied with gas, and cannot, therefore, be regarded as conforming with present practice, in which the large gas-engines are supplied with gas from pressure-producers. Numerous designs of suction-producers are described, none of them larger than 600 b.h.p., and there is only a passing reference to pressure-producers.

At the beginning of part iii., much detailed information is given in respect of the capital cost and cost of erection and running of gas-engine installations, and all this information is collected together in a tabular form, giving all the various heads of expenditure for engines varying from 5 b.h.p. to 200 b.h.p., both when using illuminating gas and suction gas. It is interesting to note that the total operating costs for 5 b.h.p. are the same for both kinds of gas, but after that the suction gas is much the cheaper. At 200 b.h.p. the suction gas is nearly one-third the cheaper.

There are some very interesting folding plates showing the pipe-work necessary for various designs of gas-engines; the various kinds of pipes—gas, water, and exhaust—are shown in different colours, and thus the matter is made very clear.

Nearly ninety pages of the book are devoted to descriptions of American gas-engines, made by Westinghouse, Allis Chalmers, the Snow Engine, and many others. Many of the drawings are dimensioned, and the results of numerous tests are given.

In part iv. various fuels available for producing gas are described, and there is an extensive table on American coals, giving for each full analysis and the calorific value per pound; there is also information with reference to blast-furnace gases and coke-oven gas, also with regard to various oils, alcohol, &c. There is an important table giving the explosive range of various gases. The remainder of the book consists of the theory of the gas-engine and producers, and in the appendix the fullest particulars are given of the methods of testing gas-engines prescribed by the American Society of Mechanical Engineers and by the German Society of Engineers. This information is of great importance, especially as at the present moment there is nothing of the kind issued by any society of British engineers in connection with gas- or internal-combustion engines.

STRUCTURE AND DISTRIBUTION OF ORE DEPOSITS.

Lehre von den Erzlagerstätten. By Dr. R. Beck. Dritte Auflage. Band i., pp. xii+540+1 map; Band ii., pp. x+542. (Berlin: Gebrüder Borntraeger, 1909.) Price, two vols., 32 marks.

PROF. BECK'S "Lehre von den Erzlagerstätten" is one of those works which disarm criticism. The predominant feeling in the mind of the geologist when using it must be of gratitude to its author for this comprehensive and up-to-date account of the structure and distribution of ore deposits. The previous edition was published in 1903, and an American version, translated and edited by Weed, was issued in 1905. The new edition has been so much enlarged that it now appears as two volumes, each almost equal in size to the original.

The book follows the same general lines as the previous editions, but there are many important changes which indicate the trend of current opinion as to ore classification. Prof. Beck divides ores into two primary divisions, the epigenetic and syngenetic, those formed respectively later and simultaneous with the rocks in which they occur. These divisions are, however, practically abandoned in the work. The author divides ores into eight groups, in which the first, seventh, and eighth in order of treatment are mostly syngenetic; the intermediate groups are epigenetic, but include some ores which are admittedly syngenetic. The term syngenetic, though it appears in the introduction, is not much used, but epigenetic recurs frequently. That term is not altogether satisfactory, as most of the epigenetic ores are subterranean, and some of them are very deep seated in origin. Hence epigenetic ores are not epigene, but hypogene, to use two old and well-established geological terms.

The ores first treated are those attributed to direct segregation in molten rocks. They are the truly igneous ores. Prof. Beck recognises fourteen types, of which all but four were included in the previous edition. The only new type of oxide ores amongst these is that of magnetite in granite, described by Vogt, from the Lofoten Islands. Prof. Beck, however, in a note added to the proofs, remarks that Sjögren's recent paper confirms his own opinion that these granitic ores are due to contact metamorphism, and not segregation. The whole chapter on magmatic segregation shows that less importance is attached now than formerly to this process of ore formation. The author includes the nickel ores of Sudbury in this chapter, but recognises that they are mainly due to secondary processes. He also quotes Loewinsen Lessing's interesting work on the famous iron ores of the Urals, which are thus shown to be contact deposits and not segregations, as has been usually maintained; and as Prof. Beck points out, the great Lapland ores, which have also been claimed as igneous segregations, must be regarded as of the same origin as those of the Urals.

The group of ores which came second in the previous edition, included those deposited by direct sedimentation and precipitation. These aqueous ores were placed next after the igneous, because both groups are syngenetic. Description of the sedimentary ores is now postponed till near the end of the book, and the ores due to contact metamorphism take their place. This significant change is a great improvement, as many of the ores now assigned to igneous segregation will probably be found to be contact deposits. The bulk of the work is occupied with a description of the epigenetic ores, which include ordinary mineral veins and certain ores in stratified rocks, due to the same process as ore veins. The author includes here the banket of the Transvaal. He gives an excellent judicial summary of the arguments in favour of the rival theories as to the origin of that ore without here expressing any very definite preference. He obviously still favours the infiltration theory which he has elsewhere supported. In reply to the suggestion that much of the pyrites in the banket is altered "black sand," he asks what has become of the ilmenite that is usually associated with magnetite in such deposits. There is, however, plenty of titanic oxide in the banket which has probably been derived from decomposed ilmenite. Little stress is laid on the old arguments in support of the infiltration theory, and according to Prof. Beck the weightiest argument in its favour is the dependence of the gold contents of the banket on its dip. This may be questioned as a matter of fact, and it is at any rate an indefinite and unconvincing argument. The author includes the West African banket as also epigenetic, though he accepts its gold as alluvial in origin. It is not surprising to find this ore described immediately after that of the Rand, for those who know both deposits regard them as of the same origin, though the iron ores of the West African banket still mainly occur as magnetite. It seems difficult to regard the West African banket as a modified placer, and the South African as an ore due to infiltration.

The feature in Prof. Beck's arrangement of ores which seems most improbable is his reference of so many metalliferous sandstones and conglomerates to the epigenetic group. He includes there, for example, the Katanga quartzite, which contains small nuggets of gold and platinum. In fact, the only pre-Cainozoic alluvial gold deposits which are included in the chapter on detrital ores are those of the Cambrian of the Black Hills of Dakota, a few occurrences of no economic value in the Carboniferous rocks of Australia, Nova Scotia, and France, and in the Mesozoic of California, New Zealand, and Saxony. Alluvial gold must have been deposited in pre-Cainozoic times, but whenever ancient gravels are of much economic value their gold is attributed to infiltration. While in some cases Prof. Beck may be disposed to underrate the extent of ancient alluvial ores, he includes the tin deposits of Mt. Bischoff in Tasmania as alluvial, having apparently overlooked a short note upon that mine, explaining its tin-bearing sands as decomposed gossan in which a pseudo-stratification has been produced by the settling of the decaying rock.

Prof. Beck's work shows remarkably thorough acquaintance with recent literature on economic geology, and his statement of rival hypotheses is always given with scrupulous fairness. This greatly enlarged edition will become even more indispensable as a work of reference than its predecessors, and is worthy of the high traditions of the Freiburg Mining School.

J. W. G.

THE SUGAR-CANE AND ITS PRODUCTS.

The Manufacture of Cane Sugar. By Llewellyn Jones and F. I. Scard. Pp. xix + 454. (London: Edward Stanford, 1909.) Price 12s. 6d. net.

A NOTEWORTHY feature in tropical agriculture is the new lease of life taken recently by the cane-sugar industry. A few years ago it appeared not improbable, to say the least, that the sugar-cane was doomed to be forced into a position permanently inferior to that of the beet as a source of the world's supply of sugar. Originally possessed of a practical monopoly, the cane had lost so much ground that in the opening years of this century the beet supplied about two-thirds of the sugar which came into the world's markets. It is true that a great deal of cane-sugar is consumed in countries where it is produced and escapes record; so far as the world's commerce was concerned beet was the chief contributor. Within, however, the last five years, the output of cane-sugar has markedly increased, whilst that of beet has slightly diminished, and a little more than one-half of the sugar of commerce is now derived from the sugar-cane.

This period of activity in the industry has been marked by the issue of various books. One of the most useful is that now under review. The authors have wide practical experience of sugar-making, as engineer and chemist respectively; with the aid of numerous illustrations they present the results of their experience in an exceedingly simple manner.

A marked feature of the book is the explanation of practical matters in clear, non-technical language, and a reader with no special engineering knowledge and no experience of sugar-making should easily understand and be able to follow the whole chain of processes by which the ripe sugar-cane is converted into sugar and the various by-products.

No pretence is made to deal with cultivation. There is in chapter i. an illustrated account of the structure of the cane (the references on pp. 3 and 4 to the figures are not accurate), and notes on the chief varieties, diseases, chemical composition, &c.; but the subject-matter proper of the book opens with crushing, in the next chapter. Whilst the novice will read this easily, the mature planter will find much worthy of consideration, as, for example, in the excellent presentment of the *pros* and *cons* of improved methods of extraction. In dealing with the boiling or concentration, the evolution of the modern vacuum pan, capable of yielding 40 tons of sugar at a single operation, is traced from the simple open pan still in use in many parts of the world. Equally here, whether dealing with the simplest or the most complicated processes, the authors have contrived to preserve a conspicuously clear and direct style.

The volume is one which should be of great value to non-technical readers who wish to obtain information regarding one of the best-organised and most scientific of the great industries of the tropics. The practical sugar-maker will appreciate the exposition of the theory underlying various processes, the clear description of methods, and also doubtless derive assistance from the useful practical hints with which the book abounds.

W. G. F.

THE PSYCHOLOGY OF THE WILL.

Ueber den Willensakt und das Temperament: eine experimentelle Untersuchung. By Prof. Narziss Ach. Pp. xii + 324. (Leipzig: Quelle and Meyer, 1910.) Price 6.50 marks.

TO the layman an act of volition is one of those obvious things, such as gravity or growth, which present no difficulty and suggest no problem. Their mechanism is so smooth in its working that the mind never dreams of the presence of a mystery. Add to which the fact that it is impossible to go through the process of willing and at the same time to contemplate and observe the process. Yet at least one difficulty has been noted by the crudest philosophy for ages past—the power of choice, the so-called freedom of the will. This, however, as Prof. Ach observes, is a function not of the will but of reason. He also well insists that the judgment "I can do that which I will," has two distinct meanings, which have often been confused. The one meaning is positive, "I have the capacity to carry out what I will"; "can" being equivalent to *posse, pouvoir, vermögen.* The other is negative, "It is my wish to do what I will." Psychologists are only too well aware that "In no department of the science of mind does there prevail greater confusion and uncertainty than in that of Volition."

In the present volume Prof. Ach continues the records and results of his prolonged investigation into will-psychology; the former instalment being his 1905 treatise, "Über die Willenstätigkeit und das Denken." An account is given of the experimental method employed, which is largely a combination of those of Ebbinghaus and G. E. Müller. He employed eighteen subjects who were practised on reproduction of syllables, rhymes, and the like components of methods well known in laboratories.

As his main result, the author claims to have shown that the act of will is a specific psychic experience. The positive phenomenal characteristics of a primary volition are (1) the perceptive moment—sensations of tension; (2) the objective moment—ideas of reference and end, purpose, and means; (3) the actual moment—the acoustic—kinesthetic, "I will actually"; (4) conditional moment—consciousness of effort. Of these the chief is (3), and he explains why it has hitherto been so often ignored. None of these moments, of course, is independent; they are sides of one fact. Great spectacular results are not expected from the minute laboriousness of experiments like these; but they are latent, and, as Weber's Law, for instance, has done, will emerge in due time. Yet light is thrown on a score of "little problems." Not the least interesting, and the most detailed, discussion is that on weakness of will. A close study of this chapter in connection with the tabulated results of the investigation which occupy the first half of the volume would be a fruitful piece of book-work for the learner. Prof. Ach rightly censures the use of such examples, as the famous "How we get up in the morning" of Prof. James, for illustrating the mechanism of volition. Trained or habituated will is precisely that form of the process which is least original. Here, by the way, in the relation between habit and will—a relation of practical, no less than theoretical, importance—is a fruitful field for investigation. Another fruitful area is the connection between will and temperament. Prof. Ach ends his volume with a few suggestive pages on this subject.

The material supplied by the author's investigation is probably rich enough to yield further results if re-studied. So far, the author has been led towards a reaction against the prevailing view of will-processes. Without doubt this and similar work is clearing the ground for a new psychology, both of feeling and of will.

A BOOK OF CHARACTERISTIC FOSSILS.

Leitfossilien: ein Hilfsbuch zum Bestimmen von Versteinerungen bei geologischen Arbeiten in der Sammlung und im Felde. Lief. I.: Kambrium und Silur. By Prof. Georg Gürich. Pp. 95. (Berlin: Gebrüder Borntraeger, 1908.)

PROF. GEORG GÜRICH has prepared a well-illustrated handbook of characteristic fossils which is now in course of publication in eight parts. It is intended for elementary students and amateurs who are occupied with geological work and desire an exact knowledge of those fossils which are of special value in determining the relative ages of rock-formations. It is not a treatise on common fossils, and those who seek in it an account of so familiar a brachiopod as *Atrypa reticularis*, for example, will be disappointed; but it deals with those species and genera which, whether common or not, happen to be restricted in their geological range, and are thus of service as unerring time-markers. The fossils of each successive period are taken in order, beginning with the earliest; and the twenty-eight plates included in the first part of the book are devoted to those of the Cambrian and Silurian formations. The figures are not original, but judiciously selected from standard works, and all are beautifully reproduced by a half-tone process. The accompanying text consists chiefly of brief definitions of the various groups, families, genera, and species, in systematic order under each geological formation. There are also useful synoptical tables, both of the formations themselves in different parts of the world and of the fossil species which are characteristic of each special stage. Occasional text-figures are added to explain structural features and the more important anatomical terms employed. In the first part, the figures illustrating the structure of trilobites and graptolites are especially good.

Dr. Gürich does not recognise an Ordovician system, but classifies the formations from the Tremadoc to the Caradoc inclusive as Lower Silurian. His work is also unusual among stratigraphical handbooks in paying special attention to fossil plants and vertebrates when they can reasonably be claimed as of value. His first reference to vertebrates, however, in the Upper Silurian is unfortunate, for it takes no account of Dr. Traquair's important discoveries, and repeats an old error in supposing that the shagreen named Thelodus belongs to the same fish as the fin-spines named Onchus. In view of present rapid progress and specialisation this oversight is not surprising, and Dr. Gürich is to be congratulated on having made an excellent beginning of a useful and trustworthy student's manual.

METALLOGRAPHY.

Metallographie: Ein ausführliches Lehr- und Handbuch der Konstitution, und der physikalischen, chemischen und technischen Eigenschaften der Metalle und metallischen Legierungen. Erster Band, Die Konstitution, Hefts. i. and ii. By Dr. W. Guertler. (Berlin: Gebrüder Borntraeger, 1909.)

THE number of investigations in metallography published up to 1902 amounted to about one thousand, but to-day reaches three times that number. This fact alone makes the appearance of a complete text-book on the subject most welcome.

The work is appearing in parts, the first two of which consist each of eighty imperial octavo pages, and it is expected that seven or eight more similar instalments will complete the first volume, which is devoted to the constitution of metallic alloys. A second volume, dealing with the physical and chemical properties of the alloys and with their technical applications is to follow.

The subject is to be treated from the technical as well as from the theoretical standpoint, and is to be made intelligible to a beginner without forfeiting its character of a complete text-book and work of reference.

Part i., after a short history of the development of metallography, deals with the "nature" of metallic alloys, the application of the phase-rule to the consideration of the various types of freezing of binary alloys, and also with solid solutions and chemical compounds of two metals. The remaining fourteen pages of the first part and half of part ii. deal with the "Zustandsdiagramme" of all the possible binary alloys of the metals manganese, iron, cobalt, nickel, copper, silver, gold, palladium, and the metals of the platinum-group. The second half of part ii. is devoted to internal kinetics, embracing such subjects as crystal growth and transformation, diffusion in metals, &c.

Whether all the objects aimed at will be achieved by the author cannot be predicted from a perusal of the first two instalments, but it may be safely asserted that a very promising beginning has been made on what can truly be described as a colossal task. The subjects already discussed are treated clearly and in a masterly style, and the arrangement (which is a matter of great importance in metallography) is excellent. The work will constitute the only complete text-book on the subject, and will undoubtedly rank as a classic.

EXERCISES IN PHYSICAL GEOGRAPHY.

(1) *Manual of Physical Geography.* By Dr. F. V. Emerson. Pp. xvii+291. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1909.) Price 6s. net.

(2) *A Laboratory Manual of Physical Geography.* By Prof. R. S. Tarr and O. D. von Engeln. Pp. xvii+362. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 6s.

(1) THE purpose of the first of these books would have been made clearer if it had been entitled "Manual of Exercises in Physical Geography," for the 273 pages of which the body of the book is composed are almost entirely made up of questions and directions to students. The manual is divided into eighteen chapters, the first on the earth as a planet, the next four on climate and others on common minerals and rocks, on the contour map, on weathering streams and stream valleys (a long chapter, in which prominence is given to the cycle of erosion and all that that involves), on land forms (three chapters), on glaciation, lakes, the ocean, shore lines and forms, harbours, and soils, the final chapter being devoted to studies of typical areas.

Now there can be no doubt that teachers of the subject could hardly fail to get many a useful hint from an examination of this volume, but, on the other hand, it is scarcely conceivable that any teacher, at least in this country, would ever try to make use of it as it stands. For this there are several reasons. In the first place, the manual is not self-explanatory. Among the questions of which the bulk of the book is made up, some are childishly simple (though, it may be admitted, not without justification in the author's way of presenting his subject), others assume that the teacher is well versed in his subject, and has either already given the necessary explanations to his students or is prepared to do so when the student is required to answer them. Some of the questions are, unfortunately, confusing and misleading. Moreover, the teacher who is sufficiently well versed in his subject to be able to use the book will be too independent to submit his mind slavishly to the lead of another in presenting the subject to his class. The author says that the exercises have for the most part grown out of his class-room experiences, and it may fit in very well with the rest of the author's teaching of the subject, but it is not likely to fit in with the method of anyone else. Finally, the exercises set in this volume must involve the consumption of a great deal of time, and the doubt cannot but suggest itself whether the result in trained intelligence will be at all proportionate to the amount of time and labour expended.

(2) The work by Prof. Tarr and Mr. von Engeln is similar in design to that of Dr. Emerson, and its distinguishing features may be best given by the following extracts from the preface:—

"The feature which will first attract attention is the leaving of space after each question for the student to write the answer. This serves a double purpose. It ensures the student's following the argument of the outline and the appreciation of every point by personal observation and deduction . . .

"Another feature which we feel sure will meet with general approval is the insertion of all maps, figures, diagrams, and tables at the exact place where they are needed." (These maps, &c., it should be stated, are all likely to be very useful.)

The authors claim, moreover, as the most marked pedagogical departure in their manual, their orderly method of presenting the physiography of the lands. We may note further a feature which is likely to attract attention even before that just mentioned. The loose-leaf construction of the manual makes it a very simple matter for the teacher to change the order or introduce other work. The pages are all perforated to allow of their being detached, and pierced with two large holes to allow of their being refixed in another arrangement, this being done because

"the authors feel that teachers who are progressive, capable, and enthusiastic over the subject should be given the greatest latitude in carrying out their own ideas."

Finally, with reference to the present reviewer's remark at the end of his notice of Dr. Emerson's work, it is only fair to say that the methods of this manual,

"are not to be regarded as experiments. The senior author has had over fifteen years' experience and the junior author four in the laboratory teaching of physical geography."

They tell us, too, that the results in their own classes have been very gratifying, and that the students pursue the work with keen interest. The reviewer, therefore, would have his "doubt" taken as no more than a doubt, and he is sure that such systematic efforts towards the improvement of teaching are entitled to sympathetic consideration. G. G. C.

OUR BOOK SHELF.

The House-fly, Musca domestica, Linnaeus: a Study of its Structure, Development, Bionomics, and Economy. By Dr. C. Gordon Hewitt. Pp. xiv+196+10 plates. (Manchester: University Press, 1910.) Price 20s. net.

IN this volume the student will find, in a convenient form, the three valuable papers on the common house-fly which Dr. Hewitt contributed to the Quarterly *Journal of Microscopical Science* in 1907, 1908, and 1909. In the first the author deals with the anatomy of the fly, in the second with the habits, development, and anatomy of the larva, and in the third with the bionomics, allies, and parasites of the insect, and its relations with human disease. The volume opens with a brief introduction, and concludes with three short appendices, comprising some facts ascertained since the issue of the original papers.

The first part is noteworthy for a full and original description of the tracheal system of the fly. In his account of the proboscis, Dr. Hewitt agrees with most recent students of the jaws of Diptera in regarding the palps as maxillary and the sucking organ as labial; in this, as in some other interpretations, he differs from the opinions expressed in Lowne's well-known work on the blow-fly. In the second part, especial attention has been paid to the muscular system of the larva, which is described and figured in detail. The rate of development is very rapid, and there are only three larval instars. While horse-dung is the most usual food of the house-fly maggot, the female fly may lay her eggs in a wide variety of unclean and decaying animal and vegetable substances, in any of which the larvæ can be successfully reared. Hence it follows that house-flies must frequently carry disease germs which they have abundant opportunity of introducing into human food, and the name "typhoid fly," which some American entomologists are trying to affix to *Musca domestica*, might be justified from certain unpleasant but instructive records which Dr. Hewitt quotes of the proximity of typhoid-infected privies to dairies.

The hygienic bearing of the insect's relations with mankind is seriously and temperately discussed by the author, who pleads for such protection or destruction of substances in which the eggs are laid as may effectually reduce the numbers of the species, and for the covering of food substances, like milk and sugar, on which the flies habitually alight. The book affords an excellent illustration of the amount of original and useful work that may be done on the commonest and best known of animals. G. H. C.

The Science of Happiness. By Dr. H. S. Williams. Pp. vi+350. (London and New York: Harper and Brothers, n.d.) Price 7s. 6d. net.

THIS might well be given the still wider title of "The Art of Living," for it concerns itself with human activity of all kinds. It is a pleasantly written series of papers on such topics as how to eat, how to sleep, how to think, and even how to die, and, though a trifle diffuse and flat revealing the fluent writer with not much that is original to say—it contains much wisdom of an everyday kind, and many apt quotations to spice up the text.

Dr. Williams is not a food faddist, and almost his only criticism on this head is that most of us eat too much. But he would not cut down the number of meals to anything below three per day, for he believes that, on the whole, experience endorses that number. He condemns alcohol, tobacco, and—less vehemently—tea and coffee. Exercise ought to be gentle and regular, and we may sleep eight hours per night if we want to, but must not doze off for another forty winks after a good night's rest. An interesting point is that Dr. Williams believes the stunted growth of the Latin races to be the result of the habit of wine-drinking.

As to the mind, the author counsels the strenuous life, as befits a good American, and stimulative examples are quoted. Mezzofanti learned fifty-seven languages. Pliny (the elder) never left off studying except when asleep or in his bath, and after the latter he had a book read to him while he was being rubbed dry. As to opinions, religious or political, think them out for yourself. Ask yourself why you believe this or that. Do not be content to inherit opinion as you inherit the colour of hair or eyes. Work your way to rational conviction.

It is all very chatty, pleasant and sensible; and we do not mean any cheap satire when we say that the book is beautifully bound and produced.

Rinaldo's Polygeneric Theory: a Treatise on the Beginning and End of Life. By Joel Rinaldo. Pp. 123. (New York: 206 West 41st Street.)

To Mr. Rinaldo, "evolution" is like the red rag to the proverbial bull; and, like most violently biased people, he has not given sufficient study to the object of his attack. For example, in arguing for the special creation of man, he says it is "ridiculous" to explain by migration the similarities found in widely separated countries. But evidently he does not realise the length of duration in past time of a being justifiably called man, for, even if we assume that duration to go back no further than the Miocene period, there is ample scope for almost unlimited migration (*e.g.* there was land at this period probably across the North Atlantic); and, indeed, human migration is not essential to the theory; migration of lower animal forms, in still more remote periods, would do nearly as well. Mr. Rinaldo seems to think that evolution implies an Adam and Eve from whom all mankind are descended. As a matter of fact, the theory of biological evolution would not be invalidated if it were proved that man appeared on various parts of the earth's surface at the same time, for these primitive human beings would be descended from other and less complex forms of life—animals of anthropoid but not yet human structure.

Mr. Rinaldo, though an amateur, is well read in some directions, but he has not studied Darwin and Huxley thoroughly, not to mention more recent biologists, and his judgment is warped, like Carlyle's, by mistaken notions of the "monkey damnification of man." The wish being father to the thought, he asserts that "Darwinism is already dead." If he will read a book reviewed in NATURE, July 14, he will see that one of our greatest authorities—Sir E. Ray Lankester—thinks it is still very much alive. But we hardly expect that he will be converted.

Letters from High Latitudes, being Some Account of a Voyage in 1856 in the Schooner-Yacht "Foam" to Iceland, Jan Mayen, and Spitzbergen. By Lord Dufferin. With an introduction by Dr. R. W. Macan. Pp. xxxvi+261. (London: Henry Frowde, Oxford University Press, 1910.) Price 1s. net.

THESE entertaining letters were first published in 1856, and are so well known that any words of praise are unnecessary. The master of University College, Oxford, in his introduction, says:—"The letters are, or ought to be, a *World's Classic*; Mr. Frowde's happy enterprise has made that concept a reality." It may be noted that the volume is the hundred and fifty-eighth to be added to the series of "The World's Classics."

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

Wiltshireite: a New Mineral.

THE dolomite quarry near Binn (Valais) affords such a large variety of grey sulpharsenites, mainly of lead and copper, that a new one is received with much hesitation; but a crystal recently obtained at Binn gives results which leave little doubt as to its independent character. The specimen consists of a number of very small crystals aggregated together in parallel orientations, and a single well-defined image is obtained from several minute end-facets.

The crystal belongs to the oblique system. The zone of pinakoids consists of smooth faces, 201, 302, 101, 001, and $\bar{1}01$, which give good images. Two other important zones are placed symmetrically on opposite sides of the symmetry-plane; they show the forms 522, 211, 111, 122, 011, $\bar{1}11$, and others. The faces, placed vertically, are striated parallel to their zone-axis, and give very imperfect images, save when they are obtained across the zone; the forms are 100, 310, 320, 010, and some others. The elements adopted are:—$100:001=79° 16'$; $100:101=48° 47\frac{1}{3}'$; and $011:001=46° 25\frac{3}{4}'$.

I propose for it the name wiltshireite, after the late Prof. Wiltshire, who was a most generous benefactor to the Cambridge museums of mineralogy and of geology.

Cambridge, August 13. W. J. LEWIS.

The Nomenclature of Radioactivity.

A FEW years ago I wrote to NATURE (vol. lxxvi., p. 638) protesting against the proposal of Prof. Boltwood to call the member of the uranium-radium series, which he had just discovered, by the fanciful name of "ionium" instead of by a name based upon the system of nomenclature started by Sir William Crookes and extended by Prof. Rutherford. Prof. Rutherford replied (p. 661) that the time had not yet come for the establishment of a definite system of nomenclature, but that he hoped that some day "physicists and chemists would meet together to revise the whole system." After such a decision from the first authority on the subject I could do nothing but collapse; but there are three reasons why the present moment seems to me suitable for a renewal of vitality.

First, Prof. Rutherford said that he thought it undesirable (I did not agree with him) to fix a method of naming until nearly all the products to be named appeared to have been discovered. I believe it is about two years since the last new member was added to any of the series previously known. Second, there is at hand an admirable opportunity for the meeting together of physicists and chemists which he suggests—the congress at Brussels next month. Third, it appears to me that reform has been made urgent by a particularly disastrous attempt at unsystematic nomenclature. In a recent number of the *Comptes rendus* Sir William Ramsay, after determining more certainly the molecular weight of radium emanation by a beautiful experiment, and finding the result to confirm his suspicion that this substance belongs to the group of inactive gases, proposes that it should henceforward be called "niton." (By a curious oversight, he suggests that the symbol should be "Ni," which is, of course, already appropriated.)

The purpose of a systematic nomenclature is to express relations between the objects named. So long as elements were regarded as wholly independent objects, the practice of naming them, as if they were dogs, on purely sentimental grounds was more or less justifiable, for there were no relations between them to express. As soon as the first general relation between the elements, the periodic "law," was discovered, a systematic nomenclature was desirable, and some feeble steps towards it were taken. With the discovery of the radio-active elements, the whole importance of which lies in their relations to each other, a complete system becomes a necessity.

Let me take an analogy. If Sir William Ramsay takes a house in the country, where buildings are scattered at random, nobody will care what he calls it. But if he takes a house in the street of a city and proposes to replace the number on the door by "Bellevue," or "Glencoe," or "Chatsworth," or any other of the names dear to lodging-house proprietors, he will meet with scant sympathy from the postal and municipal authorities. His case will not be much better if, like Prof. Boltwood, he builds a house where there was none before, instead of merely improving one that existed already.

The only defence Sir William Ramsay can offer for his proposal is that it is in accordance with chemical, if not with radio-active, nomenclature. If this were true, the question would arise whether the chemical or the radio-active properties of the element were more important; I cannot conceive that anyone would doubt the superior interest of the latter. But it is not true. The name which he proposes, interpreted according to chemical usage, suggests (1) that the substance is non-metallic, and (2) that it is not an inactive gas. It suggests (1) because it ends in -on; it suggests (2) because the root is Latin. The only names of elements ending in -on which are not those of inactive gases—carbon, boron, silicon—all have Latin roots; all the names of inactive gases have Greek roots. By the choice of a Latin name, radium emanation is placed in the former and not in the latter group. Surely, also, when in the names of the argon group we have a rare instance of terms, invented recently, which are linguistically correct, it is a crime to spoil the group by the intrusion of one of those philological barbarities the toleration of which does so little credit to the general intelligence of men of science. I do not know whether Sir William Ramsay has been troubled by the fact that the most familiar Greek word for "bright," ἀργός, is clearly inadmissible, but I am sure that any classical scholar could provide a suitable synonym.

I am not going to propose a system of radio-active nomenclature, for, if I succeeded in attracting any attention, people would then confine themselves to abusing my system, and not to considering whether any system is desirable. But I should like to point out the faults of the present method, and direct attention to two possibilities for a new method.

The faults of the old system are (1) that it does not permit of interpolation; (2) that it separates systems which are now known to be connected, such as uranium and radium; (3) that it lays far too much stress on the accidental fact that some of the elements are gases at ordinary temperatures; and (4) that it is anomalous in making X precede A.

The first possibility for a new system is to order the elements by numbers, and not by letters. Such a system admits of indefinite interpolation; between 1 and 2 there can be interpolated, first, the 9 terms 1·1–1·9, then the 90 terms 1·01–1·99, and so on. The second possibility lies in the fact that the rays emitted by the elements are distinguished by single letters, so that the radiation from an element might be expressed by the terminations -o (for no rays), -a (for α rays), -ob (for β and γ rays only), -ab for all kinds of rays. Of course, the form "radiob" would have to be avoided on account of prior rights (NATURE, vol. lxxii., p. 79), and modification would be needed if the additional termination -g were rendered necessary by a discovery that β and γ rays could occur separately.

A scientific system of names need not displace completely such well-known terms as "radium" any more than the appropriate name, according to the excellent system of organic chemistry, has displaced that of (say) "indigo." But I maintain strongly that every radio-active element ought to have a name discoverable from its properties, and a name from which, conversely, its properties may be discovered. Such a plan would not help greatly those who are so accustomed to radio-active work that the association of a fanciful name with definite properties is intuitive, but it would be an inestimable boon to those who now, when they hear of "mesothorium," have to trust an imperfect memory or else search laboriously through original memoirs.

Leeds, August 2. NORMAN R. CAMPBELL.

Perseid Meteoric Shower, 1910.

THE only night really good for witnessing the Perseid shower near its maximum this year was August 10, when the clear state of the sky afforded every facility for securing observations.

I began watching at 9h. p.m., and up to 11h. 45m. p.m. there were fifty-two meteors, so that the horary rate was nearly twenty, of which about three-fourths were Perseids. The finest specimen appeared at 10h. 6m.; it had a long and slowish flight from $328^\circ + 37^\circ$ to $301^\circ + 8^\circ$, and left a bright streak just above the small stars of Delphinus for fifteen seconds. The meteor itself was much more luminous than Venus, and was also observed by Mr. T. K. Jenkins at Nantyglo. From a comparison of the recorded paths, I find the height 75 to 48 miles over Wiltshire, and the end point near Blandford, Dorset.

The velocity was decidedly slower than that of the ordinary Perseid, its observed speed being 27 miles per second.

I saw brilliant Perseids also at 11.34 and 11.46, the former shortening towards α Andromedæ and the latter just under Polaris, and at $11.34\frac{1}{2}$ there was a beautiful slow-moving Draconid falling from $303\frac{1}{2}^\circ + 33^\circ$ to $311^\circ + 19\frac{1}{2}^\circ$. Its pear-shaped nucleus threw off a tail of yellow sparks as it sailed down the sky.

I think the display of August 10 was better than it was last year, and gave promise of a pretty abundant shower on August 11 and 12, but I cannot speak as to its actual character, the firmament being cloudy on those dates at Bristol.

There were a few breaks in the clouds on August 12, and I happened to notice a fine meteor at 11h. 49m. shooting upwards from $355^\circ + 40^\circ$ to $338\frac{1}{2}^\circ + 50^\circ$. It was as bright as Jupiter at least, and left a train, but it quickly disappeared. The meteor was not a Perseid, but apparently belonged to a shower with radiant lying eastwards of α Andromedæ, or at $9^\circ + 27^\circ$. The meteor was also seen by Mr. G. Powell at Aberdare, and I find its height 89 to 53 miles. It was nearly over Bath at end point. Velocity 40 miles per second, and certainly more rapid than the Perseid alluded to above, though it should have been the swifter of the pair.

Several observers have written me describing the Perseid shower as fairly rich on August 10, though the maximum was not due until the morning of, or night following, August 12. Some large meteors were also recorded on August 5, which was a very clear night, and the Perseid display was in pretty strong evidence even at that early date.

W. F. DENNING.

Brilliant Meteor of July 31.

AN exceedingly beautiful meteor, one of the finest I have seen, was observed from this vessel, while at sea, on the night of July 31. The time of observation was 10h. 0m. ship's apparent time, or 13h. 0m. G.M.T., the position of the ship at the time of observation being latitude 43·34° N., longitude 43·37 W. The duration of the flight was between fifteen and twenty seconds, and the meteor was much more brilliant than Venus. It pursued an almost horizontal course, about 8° above the horizon, passing below the constellations Ursa Major, Perseus, and Aries, in all traversing an arc of about 135°.

At first the meteor appeared as a brilliant steel-blue ball, with a short tail of the same colour. It disappeared at a point about 90° from its first position, reappearing almost immediately, and exploding and dividing into three or four parts, with a luminous tail some 3° in length, and of a vivid red and blue colour. Its motion was slow, and it conveyed to all who witnessed it, officers and passengers alike, the impression of being at no great distance from the ship when it exploded.

The night was very fine; and the chief officer, who was on the bridge at the time, reports that when it disappeared it left a small black cloud in the sky. At the time of seeing this meteor we were in wireless communication with the U.S.N. *Texas*, and it is hoped that other observations may be forthcoming from other vessels at sea. A. L. CORTIE.

On Board S.S. *Cymric*, August 3.

ON COLOUR VISION AT THE ENDS OF THE SPECTRUM.

IT is half a century since Maxwell [1] investigated the chromatic relations of the spectral colours and exhibited the results on Newton's diagram. The curve "forms two sides of a triangle with doubtful fragments of the third side. Now, if three colours in Newton's diagram lie in a straight line, the middle one is a compound of the two others. Hence all the colours of the spectrum may be compounded of those which lie at the angles of this triangle. These correspond to the following—scarlet, wave-length (in Fraunhofer's measure), 2328; green, wave-length, 1914; blue, wave-length, 1717. All the other colours of the spectrum may be produced by combinations of these; and since all natural colours are compounded of the colours of the spectrum, they may be compounded of these three primary colours. I [Maxwell] have strong reason to believe that these are the three primary colours corresponding to three modes of sensation in the organ of vision, on which the whole system of colour, as seen by the normal eye, depends."

Later observations, such as those of König and Dieterici,[2] have in the main confirmed Maxwell's conclusions. The green corner is indeed more rounded off than he supposed. It is with regard to the "doubtful fragments of the third side" that I have something to say. According to Maxwell's results with both of his observers the extreme red deviates from the less extreme by a tendency towards blue. Neither my friends [3] nor I can perceive anything of this. When the extreme and the less extreme red are seen in juxtaposition in the colour-box, no difference whatever can be perceived after the brightnesses are adjusted to equality. I have not any precise measurements of wave-length, but the extreme red passed a cobalt glass while the less extreme was stopped. Observations at the ends of the spectrum are more difficult than elsewhere. Owing to deficiency of illumination at these parts there is more danger of false light finding access. To get satisfactory results I found it desirable to supplement the action of the prisms by placing red glass over the slits. It is probable that Maxwell was misled by some defect of this sort, since the differences he found would appear to lie outside the errors of observation. The German observers, it should be added, also found the colour constant at the red end.

At the other extreme the tendency of the violet towards red is, to my vision, not in the least doubtful. Some remarks made a few years ago by Dr. Burch, who speaks of violet in terms which I could not possibly use, were the occasion of a more particular examination. Although, so far as I remembered, I had never made the trial, I was confident that I should be able to match violet approximately with blue *plus* red, and full blue with violet *plus* green. And it seemed further that this must be the general estimation, as there is no widely spread protest against describing the upper extreme of the spectrum as "violet"—a name which would be quite inappropriate in the absence of an approach towards red.

1 Phil. Trans., 1860.
2 Helmholtz, "Phys. Optik," 2nd edition, p. 340.
3 Mr. Gerald Balfour included.

The light which the flower of that name sends to the eye undoubtedly includes red rays.

The apparatus employed is on the model of the first described in an early paper,[1] the only difference worth mentioning being that the side upon which the movable slits are disposed is made oblique, to meet the variation in focal length along the spectrum. By this means any desired mixture of spectrum colours can be exhibited in juxtaposition with any other. For example, the violet can be shown alongside the blue, and any addition can be made to either. A few trials in 1907 confirmed my anticipations, an approximate match being easily attained by addition of *red* to the blue or of *green* to the violet. The slits by which the light entered were protected with suitable coloured glasses, cobalt glass being used for the blue and violet slits. In this way, as already mentioned, the danger of false light is obviated. I do not affirm that the mixture of blue and red looked *exactly* the same as the violet. I thought that I could recognise the violet as being more saturated, but the difference, if real, was very small and certainly a mere fraction of the original difference between blue and violet. Needless to say, the blue chosen was a full blue, showing no approximation to green.

The point of greatest interest lies in the contrast between my observations and those of Mr. Gerald Balfour, who was with me at the time. Mr. G. Balfour is one of the three brothers whom I found in 1881 (*loc. cit.*) to make anomalous matches of mixtures of red and green with spectrum yellow. To effect the match they use much smaller amounts of red than is required by normal eyes. But their colour vision is as acute as usual, and the abnormality is quite distinct from what is called colour-blindness. To Mr. Balfour's vision the violet of the spectrum is *not* redder than the blue, and such addition of red to blue as I required to make the match gave, in his estimation, a "reddish purple." Curiously enough, Mr. Enock, who was my assistant at that time, bore similar testimony, no addition of red on either side improving the match, which was indeed nearly complete as it stood. It is probably not a coincidence that Mr. Enock is also abnormal in his red *plus* green = yellow match, coming perhaps about half-way between myself and the Balfours.

When a few months ago I commenced to write out an account of these observations, it occurred to me that it would sound strange if I described my own judgments as normal and those of two other male observers as abnormal, and I sought to confirm my own judgment by that of others, especially of women. As to this, there was no difficulty. I usually showed first the simple blue and violet with about equal illumination[2] and asked the observer to describe them. In nearly every case the names blue and violet were correctly given. Can you describe one as redder than the other? was the next question. In most cases the answer came, "the violet is the redder"; but in some others all I could get at this stage was a negative. When, however, the same addition of red light that I require was made to the blue, every female observer that I have tried agreed that now the difference had practically disappeared. I can say with confidence that in this matter my own vision is normal.

Lately I have had another opportunity of repeating the observation with Mr. G. Balfour. It is certain that he sees no colour difference at all between the blue and violet. When to the blue an addition of red (less than I require for a match) is made, he describes the mixture as a reddish-purple, strongly distinguished from the violet. Mr. A. J. Balfour also could see no difference between the blue and violet, but he seemed rather less sensitive to additions of red. A determination of wave-lengths gave for the (mean) violet 415 (above G), and for the blue 440. The red was rather extreme.

That ordinary normal vision is very approximately trichromic cannot be doubted; but a question may be raised as to the possible existence of a very subordinate fourth element of colour. Thus Dr. Burch's descriptions might suggest that in his vision the sensation of violet depended upon such a fourth element. I am speaking here of fundamental sensations, not of such judgments as make yellow appear a distinct sensation to normal eyes, although certainly resolvable into red and green. The only way to get a final answer to such questions is by making matches with superposed colours; but to this method some workers seem singularly averse. In my own case I am certain that there is no fourth element of colour practically operative.

The character of the three primary sensations in normal vision is another and a much more difficult question. Perhaps in recent years we have rather lost sight of the argument which weighed with Maxwell in the passage above quoted. The better to see its significance, let us suppose that the spectrum is *accurately* represented on Newton's diagram by two sides of a triangle, and inquire into the significance of this disposition. The only explanation which does not involve highly improbable coincidences seems to be that in each spectrum colour only two of the three elements are involved. If the third is involved at all, how comes it to be involved in such a way as to make the spectrum straight? And the fact that near the red end variation of wave-length entails no variation of colour, makes in the same direction. That the green corner is rounded off and that (if it be so) the sides are not quite straight, may diminish, but cannot destroy, the cogency of the argument, while the less precise character of the conclusion is not without advantages.

RAYLEIGH.

[1] NATURE, vol. xxv., p. 64, 1881; Sci. Papers, i., p. 541.

[2] This adjustment can be made by partially cutting off the light on the side required by means of strips of glass interposed. By varying the number (up to 5 or 6) or inclination, the proportion of light transmitted can be regulated. This procedure was found more convenient than altering the widths of the slits.

MORE ANTARCTIC NATURAL HISTORY.[1]

(1) THE fifth, probably the penultimate, volume of the natural history results of the voyage of the s.s. *Discovery* has followed its predecessors without loss of time, and it resembles them in quality and interest, reflecting great credit on all concerned. The first memoir, by Dr. H. W. Marett Tims, deals with the embryos of Weddell's seal. The author finds in the musculature some additional support for Mivart's suggestion of a lutrine origin for the Phocidæ, and he has discovered in a very early embryo what seems to be the vanishing point of a vestigial external ear. Prof. Herdman deals like an old hand with the small but interesting collection of tunicates, comprising twenty-two species, of which ten are new to science. None of them are very remarkable forms in any way, but they confirm the impression which other collections

E. Buschmann.)

have suggested, that "the ascidian fauna of the far south is characterised by the abundance and the large size of the individuals of a comparatively few species." In the present collection we have a number of gigantic forms, such as *Styela spectabilis*, of 18 cm.

Mr. T. V. Hodgson, who did so much hard work in collecting from under the ice-sheet, reports on the isopods, and has some very interesting discoveries to relate. Thus seven species, out of the total of twenty-five, have their eyes on enormous peduncles, which rather takes the edge off the "sessile-eyed" character of isopods! Striking also is the sexual dimorphism of one of the Arcturidæ, *Antarcturus franklini*, the male and female of which appear on one of the plates (remarkably fine pieces of work) as two species, and not very like one another either. "It was only when all the specimens of both sexes, or as it was then thought to be, both species, came to be overhauled that the error was noticed." Prof. L. Joubin has made

is covered with minute endodermal papillæ, but whether these have the same function as the gastric filaments of the Scyphomedusæ remains to be found out. Very curious, too, is the new species of Sibogita, with its stomach completely converted into a reproductive organ when the gonads are ripe. "The stomach then ceases to function as stomach, and its cavity is filled with endoderm. The gonads are apparently in ectodermal pouches, which are embedded in the endoderm, and the pouches have openings to the exterior for the discharge of their contents." But we must pass from these exciting things to notice that the volume ends with a report by Mr. O. V. Darbishire on a collection of twenty-five species of lichens, of which five are new. As he says, they are "the outposts of plant life," occurring where no other plants at all are met with; *e.g.*, at a height of 5000 feet on the ridge of the Western Mountains. It is interesting also to notice that of four species collected on Mount Erebus at a height of 1500 feet, three are also Arctic.

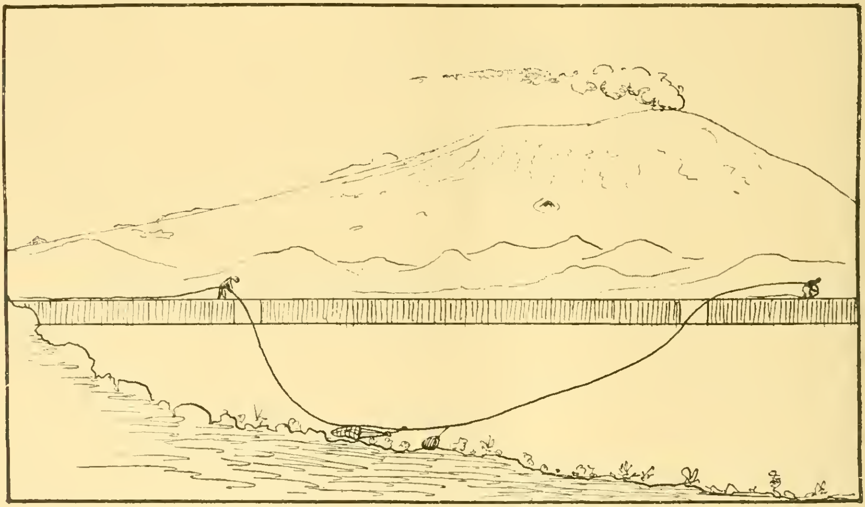

Diagram illustrating method of dredging. The ice (which is supposed to be five or six feet in thickness) and the bed of the sea are shown in section. One man is shown hauling the dredge and another is paying out the spare line to lessen the strain which tends to lift the dredge off the ground. A few feet in front of the dredge a weight is seen, which serves to keep the dredge down, and at the same time, by the length of its attaching cord, maintains it in the right position. From Vol. i., Biology, of the Reports of the British Antarctic Expedition, 1907–9.

the best of a bad business in his report on the nemerteans, for by misadventure he had only the remains of a collection to work with, which indeed only a courageous enthusiast would have touched.

Mr. Edward T. Browne has a finely executed and beautifully illustrated memoir on the Hydromedusæ and Scyphomedusæ of the *Discovery* and *Southern Cross* expeditions, seventeen species in almost as many genera. All are either new species or have been recently described as new species from the Antarctic. Some of the general results are noteworthy: there is no proof that a single species is common to Arctic and Antarctic; there is definite evidence of relatively primitive features in some Antarctic Medusæ, corroborating the view that evolution lags in the cold; it is doubtful if there are any "deep sea" Medusæ in the usual sense of that term. Among the anatomical results of interest is the discovery that the interior of the stomach in the hydromedusan genus Koellikeria

(2) We turn from what is almost the last of one series to the first of another—the reports on the scientific investigations of the British Antarctic Expedition, 1907–9, under Sir E. H. Shackleton. The editor, Mr. James Murray, has lost no time in bringing out a part of the "Biology," and what he has to tell is of much interest. The collecting at Cape Royds (about lat. 77° 32′ S., long. 166° 12′ E.) was done under great difficulties. There was no vestige of life on the beach itself, where an ice-foot persists most of the year. The black lava inshore yielded only a few tufts of moss and some lichens. The small lakes had a sheet of vegetation at the bottom, but it was hard work reaching this through over fifteen feet of ice. Some laborious collecting was done in the sea by hauling a dredge between two holes cut in the ice. Traps were also baited, which brought up amphipods, molluscs, and the like.

The mean temperature of a summer day at Cape

Royds rarely rises above freezing-point, and there is no vegetation higher than mosses. It is therefore surprising to hear of an abundant microscopic fauna and flora. Mr. Murray's experience stood him in good stead, for he made much of a very unpromising centre of operations. "The kinds of animals which are usually to be found among mosses have at Cape Royds a shelter of another sort, which, judging from their numbers, appears to suit them better. This is furnished by the foliaceous vegetation which grows so abundantly in the lakes and ponds." Thus Mr. Murray reports:—"I have never anywhere seen bdelloid rotifers so plentiful as are the two dominant species at Cape Royds (*Philodina gregaria* and *Adineta grandis*). . . . The water-bears are of only a few kinds, but one of them (*Macrobiotus arcticus*) is extremely abundant. There are nematode worms of two or more kinds, mites of several kinds, and two crustacea belonging to the Entomostraca. The ciliate infusoria are very numerous, there are a good many flagellata, but only two rhizopods were observed." Numerous microphotographs were taken under disadvantageous conditions, and some of these are printed—showing not only rotifers, water-bears, and the like, but some other creatures which the editor has wisely refrained from naming.

Some sixteen species of rotifers were distinguished, representing all the orders, though mostly bdelloids. This is the first definite record of rotifers within the Antarctic Circle, and five of the bdelloids are new species. The most interesting facts are those regarding the toughness of the rotifer constitution. Thus *Philodina gregaria* n. sp. is normally frozen in the ice of the lakes for the greater part of the year, and revives at any time that the ice is thawed. It may be alternately thawed and re-frozen at weekly intervals for several months. In England it was subjected to a temperature of -78° C. for many hours, by Mr. J. H. Priestley, of Bristol, and survived. Of *Adineta grandis* n. sp., which survived the lowest temperatures experienced at Cape Royds (-40° F.), and repeated freezing and thawing, and immersion for a month in sea-water, it is further recorded that "a proportion of them lived after the bottle containing them (in the dry condition) was immersed in boiling water for a short time. It was one of the rotifers which was to be seen alive and active in London in September, 1909, after being dry for about a year, and spending some months in tropical and sub-tropical climates." This toughness of constitution is interesting in several ways; *e.g.*, in showing that these Antarctic rotifers can stand very adverse circumstances in the course of dispersal. Another point of interest concerning the rotifers is that the two dominant species, named above, are viviparous, which seems therefore the mode of reproduction best adapted to secure success in the struggle of existence under the severe conditions at Cape Royds. M. Jules Cardot reports on four mosses; the rest of the report is due to Mr. Murray, to whom we offer congratulations.

(3) From a third Antarctic expedition, the *Belgica* (1897–9), some additional reports have been recently received. Thus Dr. H. J. Hansen, who has done such good work among the crustacea, describes some new schizopods and cumacea. He indicates, as other authorities on crustaceans have done, that the familiar title schizopods will have to go, and that the orders of Euphausiacea and Mysidacea, which it includes, are far from closely related to each other. In regard to *Euphausia superba* he notes that it is the staple food supply of seals, such as *Lobodon carcinophaga*, and that it seems to live everywhere in the Antarctic Ocean. A. Pelikan gives a petrographical account of diorites, gabbros, porphyrites, and other types of rock collected by the expedition. Prof. A. Gilkinet reports on a few fossil plants from Magellan; Fagus, Nothofagus, Myrtiphyllum, Saxegothopsis, which seem to be of relatively recent age, and bear a close resemblance to members of the present-day flora of that region. H. van Heurck reports on the diatoms and adds to the value of his work by a survey of polar diatoms in general. Henryk Arctowski gives a beautifully illustrated account of his personal observations on the different kinds of ice and their transformations. These observations are all the more interesting since very little was known of southern ice before the voyage of the *Belgica*. As the author indicates, a good deal has been done since.

ATOMIC WEIGHTS.[1]

DR. CLARKE continues to put all chemists under an obligation to him by reason of the zeal and care with which he collects and disseminates information concerning the most important of all chemical constants—the atomic weights of the elements. In the volume before us—the third edition of a work with which his name is inseparably associated—he has brought to a focus all contemporary knowledge on the subject, discussing, digesting, and weighing the experimental evidence with the same lucidity, completeness, and impartiality which have characterised his previous publications.

It is interesting and instructive to compare the present issue with the original one of 1882. The number of the chemical elements has not greatly increased during the last thirty years. Even including the inert gases of the atmosphere and such of the radio-active elements of which the individuality may be said to be established, the increase is not more than about a dozen, and such values of their atomic weights as we possess are only of the order of first approximations. The most significant feature of the difference between the two issues is seen rather in the far higher standard of accuracy which is now required in such estimations. It is absolutely useless nowadays for anybody to engage in such determinations who is not prepared to impose upon himself the most rigorous checks, the most scrupulous attention to detail, and an inflexible determination to put forward no result that will not stand the severest scrutiny.

Atomic weights to-day are required for other purposes than chemical arithmetic, and comparatively rough approximations serve for the greater number of the operations of quantitative analysis. The errors due to manipulation, and to the use of methods faulty in principle, are, as a rule, far larger than those due to the employment of incorrect values for the atomic weights. Instances, indeed, might be quoted where it is apparently necessary to adopt a confessedly inaccurate value for an atomic weight in order to compensate for the error due to an imperfect method of quantitative estimation. Certain large trade operations could not be equitably arranged on any other basis. This, of course, does not concern the chemist as a man of science, and is certainly no argument for the retention of an inaccurate constant in our tables

of atomic weights. These require to be known with all the precision of which quantitative chemistry is capable.

It is only by such knowledge that we may hope to find solutions to some of the most interesting and important problems with which contemporary chemistry is confronted. There is, to begin with, the fundamental question of the validity of the law of the conservation of mass. Is there a dissipation of matter, as of energy, in a cycle of chemical changes? Is an atomic weight a fixed and unalterable quantity? Or is it, as first suggested by Marignac, a statistical quantity varying within limits, doubtless very small, but still possibly appreciable?

There is further the perennial question of Prout's law, which, like the poor, seems to be always with us. Modern views of the genetic relations of the elements and of the dependence of their properties upon their relative masses are intimately connected with the exact values and numerical relations of atomic weights. It is these and similar questions lying at the very basis of chemical philosophy that render it imperatively necessary that these constants should be known with the greatest possible precision. The greatest possible precision is, of course, relative; it depends upon the degree of perfection of contemporary quantitative chemistry, and as this is progressive, each decade seeing improvements, both in the application of old methods and in the discovery of new, it necessarily follows that there is no such thing as finality in measurements of this kind. A large number of atomic weights are now known with accuracy to the first decimal place; even in the case of those of high values a considerable proportion indeed are known even to the second decimal, and a few, especially those elements which are habitually employed as a basis of comparison in atomic-weight work, as, for examples, silver and the halogens, are being ascertained with a still greater exactitude. It is only when atomic weights in general are known to a like degree of precision that we can hope for definite answers to such questions as have been indicated above.

It is largely due to the attention which this subject has received in America that our present position has been reached, and it is especially to the Harvard School of Chemistry that we are indebted for the high standard of accuracy which is now incumbent on every worker in this field of determinative chemistry. No laboratory in the world can point to such a remarkable sequence of memoirs as those which are embodied in the short synoptical statement in which Prof. Richards has dealt with the Harvard determinations of atomic weights between 1870 and the present year. Initiated by the late Prof. Josiah Parsons Cooke, whose determination of the atomic weight of antimony is still regarded as the best ascertained value for that element, the work has been continued by his assistant and successor, Prof. Theodore Richards, partly alone, but mainly in collaboration with pupils whom he has trained and imbued with his own high sense of exactitude. What the outcome of this work, extending over many years, has been is abundantly illustrated by the significant table on p. 90 of Prof. Richards's memoir. Of the eighty-three elements at present known, and of which the atomic weights are given in the annual tables prepared by the International Committee on Atomic Weights, no fewer than twenty-eight of those estimations which are regarded by the committee as among the best ascertained values are to be credited to the Harvard laboratory.

It is remarkable that this work should have been done in America. It is commonly held that no nation is more keenly appreciative of the utilitarian value of science than America; but there is no money to be made out of the results of an atomic-weight determination. It is quite impossible to evolve a new colouring matter out of it, or to turn it into a synthetic drug. Not even the "smartest" and most enterprising of German chemists could bring it within the protective influence of the mystic letters D.R.P. On the contrary, atomic-weight work requires money, and that frequently in no small amount; platinum vessels, and apparatus of transparent quartz, electric ovens, high-class balances, and pure materials, render such work extremely costly. No doubt Harvard is well endowed, and Prof. Richards presumably has been liberally supported by his university. But the beneficence of the university has been largely supplemented by the action of the Carnegie Institution of Washington; without the pecuniary help afforded by the Trust, the work could not, says Prof. Richards, have been carried out on so large a scale, nor could it have reached the degree of precision which it has attained.

T. E. T.

TESTS FOR COLOUR VISION.

THE agitation concerning the official colour-vision tests for seamen has entered upon a new stage. The Board of Trade has announced its decision to hold an inquiry into the matter, and the *personnel* of the committee has been published (NATURE, June 30, p. 529).

After the reiteration of the confidence of the Board in the certitude of the official tests, this change of front comes somewhat as a surprise, but that can be forgiven in the welcome possibilities of a revision of tests that have forfeited the confidence of those most concerned.

It is not to be expected that the constitution of an official committee will please everyone, and already protest has been made by letter to the Board of Trade from the secretary of the Imperial Merchant Service Guild. The Guild protests that it was given to understand that the projected new committee would be of small size and of strictly impartial character, but that it proves to be large, and in the view of the Guild heavily weighted. The Guild states that of the members of the committee, at least two were prominent supporters of the official tests in recently disputed cases where the official position was admittedly wrong.

The choice of tests for colour vision is not so simple as it may seem at first sight. The difficulties presented in appreciating the mental picture of a colour-blind person are very great; and complexity is introduced by the several conflicting theories of colour vision which, consciously or unconsciously, bias the opinion of those who essay to determine these tests.

It is perhaps unfortunate that theories of colour vision should enter into the question of colour tests, at any rate, in the present state of our knowledge. It is, of course, conceivable, nay, even probable, that the true theory of colour vision when that is formulated and proven, supposing it for the moment to be none of those extant, will show an infallible means of testing the sense of colour in any and every person. Until then it would appear better that the test should be frankly empirical, and, so far as possible, unbiased by any theory. And for the reason that, unless rival theories be eliminated from the field, we can scarcely expect a reasonable uniformity in our tests.

There are two main lines of cleavage between rival schools of testing. One insists upon the matching of colours, the other on the necessity for naming colours. The first is official and based upon Holmgren's tests. A candidate is given a skein of coloured wool, and required to pick out from a heap of skeins other wools that, in his opinion, match the wool given him. The second method of testing is performed by exhibiting a colour in wool, card, or preferably by means of light from a distant lantern, and the candidate is required to name the colour shown in whatever language he knows. The colour is exhibited detached from any other colour that could give external help, the man must judge of the exposed colour alone and unaided, and name it in common terms. Now each of these modes of colour perception are common habits with us in our daily life. We constantly match colour, consciously or unconsciously, and we as often, perhaps more often, name colours we see, matching them mentally and naming them according to a standard we have learned by experience. On the respective merits of these methods, the rival schools clash, and, so far as can be judged, the disagreement rests upon theoretic conclusions rather than practical experience.

If we consider these two tests in relation to actual life, or, at any rate, the life of a seaman, it can scarcely be denied that the second non-official test, naming the colour, is the one that most nearly tallies with his experience. The seaman is required to pick up a light, most likely a solitary light, and judge of its colour without possible comparison; he must rely on his judgment of that light in relation to the mental impressions that are part and parcel of his cerebration, and the impression he receives is instantly and unconsciously correlated with a name, the name of a colour in the language in which his mind works. To name is second nature. What the name may be matters not, so long as it be current coin; the "B" line in the spectrum may be "red" to us or "blood-colour" to the savage, and "F" "blue" to us and "sea-colour" to the savage: the intention is the same.

But it is argued by the adherents of the Holmgren test that the matching of colour is more likely to be true, for it eliminates possible errors due to ignorance in precise nomenclature, *e.g.*, three people may see the same colour and variously describe it as purple or mauve or heliotrope, with a result that a fourth might not be sure what colour was meant, yet each of the three would find no difficulty in matching the colour correctly, particularly if they were women who took an interest in their dress.

The good and bad of these tests can only be put to proof when they are tried on known colour-blind persons. Then it has been found that persons can successfully match colours who grossly misname them when the colours are shown singly. On the other hand, there are some who can name colours who fail to match well. The evidence of the cases, particularly those of the first and more important group, has been sifted and is established. Which, then, of these two persons is the colour blind, he who can match but not name or he who can name but not match? The solution of this perplexity is as follows: Matching depends rather on a keen sense of light and shade than on colour sense; colour-blind persons can be educated up to the matching test, but never to acquire a colour sense they do not possess. Those who name colour accurately yet fail to match are bunglers, folk just ignorant of what matching means; the maid-of-all-work will know, but a youth or a seaman may not.

On the mode of applications of tests, if a little pleasantry be permitted, it can scarcely be denied that in some aspects the official methods are as fine a joke as could well be devised. What would a stranger visitant think of these heaps of coloured wools? Surely he would commend a State whose paternal care extended to the examination of young ladies desiring employment in haberdashery shops, to the end that they may be good at matching their customers' patterns! That these wools were to test the seaman's ability to pick up lights in rain and shine, storm and fog, our visitant would surely find unthinkable. And yet it is so. So far has theory divorced from experiment carried us. If it be well to let the punishment fit the crime, how much more should the test of a quality fit the usage of that quality. It seems obvious that the ability to see lights and signal flags should be tested with lights and flags. That this is now recognised is shown by the number of testing lanterns that have been fathered since Edridge Green directed attention to the matter; but some of the lanterns are bad by reason of the poor range of their tints.

The next line of cleavage between rival schools is due to differences in opinion as to what are to be the crucial colours of the tests. Here theories of colour vision come in most emphatically, and until this problem is solved, we cannot expect agreement unless there be a truce to theory and a trial by ordeal.

There is one satisfactory mode of surmounting the difficulty in the choice of crucial colours, that is, by the use of the spectrum itself. Much of the experimental work on colour vision has been done with the spectroscope, and the appreciation of the value of it as an everyday appliance is shown in that, within the last two years, there has been devised three pieces of apparatus for colour testing by direct appeal to the spectrum. A very clever projection spectroscope has been devised by Dr. J. H. Tomlinson, and valuable instruments for direct view of the spectrum by Dr. Maitland Ramsey and by Dr. Edridge Green. Of these instruments, the first has the advantage that both examiner and candidate can view the spectrum together. But Edridge Green's instrument has the germ of the right principle in colour testing, for it is provided with scales which give the measurement of the aperture of the shutters in wave-lengths, so that by this means the range of distinction of colour throughout the spectrum can be measured and registered.

In conclusion, what we want is not only a trustworthy mode of qualitative test, but also a quantitative test—some mode whereby we can express a man's colour-sense in terms as stable as we can express his form-sense by Snellen's test types. At present, opinion and fact are hopelessly muddled by our inability to convey what our tests show. Say a man fails to distinguish a certain red: he must be written down "red blind," notwithstanding he can see another red. To say he is red blind is both true and false, but it is the only statement that can be made in the absence of finer modes of expression. We want to take the measure of his perception of the colours of the spectrum and register them in simple terms. Given such an absolute register of his colour sense, there will remain only the expression of opinion as to his capability for doing certain work. Requirements will vary with the work to be done. For seamen and railway men we should require the highest standard, even as is required of them for form vision.

We wish the new committee a happy issue out of all its troubles! N. B. H.

GREENWICH WATCH AND CHRONOMETER TRIALS.

"WHAT is the chief end of an astronomer?" is not so stereotyped a question as the corresponding conundrum respecting the chief end of man. This question is, however, suggested by the following statements in the last annual report of the Astronomer Royal to the Board of Visitors:—"In the year ending 1910, May 10, the average daily number of chronometers and watches being rated (at Greenwich) was 596." "The number of Government marine chronometers and watches now at the Observatory is 455." "For the annual trial of chronometers . . . 66 . . . were sent in . . . 8 were purchased for the Navy and 4 for the Indian Government." "For the annual trial of chronometer watches . . . 173 . . . were entered . . . and . . . 35 were purchased for the Navy." In addition there was a trial of pocket chronometers, seventeen being sent in and two purchased for the Navy. The average number of chronometers rated daily has, we learn, more than trebled since 1880, so that the burden of this work borne by the Observatory has enormously increased. The work is doubtless most valuable for the Navy, but is our great national Observatory exactly the place where it should be done?

The question is many-sided. Science for its own sake is regarded by the multitude as a most excellent occupation for wealthy amateurs, but a State-supported institution is expected to devote itself to immediately-practical ends. From this point of view it is only work such as supplying the national time and rating the national chronometers that justifies the existence of Greenwich. There is thus some reason to fear that if this and other obviously useful work ceased, the continuation of the financial support from Government that enables the Observatory to carry out work that is more directly astronomical might be jeopardised. On the other hand, whatever adds to the burden of routine and administrative labour borne by the Astronomer Royal, must reduce the time and energy which he can devote to what is purely scientific.

There are several points of interest in the details of the trials. The box chronometer trial lasted twenty-nine weeks, from June 19, 1909, to January 8, 1910, the temperatures to which the chronometers were exposed varying from 45·8° to 105·6° F. The chronometers are arranged in order of merit according to the value of $a+2b$, where a is the difference between the algebraically greatest and least of the weekly rates, and b the greatest difference in rate between two successive weeks. As in golf, the lowest score is the best. Pocket chronometers and chronometer watches are let off with an eighteen-week trial, notwithstanding the fact that, unlike the box chronometers, they are tried in a number of positions. Their place on the list is determined by a formula which takes account of the differences between the rates in the several positions. Even eighteen weeks is a long time compared to the duration of watch trials at the Swiss observatories, at Besançon or at Kew.

The chief obstacle to uniformity of rate, especially in box chronometers, is the effect of temperature, but a much shorter trial than twenty-nine or eighteen weeks would suffice to test the behaviour of the temperature compensation. The main object, presumably, in having so long a trial is to afford an opportunity for any weak point to declare itself. On this question one would like to know the views, both of the makers and of the Observatory authorities. A long trial means a lock-up of capital, which must presumably have an effect on the cost, especially as only a fraction—in the present case apparently only a small fraction—of the chronometers and watches were actually purchased for the Navy. In the present day, with the increase of speed, a ship is seldom isolated for any great length of time, and the breakdown of a single chronometer is unlikely to be a serious matter. Thus the case for a long trial does not seem so strong as it may have been a generation ago. Very probably ere long the development of wireless telegraphy may alter the whole situation.

NOTES.

A FINE specimen of a rare class among the scientifically eminent passed away when the Rev. Robert Harley, F.R.S., died on July 26, in his eighty-third year. Many friends will miss his hale face and hearty greeting at meetings of the Royal Society; and few of them can have had any idea that one so keen in his interest could be an octogenarian. Mathematics with him was a parergon, almost a hobby. He achieved distinction in it in early middle life, pursuing it in scanty intervals of leisure secured without neglect of engrossing non-scientific duties. The son of a Methodist minister, he had no early mathematical training. At the age of twenty-three he entered Airedale College as a student of theology, and shortly afterwards he was ordained as pastor of the Congregational Church at Brighouse, Co. Yorks. Here he found time to become a mathematician of mark. The application of mathematics to logic as developed by George Boole captivated his intelligence, and he became the most notable of Boole's admirers and followers, as also his biographer. His greatest mathematical achievements were, however, in another field. The unsolved problem of the solution of quintic equations fascinated him. Having once granted the impossibility of the solution by radicals, he proceeded to exhibit with remarkable power and patience the place of certain sextic resolvents in connection with such equations. Simultaneously, the late Sir James Cockle was engaged on like work; but Harley was the clearer writer on the difficult subject. Their work, and in particular Harley's, was welcomed enthusiastically by Cayley, who himself took it up and continued it. All three probably were not aware at the time that certain Continental writers had possessed some of their ideas beforehand; but everyone must recognise that Harley's development of the ideas was masterly. It secured for him the Fellowship of the Royal Society in 1863. Since then, as before, he carried on mathematical research only in such time as was allowed by devotion to pastoral, philanthropic, and temperance work. He laboured in Leicester, Oxford (where he was an original member of the Oxford Mathematical Society, and was given the honorary degree of Master of Arts by the University), Halifax, and elsewhere. From 1872 until 1881 he was vice-principal (and chaplain) of Mill Hill School. For the three years before his removal to Oxford in 1886 he was principal of Huddersfield College. In 1890 he took a period of rest (with pastoral work) in Sydney, Australia. Since 1895 his life was one of retirement, but far from one of inactivity, whether religious, benevolent, or scientific.

THE Berlin correspondent of the *Times* announces the death, in his seventy-sixth year, of Prof. A. Michaelis, who until three years ago was, since 1872, professor of classical archæology at Strassburg University. In addition to being the author of a large number of works on archæological subjects, Prof. Michaelis organised the admirable archæological museum of Strassburg University.

We learn from *Science* that Dr. Frank H. Bigelow has resigned his positions in Washington, D.C., as professor of meteorology, U.S. Weather Bureau, and professor of astrophysics, George Washington University, in order to travel in Europe for a few months. He will then resume his studies in solar physics and terrestrial meteorology.

In view of the removal of the work of the Meteorological Office to the new building in Exhibition Road, South Kensington, which is being arranged to take place in the autumn, Mr. R. G. K. Lempfert, superintendent of statistics, has been appointed by the Meteorological Committee to be superintendent of the forecast division; Mr. E. Gold, fellow of St. John's College, Cambridge, Schuster reader in dynamical meteorology, has been appointed superintendent of the statistics and library division; Mr. R. Corless has been reappointed special assistant to the director, with additional duties as secretary and clerk of publications. The appointments date from October 1.

Apropos of Prof. W. J. Pope's discourse on "The Chemical Significance of Crystal Structure" at the Royal Institution, a full report of which appeared in last week's number of Nature, it may be noted that the models which illustrated the lecture, together with explanatory labels, are exhibited by Prof. Pope in the Crystallography Section of the Science Hall at the Japan-British Exhibition. Next to this exhibit will be found also models of Bravais's fourteen space-lattices, and of certain of Sohncke's point-systems shown by Prof. H. L. Bowman. Among other interesting exhibits in the same section, in addition to those referred to in an article in Nature of July 28, may be mentioned the series of goniometers, showing the great change that has taken place in the form of the instrument since it was first devised, the refractometers and protractors, and the pictures, obtained in natural colours by direct photography on autochrome plates, of the interference figures displayed by certain crystal-sections.

In *L'Anthropologie* for May–June M. Louis Seret brings to a close his essay on the colonial empire of the Phœnicians. To this he attributes the spread of Neolithic culture in western Europe. In the sixteenth century B.C., the Phœnicians, after the first Egyptian incursions into Asia, started on their maritime career. The period of constant warfare which succeeded produced a demand for large supplies of arms of bronze, and the Cassiterides were the only source from which tin in the necessary quantity could be provided. But the accessible mines soon became exhausted, and in the twelfth century the increasing use of iron made the bronze trade much less important. He connects the menhirs of western France with the cult of a deity of reproduction, like the Greek Hermes. These brilliant generalisations will probably not meet with universal acceptance; but this important study throws new light upon the connection of the Phœnicians with the spread of Neolithic culture in western Europe.

In a third instalment of a "symposium" on the palæontological record, published in the August number of the *Popular Science Monthly*, Prof. R. S. Lull discusses the relation of embryology and vertebrate palæontology. He mentions that the dinosaur Compsognathus was probably viviparous, and refers to the importance of ascertaining the origin of the peculiarity that the presumed ribs of chelonians are external to the limb-girdles. He also comments on the similarity between the head of a fœtal manati and that of a modern ungulate.

In the course of a note on the first skull of the species obtained from the Pleistocene of Saxony, Dr. K. Wanderer, writing in *Sitzungsberichte und Abhandlungen der naturwis. Ges. Isis* for 1909 (1910), reviews recent literature relating to the local races of the musk-ox. In 1908 Dr. R. Kowarzik pointed out that the living representatives of the species are divisible into two main groups—an eastern and a western—distinguished by skull characters. The line of division between the two types is formed in North America by the Atlantic watershed and its continuation in the islands of the Arctic Ocean. The western type, *Ovibos moschatus mackenzianus* (of which Gidley's *O. yukonensis* appears to be a synonym), inhabits the Mackenzie Valley and the districts to the west, but appears to have been originally a native of Europe and northern Asia, whence it reached America by way of Bering Strait. The skull is characterised by the nearly quadrangular outline of the basioccipital, the flattened but large horn-bases, the close approximation of the stout sheaths of the horn-sheaths to the forehead, the presence of distinct lacrymal pits, the marked curvature of the tooth-line, and the long interval between the sphenomaxillary fossa and the last molar. The eastern American form is, it may be presumed, *O. m. typicus*, allied to which is the Greenland *O. m. wardi*. The skull described by Dr. Wanderer was obtained from Prohlis, near Dresden, in association with remains of *Rhinoceros antiquitatis*, and is referred to the western form.

Two volumes by Mr. J. Wright on the cultivation of allotments have lately been added to the series of "One and All" garden booklets. The first supplies information with regard to the preparation and improvement of the soil; the second deals with the production of vegetables, fruits, and popular flowers.

A new volume, the fifth, of the botanical section of the *Philippine Journal of Botany* begins with a number devoted to the first part of an enumeration of Philippine Leguminosæ, provided with keys to the genera and species, for which Mr. E. D. Merrill is responsible. The enumeration covers 90 genera and 285 species, of which 14 entire genera and 53 species are considered by the author to be introductions. The proportion of endemic species is low as compared with many other families. None of the genera are very large, Desmodium being predominant with twenty-nine species, while Monarthrocarpus and Luzaria are monotypic and endemic. Several species yield valuable timbers, notably *Pterocarpus indicus*, *P. echinatus*, *Albizzia acle*, *Intsia bijuga*, and *Pahudia rhomboidea*.

A note by Mr. W. R. G. Atkins on the cryoscopic determination of the osmotic pressures in some plant organs, chiefly fruits, appears in the Scientific Proceedings of the Royal Dublin Society (vol. xii., No. 34). Following the methods adopted in earlier experiments, the osmotic pressures were calculated from the data obtained by measurement of the freezing point of the expressed cell sap. The values so obtained justify the deduction that similar organs of any plant species have approximately equal osmotic pressures, although a wide range of values is obtained for similar organs of different plants. Thus tomato fruits gave a value varying from six to nearly eight atmospheres, and greengages a pressure of twenty-nine atmospheres. The variation in pressure recorded for the tomato is connected with the ripening of the fruit, the lower pressure in this case referring to the ripe fruit, and is accounted for by the chemical changes in the cell sap.

Bulletin No. 55 of the West of Scotland Agricultural College contains an account of experiments on soil inoculation for the lucerne crop. Lucerne is not at present cultivated in Scotland, and the necessary bacteria are presumably not present to any great extent in the soil. Addition of the organisms by inoculation has proved successful.

The changes taking place during the storage of butter have been investigated at the Michigan Agricultural College Experiment Station by Messrs. Rahn, Brown and Smith. There was a distinct increase in the non-protein nitrogen, indicating a certain amount of proteolysis, but the exact agent was not determined. There were, however, micro-organisms found multiplying even at $-6°$ C., whilst a torula proved extraordinarily resistant to salt, even growing in a 25 per cent. salt broth.

The use of insecticides containing arsenic appears to be attended with considerable disadvantage in India, and experiments have for some time past been carried out at the Agricultural Research Station, Pusa, with the view of discovering some other compounds equally effective. Lead chromate was finally selected; being yellow, it is easily visible on the plant; it does not burn the foliage, and it adheres well. A suspension of 1 lb. in 64 gallons of water proved effective on plants that are being attacked, while 1 lb. in 100 gallons of water proved a sufficient preventive.

A recent circular of the Royal Botanic Gardens, Ceylon, contains an account, by Mr. Petch, of the root disease of the cocoa-nut palm caused by the fungus *Fomes lucidus* (Leys). No method of curing a diseased tree is known; once a tree is attacked there is little hope of saving it unless some only of the roots are affected and can be cut off. This only rarely happens, and it is usually best to fell the tree at once. Methods of treatment are badly needed for cases such as this; there seems to be no prospect of successful treatment by the internal application of a fungicide, since the tree is more easily killed than the fungus.

The renewed interest now being taken in the United States in all questions affecting natural resources, and particularly the soil, is reflected in the articles in the *Popular Science Monthly* (No. 6). Dr. McGee describes the scientific work of the Department of Agriculture, which includes more than half of the official bureaus in the States. Prof. Brigham gives a popular account of soil formation and of weathering, and shows how such apparently trifling details as the lowering of the level of water in the soil through the operations of man may in course of time lead to profound changes. There is also a well-illustrated paper by Prof. Herrick on instinct and intelligence in birds.

The July number of the *Journal of the Board of Agriculture* contains a paper by Messrs. Robinson and Watt describing the Coombe plantation, Keswick, which was planted in 1848, and is now being cleared. It is remarkable in that careful accounts have been kept of all costs and of all returns, and further in that experimental groups of trees have been periodically measured. A discussion of the data is given, and there are a number of good photographs. Another paper, by Mr. A. B. Bruce, aims at giving the stock-breeder a general account of Mendelism which should go far to satisfy him that the scientific treatment of his problems is likely to lead to valuable results.

Recent bulletins from the United States Department of Agriculture Bureau of Entomology deal with (1) the western grass-stem saw-fly (*Cephus occidentalis*, Riley and Marlatt), which causes trouble to the wheat-growers of North Dakota and elsewhere; (2) the woolly white-fly (*Aleyrodes howardi*, Quaintance), a new enemy of the Florida orange, which hitherto has only been known to infest orange trees in some of the West India islands, and especially Cuba; (3) the oyster-shell scale (*Lepidosaphes ulmi*, L.) and the scurfy scale (*Chionaspis furfura*, Fitch), now very generally distributed through the States, and sometimes confounded with the more serious San José scale; although they do not actually kill the trees, they cause serious financial loss; (4) the "brown rot" (*Sclerotinia fructigenia*, P. Schröt.) and plum curculio (*Conotrachelus nenuphar*, Herbst.) of fruit trees; the former is a fungus disease of the flowers, twigs, and fruit, especially harmful at the time of ripening; the latter is an insect that, in the course of its feeding and egg-laying, punctures the fruit, often so copiously that much loss is suffered; (5) the sorghum midge (*Contarinia* [*Diplosis*] *sorghicola*, Coq.), which is by far the most destructive agent affecting sorghum. A general description of the insects attacking crops in Michigan is issued by the Michigan State Agricultural College Experiment Station; the bulletin is well illustrated, and contains a considerable amount of useful information.

Messrs. Burroughs, Wellcome and Co. have issued, in connection with their exhibit at the Japan-British Exhibition, an illustrated descriptive pamphlet (in English and in French) of the Wellcome Physiological Research Laboratories and of the work done there. This includes the preparation and standardisation of diphtheria anti-toxins and other therapeutic sera, bacterial vaccines, the physiological standardisation of drugs such as ergot, &c.

The fourth annual report of the Metropolitan Water Board, by Dr. Houston, on the results of the chemical and bacteriological examination of London waters for the year ending March 31 last, has recently been issued. It contains a mass of figures relating to the bacterial content and chemical composition of the raw, stored, and filtered water supplied to the metropolis, valuable on account of the systematic examination of the water and as showing how our water supply is, so far as possible, safeguarded. Dr. Houston again insists that the *raw* waters are undoubtedly unsatisfactory in quality, but that storage with sedimentation effects a considerable improvement, and he emphasises the supreme importance of storage as a means of preliminary purification of the raw water.

The new catalogue of the Cambridge Scientific Instrument Co., describing Duddell oscillographs, gives particulars of the latest type of these instruments. The improvements incorporated in this instrument include greater accessibility and ease of repair of the vibrators and alteration of the design in such a manner as to prevent the leakage of oil from the damping chamber, which was such an unpleasant feature of the old type. Particulars are given of the accessory apparatus required and of the methods of using the instrument, and an appendix contains reproductions of a number of interesting records of wave shapes.

We are in receipt of a copy of the "Catalogue of Mechanical Engineering and Electricity," containing information concerning the British exhibits in these sections at the Brussels Exhibition. The preface is written by Prof. W. C. Unwin and Mr. John Goodman, and gives a summary of the progression and tendencies of engineering science as exemplified by the exhibits referred to in the body of the catalogue. The nine sections include mechanical engineering, electricity, civil engineering, agriculture, horticulture and arboriculture, food products, mining and metallurgy, textile industries, and chemical industries. A plan at the end shows the positions of the stands of the various exhibitors.

The *Physikalische Zeitschrift* for August 1 contains a review of the present state of our knowledge of the properties of the α particles sent out by radio-active substances, by Dr. H. Geiger, of Manchester. The velocity of the homogeneous rays sent out by radium C appears to be $2{\cdot}06\times10^9$ centimetres per second, and the quotient of the electric charge by the mass $5{\cdot}07\times10^3$ electromagnetic units. The mean number of α particles sent out by a gram of radium per second is $3{\cdot}1\times10^{10}$, and each carries a charge $9{\cdot}3$ to $9{\cdot}6\times10^{-10}$ electrostatic units, and appears to be a helium atom. The progress of each is checked by the molecules of a gas, and in air the path described does not exceed a few centimetres in length. During the description of this path each is capable of producing $1{\cdot}72\times10^5$ ions by collision. The results of the recent measurements of the diminution of the velocity of the particles as they pass through solids, their scattering, and their ultimate absorption are all discussed in a clear and thorough manner.

A letter from Sir William Ramsay, in the *Chemical News* of August 5, directs attention to a new fact in the history of the development of the Leblanc process for the manufacture of soda. It has generally been believed that Leblanc perfected a process devised by De La Métherie in 1789. A letter to Dr. Black, written by a Mr. Geo. Golder, of Edinburgh, and dated March 19, 1782, shows, however, that the black ash process had already been devised and patented by an English inventor named Collinson. A specimen of black ash prepared by Collinson's process was submitted to Dr. Black, who reported that it contained "more alkali than the best Alicant Barilla in the proportion of 68 to 44, and more than the best keip in the ratio 68 to 10." "It is an excellent ash for the soap-boilers . . . and there is no need to use lime in drawing the leys from it, as it is already in a caustic state." "After this," the writer adds, "there appears little doubt who invented the black-ash furnace."

Many examples of smoky chimneys are no doubt owing to carelessness and lack of knowledge in those concerned with the work, but we also find many architects and builders of repute being occasionally nonplussed by the problem. Some important points in chimney design are given in the *Builder* for August 13. The grate should be provided with a blower to induce a good draught at the start. The flue should be expanded laterally to a width of about 2 feet a short distance above the grate, and then brought in again, forming what is usually termed a "bottle." Above this, one or two bends of about 150 degrees should be made. The top should be slightly contracted, and the chimney-cap sloped up sharply all round the aperture or pot; outside chimneys should be avoided; stacks should come as near the highest part of the roof as practicable; a number of flues should not be packed too closely together in a large stack, but kept as distinct as possible; the outer walls of stacks should be 9 inches thick.

In an article on the International Road Congress, which opened in Brussels on August 1, *Engineering* for August 12 gives the altered form of a rejected resolution, which in its original form condemned macadam. The resolution finally adopted is as follows:—"Macadam, carried out by the methods of Tresaguet and Macadam, causes dust and mud, is expensive to maintain, and is suitable in large cities only for streets where the traffic is not very great or heavy. The experimental work carried out in recent years with macadam, improved by using a bituminous or tarry coating or binder, ought to be continued to determine the best method of utilising this kind of construction under varying conditions, and the results considered at the next congress." Our contemporary directs attention to a point which requires scientific investigation, viz. the exact behaviour of a sand foundation under stone pavement. On the Continent, a bed of sand from 3 inches to 6 inches deep is almost invariably used, and the setts are bedded directly on and in the sand. The sand is spoken of as a "cushion," and is said to be elastic. Another view is that it absorbs the shock on the pavement, saves the stones from damage, and reduces the noise of traffic. It would be easy to settle the points in doubt by experiments in an engineering laboratory.

OUR ASTRONOMICAL COLUMN.

A New Comet.—A telegram from the Kiel Centralstelle announces the discovery of a new comet by the Rev. J. H. Metcalf at Taunton, Mass., on August 9. The position, at 9h. 15·2m. (Taunton M.T.), is given as R.A. = 16h. 10m., dec. = 15° 20′ N., and the comet was said to be moving in a south-westerly direction; at the time of discovery the brightness of the comet was about equal to that of an eleventh-magnitude star.

A later telegram gives the position of the comet as observed by Mr. Burton at Boston on August 10; at 12h. 28·8m. (Boston M.T.) R.A. = 16h. 10m. 29·3s., and dec. = 14° 56′ 41″. The comet is on the meridian at about 6h. 30m. p.m.

Observations of Comets.—Dr. Max Wolf records an observation of comet 1910*a*, on July 15, in No. 4429 of the *Astronomische Nachrichten* (p. 210). The comet was then a little to the south-east of υ Cygni, and its photographic magnitude was 16·5.

In No. 4430 of the same journal he states that on plates taken on April 11 he has found images of comet 1909*e* (Daniel); the comet was then fainter than Halley's at the time of discovery, and was not shown at all on a plate which had a longer exposure on May 12. In compliance with a request from Herr Jan Krassowski for unpublished observations of comet 1909*e*, Dr. Rambaut also publishes some positions of this comet, secured at the Radcliffe Observatory during December, 1909, and January, 1910.

Observations of Mercury.—During July and September, 1909, observations of Mercury were made at the Revard (Aix-les-Bains) and the Massegros (Lozère) observatories by MM. G. and V. Fournier, and the drawings are now reproduced and discussed by M. Jarry-Desloges in the August number of the *Bulletin de la Société astronomique de France*. Those made at Massegros, with a refractor of 29 cm. (11·5 inches) aperture at an altitude of 900 m., show that there are definite markings on the surface of the planet which can be seen and delineated by different observers at different times with striking agreement, although the observing difficulties are very great. A dark patch on the southern horn is shown on all the drawings, and in some even obliterates the actual cusp. Other markings agree on different drawings, and can also be identified with some observed by Schiaparelli and Lowell. The observations confirm the statements that the rotation period of Mercury is probably equal in length to the planet's revolution period.

Dispersion of Light in Interstellar Space.—Recognising the importance of the results obtained by MM. Nordmann and Tikhoff regarding the differential velocities of light of different wave-lengths through interstellar space, Herr Beljawsky made a number of observations of the Algol variable RZ Cassiopeiæ during the autumn of 1909. Using filters which transmitted either visual rays alone or photographic rays alone, he photographed the star with short exposures, taking a large number of photographs in quick succession, and from these he subsequently reduced the times of the photographic and visual minima respectively. The results first obtained showed a time-difference of six minutes, on the average, between the two divisions of radiations. But this difference was in the opposite direction to that found by the earlier observers: that is to say, the visual rays were "retarded" more than the optical.

A subsequent revision and refinement of the data confirmed this result qualitatively, but slightly reduced the time-difference (*Mitteilungen der Nikolai-Hauptsternwarte zu Pulkowo*, vol. iii., No. 31, 1910).

Anomalous Scattering of Light.—No. 5, vol. xxxi., of the *Astrophysical Journal* contains an important paper in which Dr. Julius upholds his hypothesis as to the causes which produce the unequal distribution of light over the sun's disc, as shown on spectroheliograms. He states that the results so far obtained are no less favourable to the anomalous-dispersion theory than they are to that hypothesis which ascribes the variable illumination to absorption effects, and proceeds to support his statement by the discussion of the several phenomena.

Dr. Julius also defines his terms more rigorously than in former papers. "Anomalous dispersion" is reserved for the general property of matter, that its refracting power varies rapidly in the neighbourhood of an absorption line. Previously this term was used indiscriminately with "anomalous refraction"; but the latter is now to be used exclusively for the irregular phenomena with which Dr. Julius deals in all his papers; "anomalous scattering" is also introduced, and is shown to be an active agent in modifying various effects.

The Spiral Nebula M51 (Canum Venaticorum).—As an extract from the *Rivista di Astronomia* (Turin), we have received a paper in which Madame Dorothea Isaac-Roberts discusses in detail the numerous condensations, spires, &c., shown on Dr. Roberts's photograph of the spiral nebula M51 Canum Venaticorum. Each feature is described, and the position-angles, distances, &c., are given, so that any future worker may determine, with a minimum of labour, whether or not any variation has taken place since the epoch when Dr. Roberts's photograph was taken. Madame Roberts also shows that the present form indicates a process of evolution which has led, and will probably lead, to the partition of this remarkable object into secondary nebulæ and condensations.

Supplement to the "Astronomische Nachrichten."—We have received, as a supplement to the *Astronomische Nachrichten*, No. 17 of the *Astronomische Abhandlungen*, edited by Dr. Kobold. Among its six articles, it contains papers dealing with an experimental research on phase action in regard to heavenly bodies, a new explanation of the origin of comets, and a description by Prof. Lowell of the new canals discovered on Mars. The price of the supplement is 3 marks.

THE FIRST INTERNATIONAL CONGRESS OF ENTOMOLOGY.

THE first International Congress of Entomology was held at Brussels on August 1–6. The establishment of the congress was in great measure due to the initiative of Dr. Karl Jordan, of Tring, whose tact and energy have throughout contributed largely to the success of the undertaking. Having, in the first place, secured the support of leading entomologists in this country and abroad, Dr. Jordan organised, in the course of last year, a series of preliminary meetings in London, which were attended by Dr. Horn, of Berlin, M. Janet, of Paris, Prof. Poulton, F.R.S., of Oxford, and others, under the chairmanship of Dr. F. A. Dixey, F.R.S., president of the Entomological Society of London. At these meetings it was arranged that the first congress should be held at Brussels in 1910, and local secretaries were appointed to promote the interests of the movement in all countries of the civilised world. So well did these representatives perform their part, that no fewer than 292 entomologists assembled in Brussels for the opening of the congress.

Proceedings began on the evening of July 31 with an informal reception by Prof. Lameere (who, as president of the Entomological Society of Belgium, had been invited to preside over the congress) and the other members of the Belgian society. The gathering was highly enjoyable from the social point of view, and gave acceptable opportunities to entomologists from other parts of the world for making each other's personal acquaintance.

On August 1 the official proceedings were opened by Prof. Lameere in the Salle des Fêtes, a large building within the precincts of the exhibition, the use of which for the general and sectional meetings of the congress had been liberally granted by the authorities. His address of welcome to the delegates and other members of the congress included an eloquent vindication of the claims of entomology to serious attention, both as a science and also as a study having practical bearings of the highest importance. The address, which was well received, was followed by the reading of a report by the secretary of the congress, M. Severin, on whose shoulders the chief labour of organisation had fallen. After the conclusion of the more formal proceedings, the congress turned to the regular business of entomological communcations. Some of the most interesting items on the programme bore reference to subjects of economic importance. Prof. Theobald (Wye) had a paper on the artificial distribution of insect pests, and M. Andres (Alexandria) contributed notes on the lepidopterous enemies of the cotton-crop. Dr. R. Stewart MacDougall (Edinburgh) discoursed on the beetle *Galerucella lineola*, so destructive to the Midland osier-beds, and Sir Daniel Morris, formerly director of the Imperial Department of Agriculture in the West Indies, gave a graphic account of the progress of economic entomology in the West Indies and in India, to which progress, it may be noted, Sir Daniel's own efforts have very largely contributed. Among other items of interest were communications from Prof. Kolbe (Berlin) on the comparative anatomy of the Coleoptera, and from MM. Janet (Paris), Speiser (Sierakowitz), and Lyman (Montreal) on various points connected with classification.

The proceedings on August 2 opened with a luminous and admirably delivered discourse by M. Blanchard (Paris) on medical entomology. The eloquence of the lecturer, and the vast importance of the subjects with which he dealt—malaria, yellow fever, and the sleeping sickness, all of which are directly dependent for their spread on the agency of insects—made a great impression on his audience. The day's programme also included an excellent lecture by Father Wasmann on ants and their guests, illustrated by lantern-slides; communications by Prof. Theobald on the distribution of the yellow-fever mosquito, *Stegomyia fasciata*; by Prof. Carpenter (Dublin) on the warble-flies; and others of equal interest.

The business on August 3 was largely taken up with the subject of mimicry and its bearing on evolution. The proceedings began with the delivery of a discourse by Dr. F. A. Dixey, F.R.S. (Oxford), on the general subject of insect mimicry. The lecture, which was plentifully illustrated by lantern-slides, directed especial attention to the ascertained data of mimicry in relation to affinity and to sexual, seasonal, and geographical conditions. Various suggested explanations of the phenomena were discussed in the course of the lecture, and the opinion was advanced that natural selection afforded the only reasonable interpretation of the facts at present within the knowledge of entomologists. Special aspects of the subject were afterwards dealt with by Dr. Karl Jordan (Tring) and Prof. Poulton, F.R.S. (Oxford), the former exhibiting an interesting series of lantern illustrations, and the latter showing a wonderful series of models and mimics captured at the same time and place by Mr. Wiggins in Uganda. A note of scepticism was struck by Mr. Schaus, who, on the strength of many years' observation in the neotropical region, was disposed to deny that mimicry was of any service to the insects exhibiting it. A lucid exposition of Mendelism as applied to the Lepidoptera was given by Prof. Punnett (Cambridge), and an interesting account of his experiments on the influence of temperature on seasonally dimorphic moths was contributed by Mr. F. Merrifield (Brighton).

On August 4 much interest was excited by Mr. Donis-thorpe's lecture on ants, with their bidden and unbidden guests, and also by Prof. Sjostedt's narrative of the Swedish expedition to Kilimanjaro. Able communications were also received from Dr. Horn (Berlin), M. Bouvier (Paris), M. Honrath (Budapest), and others.

On August 5 Mr. Howlett, of the Agricultural Research Institute at Pusa, India, gave an excellent account, illustrated by numerous photographs, of the work of that most useful institution; and M. Lahille (Buenos Aires) discoursed to an appreciative audience of the progress of economic entomology in the Argentine. The sectional programme also contained, amongst others, contributions from Dr. W. J. Holland (Pittsburg), Mr. H. Skinner (Philadelphia), and Dr. Horn (Berlin); but the chief business of the day consisted in the winding-up address of the president, Prof. Lameere, and the selection of Oxford as the scene of the next International Congress of Entomology, to be held in 1912, with Prof. Poulton, F.R.S., as president.

The evening of August 5 was devoted to a banquet at the Taverne Royale, and on August 6 M. Max, Burgomaster of Brussels, entertained the members of the congress at a grand reception in the Hôtel de Ville. The exhibition buildings were open to members throughout the whole of the congress, and excursions were organised in the course of the week to the Congo Museum, the Ardennes, the Field of Waterloo, and other places of interest. The Brussels Museum of Natural History was also visited, and its treasures described by members of the staff.

The congress, as a whole, was an undoubted success. Any defect that may have been noticed in the arrangements was probably due to the fact that, this being the first occasion of the kind, there were no precedents to guide those responsible for the administration. Some inconvenience was suffered from the circumstance that the Salle des Fêtes was in request for other purposes, which interfered to an appreciable extent with the scientific business of the general and sectional meetings; for this, however, compensation was found in the varied attractions of the exhibition, free access to which, by the liberality of authorities, was allowed to all members of the congress.

It is satisfactory to be able to record that, of the 292 members, 67 were representatives of the United Kingdom, its colonies and dependencies. The contributions made by our countrymen to the scientific work of the congress may fairly be said to have surpassed in extent and value those of any other nation—a fact which is of good augury for the future of entomological research within the borders of the British Empire.

THE FIFTH INTERNATIONAL CONGRESS OF PHOTOGRAPHY.

THE International Congresses of Photography, the first of which was held in Paris in 1889, are arranged at irregular intervals as opportunities offer or necessity renders desirable, that representatives of all countries may meet and discuss questions of general importance. It is hoped by this means to avoid, or at least mitigate, the confusion that results from variations in standards, nomenclature, and methods, especially when such variations are due more to accident than intention.

The fifth congress, which has just been held in Brussels, was well supported, most of the European nations, as well as America, being represented. More than eighty communications were included in the programme, and these were classified into three main sections:—(1) Scientific questions; photochemistry; scientific applications of photography. (2) Technique of photography; artistic questions; industrial applications of photography. (3) Photographic documentation and archives; bibliography; legislation. The proceedings of the congress will be published in full in the report that will be issued in due time.

Several of the communications were of the nature of reports setting forth the present state of the section of photographic work dealt with. Captain Th. J. Saconney dealt with aërial photo-surveying. E. Deville gave details concerning photo-surveying in Canada, from which we learn that the extent of the region so surveyed is somewhat greater than the combined areas of Holland and Belgium, the most interesting application of the method being its application in defining the frontier between Alaska and Canada, a district of lofty mountains. A commission was given three years to report concerning a frontier of one thousand kilometres in length, and as only the short summer season of each year was available, on account of the climatic conditions, other than a photographic method would have been impossible. A satisfactory map was prepared from the three thousand photographs made. The photographic method of surveying employed in Canada is eminently practical, not excluding other methods, so that it should be understood merely that photography plays the most important part in it.

Prof. Wilder D. Bancroft contributed a long report on the photographic emulsion, and from the facts that he has set in due order concludes that the silver bromide grain is a complex of silver bromide, gelatine, and water, and that "the process of ripening consists in changing the composition of the silver bromide grain towards an unknown, optimum concentration." He concludes, too, that it seems theoretically possible to make an almost infinitely fast plate having a very fine grain. Dr. R. Luther set forth the various arguments concerning the nature of the developable image, and J. Desalme reported on present notions concerning the theory of development. The latter considers that the electrolytic hypothesis affords a much better explanation of development than that based on a reduction by a purely chemical process, that is, that a developing solution contains an electrolyte and a depolariser suitable to the positive ions produced. This explains the non-equivalence of the alkalies if substituted in the proportion of their combining weights.

The difficulties of measuring the true opacity or obstructive power of photographic plates were described by F. F. Renwick, who stated that the apparent opacity of a negative under any given conditions is the algebraic sum of several variable properties. These he classifies as the simple obstructing power, the diffracting power of small particles and of the slightly rough surface of the film, the increase in transmitted light when the incident light falls obliquely on the surface, and the increase when the plate being measured is placed close to a reflecting surface if the difference between the readings with the negative so placed, and when the negative is removed, is taken as the opacity. He also criticised adversely the use of acetylene flames as light standards unless many stringent precautions are taken. The principles involved in attempting to measure the diffuse reflecting power of photographic plates were enumerated by A. Callier and R. von Camvenberghe, but they gave no practical details. Drs. Mees and Sheppard described various improvements in acetylene burners when used as secondary light standards, to meet objections that have been urged against earlier forms, and referred shortly to other standards. Dr. E. Goldberg described an apparatus that he has devised (made by Schmidt and Haensch, of Berlin) by means of which the characteristic curve of a plate can be obtained without the more or less tedious plotting generally done. From the group of papers dealing with these branches of the subject, it is clear that the measurement of the densities of photographic plates is a process still set about with difficulties and confusions, and that much work remains to be done in this direction.

Coming to the more technical branches of the subject, we find that a great many widely different matters were treated of. Prof. R. W. Wood described how to take photographs with infra-red and ultra-violet lights. For the infra-red he uses, as a screen, a very dense cobalt glass with either a saturated solution of potassium bichromate or a suitable red aniline dye, and, of course, a suitably red-sensitised plate. Under such conditions grass and trees in full sunshine appear snowy white and the sky as black as midnight. All shadows are very black, as there is practically no light from the sky to illuminate them. For the ultra-violet photographs, quartz lens were used coated with metallic silver to such an extent that a brilliantly lighted window was barely visible through them, and appeared of a deep violet colour. The light transmitted was of wave-lengths from 3100 to 3250. When photographed under these conditions, certain white flowers (as phlox) and Chinese white (zinc oxide) appear as if absolutely black, but ordinary landscapes do not show points of much special interest. Prof. Wood suggests various possibly useful applications of such methods. Prof. R. Namias has examined prints toned with gold and platinum to ascertain the amount of precious metal entering into the finished print. C. W. Gamble described a method of determining the melting point of gelatine jellies. He uses capillary tubes, and notices when the concave meniscus changes to a flat surface.

A. and L. Lumière and A. Seyewetz classified and compared the various gelatine-hardening agents, and recommend the use of quinone and its sulphonic derivatives when the gelatine is on a rigid support, in preference to formalin, as the latter tends to contract the gelatine and detach it. They find that quinones in acid solution are serviceable for the reduction of photographic silver images, and that their action is comparable to that of ammonium persulphate in appearing to attack by preference the denser deposits. They suppose that the resulting hydroquinone tends to deposit silver, by reduction from the solution, on the surface, and so to prevent the loss of the thinner deposits.

A method for getting instantaneous exposures on autochrome plates was described by Ch. Simmen. The plate is sensitised to red by bathing, and with a suitable compensation filter is eight times more sensitive than the untreated plate. N. S. Amstutz reported on recent progress in process work in the United States of America. We notice that Paynetype has not yet come into general use; that collotype has not made much headway, in spite of the hopes of its adherents, presumably for lack of attention to climatic conditions; but illustrative telegraphy is taking its place as a practical method of transmitting pictures. W. F. Cooper and G. A. Freak have compared nickel (or nickel-surfaced plates) as a substitute for copper for half-tone work, and find that ferric chloride acts on it (for etching) at something less than half the rate that it acts on copper.

Telephotography is the subject of a report by Captain Owen Wheeler; other than this, photographic optics was hardly represented. It will, of course, be understood that in this summary it has not been possible to refer to more than a comparatively few of the communications made to the congress. C. J.

THE ORIGIN AND CLASSIFICATION OF MAMMALS.[1]

A HEARTY welcome may be accorded to the work referred to below, which contains a well-elaborated and highly philosophical digest of the present state of our knowledge of the past history and relationships of the various groups of mammals, and the inferences which may be legitimately drawn from such knowledge. The work owes its inception to the need for a brief outline of the history of the ordinal classification of mammals for use in Columbia University; but it was soon found inadvisable to limit its scope to this portion of the subject, and it consequently covers a much wider range. It retains, however, traces of its original limitation in consisting of two distinct parts, namely, an account of the typical stages in the history of the classification of mammals, and, secondly, of the genetic relations of the orders and a discussion of the origin of the class as a whole, with special reference to the problem of the auditory ossicles.

The first part, although of great value to the student, may be passed over without further mention on this occasion, and attention concentrated on the second. Before proceeding to a brief survey of the latter, reference may be made to the author's endeavours to give a rational explanation of the meaning of each important feature with which he has to deal, and not to rest content with a mere catalogue of bare facts. Indeed, the adherence to mere facts on the part of so many of his predecessors has been, in the author's opinion, a fruitful source of our lack of progress in getting a real grasp of mammalian evolution, and he specially urges the need of an osteological treatise written from this newer point of view. It is added that the importance of osteology in the study of mammals cannot be overestimated, as the clue to the origin of the class and the relationships of its constituent orders can be obtained from palæontology alone, which in this case is restricted to the osteology and dentition.

As regards the origin of mammals, Mr. Gregory adopts the view that the class is descended in all probability from that section of the anomodont reptiles which Dr. Broom has proposed to designate cynodonts, but which are more commonly included in the theriodonts, although not from any known member of the same. The features in which cynodonts approximate to mammals on the one hand and to more ordinary reptiles on the other are carefully formulated. The difficult question of the fate of the reptilian quadrate and the homology of the mammalian malleus and incus is left to a great extent open, although the author seems inclined to favour the view that the incus represents the quadrate and the body of the malleus the articular.

The second chapter of this part is devoted to the monotremes, which are regarded as undoubted mammals, with evident relationships to the marsupials, as is indeed indicated by their geographical distribution. Nevertheless, monotremes are taken to represent a subclass by themselves, while marsupials and placentals are brigaded together in a second group of equivalent value, and it is added that the divergence of the monotreme from the marsupio-placental stock must have taken place at a relatively early date. Within the same section as the marsupials are grouped, as a second and equivalent order, the Mesozoic triconodonts, which cannot be regarded as true marsupials, and it is noteworthy that the theory of the conversion of the triconodont into the tritubercular type of molar by means of torsion is now definitely abandoned. On the other hand, in view of Gidley's study of Ptilodus, the Multituberculata are now re-admitted to the marsupial order, although the author will not allow that they are diprotodonts. The evidence of the Triassic Microlestes, supplemented by that of the structure of the teeth themselves, indicates that the multituberculate molar is a far older type than the tritubercular, which is first known—in an incompletely developed condition—in the Middle Jurassic Amphitherium.

The view that the carnivores of the Santa Cruz beds are not only marsupials, but likewise members of the same family as the Tasmanian wolf, is definitely accepted, and it follows from this that there is no definite genetic relationship between creodonts and carnivorous marsupials. Indeed, the author considers each group to have been independently derived from small insectivorous and completely or partially arboreal Mesozoic forms, this being, if true, sufficient to indicate that the resemblance between the larger Tertiary forms is due to convergence. In opposition to some of his contemporaries, Mr. Gregory regards creodonts as nearly related to the Insectivora (from which tupais and jumping-shrews are separated as a distinct order, Menotyphla), and likewise considers the latter to be more closely related to marsupials than is the case with any other placental group. On the other hand, he looks upon the palatal vacuities of Erinaceus as secondary rather than marsupial features. The date of separation between Carnivora and Insectivora is considered to be pre-Tertiary, and it is left an open question whether the ancestors of the latter had their incisors extending along the sides of the jaw (instead of being restricted to the front) as in their modern representatives.

Only very brief reference can be made to some of the other orders, among which it is important to notice that the extinct zeuglodonts are included in the Cetacea. Perhaps the greatest changes in classification are proposed in the case of the ungulates, from which the Artiodactyla are removed to form a separate ordinal, and supraordinal, group, as the author believes they have no near relationship with Perissodactyla. On the other hand, the Ungulata are taken to include, not only elephants, hyraxes, perissodactyles, and the South American groups, which are brigaded as Notoungulata, but likewise sirenians. Much is to be said both for and against these proposed changes, but space does not admit of discussing the matter, and it must suffice to add that we find the Primates, with man at the head, forming part of a "superorder" in the middle of the class instead of standing at the head. Whether we accept all his views or not, there can be no question that in this volume Mr. Gregory has accomplished a most valuable and important piece of work. R. L.

[1] "The Orders of Mammals." By W. K. Gregory. Bull. Amer. Mus. Nat. Hist., vol. xxvii., 1910. Pp. 524.

THE MINERAL SURVEY OF PERU.

THE Cuerpo de Ingenieros de Minas del Peru continues to issue actively its valuable bulletins on mining areas. In No. 58 (1908) Mr. A. Jochamowitz reviews the mineral resources of the somewhat remote department of Apurimac, in the mountains south-east of Lima, where the rivers run northward along the ranges to join the great flow of the Amazon. The level lands are mainly devoted to the cultivation of sugar-cane for the production of alcohol; but alluvial gold-areas exist, and gold occurs in decomposed ferruginous zones among the prevalent stratified quartzites. Portuguese miners in old days appear to have secured most of the spoil that could be readily obtained.

FIG. 1.—View from the Lower Cretaceous Coal-beds of Cupisnique, Peru.

Mr. E. T. Dueñas describes, in *Boletin* 62, the provinces of Tayacaja, Angaráes, and Huancavelica, famous for their mineral wealth, from silver-lead to mercury and gold. Here again alcohol is one of the main agricultural products, and the soil of the valleys, when watered, is highly productive. The sugar-cane crop, however, at present suffers greatly from locusts. The three provinces lie in a basin of the Andes, between Lima and Cuzco, and at the head-waters of the Mantaro. The rocks are much faulted, with crystalline masses thrust in among them. A series of slates is regarded as Silurian, and a red-rock series, containing salt, and traceable into that of Cuzco, is referred to the Trias. Mesozoic limestones and sandstones occur in places, and fossils prove some of these to be Liassic and others Upper Cretaceous (p. 154). The author (p. 24) explains the course of the Mantaro as of double origin. The western cañon above Anco is ascribed to the overflow of a lost lake in the upland south of Jauja—this town, by the by, might have been just squeezed into the margin of the map. The second cañon past Coris and Surcubamba was cut by the waters of another lake, the "Lago de Huanta," which has left its gravels below Anco and as far south as Acobamba. The Jauja lake drained into this near Anco. Both cañons are connected with faults running out from the Andes, and their excavation in Quaternary times was thus facilitated, until they grew large enough to drain off their respective lakes and unite in the sinuous course that now forms the Mantaro. We wish that the resources available in the United States Survey for the topographical representation of such problems had been at the disposal of Mr. Dueñas in Peru. Wolfram occurs at Lircay, in the province of Angaráes, and the author reviews the world's production of tungsten, now so important an element (p. 118). Mesozoic coal-seams are found in Huancavelica. It would have been convenient for reference if the name of this province had not appeared at the top of all the pages of the memoir.

The great rise in the price of antimony in 1907 leads Mr. E. Weckwarth (No. 68) to review the occurrences of antimony ores throughout Peru, including antimonial lead and silver ores. The bulletin also forms a compact monograph on the uses of antimony and its metallurgical extraction. No. 69 (1909), by Mr. E. du Bois Lukis, has geographical and geological interest, in addition to its description of a mining area. It describes the coal-bearing strata of the country near Cajamarca, in the midst of the Andes, and contains numerous photographs of the somewhat barren scenery of the highland. Even at Cupisnique, only 40 km. from the coast, we are up among rocky walls and desert features that remind one of the Wittebergen of South Africa (Fig. 1). Steinmann has referred the coal-bearing sandstones at this point to the Lower Cretaceous. In the extensive Piñipata field away to the north-east, above the long Maranon valley, the coal is probably of much the same age (p. 31). These Peruvian coals, which crop out on the hillsides, among strata that can be traced for miles across a rocky country, are mostly anthracitic, with a rather high percentage of ash; but a considerable future is predicted for them, and the Department of Mining Engineers, as in other bulletins, sounds a patriotic note, and urges the Peruvians themselves to do something towards the development of their resources.

The coast of southern Peru, and the Pampas west of the Andes, are studied by Mr. V. F. Marsters in *Boletin* 70 (1909). Here again the numerous illustrations appeal to the geographer, and include several features due to recent volcanic outbreaks. The huge cone of Misti (Fig. 2), more than 22,000 feet in height, appears in several views. A small picture even shows the snow-flecked rim of the crater, with its broad central cone. The pampas are swelling plains of detrital material, which is often of volcanic origin, and volcanic cones sometimes break their surface. They rarely show features due to erosion, and in places contain traces of saline pools. The discovery of a limited deposit of caliche, or nitrate-bearing earth (p. 61),

FIG. 2.—Cultivated alluvial valley-floor near Arequipa, with the volcano of Misti beyond.

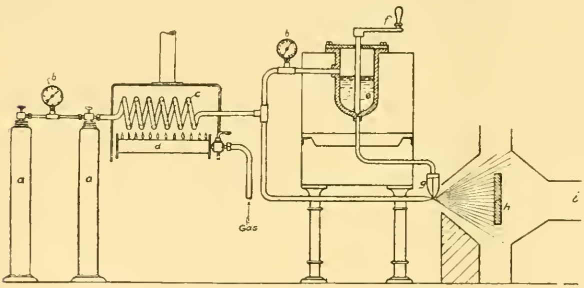
in the hollow of Indio Viejo, leads Mr. Marsters to urge a thorough examination of the pampas between the valleys of the Caraveli and the Chaparra.

Bulletins 71 and 73, on water-supply for agricultural districts, show the wide view taken of their responsibilities by this energetic body of engineers. G. A. J. C.

NEW PROCESS FOR PRODUCING PROTECTIVE METALLIC COATINGS.

THERE are various means of coating metals with other metals, generally of a protective nature; thus, for example, electroplating, galvanising, and drawing the metal. A new process of considerable interest, invented by M. U. Schoop, of Zurich, was described in a paper read before the Engineers and Architects Society of Zurich on April 13, and reproduced in *Metallurgical and Chemical Engineering* (vol. viii., p. 404).

The chief point in the new process is that the metal in the liquid condition is sprayed upon the surface to be coated. The atomising of the metal may be brought about in a variety of ways. The metal is melted in a closed crucible, and is forced out of a nozzle by the pressure of gases or vapours; or the subdivision of the metal may be brought about by causing two jets of metal to pass out of separate nozzles, so that they meet at a suitable angle. These, being under pressure, break up into a fine spray, which is carried forward and coats any object placed near to the spray.



Schoop Process for Production of Metallic Coatings.

The most satisfactory method, however, appears to be to cause the subdivision of the metal by the use of compressed gases. The metal which is to be employed for coating purposes is melted in a closed crucible which has a pipe at the bottom, ending in a nozzle with a capillary opening. Another pipe enters the upper part of the crucible, which is connected with a source of compressed gas, the gas being pre-heated by passing through a coil, *d*. Another tube is connected externally with the gas-pressure tube and ends in a nozzle, which is situated below the metal outlet. The compressed gas impinges with great pressure on the fine stream of metal, which is also being forced out under great pressure. The metal is thus very finely atomised, and is blown against the article to be coated, *h*. Various gases may be used to press the metal out of the nozzle, for example, an inert gas such as nitrogen, and this may also be used for atomising; but, on the other hand, for atomising agent an oxidising gas may be used. It has, for instance, been found possible to produce coatings of lead peroxide of a firmly adhering character.

Different metals naturally behave differently, depending upon their fluidity, melting point, oxidisability, and so on. The material of the crucible also depends upon the metal which is to be melted in it. Thus for melting aluminium and its alloys iron or steel crucibles cannot be used. It appears, indeed, that under high pressures metals alloy much more readily and quickly than under ordinary atmospheric pressure. Obviously alloys may be melted and sprayed, but the metals require to be mixed in their eutectic proportions.

What probably happens in the spray process is that when the metal forced out under pressure leaves the nozzle, it is met by the gas stream, also under pressure. The stream of metal is thus torn up and converted into a mist. The individual particles of the metal when sprayed on to the surface to be coated lose their surface tension and their globular form, and are pressed out on the surface in the form of a circular film. These circular films overlapping become automatically welded into a continuous homogeneous coating. Calculation shows that with a pressure of 25 atmospheres the metallic particles have a speed of 20 km. per second—*i.e.* twenty-five times the speed of the bullet from the gun used in the German Army. Owing to this enormous speed of the metal mist, metallic surfaces of a surprisingly high density are produced. For example, the density of rolled tin was found to be 7·47, and that of the sprayed tin 7·42.

A point of great interest is that the metallic mist is at a comparatively low temperature, at about 40° C. to 60° C., in spite of the fact that the molten metal as it is ejected has a temperature of several hundred degrees, and also the atomising gas. This rather surprising fact is probably due to the sudden reduction of tension of the gas, whereby the metal mist, which presents a relatively very great surface, is also cooled. This is, however, a very great advantage, because it is possible to give a metal coating to substances of low melting point or of high inflammability, such as paper, wood, celluloid, wax, &c.

The hardness of the metal film is greater than the hardness of metallic films produced by other methods, *e.g.* casting or rolling. This great hardness should be of advantage in the manufacture of electrotypes and cuts, in which hardness is an important feature. Microscopic examination also shows that the surface is absolutely homogeneous.

In carrying out the operation, the metallic surface to be coated is first freed from oxide or adhering dirt. In many cases, especially when metals are to be coated, it is found advantageous to pre-heat the surface before spraying on the metal. It is not, however, absolutely necessary to pre-heat; consequently, with a portable apparatus, metallic structures such as bridges, machinery, and so on, could easily be coated, and it is claimed that it would be no more expensive than painting. At to the applications, they are almost numberless. It may be used for all cases in which plaiting is at present employed. Paper may be coated with metal so that it can be used for packing such things as chocolate, tea, and so on, in place of tin foil. The cases of balloons can be coated—an aluminium coating 1 30th mm. thick is sufficient to render it quite gas-tight.

The wooden propellers of aëroplanes coated in this manner are protected against the action of the weather, and the air friction is considerably reduced. Wall-paper, stage scenery, and textiles can all be coated with metals.

Certainly the process is one of great interest; and one point of particular note is, it is now possible to coat metals with aluminium, which will be perhaps one of the most useful applications of this new process. In this case it will be necessary to employ a crucible the material of which will not alloy with the aluminium.

THE GALITZIN SEISMOGRAPH.

DR. SCHUSTER has recently presented to Eskdalemuir Observatory a pair of Galitzin seismographs, and the instruments have been set up under the personal direction of Prince Galitzin, member of the Imperial Academy, St. Petersburg. Similar instruments have been in use in Russia for some time, with very remarkable results, and they are rapidly being adopted by the principal Continental observatories.

The object secured by these instruments is that they record, not merely the occurrence of an earthquake on a large scale of magnification, but also give an exact reproduction of the horizontal motion of the earth at the observing station.

Primarily, the seismograph is a horizontal pendulum on the principle of Dr. Milne's apparatus, but instead of reducing friction to a small amount, Prince Galitzin increases it until the pendulum reaches the limit of "aperiodicity" or "dead-beatness." Electromagnetic damping is so strictly proportional to the velocity that it is immensely superior to other forms of frictional damping. A copper plate attached to the pendulum moves across the field produced by two strong horse-shoe magnets, and the pole distance is adjusted until the required degree of damping is attained. There is no other friction, as the pendulum is carried by steel wire.

A heavily damped and truly dead-beat pendulum reproduces with great precision the motion of the earth, which sets the pendulum in motion.

The actual movement of a heavily damped pendulum is very small, but Prince Galitzin has shown how to magnify the movement to any required degree without loss of accuracy. A coil of fine wire attached to the pendulum moves in the field of a second pair of horse-shoe magnets, and the currents so generated in the coil when the pendulum moves are measured by a D'Arsonval galvanometer which has the same natural period as the pendulum, but the circuit resistance is chosen so that the galvanometer is also "dead beat." It can be shown that, except for a few special cases, the motion of the galvanometer mirror is a precise reproduction of the pendulum motion, and hence of the earth motion. By means of an experimental table on which the instruments are tested, Prince Galitzin has shown that impressed motions of great complexity are faithfully reproduced on the galvanometer. It is true that the final scale of magnification differs for different periods of incident waves, but in actual seismological practice it is comparatively easy to allow for this.

The registration is made photographically by reflecting light from a fixed source and producing a dot of light on a strip of photographic paper carried on a rotating circular drum. The paper moves at a rate of 3 cm. per minute, and the drum is carried sideways, so that it can be used for a twelve-hour record. The trace is interrupted every minute by an electrical time break, and so the times can be estimated with ease to half a second.

The pendulum and galvanometer are duplicated, so that two records are obtained on the paper. One of these gives the motion of the earth from north to south and the other the motion east to west. They are arranged so that a movement of the earth to north or to east is represented by a motion of the corresponding dot up the sheet.

Prince Galitzin has shown that the ratio of the amplitudes of the very first impulse on the two pendulums gives the tangent of the azimuth of the epicentre. He has proved practically that this determination of the direction is accurate to $\frac{1}{2}°$ of arc.

The usual method (Wiechert Zöllpritz) of calculating the distance from the times of occurrence of the first and second phases is followed.

Thus a pair of Galitzin seismographs enable an observer at a given station to determine the epicentre of an earthquake with great precision. Further, one can follow the complete movement with confidence, although a certain amount of computation is strictly necessary when waves of widely different periods actually occur. Intelligent examination of the record shows when this is necessary.

Identity of natural period of pendulum and galvanometer and strict "aperiodicity" is the ideal. In practice it is sufficient to get approximate equality, and determine the differences by a simple process of standardisation. For information on this point the reader is referred to Prince Galitzin's original memoirs in the publication of the Imperial Academy, St. Petersburg. G. W. W.

RECENT AGRICULTURAL PUBLICATIONS IN GREAT BRITAIN.[1]

THE Board of Agriculture issues each month a Journal intended for farmers, small holders, and others interested in agriculture, and, in order that it shall be accessible to all, the price is fixed at the very low sum of fourpence. It represents a very laudable, and on the whole successful, attempt to bring to the farmer the best scientific work on the problems confronting him; it also deals with matters of agricultural importance in foreign countries.

A large proportion of the papers is devoted to plant diseases. In a recent issue, Mr. Salmon describes the Sclerotinia disease of the gooseberry. The mycelium of the fungus penetrates into the tissue of the stem, permeating the cortex and the bast; in time the stem is completely "ringed" and the bush dies. Sometimes the attack is not in the main stem, but in the young wood, the leaf, or the berry. Burning all infected old and dead wood has been found the best method of control. Mr. Salmon points out that this fungus is capable of developing vigorously on dead parts of the bush, while the American gooseberry mildew, with which growers have sometimes confused it, is not. Where burning is not practicable, recourse may be had to spraying with copper sulphate solution.

Other papers deal with possible improvements in agricultural practice. Of these, one is by Mr. Priestley on the effect of overhead electrical discharges on plant growth. It has been known for some time that an electrical discharge in some way increases plant growth, but the practical difficulties have only recently been overcome by the use of Sir Oliver Lodge's high-tension valves, in conjunction with a Ruhmkorf coil of a type similar to that used in X-ray work. The physiological problems are not yet solved, and the practical application of the method is, of course, very limited so far as can be seen at present. But the fastidiousness of the present generation demands fruit and vegetables in unnatural seasons, and the market gardener, in furnishing the supply, is prepared to adopt any methods likely to increase the rate of growth, provided the cost is not too high. Mr. Priestley's data show that a good case can be made out for the use of electrical discharges.

Supplements to the Journal are periodically issued, each dealing with a special subject. One deals with the work of the International Agricultural Institute, but it is not very clearly arranged. Another gives *in extenso* the papers read at the discussion on wheat at a joint meeting of Sections B and K with Subsection K of the British Association last year. As this discussion has already been dealt with in these columns, it is unnecessary to say any more here; the plan of printing and distributing widely these British Association discussions is admirable, and will, we trust, be acted upon again.

Under the able guidance of Mr. Mackenzie, the Journal of the Royal Agricultural Society is steadily making up lost ground. This Journal has had a remarkable history. The early volumes, from 1840 (when it began) to about 1860, contain some of the finest papers that have been written on agriculture and agricultural science. Then it had a long series of lean years, due, no doubt, in part to the decadence of agricultural science in England during that period. It is now taking its place in the remarkable revival that the last few years have witnessed. Mr. Hall gives a connected account of the various investigations he and other workers at Rothamsted have made on the secondary effects of manures on the soil. Sulphate of ammonia tends to make the soil acid, and therefore infertile, unless sufficient lime is present; the acidity is caused by certain fungi in the soil which decompose the salt to obtain the ammonia and thereby set free sulphuric acid. On the other hand, nitrate of soda tends to make the soil alkaline and to get it into a sticky, unworkable condition. The decomposition is in this case brought about at the roots of the plant in some way not yet understood, and results in the acid radicle entering the plant while the base remains outside as sodium carbonate. The latter substance is known to deflocculate clay, and is the cause of the unfavourable soil condition thus induced. Suitable methods of treatment are suggested.

Mr. F. H. A. Marshall discusses some of the physiological problems of the stock-breeder. This subject has been curiously neglected, and it is of interest that Cambridge, which has taken the lead in plant-breeding work on Mendelian lines, should now be turning its attention to stock-breeding. The practical man has acquired by long experience a vast fund of information, which, however, needs sorting out and systematising. Apart from the problems involved in raising pedigree stock—a highly

[1] Journal of the Board of Agriculture, and Supplements; Journal of the Royal Agricultural Society; Agricultural Students' Gazette.

specialised and valuable, though restricted, branch of agriculture—there are many other questions of interest to the physiologist. Thus it is a very common practice to castrate male animals in order to increase their docility and their capacity for laying on flesh. Ovariotomy of the females is also practised, though much less commonly, but with the same object. Abortion is another matter to which attention is directed. Enormous amounts of money are involved in these stock-breeding problems, and in addition many of them are of considerable physiological importance.

The *Agricultural Students' Gazette*, the organ of the Royal Agricultural College, Cirencester, contains articles by old students or members of the staff dealing with questions of general agricultural interest. Mr. B. Bathurst writes on tariff reform and the tenant farmer, and Mr. Boulger on the biology of the soil. The scientific work of the college is published in a separate bulletin, which has already been reviewed in these columns.

THE EDUCATIONAL VALUE OF THE SCHOOL GARDEN.[1]

It is becoming increasingly common for rural elementary schools to start a garden in which the scholars may take a certain number of lessons during the season. The idea of a school garden appeals to the village community; the village critic is nothing if not practical, and he insists, and with a good show of reason, that if book-learning is any good at all it ought to teach a man how to raise onions and potatoes well. So successful has the movement been that it has spread widely, and has reached a stage when the whole question of the relation of gardening to rural education may usefully be considered.

The circular before us contains a highly suggestive discussion of the place of the garden in the school curriculum. The garden, it is pointed out, makes two very powerful appeals to those who wish education in our public elementary schools to be more practical; it leads to the formation of habits of thoroughness, and it is eminently useful. But it may also be dealt with on a much higher plane. The purpose of the garden should be to educate boys and girls, and not merely to show them the usual ways of cultivating the common vegetables and flowers, or to practise them in the manual operations of gardening. The scholar must be led to understand the reasons of the common processes in their relation to the soil and climate, the causes and conditions of health or disease in plants, and something of the principles on which the selection and improvement of seeds and plants depend. It is, indeed, a branch of nature-study rather than a training for a profession, and it has two great advantages over many other branches: it produces visible and tangible results—thereby appealing forcibly to the utilitarian instincts of the child—and it does not, or should not, degenerate into the series of disconnected object-lessons of little educational value that sometimes passes under the name of nature-study.

Gardening has another great advantage over other subjects in that it is essentially experimental. Set experiments cannot easily be made because the areas are far too small for inequalities of the ground to be smoothed out; indeed, they may be wholly misleading. But throughout the scholar is trying and trying again, observing his results, attempting to account for his failures and to devise better methods for the future. The teacher has to strike the happy mean between doing too much for the scholars, thus relieving them of the responsibility of thinking, and of doing too little, and leaving them overwhelmed with a sense of failure.

Of course, the garden is not necessarily a success. If the teacher has no taste for gardening or nature-study he had much better let them alone; he will save himself a good deal of discredit and the children a good deal of trouble. There is no particular virtue in a wide curriculum. If the subjects are treated in a dry and illiberal fashion, no appeal is made to the child's natural interests and his imagination is left untouched, in spite of the range of the syllabus. On the other hand, a restricted choice of subjects liberally treated may have great educational value. It all turns on the teacher himself; his choice of material must be largely determined by what interests him most.

In order to get the fullest value out of the gardening lesson, it should be correlated as much as possible with the other school work—with drawing, arithmetic, composition, nature-study, and so on. A number of hints are given showing how this may be done.

The publication is very interesting, and shows a lively appreciation by the Board of the possibilities of the case. A teacher who works in accordance with the spirit of these suggestions will do some distinctly useful work.

[1] Suggestions for the Consideration of Teachers and others concerned in the Work of Public Elementary Schools. (Circular 746 of the Board of Education.)

THE TELEGRAPHY OF PHOTOGRAPHS, WIRELESS AND BY WIRE.[1]

It frequently happens that when two alternate processes are available for certain work, and one of them is considerably less practical than the other, the less practical one is possessed of much higher scientific interest. This may certainly be said of the telegraphy of pictures and photographs. The whole of the methods of transmission can be classed as either purely mechanical or dependent on the physical properties of some substance which, like selenium, is sensitive to light.

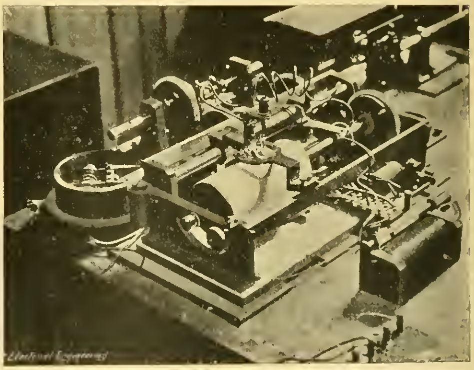


FIG. 1.—Photograph showing a Portion of the Photo-telegraphic Apparatus.

The latter methods are of no little scientific interest, and, although very delicate and for the moment obsolete, there is every likelihood of their coming into more extended use later on.

The telegraphy of pictures differs only from the transmission of ordinary messages in that the telegraphed signals, recorded by a marker on paper, must essentially occupy a fixed position. In the case of an ordinary telegram, it matters little whether the received message occupy two, three, or more lines when written out on paper, but when a picture is telegraphed every component part of it must be recorded in a definite position on the paper.

Suppose you greatly enlarge a portrait, and divide it up by ruled lines into a thousand square parts. Suppose, also, that the photograph is printed on celluloid, so that it is transparent. If, now, the portrait be held in front of some even source of illumination, it will be seen that each square—each thousandth part—is of different density. The light parts of the photograph will consist of squares of little density, the dark parts of squares of greater density, and so on. In this way the photograph is analysed into composite sections, each section corresponding precisely to a letter in a message; letters and spaces recombined form

[1] Discourse delivered at the Royal Institution on Friday, April 22, by Mr. T. Thorne Baker.

words and messages; squares of different densities recombined, in correct position, form a photograph.

I propose to deal with the more practical system first, which, as already pointed out, is perhaps the less interesting from the theoretical point of view. The telectrograph system has been employed by the *Daily Mirror* for the transmission of photographs since July, 1909, and has been worked very regularly between Paris and London and Manchester and London.

Instances of its use may be recognised in the publication of photographs taken in court in the recent Steinheil case at Paris, when photographs of witnesses or prisoners were sometimes received in London actually before the court rose at which they were taken, a clear day being gained in the time of publication.

The method of telegraphing photographs that has been employed on a large scale by the *Daily Mirror* may be called a practical modification of several early attempts.

Fig. 2.—Fashion Plate Transmitted by Prof. Korn's Telautograph.

The effect of an electric current to discolour certain suitable electrolytes or to set free an element or ion that can be used to form with a second substance a coloured product was employed in many early forms of instruments for telegraphing writing, &c. If we break up a photographic image in the way already described into lines which interrupt the current for periods depending on their width, these interrupted currents can be used at the receiving station to form coloured marks, which join up *en masse* to form a new image. My telectrographic process is thus briefly as follows:—

At the sending station we have a metal drum revolving under an iridium stylus, to the drum being attached a half-tone photograph printed on lead foil. Current flows through the photographic image to the line, and thence to the receiver. The receiver consists of a similar revolving metal drum, over which a platinum stylus traces. Every time the transmitter style comes in contact with a clear part of the metal foil, current flows to the receiver, and a black or coloured dot or mark appears on the chemical paper. But you will readily understand that if our reproduction—built up of these little marks, which have to be made at the rate of some two hundred per second—is to be accurate, each mark must be only exactly as long, in proportion, as the clear metal space traversed by the stylus.

It will be easier to explain the system by means of the rough diagram shown in the figure (Fig. 4). The transmitting instrument is shown on the left, the receiver on the right. A metal drum is revolved by a motor, one revolution every two seconds; over this a metal stylus or needle traces a spiral path in the same way as a phonograph. On the drum is fixed a half-tone photograph broken up into lines, and printed in fish-glue upon a sheet of lead foil. I will show one of these line photographs on the screen, and you will see that the light and shade of the picture are made up of masses of thinner or thicker lines, with clear spaces in between.

As the stylus traces over such a photograph, its contact with the metal base is interrupted every time one of these fish-glue lines comes beneath it, and for such a time as depends, of course, on the *width* of the line. The transmitting instrument thus sends into the telegraph lines a series of electric currents the periods of duration of which are determined by the width of the lines composing the photograph.

A similar stylus, S_2, traces an exactly similar path over a revolving drum in the receiving instrument, but round this drum is wrapped a piece of absorbent paper impregnated with a colourless solution, which turns black or brown when decomposed by an electric current.

Fig. 3.—Photograph Wired from Paris to London by the Author's Telectrograph.

What happens, then, is that every brief current which passes through the paper causes a mark to appear on it. The width of the mark depends on the duration of the current—or should do—so that you will see that these marks gradually combine to recompose the photographic image.

This method is all very well in the laboratory, but when we come to try it over a long distance the capacity of the line at once causes serious interference. It is well known that if a current be sent to some apparatus, such as a telegraph, from a distance, the current having to pass through long wires the capacity of which is appreciable, a certain time is taken for the current to charge the line, and the line discharges itself into the apparatus with comparative slowness. If the circuit be closed by means of a Morse key, the time of contact at the key being a sixth of a second—a common time of duration of a short tap—the discharge of current from the cable would be considerably longer than one-sixth of a second. When, therefore, we are sending signals through the line at the rate of 175 per second, it is not difficult to see that every signal will run into the next dozen or so at the receiving apparatus, and the result will be a hopelessly confused mass of overlapping marks. This is well illustrated in Fig. 5, where A shows a series of taps passed through a cable of high capacity into the telectrograph receiver; instead of getting a series of sharp dots or short lines, we get elongated lines ending off in tails. Without the capacity, we get the short lines as shown in the B series. These short, definite lines are again obtained, even when the capacity is present, in series C; but in this case I had shunted on to the receiver what I have termed the line balancer, a modified form of shunt apparatus embodying the principles of *wiping out* residuary currents from the cable in the way frequently made use of in duplex telegraphy.

The use of this apparatus has rendered commercial the old ideas of telegraphing by the electrolytic method, and as many as three hundred sharply defined chemical marks can be recorded in one second by its means. The method of application will be seen if we have the last slide shown again (Fig. 4); here, shunted on to the line (which is closed by the stylus S_2 and the metal drum), is a circuit containing two batteries, B_1 and B_2, and the two sections of a divided 1000-ohms resistance, W_1 and W_2. Shunted across the variable contacts of the resistances is a variable condenser K. By varying the resistances, W_1 and W_2, we can vary the power of the current used to sweep out the residuary charges in the line; the current can, of course, flow through the chemical paper on the drum, but the pole of the battery B_1, connected to the style, is of opposite sign to that of the line unit connected to it.

When the leakance on the line is great and evenly distributed, less reverse current from the balancer is necessary, this being quite in accordance with Heaviside's formulæ for telephony over lines with capacity and inductance. It is interesting to note, also, that by increasing the voltage of the reverse batteries B_1 and B_2, considerable greater contrast can be obtained in the pictures; the finer the half-tone screen employed in splitting up the photographs into lines, the higher, again, must the voltage of B_1 and B_2 be made.

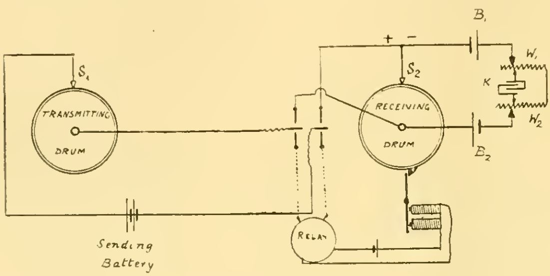

Fig. 4.

I should like to take up a few moments in referring to the actual utility of photo-telegraphy. The demand by the public for illustrations in their daily papers must be admitted. News is telegraphed in order to expedite its publication, and photographs illustrating this news can therefore be telegraphed advantageously. But where a large installation and establishment, with accumulators, a large instrument and an operator to work it are required, the cost of telegraphing every individual picture becomes quite out of proportion to its value. It is therefore desirable to direct especial attention to the portable instruments, the first one of which is shown for the first time to-night. A photographer going to obtain pictures of some important function or interesting event can take the machine with him, prepare his pictures, and telegraph them to his head office, and when the event is over he simply returns with the apparatus. For criminal investigations the portable instrument will, I feel sure, become of considerable value also. Through the continued courtesy shown by the Postmaster-General and Major O'Meara, the engineer-in-chief, we have been given every facility for developing the work, and I believe that the uses of the portable instrument will before long have been amply demonstrated.

If a picture revolving beneath a tracer has to re-draw itself, as it were, on a piece of paper perhaps hundreds of miles away, it is obvious that each mark re-drawn must occupy a precisely similar spot on the new paper as it does in the original picture. As cylinders or drums are used in picture telegraphy, this means that they must revolve in perfect unison. If one drum were to gain on the other we should have, in the case of a portrait, a nose being recorded where the eye ought to be, or something equally disastrous; in fact, if the two machines get the least bit out of step, the received picture is completely ruined. The method of synchronising used by Prof. Korn has proved very satisfactory, and has been adopted in practically all systems of photo-telegraphy. The motors which drive each drum are run at about 3000 revolutions per minute, and geared down very considerably, so that the drums themselves revolve, perhaps, at 30 revolutions per minute; the motors are run from secondary batteries of ample capacity to ensure smooth working, and should be run for a sufficient time before beginning a transmission, to allow of their warming up.

The speed of each motor is controlled by a regulating resistance in series with the field magnets, and the speed is ascertained by means of a frequency meter, which indicates the number of revolutions per second. The dial of this meter is shown on the screen. A set of tuned steel tongues are fixed in front of a magnet, which is supplied with alternating current obtained from slip rings on the motor, and each tongue has a different period of vibration. When the alternations in magnetism correspond with the period of vibration of any one spring, that spring vibrates, and thus serves as an indication of the speed of the motor.

The receiving drum is revolved a little quicker than the transmitting drum. It consequently completes its revolution before the transmitter. It is then stopped by a steel check, and is obliged to wait until the other drum has caught it up. When the transmitting drum has completed *its* turn, a fleeting contact comes into play, a reverse current is sent to the receiving instrument; this is led into a polarised relay, which actuates an electromagnet, and this magnet removes the check.

Thus, however much one drum gets out of step with the other, the fault is limited to each revolution, and both drums must always start off in unison for each new revolution. I have found that where each operator endeavours to keep his motor running uniformly by regulating the resistance according to the fluctuations recorded by the frequency meter, the personal element makes itself visible in the results; straight lines appear wavy, and the synchronism is not at all good. I therefore tried very carefully calibrating the motors by timing first, and then arranged that, once started, the motors should not be touched; the gain in speed of each is approximately the same if both motors are run from secondary batteries of the same ampere-hour capacity, and in this way we have obtained the most perfect results as regards synchronisation.

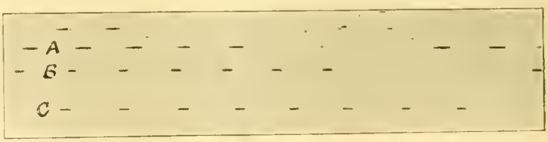

Fig. 5.

The great advantage of this process is that the whole operation is in full view, whereas with systems in which the received picture is obtained on a photographic film one has to develop such film before it is possible to discover whether anything is wrong. With the receiver described, the operator keeps his hand on the sliding contact of the resistances, and merely adjusts their position during the first two or three seconds, according to the condition of the electrolytic marks, *i.e.* whether crisp and concise or not. The transmitting cylinder can be used as the receiving cylinder, and the apparatus is thus reduced to the limits of simplicity.

Towards the end of last year I designed a portable machine, two of which Mr. Sanger-Shepherd has just completed, embodying in them a number of improvements of his own, and these machines, which have worked successfully on their trials, are shown on the lecture table to-night. They are suitable for line or wireless work, and will, I believe, prove of great value in naval and military operations.

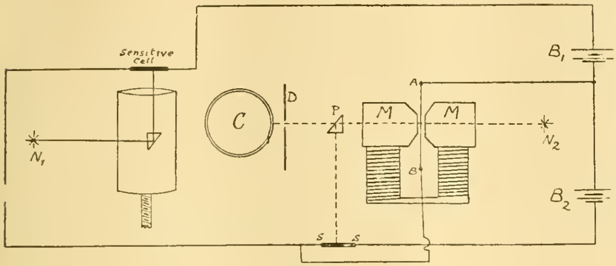

FIG. 6.

The *Daily Mirror* inaugurated the Paris-London photographic service in November, 1907, with Prof. Korn's selenium instruments, which I shall briefly describe, as Korn is now making two new selenium apparatus with the view of transmitting photographs from New York to London. In this system use is made of the fact that the electrical resistance of the metal selenium varies according to the strength of illumination to which it is subjected, a beam of light passed through the light and dark parts of a photograph in succession being used to vary the strength of an electric current sent to the receiving apparatus.

In Korn's selenium transmitter light is concentrated from a Nernst lamp to pass through a revolving glass cylinder, round which a transparent photograph (printed on celluloid) is fixed, the beam traversing the film at its brightest part, where the rays come to a focus (Fig. 6). The light which passes through the picture is reflected by a prism inside the cylinder on to the selenium cell, through which the current passes. Across the circuit is shunted a galvanometer of the Einthoven pattern, containing two fine silver strings free to move laterally in a strong magnetic field. These are represented by AB, the magnet poles being MM. When a bright part of the photograph admits of light falling on the sensitive cell, current passes through AB, and it shifts aside, allowing light from a Nernst lamp N_2 to enter the prism P, whence it is reflected on to the second cell SS. The telephone lines connecting the two instruments go direct to the wires of a similar galvanometer, which is in series with the galvanometer of the transmitting instrument. If we imagine MM to be the receiving galvanometer, then we remove the prism P, and the light acts on a sensitive photographic film attached to the drum C, which revolves synchronously with the glass cylinder of the sending instrument.

The inertia of selenium, once overcome, the metal immediately becomes of great use for many purposes. Prof. Korn's method of *compensation* is to let the light fall at the same time on two cells of opposite characteristics; one has great inertia and small sensitiveness, the other low inertia and great sensitiveness. By using the two cells on opposite sides of a Wheatstone bridge, dividing the battery into two parts for the other sides, the deflection in the galvanometer is very rapid. You will see the effect from the two curves now shown on the screen; that above the axis along which exposure is measured is the sensitive cell, that below this axis the cell of low sensitiveness. Clearly the current passed through the galvanometer is that obtained by joining the sums of the ordinates. This gives the small curve shown as the shaded portion. When the illumination is thrown on the cell the current rises very rapidly instead of gradually, whilst when it is suddenly shut off (at P in the upper curve) it drops to zero almost instantly instead of falling gradually.

I shall now show, by means of a meter, an image of the pointer of which will be projected on to the screen, how the inertia of selenium is overcome. You will first see that if I take away the screen so as to allow light to fall on the selenium cell, current passes into the galvanometer, and the needle slowly deflects several degrees. Now, I quickly shut off the light by intercepting it with the screen, and the needle comes slowly backwards. Such sluggish movement would be impossible for the purposes of photo-telegraphy, where at least half a dozen changes per second are required to be recorded abruptly even in transmitting the simple portraits to which the selenium process is limited.

Now, using two cells of different characteristics and a Wheatstone bridge arrangement, I will once more allow light to fall suddenly on the two cells simultaneously, and you will see that the galvanometer needle records the change in resistance of the combination quite quickly; the combination is even more noticeable when the light is suddenly shut off again, the needle returning to zero with great rapidity. This compensated arrangement of selenium cells at once renders their use of practical value for various physical and optical measurements. Prof. Korn has found that for an increase in the illumination δI, the current obtained is given by the equation $y = \alpha . \delta I . e^{-\beta t^{-\frac{1}{m}}}$, where y is the current, α the sensitiveness of the cell, β and m its inertia constants, and e the base of Naperian logarithms. For two cells to be combined to the greatest advantage, we must have them such that if their equations are respectively

$$y_1 = \alpha_1 \delta I . e^{-\beta_1 m^{-\frac{1}{t}}}$$

and

$$y_2 = \alpha_2 \delta I . e^{-\beta_2 m^{-\frac{1}{t}}}$$

then

$$\frac{d(y_1 - y_2)}{at} = 0.$$

This makes the condition for good compensation that

$$\alpha_1 \beta_1 = \alpha_2 \beta_2 .$$

m is usually almost constant, and with suitable Giltay cells is about two-thirds.

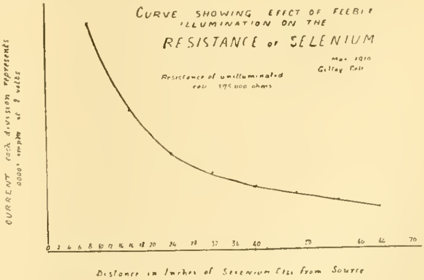

FIG. 7.

In practical language, the condition for compensation is that the principal cell should have great sensitiveness and a small inertia constant, the compensation cell low sensitiveness and a high inertia constant, the product of sensitiveness and inertia constant being the same in the case of both cells.

The physical properties of selenium are of such importance that I feel I may be allowed to digress for a few moments to show one way in which they may be utilised to solve a problem that has long occupied many investigators, viz. the satisfactory measurement of the beam of heterogeneous rays from an X-ray tube. Whenever a new tube is used in radiographic work, a different voltage, or different interrupter or coil, the time of exposure for the photographic plate has to be determined anew. The strength of the tube under any conditions can, however, be determined by means of a simple piece of apparatus which I have constructed, the working of which I shall now be able to show you.

If the X-rays fall on a fluorescent screen of barium platino-cyanide, the screen absorbs them and emits yellowish-green visible rays; this transformed energy is capable of affecting a very sensitive selenium cell when placed in contact with the screen, the resistance becoming less the greater the fluorescence. You will see here a selenium cell of approximately 395,000 ohms resistance, over which is placed a small fluorescent screen of the same size; the cell is put in series with a battery of 100 volts and a milliampere meter, the divisions of which may be made to correspond to some arbitrary scale or to the time necessary for the exposure of a given make of photographic plate.

The dividing of the dial depends on two things: first, the characteristic curve of the selenium cell connecting its resistance with the strength of illumination, the linear distance of the source from the cell being, in this case, the most convenient to employ.

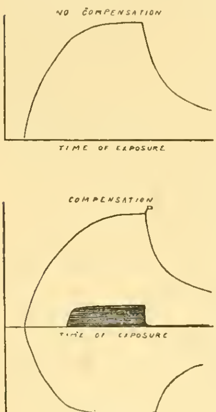

FIG. 8.

Second, this characteristic curve must be modified to meet the case of illumination by the rays from the anti-kathode, which do not necessarily diminish in their power to make the screen fluoresce as the square of the distance from it. You will see on the screen the characteristic curve of a selected selenium cell for feeble illumination, the maximum being of about the same wave-length as that of the fluorescence, showing the relation between resistance and distance separating the source of illumination and the cell, and also the modified curve showing a similar relation between resistance and distance between anti-kathode and cell, with the screen in contact. The portion of the first curve most nearly asymptotic is best to employ for the work, and from the second curve the dial scale of the metre can be easily calibrated. If, now, I vary the height of the X-ray tube from the measuring apparatus, you will see that the metre needle is deflected less as the distance between tube and cell is increased. The actual instrument is provided with a scale divided so as to show comparative times of exposure, and by its use radiographic work can be greatly facilitated.

It is interesting to note that the effect of the rays on the fluorescent screen, as estimated by the selenium cell, differs less with increasing distance the further the anti-kathode is from it:—

Distance of anti-kathode from apparatus Inches	Current recorded in milliamperes	Difference
6	0·33	—
8	0·27	0·06
10	0·22	0·05
12	0·20	0·02
14	0·18	0·02
16	0·16	0·02

A good deal of time has, I am afraid, been taken up in giving details of apparatus; but I will now show some of the results that have been obtained in practice. The selenium machines already referred to were operated between Paris, Manchester, and London until the end of the year 1908. The first photograph received (slide) was of King Edward, and was received at the *Daily Mirror* installation in November, 1907. Several results will now be shown in the lantern, and you will observe that they are all composed of parallel lines, which widen or "thin" according to the density of the picture. These lines correspond to the movement of the shutter attached to the strings of the Einthoven galvanometer, which regulates the thickness of the spot of light focussed on the revolving sensitive film. This spot of light traces a spiral line round the film, which, when developed, is laid flat, and the spiral becomes resolved into so many parallel lines.

Late in 1908 Prof. Korn introduced his telautograph, in which a Caselli transmitter, such as already described for the telectrograph, is used, and a line sketch or half-tone photograph is attached to the drum. The receiver is similar to that used in the selenium machines, a spot of light cast on a revolving sensitive film being shut off every time current flows through the wire of the galvanometer and displaces it; when displaced, the shadow of the wire falls over a fine slit placed in front of the film, and so prevents the light from passing through to it. A line sketch transmitted from Paris to London in this way is now shown (Fig. 2). The methods of synchronising the sending and receiving cylinders is the same as that used in

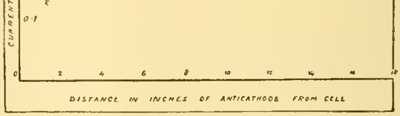

FIG. 9.

the telectrograph; but Prof. Korn's work was done prior to mine, and his arrangements were therefore copied by me. Similar methods have been adopted for many years, however, in certain systems of ordinary telegraphy.

There is a great deal of interesting matter connected with the efficiency of the galvanometer-receiving apparatus, and the vast amount of careful work done by Prof. Korn to increase it, which time quite forbids my mentioning; and I will therefore pass on to the latest phase of phototelegraphic work—the experiments now being carried out to effect wireless transmissions.

The wireless apparatus for transmitting sketches, writing, or simple photographic images over distances up to about fifty miles may perhaps be looked upon as rather rudimentary, but I shall be able to show, from actual results, that it is at any rate practicable, and it is certainly more simple than any method based on later wireless researches.

I will first show you an experiment, for the simplicity of which I must ask your pardon; but it illustrates so clearly how easy it really is to transmit a photograph by wireless under ideal conditions. I have here a small electric lamp, coupled up with the local side of a relay and battery, the relay being actuated by means of a coherer detector. At the other side of the platform there is a Morse key, which, when depressed, closes the primary circuit of an induction coil, the secondary being coupled up in the usual way to give oscillations. When I press the key, and thereby send a signal, you see that the lamp at once lights up. If the coherer be tapped, the lamp is extinguished, and another tap of the Morse key causes it to light again.

Now suppose that the taps of the Morse key were controlled by the lines in a photograph or sketch, and that the light from the lamp were concentrated on a revolving photographic film, and you will see at once how a photograph could be transmitted by wireless telegraphy.

Such a process would be utterly impracticable commercially, but my telectrographic system can be used with success in its place. A line picture prepared in the way already described is attached to the drum of the transmitter, and the intermittent current, which is ordinarily

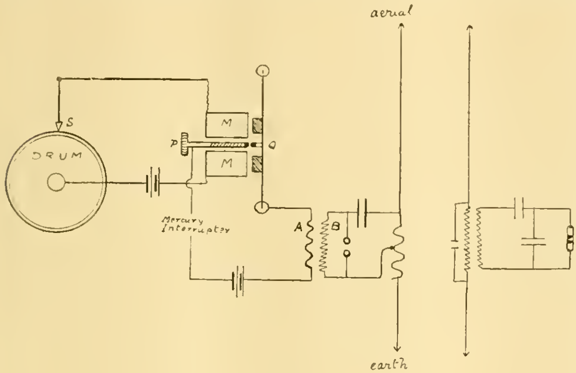

Fig. 10.

passed into the telephone line, goes into an electromagnet, M in Fig. 10, which then attracts a soft iron diaphragm attached to brass springs, which are fixed to two rigid supports. Every time current flows through the magnet coils this diaphragm is attracted to it, and the platinum contacts PQ are brought together; when the current flows, and PQ are in contact, the primary circuit of a transformer is closed, and the secondary having a spark gap and being inductively coupled to the aërial and earth, a signal is transmitted into space. Thus in the wireless transmitter the only difference from ordinary telegraphy lies in the fact that the length of the signals and their distance apart are regulated by the lines composing the sketch or photograph.

When working with high voltages in the primary, such as 110, arcing is liable to take place, and hence the distance between *p* and *q* when not attracted must be considerable. This means that the distance between the diaphragm clamps, *ss* in the figure, must be short, and the German-silver spring of which the diaphragm is made must be thick, these two conditions making the natural period of vibration very short. I have, however, found that by interposing a mercury motor-interrupter in the primary circuit, arcing is almost entirely avoided, as if an arc be formed the current is interrupted an instant later, and the arcing ceases in consequence.

The receiving apparatus is very simple, and depends, for short-distance work, upon a coherer cymoscope, the decohering apparatus being of a particular character. Every time an oscillation passes to the antenna, the coherer becomes conductive in the ordinary way, and a relay is actuated; this relay is usually made to start a hammer vibrating, the hammer hitting the coherer, and thus causing it to lose its conductive power. But a vibrating hammer is useless for the photo-telegraphic receiver, and it is essential to have one strike only on the coherer for each signal detected.

The form of apparatus I have employed for this purpose is seen diagrammatically in the next lantern-slide (Fig. 11). EE is the magnet which is actuated by the relay R. It then attracts an armature MN, which moves towards the magnet poles and brings a resilient hammer H, fitted with a platinum contact *p*, against the coherer. The coherer AB is also fitted with a collar F and contact pin, so that in the act of striking the coherer the hammer closes a local circuit, and so causes a black mark to appear on the chemical paper. Successive distinct marks can be obtained in 0·017 second in this way, which is considerably more rapid, I believe, than a decoherer was given credit for.

There is not sufficient time to show an actual transmission by wireless, and I should like to make it clear that only sketches of the simplest character are at present being transmitted; but, as you will see from the result thrown on the screen—a simple portrait of His Majesty the King—the images are recognisable, and merely require slightly more detail to make them quite comparable with the early results in line obtained by Prof. Korn's telautograph.

Another result shows a plan transmitted by wireless; here an island is seen represented, and a lighthouse—or it might be a fort—and by means of letters the positions of sections of an army on the island are supposed to be designated, while the shaded portion might mean that the "enemy" is in that part of the island. Such plans as these could be drawn direct in shellac ink on a slip of metallic foil, placed upon a portable machine coupled to a portable military wireless set, and communicated from one section of an army to another. The small portable machines I have already shown are used for the wireless transmissions, and they possess the advantage that "tapping" of the communications would be quite impossible. It is for this reason that I think the method would be of such value for military and naval purposes; even supposing that anyone wishing to intercept a plan or written message were to have an exactly similar instrument, with the same dimensions, screw-threads, and so on, by merely altering the rate of running by 5 or 10 per cent., according to prearranged signals, the picture as received by the intercepting party would be quite unintelligible and confused.

We have already seen that in the telegraphy of a picture by any system, accurate synchronising of the sending and receiving apparatus is essential. Where a metallic circuit links the transmitting and receiving instruments together, the matter is an easy one, and we have seen in what way it is effected. But when dealing with wireless work, the question of synchronism becomes more

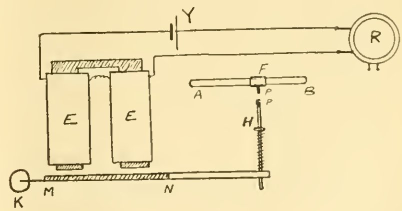

Fig. 11.

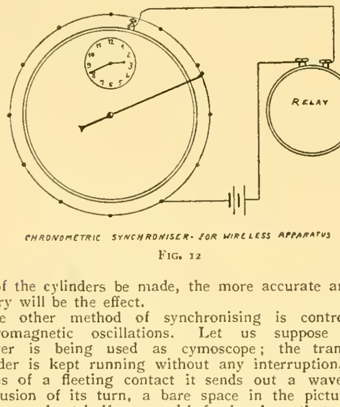
serious. I have employed two methods, each of which appears to answer satisfactorily, and as they are very important I will devote a few moments to their description.

The first method secures accurate synchronism independently of any wireless communication. You have already seen how, in the ordinary telegraphic work, the receiving cylinder is driven rather faster than the sending one, and when it finishes up a complete turn too soon it is arrested until the sending cylinder has caught it up, when the latter sends a reverse current, which is responsible for its release. But in the wireless apparatus both sending and receiving cylinders are driven too fast, so to speak—that is, they are made to revolve in $4\frac{7}{8}$ seconds instead of a nominal 5. A check comes into play at the end of the revolution, and the cylinder is stopped until the 5 seconds are completed, the motor working against a friction clutch in the ordinary way during the stop. At the end of the fifth second each cylinder is automatically released by chronometric means, in the manner shown in the next diagram (Fig. 12).

Here you will see that a special form of clock is used, with a centre seconds' hand which projects beyond the face by about an inch, and to the end of it is attached a brush of exceedingly fine silver wires. At every twelfth part of the circumference of the clock dial is fixed a platinum pin, and consequently every five seconds the little brush wipes against the convex surface of one of them. Each of these pins is connected with one terminal of a battery B, the other side of the battery leading to the relay R, as does also the centre seconds' hand. Therefore each time the brush wipes against a pin the circuit is closed, and the relay throws into action the local circuit connected up with the terminals TT. This circuit excites an electromagnet, which attracts an armature and pulls away the check which is holding back the cylinder. At the end of each 5 seconds the cylinders consequently recommence turning.

Well calibrated clocks of the pattern used will keep good time for the period taken to transmit a picture, one gaining on the other quite an inappreciable amount, depending on the friction of the brush against the pins. By this means the two cylinders are kept in very fair synchronism independently of any wireless communication, and the less the interval between the stopping and restart-



CHRONOMETRIC SYNCHRONISER. FOR WIRELESS APPARATUS

FIG. 12

ing of the cylinders be made, the more accurate and satisfactory will be the effect.

The other method of synchronising is controlled by electromagnetic oscillations. Let us suppose that a coherer is being used as cymoscope; the transmitting cylinder is kept running without any interruption, but by means of a fleeting contact it sends out a wave at the conclusion of its turn, a bare space in the picture being necessary about half a second beforehand, so that no waves are sent out for the half-second previously. The receiving cylinder is driven too quickly, and checked at the end of the revolution. It then, by means of a cam pressing down a spring lever, throws out of circuit the marking current, and brings into circuit the relay which actuates the electromagnetic release. Consequently, when the synchronising wave is received, the coherer causes the relay to work, the release is effected, and the receiving cylinder starts a new revolution in unison with the transmitter.

This means of synchronising is only possible in cases where a cymoscope is employed that is capable of actuating a relay, and you will therefore see that it is out of the question, except for short distances. I am therefore using the chronometric system already described in the apparatus, and it is being embodied in the quartz fibre apparatus I am now about to describe. I must first remark that the wireless work has been greatly facilitated by the courteous assistance so readily given by the Marconi Company.

The general form of the Einthoven galvanometer is well known, and the modified type of it used by Prof. Korn for photo-telegraphic purposes has been already shown. If, now, we make the magnetic field very much more intense by building the field magnets heavier, and using a large number of ampere turns in the winding, and also employ a "string," which is very much more elastic than the silver ribbon, the displacement of the string will be correspondingly greater. The silvered quartz fibre used by Duddell for this purpose gives an extremely sensitive instrument, and very appreciable displacement is obtained with the current from one dry cell passing through 35 to 90 megohms resistance.

It is not long since Prof. Fleming explained at this institution the valve receiver for detecting wireless oscillations; in ordinary wireless telegraphy, the minute alternating currents are rectified, and sounds are heard in the telephone in circuit owing to small unidirectional currents. If these currents be passed through the silvered quartz string of the galvanometer, the string is shifted. If, therefore, we cause a shadow of the string to lie over a fine slit, any displacement will cause the slit to be opened, as it were; the shadow will be shifted off the slit, and light will be free to pass through it. Oscillations corresponding to the lines in a photograph or sketch could therefore be utilised to cause shifting of the shutter in the manner I have already described for Korn's telautograph, and a sensitive photographic film could be revolved on a drum beind the slit to receive the picture. Such an apparatus is now in course of preparation; but the amount of light that passes through the slit is extremely small, owing to the fineness of the fibre. Mr. Sanger-Shepherd has therefore attached a minute shutter to the fibre, crossing the optic axis; this enables me to use a very much wider slit, and also to adopt the alternative procedure for reception, which you will now see represented in the diagram on the screen.

For photographic reception, the oscillation is passed into the valve detector, and thence to the quartz fibre AB, which is stretched across the field of the magnets (not shown), the poles of which are bored with a tunnel, through which the beam of light is directed. When the fibre is displaced, light is enabled to pass through a fine slit W, and so act on the photographic film. Where, however, the shutter is attached to the fibre, a much wider slit can be used, and then a pair of narrow compensated selenium cells SS are placed behind the slit W, a positive lens being interposed. When a signal corresponding to a dot in the photograph (*i.e.* the traversal of a line by the stylus) is received, the fibre shifts, light falls on the cells SS, and their resistance is decreased sufficiently to enable the battery E to actuate the relay R. This closes a local circuit, in which the telectrograph receiver is included, and a mark appears on the paper. In this way a visible record is obtained, which greatly facilitates the process.

Wireless photo-telegraphy may eventually prove of more utility than the closed-circuit methods, because it would bring America within reach of this country, and would enable communication to be made where telephone or telegraph lines did not exist. It is not limited to photographs—banking signatures, sketches, maps, plans, and writing could be transmitted. But I would point out most particularly that the work is as yet in the very earliest stages, and that in giving you some account of it to-night I may be bringing before your notice methods and systems on which a few years hence you will look back with a smile—as curious merely from a historical point of view.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE inaugural address on the occasion of the opening of the winter session of the London School of Tropical Medicine will be delivered by Prof. H. A. Miers, F.R.S., principal of the University of London, on Friday, October 14.

THE calendar of the faculty of medical sciences of University College, London, is now available. The college is a university centre for preliminary and intermediate medical studies, and its faculty of medical sciences comprises the departments of physics, chemistry, botany, and zoology (the preliminary medical sciences); also the departments of anatomy, physiology, and pharmacology (the intermediate medical sciences), and the departments of hygiene and public health and of pathological chemistry (post-graduate study). Prof. G. D. Thane is the dean of the faculty, and Prof. J. P. Hill the vice-dean. The calendar contains full particulars of the general arrangements for the coming session and of the scholarships and exhibitions open to competition.

THE following courses in illustration of recent progress in various departments of physical investigation will be delivered at the Royal College of Science (Imperial College of Science and Technology), South Kensington, during the autumn:—About ten lectures on "Colour Vision," by Sir William De W. Abney, K.C.B., F.R.S., beginning on Tuesday, November 8; about ten lectures on "Spectroscopy," by Assistant-Professor A. Fowler, F.R.S., beginning on October 10; about ten lectures on "The Internal-combustion Engine, illustrated by a Study of the Indicator Diagram," by Dr. W. Watson, F.R.S., beginning on October 13; about nine lectures on "Radio-activity and Electric Discharge," by Prof. the Hon. R. J. Strutt, F.R.S. The following courses, of about ten lectures each, will be given after January 11, 1911 (details to be announced later):—"Measurement of High Temperatures, and Optical Pyrometry," by Prof. H. L. Callendar, F.R.S.; "Magnetic Properties of Metals and Alloys," by Dr. S. W. J. Smith.

ON December 21, 1909, the London County Council decided to make a maintenance grant of 8000*l*. to the Imperial College of Science and Technology, South Kensington. In return for this grant it secures the privilege of nominating twenty-five students for one year's free instruction at the Imperial College. These are now to be filled for the first time. The instruction will be of an advanced nature, and therefore only advanced students who are qualified to enter on the fourth year of the course should apply. There is no restriction as to income, but intending candidates must be ordinarily resident in the administrative county of London, and must be students at an institution aided, maintained, or approved by the Council. The free studentships do not entitle the holders to any maintenance grants, but cover all ordinary tuition fees. No examination will be adopted for the final selection of the students from the applications received. The free studentships will be awarded on consideration of the past records of the candidates, the recommendations of their teachers, the course of study they intend to follow, and generally upon their fitness for advanced study in science applied to industry. It is quite possible that, in special cases, the free places may be extended to two or more years. Owing to the summer recess, it has been decided to accept entries for the free places until Saturday, October 1. Application forms (T. 2/268) can be obtained from the Education Officer, London County Council, Victoria Embankment, London, W.C.

THE new University of Queensland is now inviting applications in England and Australia for four professorships, in classics, in mathematics and physics, in chemistry, and in engineering. The selection committees will enter on their duties at the end of this month, and it is expected that the men who are to be the nucleus of the first staff of the University will be ready to begin work in the new year. The inauguration of the University was held on the fifteenth of last December, the fiftieth anniversary of the day when Queensland first became a self-governing colony. The event was the occasion of a very large gathering at Government House in Brisbane, when the Premier, Mr. Kidston, announced that his Government had set aside 50,000*l*. to meet initial costs; that 10,000*l*. a year was to be provided for working charges; that the historic building where the meeting was held, together with its beautiful grounds and gardens, was to be dedicated to university purposes; and, finally, that a large number of scholarships, including research scholarships, were to be offered to students. The unveiling of the commemorative tablet was one of the first acts performed by Sir William MacGregor in his capacity as Governor of Queensland. With one exception, all the Australasian States have now placed universities at the head of their educational systems, and it is expected that Western Australia will soon follow the example of her sister colonies. Considering the youth of these States—Queensland herself is only celebrating her jubilee—this is surely a very notable thing. Moreover, some of these universities are magnificently endowed and equipped, and all of them exercise considerable and fast-growing influence over the thoughts and the material progress of the countries which they serve.

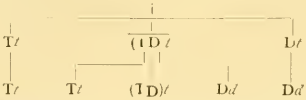
THE address on schools of dyeing, delivered by Mr. S. H. Higgins to the Manchester section of the Society of Chemical Industry last March, has been reprinted from the journal of the society, and a copy has reached us. Mr. Higgins thinks that British schools compare very favourably with those in other countries. England does not, he maintains, occupy a second place to Continental schools so far as equipment is concerned. Moreover, to quote from the paper, he says,—"In Germany the schools are not very particular as to the quality of the student they admit; they make an effort to get as many as possible. It has been said that students from the high schools pass through the schools of the Crefeld type before entering industry; but such cases are exceptional, as these men have other outlets for their training. A student from a technical high school does sometimes find his way into a trade school, and then the authorities show their delight; they do not say anything as to the educational standard of the bulk of their students. The technical high schools themselves are known to accept in their specialised technical chemical laboratories students who have had little previous chemical training. The volunteer departments of the German colour works are now much patronised in place of the schools mentioned, but it must be remembered that the training obtained in these departments, although good, cannot be a substitute for attendance at technical schools." The tone of the address is optimistic throughout, and by way of summary the address states:—"The dyeing schools of other countries do not compare with those at, *e.g.*, Leeds, Manchester, Bradford, and Glasgow, and even with many others of lesser importance in these islands. Just as we lead in the production, preparation, dyeing, bleaching, printing, and finishing of textiles, so also is this lead maintained as far as the technical instruction applied to these industries is concerned. Also it must be said that there is little difference between the positions of England, Germany, and America as regards the appreciation which manufacturers show of the training received at these institutions." In the discussion which followed, the principal of the Manchester School of Technology said he had more respect for the school at Crefeld than Mr. Higgins, and went on to emphasise the fact that in nine German technical high schools there were 13,500 students, none of whom were under eighteen years of age, while in ninety-nine English institutions, including the science sides of the universities, and students from fifteen years of age and upwards, they did not reach more than 5000 a few years ago. The greater number of students in technical schools in Germany were undoubtedly men who had passed the gymnasia or the Ober-Real Schule, where they remained until they were at least eighteen years of age. The technical schools in this country had comparatively few students in the daytime. The preparation of the student made all the difference.

SOCIETIES AND ACADEMIES.

EDINBURGH.

Royal Society, July 18.—Dr. R. H. Traquair, F.R.S., vice-president, in the chair.—Francis J. **Lewis**: Plant remains in the Scottish peat mosses, part iv. Four areas are considered: (1) the Shetland Islands; (2) Poolewe district in Ross-shire; (3) Rhilochan district of east Sutherlandshire; (4) raised beaches at Ardgour and Banavie, with an appendix on some peat areas in south-west Iceland. In the Shetland deposits there are two peat growths at two distinct periods, the earlier being stratified, the newer not. Special attention was paid to the position and the flora of the forest bed, the wide distribution of well-grown trees of birch, alder, and mountain ash in districts now quite devoid of trees, indicating a decided change in meteorological conditions. Evidence was brought forward that the first and second Arctic beds and the lower and upper forest are true datum lines traceable through extensive areas in Scotland. The view is taken that the first Arctic bed, the lower forest, and the second Arctic bed represent distinct climatic phases during early post-Glacial times.—Dr. D. Berry **Hart**: The validity of the Mendelian theory. In Mendel's well-known experiment of the crossing of the tall and dwarf varieties of pea, the first generation of plants gave all talls, and these when self-fertilised gave *somatic* talls to dwarfs in the ratio of 3/1. The dwarfs then bred pure, while the somatic talls gave pure talls and impure talls in the ratio of 1/2, and so on. The tall character being called dominant and the dwarf recessive, the question has to be answered, "How is the recessive quality represented in the plant of the first generation?" By regarding the plant as having a propagative and somatic part, and the oospore or zygote as having a part set aside for the propagative and one for the somatic part, Dr. Hart proposed to amend the Mendelian scheme as follows. Using TD to represent the tall and dwarf propagative parts, and *td* their somatic parts, then T*t*, D*d* will represent pure talls and dwarfs respectively. In the first generation of plants only *t* is present, although T, D both exist pure or mingled. Hence the following scheme:—

Egg-cells of Dwarf × Pollen Grains of Tall.



All the Mendelian ratios are satisfied. The answer to the question, "Where is the recessive quality in the first generation?" is that it is present pure in the propagative part of a quarter of the zygotes, present along with the tall determinants in a half, and not at all in the somatic part of the zygotes. The unit characters segregate out in the Mendelian ratio in plants because the determinants of these combine in the propagative part by the law of frequency. This explains why biometric results, measurements of organs, &c., follow the law of frequency or some modification of it.—Dr. John **Aitken**: Did the tail of Halley's comet affect the earth's atmosphere? The measurement of the number of dust particles during the passing of Halley's comet was made in the West Highlands at a place where in previous years Dr. Aitken had made a series of similar measurements. Some curious results regarding the prevalence of haze during May of this year were obtained, but none of these could be connected with the comet.—Sir David **Gill** exhibited some photographs of the comet which had been taken in the Transvaal just before the comet passed in front of the sun.

PARIS.

Academy of Sciences, August 8.—M. Boussinesq in the chair.—H. **Deslandres**: The properties of the polar filaments of the sun. As the sun-spots diminish, the filaments at the centre are also reduced, but the filaments round the poles remain. The causes of this are discussed.—Ch. **Lallemand**: The changes of level caused by the Messina earthquake. The changes of level produced by the earthquake are shown on a map of the Messina and Reggio districts. In the neighbourhood of these two towns the displacement is about 60 centimetres.—A. **Laveran** and A. **Pettit**: An epidemic disease in trout. This disease has been proved to be identical with the *Taumelkrankheit* of B. Höfer, and is caused by a parasitic Protozoa, resembling *Rhinosporidium kinealyi*, described by Minchin and Fantham.—Alfred **Picard**: The floods in the basin of the Seine during January and February, 1910. Remarks on the report of the committee on the Paris floods. A comparison of this flood with earlier inundations, and a discussion of the various proposals for preventing a recurrence.—A. **Perot**: The rotation of hydrogen in the solar atmosphere. The results obtained by the application of the interferential method accords with observations recently published by Hale.—G. **Darmois**: Correspondences with concurrent normals.—R. **de Saussure**: Concerning a reclamation of priority by E. Study.—H. **Larose**: The problem of a cable with transmitter.—Gabriel **Sizes** and G. **Massol**: The vibration of a tuning-fork. Rotating vibrations. The fork has two sets of vibrations, one in the plane parallel to that of the prongs and the other perpendicular to this plane. From these two as fundamentals, sixteen notes are produced.—G. **Austerweil** and G. **Cochin**: Certain causes of geranium smells. A study of the connection between smell and composition. The results are applied to the question of the formula of nerol.—G. **Friedel** and F. **Grandjean**. Lehmann's anisotropic liquids. The authors regard the conception of these fluids as liquid crystals as erroneous; they should be considered as representing a new state of matter as different from the crystalline state as an ordinary isotropic liquid.—H. **Hérissey**: The preparation of pure arbutine. The arbutine of commerce is a mixture of arbutine with its methyl homologue. A method of separating these two substances is described, based on the conversion of the arbutine into a potassium salt, insoluble in alcohol.—C. **Tanret**: The relations between callose and fungose. In opposition to the views recently expressed by M. Mangin, the author regards callose and fungose as distinct substances.—Raoul **Bayeux**: Experiments made on Mt. Blanc in 1909 on the variations of glycemia and hematic glycolysis at very high altitudes.—C. **Jouan** and A. **Staub**: The presence of hæmolytic and bacteriocidal alexine in the plasma of birds.—Charles **Nicolle** and E. **Conseil**: Some new experimental data on exanthematic typhoid.—Ed. **Retterer** and Aug. **Lelièvre**: The epithelial origin and development of Peyer's patches in birds.—Armand **Dehorne**: New interpretation of reduction in *Zoogonus mirus*.

THURSDAY, AUGUST 25, 1910.

RECENT AERONAUTICAL PUBLICATIONS.

(1) *The Art of Aviation. A Handbook upon Aëroplanes and their Engines, with Notes upon Propellers.* By R. W. A. Brewer. Pp. xiii+254+12 plates. (London: Crosby, Lockwood and Son, 1910.) Price 10s. 6d. net.

(2) *How to Build an Aëroplane.* By R. Petit. Translated by T. O'B. Hubbard and J. H. Ledeboer. Pp. xiii+118. (London: Williams and Norgate, 1910.) Price 2s. 6d. net.

(3) *How to Build a 20-foot Biplane Glider.* By A. P. Morgan. Pp. 60. (New York: Spon and Chamberlain; London: E. and F. N. Spon, Ltd., 1909.) Price 1s. 6d. net.

(4) *Les Aéroplanes, considérations théoriques.* By P. Raybaud. Pp. 24. (Paris: F. Louis Vivien, 1910.) Price 1 franc.

(5) *Ballons et Aéroplanes.* By G. Besançon. Pp. 346. (Paris: Garnier Frères, 1910.) Price 1.75 francs.

(6) *L'Aviation.* By Prof. Paul Painlevé and Prof. Emile Borel. Pp. viii+266. (Paris: Felix Alcan, 1910.) Price 3.50 francs.

(7) *Navigation in der Luft.* By Prof. A. Marcuse. Reprinted from the *Denkschrift der ersten Internationalen Luftschiffahrts-austellung zu Frankfurt a. M.*, 1909. 1., pp. 46–59. (Berlin: Julius Springer.)

(8) *Stabilitié des Aéroplanes, Surface métacentrique.* By Prof. M. Brillouin. Reprinted from the *Revue de Mécanique*, 1909. Pp. 80. (Paris: H. Dunod and E. Pinat, 1910.)

(9) *Die Seitensteuer der Flugmaschinen.* By Prof. H. Reissner. From *Flugtechnik und Motorluftschiffahrt*, 1910, 8, 10. (Munich and Berlin: R. Oldenbourg.)

(10) *IV. Congrès international d'Aéronautique*, 1909. *Procès verbaux, Rapports et Mémoires.* Pp. iv+473. (Paris: H. Dunod and E. Pinat, 1909.) Price 8 francs.

(11) *Bibliography of Aëronautics.* By Paul Brockett. Pp. xiv+940. (Washington: Smithsonian Institution, 1910.)

(12) *Petite Encyclopédie aéronautique.* By L. Ventou-Duclaux. Pp. 144. (Paris: F. Louis Vivien, 1910.) Price 1.75 francs.

(13) *The Encyclopaedia of Sports and Games.* Edited by the Earl of Suffolk and Berkshire. New and enlarged edition, in monthly parts. Part i., pp. 80, with numerous plain and coloured illustrations, including article "Aëronautics." (London: William Heinemann, 1910.) Price 1s. net each part.

THE present season has been, so far as aviation is concerned, a record of brilliant successes and terrible calamities. The recent fine performance of Mr. Moisant in flying from Paris to near Dover forms the fourth cross-Channel record, the preceding one being the late Mr. Rolls's flight to France and back without a stop on June 2. Mr. Moisant's performance differs from the previous ones in that he carried his mechanic as a passenger, and that he steered his entire course by compass, not having been over the ground before. His flight was not performed under by any means ideal weather conditions, for within a few miles of the English coast he ran into a rainstorm, which, owing to the high relative velocity at which the machine was being driven, or, as a newspaper reporter imagined, "with the high wind prevailing coupled with the speed at which the aëroplane was travelling" beat on the aviators' faces and on the machine with the violence of hail. Again, when approaching the English coast, the machine is stated to have been sucked down from 800 to about 200 feet, as the result of air currents set up by the cliffs. And while the Holyhead to Dublin course still awaits completion, it cannot but be said that Lorraine's preliminary flight from Blackpool to North Wales was an excellent performance, and it is quite possible that the Irish Channel may be crossed before this review is actually printed.

On the other side, we have a terrible list of fatalities, and the mere smash up of a machine that has cost hundreds to build has become a matter of such everyday occurrence as to confirm the view often expressed by the present reviewer, that it would have been better, cheaper, and probably quite as quick in the long run to have first got everything done that could be done in studying the problem of aviation by the methods of exact science and to have developed the practical side subsequently.

Mr. Brewer's book has only been out a short time, the preface being dated April, 1910, and yet in his introduction he directs attention to the small loss of life that has been incurred in the development of flying machines. The tide of good fortune would certainly seem to have recently turned, as we have before us records of no fewer than eleven deaths through accidents with either balloons or aëroplanes during the month of July, while the preceding three months claimed a death-roll of twenty-eight or more. The *Standard* of July 13 gave a list of eleven fatal accidents precedent to the death of Mr. Rolls, commencing with Lieutenant Selfridge in 1908, and not including previous fatalities, such as those of Lilienthal and Pilcher, and the death of the Marchese Vivaldi Pasqua has just been announced, following on a series of fatal accidents in Belgium, America, and elsewhere.

The fact that Mr. Brewer (1) has acted as assistant to Mr. Grahame White will probably secure for his book a large circulation, but for the more intelligent reader a greater recommendation probably arises from the fact that the author has concentrated his attention mainly on those features of the aviation problem on which he is most competent to speak with authority as the result of practical experience, namely, the structural details of aëroplanes, propellers, and particularly of internal-combustion engines. In fact, an important feature of the book is that we find here illustrated descriptions of the main features of the principal types of motor, such as the Antoinette, Gnome, Panhard, Wright, and similar information regarding the different leading types of monoplane and biplane. To add to the completeness, tables are given showing the numerical data (dimensions, weight, horse-power, speed, and so forth), both in regard to motors and aëroplanes. The reader can see at a glance what the present position is with regard to details of construction.

The book is a compilation of useful information, and not a mere exposition of the author's fads; in fact, it is conspicuously free from dogmatic expressions of opinion. Indeed, the author carefully states that "it is not intended that an aëroplane could be designed upon the data contained herein." He has, however, directed attention clearly to the great improvements still required in those details of construction with which he is most conversant. For example, he says:—

"The study of aërial propellers is only in its infancy, and an enormous amount of experimental work remains to be done. The efficiency of present-day designs is abnormally low, and in many cases not more than 50 per cent."

Again, in the chapter on "future developments," we are told:—

"The depreciation of the 1909 flying machine is enormous, the life of the engine is seldom more than 200 miles; in some cases it is a very few miles indeed, and breakdowns or seizures are a constant evil."

The author believes in an internal-combustion turbine. This might obviate the rotatory inertia of the present Gnome motor, which must affect the steering by its gyroscopic action. "Strength of materials" also receives discussion, and derives additional interest from the fact that it is a moot point whether defect in this respect or instability was the cause of certain recent fatalities. Mr. Brewer believes that the flying machine of the future will, like a ship, have living accommodation for passengers and crew; and had he permitted himself to go a little outside his own speciality he would have seen that a necessary condition for progress is the abolition of "ailerons," "gauchissement," or "warping." But the author very wisely fights shy of stability considerations, though he has, on the other hand, an instructive chapter on the art of flying, in which he says:— "Mr. Rolls has described the initial sensations as those received in driving a motor-car which is skidding in all directions at once."

The details of Henson's model of 1843 show that the conception of an aëroplane is by no means new, but that the want of a sufficiently light and powerful motor is the obstacle which has hitherto prevented its realisation.

As the author carefully disclaims any attempt to deal with mathematical considerations, one cannot, of course, take very serious exception if the few references which he gives are occasionally inaccurate or obscurely stated. It will be sufficient to take a few examples. On p. 12 he says, when speaking of the components of pressure he refers to the lift, as one of them, "and that, acting in a horizontal direction to overcome the skin friction of the machine, this is called the drift," forgetting that in an inclined plane drift exists independently of skin friction. On p. 15 he states Joessel and Avanzini's formula for the centre of pressure, and proceeds to explain that the coordinate of this point has a maximum value—a conclusion at variance with the formula in question. In the next sentence he speaks of "conditions of stability" where equilibrium is meant. On p. 87 he reminds us of the Irishman who said, "There were five of us; there was myself, that's one, there were the two Flynns, that's two, there was Mike Murphy, that's three," and so on. For of the "five variables" in propeller design, the first is "the speed of the machine and the power available." (This is, however, a trivial objection.) On p. 20 he says that the sum of the sine of a certain angle and the tangent of another angle may be written down as twice the sine or tangent of either angle; but there is no evidence that the angles are meant to be equal or nearly so. And the statement of von Loessl's law of resistance (p. 236) gives $P = P_0 \sin \alpha$, whereas on p. 15 we have $P = 2P_0 \sin \alpha$ with α small.

Criticisms of a similar character apply with greater force to M. Petit's book (2), for which we have to thank Messrs. Hubbard and Ledeboer, editors of the *Aëronautical Journal*, for an English translation.

It would have been better if M. Petit had confined his attention to the theme described by the title "How to Build an Aëroplane," and had not trenched on dangerous ground of a theoretical character. To begin with, the author bases his discussion of thrust on a moving plane on Wegner von Dallwitz's formula. According to this the thrust varies as the tangent-squared of the angle of attack. When this angle is small the thrust would thus become a quantity of the second order of small quantities, and the law would approximate to the "sine-squared" law originally proposed by Newton. That this result is not in accordance with experiment has been sufficiently shown by Langley and others. If in order to cut matters short it is necessary to confine the discussion to one theory of air resistance, the choice is therefore a bad one. English readers will do well to remember that tg stands for tangent, otherwise the printing of this in italics, while sin and cos are in Roman type, may mislead them.

On pp. 22–36, in discussing lateral stability, the author falls into a very common error in regard to the effects of varying the height of the centre of gravity, and when his treatment of the subject contains such statements as that "this application of the centre of gravity is shown in elementary physics by the pendulum," misunderstandings are likely to arise. In reality equilibrium and stability are but little affected by raising or lowering the main planes relatively to the centre of gravity, or, what is the same thing, lowering or raising the centre of gravity relatively to the main planes. If the resultant pressure always acts along a perpendicular to the main planes through their centre of pressure, and if this perpendicular passes through the centre of gravity, it will continue to do so when the aëroplane receives an angular displacement, and there will be no moment tending to right the machine. In this respect an aëroplane differs from a pendulum and a balloon. The matter is a little difficult to make clear, and will probably have to be explained elsewhere at greater length than is possible in this review; for this reason it is useful to have a name for the result, and I call it the Principle of Independence of Height. It is, of course, liable to modification in consequence of skin friction and other causes. In the meantime, it is an error, into which it is easy to fall, to imagine that because the weight has a moment about the centre of pressure, the aërodrome will swing about that point. It will acquire angular momentum about that point by slipping sideways without rotating. To examine the tendency to rotation, moments must be taken about the centre of gravity.

The mistake was indeed a very excusable one, but the wording of such statements as

"The force G_1E and the angle ϕ produce a component O_1D." "Which is the best way to obtain a low centre of gravity? The oldest method was to arrange the planes so that they formed an obtuse dihedral angle,"

hardly tends to make matters clearer.

The book contains much descriptive matter regarding motors, the fuselage, and methods of starting and landing, but the author would have been more convincing if he had been less dogmatic in the chapter on "The Future" in his attacks on the ornithopter and helicopter, and his claims for the monoplane as against the biplane.

We hope the criticisms contained in this review will not deter Messrs. Hubbard and Ledeboer from making further contributions to our aëronautical literature. So many books have recently appeared in France of about the same size and character as "How to Build an Aëroplane" that English translations are at present particularly useful in giving some insight into the state of progress on the other side of the Channel.

Theoretical considerations of all kinds have been carefully avoided in Mr. Morgan's little book (3), which deals purely with the details of construction of a biplane glider. Now that public attention has been centred on record-breaking flights, it is peculiarly important that the initial requirements for "learning to fly" should be brought before our notice, and the author strongly emphasises in his preface the fact that all our most successful flyers have commenced with gliders before taking to motor-driven machines, the Wright brothers having spent no fewer than three years in gliding flights. The author shows how anyone can build a glider of the type developed by Octave Chanute at a cost for the materials of about *2l.* or *3l.*, and it is much to be hoped that the book will induce would-be aviators to start in the right way.

M. Paul Raybaud's pamphlet (4) of twenty-four pages is intended to advance certain views regarding air resistance, such as, for example, that the air resistance on a moving surface does not act normally to the surface, but in a direction determined by the law of equality of action and reaction, that the centre of pressure of a plane area is fixed relative to the plane, that if any area is projected on a plane perpendicular to the line of relative motion, the projection of the centre of pressure is the centre of pressure of the projection (p. 9), and so forth. The arguments are of a superficial character, such as "it is evident" (p. 9), and when it comes to explaining the behaviour of a plane let fall obliquely (p. 13), he is compelled to introduce a force Q, which is statically equivalent to admitting a shifting of the centre of pressure, contrary to the previous statements.

Histories of balloons have been published in France at various times, some of them illustrated by grotesque figures of flying machines imagined or proposed. M. G. Besançon has now given us, in a small pocket-book (5), a pretty complete history of the actual development of aërial navigation from Galileo's experiments on the density of the atmosphere and Montgolfier's discovery of the balloon down to Blériot's cross-Channel flight. The first section, which deals with balloons, contains a brief account of the construction of their envelopes, of motors and propellers, and a reference to the advantages and disadvantages of various gases for the purpose of inflation.

Profs. Painlevé and Borel (6), on the other hand, condense their historical introduction into the first twenty pages, where they divide the history into four periods, namely, the legendary period, the heroic period, the scientific period, and the industrial period. They discuss the laws of air resistance, and briefly refer to the well-known controversy on the sine law *versus* the sine squared law, and the discussion embraces not only aëroplanes, but also bird-flight, ornithopters, and helicopters. Stability is referred to, but not at great length; the property which we have described as the principle of independence of height is, however, mentioned. In an appendix of more than eighty pages, certain elementary applications of mechanical principles are discussed at greater length than would be possible in the text.

The term "aërial navigation" is now used in so wide a sense that it is necessary to explain that Prof. Adolf Marcuse's article, "Navigation in der Luft" (7), deals with navigation proper, or the steering of a dirigible by means of charts and geodetic and astronomical observations. It is a general summary of progress made up until the autumn of 1909, in a subject which is much studied in Germany, but is altogether neglected in England. The author distinguishes three methods of place-determination, giving rise to terrestrial, astronomical, and magnetic navigation; of these the first three will be readily understood, while the third embraces not only steering by the compasses, but the determination of position by observation of the magnetic elements and the use of magnetic charts.

We now come to two papers which represent substantial progress in developing mathematical theories of equilibrium and stability. Prof. Marcel Brillouin's paper on metacentric curves and surfaces (8) is an important contribution to the theory of statical equilibrium and stability. When an aëroplane is moving uniformly and the lines of action of the resultant thrust are plotted relative to the aëroplane for different inclinations of the relative wind these lines will envelop a curve which the author calls the metacentric curve. Diagrams are given of these curves for different arrangements of two planes, showing that they are of very varied forms, and furnished, as a rule, with eight cusps, four of which correspond to grazing incidence of the air on one or other plane. Into the relative uses of statical and dynamical methods of approaching the problem of stability it is not necessary to enter at great length, although Prof. Brillouin refers to this question in the introduction. It must be pretty evident to anyone who has studied the problem that both methods must be pushed to their ultimate conclusions before aviation is reduced to an exact science; and further, our 1904 papers on dynamical stability were never intended to be final. What Prof. Brillouin has done is to reduce materially the amount of work still remaining to be done in a field of investigation of a new and difficult character.

Exactly the same remarks apply to Prof. Reissner's article (9). The steering of aëroplanes in turning curves is a difficult problem, which up to the present has not received the attention that it deserves, with the result that a great deal of an aviator's attention is devoted to counteracting the tendency of aëroplanes to turn in circles, or sometimes, not improbably, to describe spirals with decreasing convolutions until, if unchecked, they would twizzle round and fall like the seeds of certain trees. In fact, as Dr. Reissner himself points out in his introduction,

"on the motion in a curved path we find only meagre references, in which it is only attempted to satisfy one equation of equilibrium, instead of considering the six, as is necessary with every body moving in free space."

Dr. Reissner has used approximate methods; for example, in places he assumes the radius of the curve to be large. Anyone working at problems of this class will realise the necessity of employing such methods of approximation in order to reduce the mathematical work to a minimum in the early stages of the investigation. When one is thoroughly familiar with the simplest solutions, it becomes much easier to take account of modifications in which some of the terms previously neglected are re-introduced.

While on the subject of steering, it is interesting to refer to the Dunne biplane, of which a short account is given in the *Aëronautical Journal* for July, and of which a noticeable feature is that the planes actually have a negative angle of attack near the tips, so as to receive a downward pressure there. It is evident that by such a method it is possible to counteract the tendency of most aëroplanes to heel over excessively to the inside when rounding curves without making the lift vanish.

The report is before us (10) of the fourth International Congress of Aëronautics, which met at Nancy from September 18 to 23, 1909. The attendance at this congress was smaller than one might have expected, the membership list containing just over seventy names, but including Government delegates from the United States, Belgium, France, Italy, and Russia. The congress was divided into three sections, of which the first, devoted to aërostation, appears to have given considerable attention to aëronautical cartography and navigation proper. In the reports of the second section (aviation) we find discussions of propeller-thrust, laws of air resistance, the efficiency of motors, and other matters of like character, while the third section was devoted to scientific and other questions of a somewhat more miscellaneous nature.

The interest of the Smithsonian Institution in aëronautics dates almost from the commencement of its work, and this interest has been greatly stimulated through the secretaryship of the late Dr. Samuel Pierpont Langley, who brought with him to the institution the nucleus of a library of aëronautical literature. A most fitting memorial or tribute to his services to aëronautics is afforded by Mr. Paul Brockett's "Bibliography of Aëronautics" (11). While primarily intended as a catalogue of the material contained in the Smithsonian collection, this volume of 940 pages will prove a valuable—perhaps an indispensable—work of reference in the hands of every student of aëronautics.

A work of reference of a rather more popular character is M. Ventou-Duclaux's "Petite Encyclopédie aéronautique" (12). The reader who wishes to follow intelligently the records in the daily Press of aviation meetings and fatalities requires some information regarding the meaning of such terms as Gnome motor, carburettor, Curtiss biplane, Panhard motor, centre of pressure. All such expressions he will find explained if he consults this little dictionary. For some reason "Virage" does not occur.

The "Encyclopædia of Sport" (13), which is to be completed in thirty parts, opens with an article by Lord Montagu of Beaulieu on aëronautics. It contains a good, popular account of the subject, well illustrated by photographic reproductions of the chief aëroplanes and dirigibles, and of most of the "record" flights, such as Blériot's Channel flight, Paulhan's Manchester flight, and the flights of the principal French and German military dirigibles. The other articles in this number are on "Alligator," "Ammunition," "Angling," "Antelopes" (the last unfinished).

In the *Revue des Sciences* for June, 1908, Captain Paul Renard discussed the problem of the dirigible balloon. In the issues for April last he has given a couple of general articles on the problems of aviation.

Mr. Walter Child, of 35 Alfred Place West, London, S.W., has printed on a small card a diagram showing graphically the results of a new determination of the position of the centre of pressure of a lamina (a rectangular plate of magnalium) for varying angles of attack. According to him the centre of pressure approaches the front edge when the angle of attack vanishes. The method employed was to poise the plate on any assumed axis, to revolve it on a whirling table, and to read off the angle after the plate has come to the position of equilibrium. It may be mentioned that a rough and ready way of demonstrating the shift of the centre of pressure is by loading a rectangular glider and balancing it upon a finger, so that the centre of gravity occupies a known position, and then ascertaining by trial at about what angle the glider will fly if suitably projected. Mr. Child would have been wise to state the length and breadth of his lamina, and in view of the divergence of opinion regarding the limiting position of the centre of pressure for vanishing inclination, and the probable influence of skin friction, careful examination of the conditions of experiment seems desirable.

We have before us a prospectus, issued last April, of "Aviation Investment and Research, Limited," promoted with a share capital of £100,000, with Major J. A. Meldon and Mr. Ernest Dawe, 33 Southampton Street, as secretaries, a venture the progress of which will be watched with considerable interest.

If there is one inference to be drawn from a survey of the papers mentioned in this review, it is that a large amount of attention has been given to the application of the statical formulæ, $X = R \cos \alpha$, $Y = R \sin \alpha$, to problems of lift and drift, but that the other equations of equilibrium or of motion of a solid body have been until now largely left to chance, the skill of the aviator being made to take the place of exact mathematical calculation, with uncertain results. It may be safely stated, however, that the time is not very distant when "equilibrium and stability of aëroplanes" will become a subject suitable for courses of lectures in the mathematical departments of our universities. G. H. Bryan.

ECONOMIC MYCOLOGY.

Fungous Diseases of Plants; with Chapters on Physiology, Culture Methods, and Technique. By Prof. B. M. Duggar. Pp. xii+508. (London: Ginn and Co., n.d.) Price 8s. 6d.

Prof. Duggar's book, although intended primarily for the student in the United States, will be welcomed by the plant pathologist in all countries.

The plan on which the book is arranged is excellent, and the subject-matter is illustrated with 240 drawings and photographs, which are almost all good, while some of the photographs of diseased plants (especially those taken by Prof. H. H. Whetzel) stand out with an excellence which could not be surpassed. In the first fifty pages a full and lucid account is given of isolation and pure-culture methods and the technique of fixing, imbedding, and staining; this is followed by chapters on various physiological phenomena, such as the requirements of fungus spores for germination, aspects of parasitism and saprophytism, and so forth, concluding with a valuable chapter on environmental factors. A short chapter deals with the "principles of disease control," including the preparation of fungicides. This chapter might with advantage have been amplified, and information given on such points as the strength of Bordeaux mixture to be used in potato spraying, the nature of the spray required in the various washes, and the main types of spraying machinery. The information given concerning the lime-sulphur wash is too scanty to be of much practical value. With regard to the fungicidal action of Bordeaux mixture, the statement is made:—

"It has been fairly well demonstrated that the germinating spore will absorb from the nearly insoluble copper compounds of Bordeaux mixture sufficient toxic substances to cause its death."

No account is given of the legislative control of plant diseases, an omission which should be rectified in any future edition. America was the first country to take State action in this direction, and many inter-State regulations controlling the spread of diseases are now in force. At the present time the Government of the United States is considering the best means of putting into force an Act to secure the examination of all plants at the ports of entry in order to prevent the importation of fungus and insect pests.

The remaining part of the book, consisting of 400 pages, describes the various species of fungi and bacteria which are known to cause injury to plants of economic importance in America. The aim of the author has been, in the treatment of each disease, to keep in view three considerations—(1) to describe the pathological effects and other relations of host and parasite; (2) to make clear the life-history of the organism causing the disease; and (3) to indicate the methods of prevention and control. A short bibliography, which will be very valuable to the student in other countries besides America, precedes the account of each disease.

Considering the amount of information which is given on so large a number of diseases, the suggestion that some of the more important diseases might have been given a fuller treatment must seem somewhat ungracious. It is, however, unsatisfactory for a student to be merely told, *e.g.* concerning *Botrytis cinerea*, that "much interesting biological work has been done upon this fungus." The bare statement that follows, viz., "infection frequently fails when conidia germinate directly upon the surface of delicate parts," is likely to be somewhat misleading, since it is not qualified by any reference to the results obtained by Kissling (whose name is quoted in the bibliography), which demonstrated that certain plants can be easily infected in this way. One or two omissions in the list of diseases may be noticed. The mildew (*Sphaerotheca humuli*) which attacks the hop and other plants (but not the rose) in Europe is in the United States commonly found attacking the leaves of roses; no mention is made of this disease, the "mildew" of the rose being attributed entirely to *S. pannosa*, which, in the States, is apparently the less common of the two species. It is curious to find no reference to the "mildew" of the cultivated hop. Another omission is the "covered smut" of barley (*Ustilago hordei*), which is not uncommon in the States. The "crown gall" of lucerne (*Urophlyctis alfalfae*) is found, not only "in South America and Germany," but is known also in Switzerland and Italy, and has occurred in England in Kent.

Except for a few comparatively unimportant omissions, however, this manual is thoroughly comprehensive. Throughout the work there is evidence of much first-hand knowledge of the diseases described. In some cases Prof. Duggar has followed up his researches in the States by paying a visit to Europe to study the same disease there, and in this way he has been able to throw light on certain vexed questions of diagnosis and nomenclature. For instance, the true relationship of the Rhizoctonia fungus which causes diseases of various cultivated plants is made clear; the Rhizoctonia disease of potatoes is the same in Europe and America, while *R. medicaginis*, which attacks lucerne, asparagus, and sugar-beet in Europe, is a distinct species which does not occur in America.

Since many of the fungus diseases described occur in England, there is a considerable amount of information of direct practical value to the fruit-grower and market-gardener in this country. We find, for instance, an account of the recently discovered bud infection of peaches in the case of the peach "leaf-curl" fungus (*Exoascus deformans*), and of the best method of treating this disease. Excellent descriptions are given of such common diseases as the "brown rot" of fruit-trees (*Sclerotinia fructigena*) and apple and pear "scab" (*Venturia pomi* and *V. pirina*). Especially interesting is the account given of the various apple "cankers" which occur in the United States—the "blight canker" (*Bacillus amylovorus*), the "blister canker" (*Nummularia discreta*), the "European apple canker" (*Nectria ditissima*), the "bitter-rot canker" (*Glomerella rufo-maculans*), and the "black-rot canker" (*Sphaeropsis malorum*). A sharp look-out for the American "canker"-producing fungi should be kept by the apple-grower and economic mycologist in this country. It may be noted here that the Sphæropsis-canker has just been detected in Surrey. The exact appearance of the injury produced on the bark by the various "canker" fungi is shown by means of excellently reproduced photographs; one is tempted to say that Prof. Whetzel's photograph at Fig. 170 of the "Sphæropsis-canker" is the best of its class that has appeared in any book.

One of the most interesting chapters deals with the recent outbreak in the States of the European currant rust (*Cronartium ribicola*), a disease which was unknown in America until 1906. Investigation showed that the fungus was being introduced in its *aecidial* stage on seedlings of white pine (*Pinus strobus*) imported from Germany. A determined effort is being made to destroy all the diseased pines which have been introduced, and to prevent further importation of infected seedlings.

Sufficient has been said as to the scope of this work to indicate that it can be heartily recommended to the student of fungus diseases in this country; it is, in fact, indispensable, for no such manual previously existed in this country. E. S. SALMON.

HERTWIG'S TREATISE ON ZOOLOGY.

Lehrbuch der Zoologie. By Prof. R. Hertwig. Pp. xii+670. Neunte Auflage. (Jena: G. Fischer, 1910.) Price 11.50 marks.

THE new editions of Prof. Hertwig's text-book of zoology follow one another with such startling rapidity that it must be clear to everyone that on the continent at least it must have met with extraordinary success. This is perhaps not surprising, for, apart from the influence which Prof. Richard Hertwig's prominent position among the zoologists of the world must command, the "Lehrbuch der Zoologie" is certainly one of the best—if not the best—treatises on the subject in the German language.

There was a time not so very long ago when the English student of zoology was almost dependent upon the translations of the text-books of German authors, but in later years his wants have been supplied by his own countrymen, and it does not seem probable that Prof. Hertwig's book, excellent as it is in many respects, will find a large circulation in this country.

If it should fall into the hands of our own students, the parts which they will find most useful are those which deal with the more general problems of cytology, fertilisation, and inheritance. On these subjects the author writes with the authority of one whose own personal researches and those of a large number of his pupils have commanded the attention of the scientific world, and although there may be many who cannot fully accept the views set forth in explanation of the facts, the charm of their concise statement and the ingenious manner in which they are woven together are bound to create interest and reflection.

In dealing with the problem of fertilisation, for example, Prof. Hertwig considers that we can now accept—"mit grosses Bestimmtheit"—that it is the chromatic nuclear substance from which the chromosomes are derived that bear the hereditary characters, and in support of this he quotes some striking evidence drawn from the recent researches on the cytology of the germ-cells, and brings them into line with the results of the Mendelian experiments on inheritance. As Prof. Hertwig puts it, the theory seems very convincing, but there are some authorities who still doubt whether this theory will really bear the weight that is put upon it, and we should like to see the evidence that clearly tends to disprove it given some credit in a book that should be an impartial review of the present state of knowledge.

In the systematic part of the book the student will find a clear description of the principal characters of the classes and orders of the animal kingdom illustrated by many excellent figures. It cannot be expected that in the attempt to cover such a wide field within the limits of a single volume, the book will be entirely free from serious omissions and inequalities of treatment, but there are some features carried over from the earlier editions which really require some amendment if it is to maintain the undoubted success it has already achieved. The Enteropneusta, for example, are still classified as a class of worms. This is a position which has still some defenders, and in itself does not call for special comment; but as the author directs attention to the points of relationship between Balanoglossus, Rhabdopleura, and Cephalodiscus, surely the student will expect to find some position assigned in the text to the last two genera.

There are several other points, too, in which the book will hardly meet with the requirements of modern students. There is no figure, and a very meagre description of such important forms as Kœnenia and Anaspides; there is no mention made of the interesting trematode Temnocephalus, and, what is perhaps more astonishing still, there is no description or statement of any kind about the septibranch Pelecypoda. The statement that there are nephrostomes in Amphioxus needs correction, and the retention of the Ctenophora as a class of Cœlenterata justification.

Several new figures have been introduced into the ninth edition, and these are all of considerable value, but it is a pity that the only illustrations of the large and important order of the Alcyonaria are copied from the old, and in some respects incorrect, figures by de Lacaze Duthiers of *Corallium rubrum*. It is very desirable that a figure of a Pennatulid and some drawings of Alcyonarian spicules should be added. A better figure of Millepora should be found than that which appears on p. 217. But with all these faults, which are many when the book is critically examined, there can be no question that in general scope and breadth of treatment Hertwig's "Lehrbuch der Zoologie" is one of the most notable of the textbooks of our times.

COSMOGONY AND GEOPHYSICS.

Scientific Papers. By Sir George Howard Darwin, K.C.B., F.R.S. Vol. iii., Figures of Equilibrium of Rotating Liquid and Geophysical Investigations. Pp. xvi+527. (Cambridge: University Press, 1910.) Price 15*s*. net.

THIS volume opens with the well-known paper, "On the Influence of Geological Changes on the Earth's Axis of Rotation" (1877), in which Sir George Darwin investigated whether it was possible for known causes to produce a motion of the earth's axis comparable with that required by geologists to account for the supposed "Glacial period" in the earth's history. The result is definitely established that any change in the obliquity of the ecliptic which can have been produced by gradual deformation of the earth's shape is necessarily very small, about 1/2200 of a second of arc at most. The possibilities of wanderings of the pole are shown to be greater—from 1° to 3° in each geological period is possible. Cumulative motions of this type might account for the change since the supposed Glacial period, but any such explanation would be incompatible with the belief of geologists that where the continents now stand they have always stood.

This important paper is followed by six shorter ones, and the remaining eight papers, all of them of extreme complexity, deal with figures of equilibrium of rotating liquid.

A mass of fluid left to itself will, of course, form into a sphere under the gravitational action of its parts. If set into rotation this sphere will flatten at the poles, and Maclaurin showed that the flattened bodies corresponding to all degrees of rotation may be a series of spheriods so far as conditions of equilibrium are concerned, although obviously the very flat figures would be unstable. It has been known for some time that these spheroids are not the only figures of equilibrium. Jacobi found that certain ellipsoids with three unequal axes were possible figures, while Thomson and Tait pointed out that figures consisting of one, two, or more rings may be figures of equilibrium, although probably few of these will be stable.

The subject, of course, derives its great interest from its bearing on the origin of stellar systems and on Laplace's nebular hypothesis in particular; consequently the question of stability or instability is one of extreme importance. As an actual nebula in space loses its heat it will shrink in size, while keeping its angular momentum constant. For abstract discussion it is easier to deal with a fictitious mass of fluid of constant size, the angular momentum of which continually increases. Unless some cataclysmic breakdown occurs, this rotating mass must find for itself a continuous path through series of configurations of equilibrium all of which are stable. The problem of fundamental importance for cosmogony is that of discovering the far end of this path. Do we see it represented, as Kant and Laplace may have thought, in Saturn and his rings, or do we see it, as Sir George Darwin and others now think probable, in the earth-moon type of system? Or does the path lead only for a certain way through stable continuous configurations, and then end in a cataclysm?

This is the problem on which Sir George Darwin has for some years been leading the attack. Obviously there are the two methods of trying to trace out the path from the beginning to the end, and of trying to guess at the end and construct the path back to the beginning. Papers ix. and xv. of the present volume are devoted to the latter method. If increased rotation is going to lead to an earth-moon system, it ought to be possible to trace back the earth-moon system through diminishing rotation and through continuous stable configurations to the initial spherical form. In this connection, Sir George Darwin has directed attention to some almost overlooked, although highly important, work of Roche, who showed that a system consisting of a planet with an infinitesimal satellite in contact cannot be stable. He has accordingly attempted to examine above what limit the ratio of the masses of satellite to primary must lie for stability to be ensured. No perfectly definite conclusion is reached, but it seems as if the limit must be greater than the ratios observed in the solar system. This somewhat nugatory result is disappointing, and suggests that a better way of attacking the problem may be the direct one of examining all possible series of configurations, starting from the initial sphere.

The only road which the fluid can take on leaving the spherical form consists of the series of Maclaurin's spheroids, but this road is intersected by an infinite number of cross-roads at different points ("points of bifurcation"). At the first point of bifurcation, the series of Maclaurin's spheroids loses its stability, and the configurations represented on the cross-road through this point are found to be stable. Moreover, it appears that this particular cross-road represents the well-known series of Jacobian ellipsoids. Poincaré has shown that this road also is intersected by an infinite number of cross-roads, and that the first of these cross-roads represents a series of pear-shaped figures which look as though they might end by dividing into a large and a small mass. At this stage everything turns on the question of which is stable of the series of figures through this point of bifurcation, the Jacobian ellipsoids on the main road, or the pear-shaped figures on the cross-road. Sir George Darwin believes he has proved the pear-shaped figures to be stable, but M. Liapounoff challenges this, and, as the result of an independent investigation, thinks these figures are unstable. Each investigator has again verified his own calculations, and Sir George Darwin has applied various checks to his work which afford some evidence, although not proof, that his original conclusion was accurate.

Here the problem at present stands, at a deadlock. Short of discovering a serious error in one or other of the two investigations, the only explanation of the discrepancy seems to lie in the rejection of certain remote, and apparently very small, terms by Darwin. These might possibly be found to turn the balance, but it is almost inconceivable that they should.

Whatever the outcome may be, the present volume stands as a record of the amount of patient labour and degree of mathematical and scientific skill brought by one worker to the examination of one theory of cosmogony. Before the scientific world permits other theories to take their place by the side of this one, it will do well to ask whether the truth of these other theories has been investigated with a degree of patience, skill, and power at all comparable with what is shown here.

THE POLAR WORLD AND GLACIAL GEOLOGY.

Die Polarwelt und ihre Nachbarländer. By O. Nordenskjöld. Pp. vii+220; 77 figures. (Leipzig: B. G. Teubner, 1909.) Price 8 marks.

DR. OTTO NORDENSKJOLD is especially well qualified for a comparison of the Arctic and Antarctic regions, which he has personally explored in Greenland, Iceland, Spitsbergen, Alaska, Patagonia, and during his leadership of the Swedish Antarctic Expedition. He has now issued a short work on the polar world, in which he has given a general geographical description of the Arctic and Antarctic lands, and reference to the interesting problems connected with their geographical structure, inhabitants, and glacial geology. The book is based on a series of popular lectures and is issued without references. It is illustrated by seventy-six views, mostly taken by the author or on expeditions of which he was a member. The only map is a sketch of part of southern Patagonia.

The book owes its main value to its statement of the author's conclusions relating to various geographical and geological problems in which he is especially interested. Greenland is naturally described first, as it is the typical polar country, it being the most accessible and best-known land still covered with an ice-sheet. The author rejects Nansen's view of the nature of its ice gradient, and says that the problem of the Greenland inland ice was not solved by his expedition, which crossed the country at its narrow southern end, where the glacial conditions are not fully representative.

Dr. Nordenskjöld describes the fiord system of north-eastern Greenland, which he considers as the greatest in the world. Its valleys were once occupied by glaciers during a former greater extension of the Greenland ice cap; unless they had been filled with ice he would refuse them the name of fiords. He admits that part of Greenland has never been covered by ice, though he remarks that the evidence for this conclusion must be treated with caution. He briefly discusses the Eskimo, the most interesting of polar people. He accepts their Asiatic origin as apparently beyond question; the problem regarding them which he regards as still unsolved is the home of their present culture. Hamberg has suggested that the race developed its special characters in Alaska, but Dr. Nordenskjöld doubts this conclusion, as he thinks it probable that, if so, they would have spread westward into Asia, where but few of them occur, as well as eastward. He thinks their last home was probably within the centre of their present area of distribution, and not on its margin.

After describing Iceland and Jan Mayen, Dr. Nordenskjöld turns with enthusiasm to Spitsbergen, which he describes as the classical land of Arctic research. It is at present of little economic value, as it has been abandoned alike by whale, walrus, and seal hunters. Since 1905 attempts have been made to mine its coal, but Dr. Nordenskjöld regards the success of these attempts as very doubtful; and he thinks the country will be mainly of value as a tourist resort. He raises the question of the ownership of Spitsbergen, refers to the respective titles to its possession by Holland, Great Britain, Norway, Sweden, and Russia. A conference between the last States is now discussing the political status of the archipelago.

Dr. Nordenskjöld also describes the Arctic areas of America and Siberia, and gives a brief summary of recent work on the Antarctic, with an account of southern Patagonia, and a reference to Tasmania and New Zealand. He directs attention to the evidence of the former greater extension of ice in nearly all polar and subpolar countries, and he recurs frequently throughout the lectures to glacial problems. As the cause of the former glacier extension he regards Arrhenius's theory of refrigeration of the earth owing to the diminution in the carbonic dioxide in the atmosphere as inherently probable; he admits, however, that the chief different glacial centres of North America and elsewhere are not contemporaneous, that there was no equivalent glaciation of Siberia, and that there is no evidence of a former existence of ice in some parts of Alaska as in the Yukon district. The oft-made suggestion that the ice developed in localities which had a moist climate and heavy snowfall he rejects from the evidence of Kerguelen, where, in spite of these conditions, there is much ice-free land. Kerguelen, however, is only in the latitude of Paris.

Consideration of the westward extension of the Scandinavian ice-sheet leads him to consider the general belief that the Scandinavian ice filled the North Sea and deflected the local glaciers northward.

Dr. Nordenskjöld concludes that there is no proof that the Norwegian ice extended to the British coast, and an alternative explanation that the North Sea was filled with such heavy pack-ice as to press back the glaciers which flowed from the English mountains he rejects as "extraordinarily improbable" from all the evidence given by Arctic and Antarctic ice. He makes the interesting suggestion that the shallow areas of the North Sea were filled with barrier-ice formed *in situ*, like that of the Ross Sea, and that its obstruction was the cause of the deflection of the British glaciers.

J. W. G.

STRUCTURE AND CARE OF TEETH.

Our Teeth. How Built Up; How Destroyed; How Preserved. By R. Denison Pedley and Frank Harrison. Pp. 99. (London: Blackie and Son, Ltd.) Price 5*s*. net.

THE authors of this little book are well known to the members of the dental profession, but as the work is obviously intended for the lay public it may be as well to state at once that both Mr. Pedley and Mr. Frank Harrison occupy a high position in dental surgery; indeed, the fact that Mr. Harrison was chosen as president of the Odontological Section of the British Medical Association and Mr. Pedley as one of the vice-presidents in 1908 sufficiently demonstrates their title to advise and instruct the general public upon things dental. The book opens with a discussion of dental anatomy and physiology, illustrated with diagrams and photomicrographs of remarkable excellence. The authors have not hesitated to employ quite high powers, even such a magnification as ×2250; into the actual photomicrograph they have introduced explanatory labels with lines pointing to the special objects to which it is desired to direct attention.

Obviously in a work of this kind an abstruse dissertation upon tooth-development would be out of place; the authors plump for a theory and instal it as correct. Thus on p. 30 there occur illustrations and letterpress which would lead the reader to believe that the process of enamel calcification was quite understood, and that the process in the case of dentine was universally acknowledged to consist of the conversion of the odontoblast, whereas the former is very far from settled and the latter is supposed by some of the best living authorities to be a matrix calcification not involving the cells at all; however, the process as described in the book has the sanction of very good observers in the past, and it is no drawback for a writer on a technical subject addressing a lay audience to be dogmatic.

The pictures and description of dental caries and its pathology are both excellent; the valuable work done by Dr. Miller, of Berlin, is duly recognised, but the pioneer work of Milles and Underwood in 1881 (two years before Miller's first essay) is not noticed, which seems an omission. In the 100 pp. the authors run over structure, development, nourishment, growth, disease, allied disease, and treatment, so that the gift of condensation has been required to no small extent. The style throughout is lucid and interesting, the illustrations quite remarkably good and well reproduced, and if the opinions of the authors, or the authorities upon whom they rely, are stated occasionally as *ex cathedra* and unquestionable, such treatment of scientific questions is very difficult to avoid in a work addressed to a popular audience. The authors are to be congratulated upon having produced a thoroughly clear and useful manual, and on having left no doubt possible in the reader's mind as to their own views.

OUR BOOK SHELF.

The Funeral Papyrus of Ioniya. (Theodore M. Davies' Excavation: Bibân el Molûk.) With Introduction by Edouard Naville. Pp. viii+20; plates 34. (London: Archibald Constable and Co., Ltd.) Price 21*s*. net.

AMONG the objects discovered by the American explorer, Mr. Theodore M. Davies, in the tomb of Queen Thîy's parents in the Bibân el Mûlûk at Thebes was the funeral papyrus of Ioniya, the father of Amenophis III.'s great Queen. This was first worked over by Prof. Newberry in 1906, who published a summary of its contents in Mr. Davies' "The Tomb of Ioniya and Touiyou" (Constable and Co.) in 1907. Photographs of the document were then placed in Prof. Naville's hands for fuller publication, and the volume now before us is the Swiss Egyptologist's account of this important eighteenth-dynasty copy of the Book of the Dead. The papyrus itself measures 9 metres 70 cm. long; it is written in linear hieroglyphs with vignettes finely executed in colour, and contains some forty chapters, one of which is new to science. This new chapter is illustrated by a vignette of nine serpents, and is entitled "Coming out of the Day." It belongs to the group of chapters of the gates and pylons where the deceased has to show his knowledge of the names of the occupants and warders. To the finely reproduced facsimiles of the document M. Naville has added a translation, based mainly on that of the standard edition of the Book of the Dead by the late Mr. Le Page Renauf—the edition which Mr. Naville himself completed and edited.

Helmholtz. Eine Zeitschrift für die exakten Wissenschaften mit besonderer Berücksichtigung ihrer Anwendungen. Herausgegeben von Dr. Th. v. Simson. Bd. i., No. i. (Helmholtz-Verlag: Neustadt au der Haardt, April, 1910.) Price 16 marks per volume.

ANOTHER scientific journal! It must be confessed that the necessity for the existence of this journal is not at all evident. There is no particular reason, so far as the reviewer can see, why the contents of this number could not have found a place in many other quarters.

The *pièce de resistance* is the article by Arrhenius on "The Laws of Digestion and Resorbtion." This consists in a "quantification" of the experimental work of E. S. London in St. Petersburg, and is decidedly interesting. After this comes a series of portentously solemn "scientific aphorisms" by C. H. Walter, which the reviewer has been quite unable to digest. There is an article by F. Fittica on "The Transmutation of the so-called Elements," in which this author tells us again how he transmuted phosphorus into arsenic (by heating it with ammonium nitrate), &c. To borrow the language of a sister science, there exists a slight doubt as to the veridical nature of these phenomena. However, an editorial footnote commends them to the reader's notice.

In an interesting article, H. Lunden gives a description (with sketch-plans) of Arrhenius' new Nobel Institute laboratory at Stockholm. Several other short articles deal with such varied topics as sun-spots and magnetic storms, precautions against coal-dust explosions in mines, &c. Enough has been said to indicate the catholicity of the editor's views concerning the scope of his new journal.

List of Documents in Spanish Archives relating to the History of the United States, which have been printed or of which Transcripts are preserved in American Libraries. By J. A. Robertson. Pp. xv+368. (Washington, D.C.: Carnegie Institution of Washington, 1910.)

THIS publication of the Carnegie Institution is the most recent of the "papers" of the Department of Historical Research of the Institution at Washington. The editor of the series points out in a preface that the volume may be regarded as an accompaniment to Prof. W. R. Shepherd's "Guide to the Materials for the History of the United States in Spanish Archives."

The two lists contained in the present book concern the history of the territory included within the boundaries of the continental United States of to-day. All matter touching that territory only indirectly or by inference as a part of the Indies has been rejected. The first list consists of published material, the original manuscripts of which exist in Spanish archives, or which, with good reason, are conjectured to exist in Spain; the second is much the longer, and is a list of transcripts in libraries and archives in the United States from originals in Spanish archives.

Lightning and the Churches. By Alfred Hands. Second edition. Pp. 92. (London: J. W. Gray and Son, 1910.) Price 1s. net.

THE first edition of this interesting pamphlet was dealt with in a note in our issue of April 22, 1909 (vol. lxxx., p. 228), and we welcome this second edition as indicating that increased attention is being directed to the important matter of protecting buildings from damage by lightning. Mr. Hands, who has expert knowledge of the subject, says that investigation shows that about twenty churches are struck and damaged in Great Britain every year. In some years the number is much greater; in 1907, for instance, thirty-nine suffered from this cause, and in 1908 there were thirty-one. Architects and others, whose business makes them responsible for the protection of buildings against lightning, would do well to study this little work.

The British Isles in Pictures. A Geographical Reading Book. By H. Clive Barnard. Pp. 64, containing 58 illustrations. (London: A. and C. Black, 1910.) Price 1s. 6d.

THERE are thirty-two beautiful coloured pictures in this volume, which will delight young pupils of geography, and serve also to explain graphically to them the characteristics of many kinds of scenery found in their native land. The black and white illustrations will also help to secure and maintain the interest of a class. The letterpress provides useful information; and, though it is hardly suitable for a text-book, it will serve admirably to supplement the geography lesson proper. The cheapness of the volume should ensure it a wide popularity.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Temperature Coefficients of the Ferromagnetic Metals.

EXPERIMENTS on the temperature coefficients of magnets published some years ago (Roy. Soc. Phil. Trans., vol. cciii., 1903) showed that the magnitude of the coefficient is largely dependent on the dimension ratio of the magnet, but that when the dimension ratio is sufficiently increased to make the self-demagnetising factor negligible, the coefficient is then characteristic of the ferromagnetic material. Observations made at that time, but not published, on iron, nickel, and cobalt magnets heated up to 100° C. showed that the coefficient was large in nickel, less in iron, and least in cobalt, the order being the inverse of the order of the magnetic critical temperatures of these metals.

I have recently repeated these experiments, carrying the temperature to 300°–400° C., and within this range it appears that when the magnetic intensity in the cyclic state is plotted against a scale, in which temperatures are calculated as percentages of the critical temperatures, then the points lie very nearly on one curve. In short, if corresponding temperatures are chosen, the temperature coefficient is the same for iron and nickel, and probably for cobalt. (The details of the experiments I omit here, but I should say that the cobalt employed was not pure, and behaved irregularly at 300° C.)

For example, the temperature coefficient of nickel between 15° and 115° C. is 0·0005, and it is the same for iron between 250° and 430° C., the corresponding temperatures; the temperature coefficient of iron between 7° and 107° C. is 0·0002, and it is nearly the same for cobalt between 90° and 220°, the corresponding temperatures.

Curie has shown that when iron is heated it passes continuously through the critical temperature from the ferromagnetic to the paramagnetic condition (in the latter state obeying the gas laws *mutatis mutandis*), and that the curves which trace the change from one state to the other are the counterpart of the curves which trace the passage of a liquid to a gas. An equation to the fluid curves may therefore be applied to the magnetic curves, and van der Waals's equation may be appropriately used, since it takes account of the facts that there is mutual attraction of the molecules and that there is a limit to fluid density, facts which have their counterpart in ferromagnetism in the mutual attraction of the molecular magnets and in the limit to magnetic intensity. One of the conclusions drawn from van der Waals's equation and the theory of corresponding states is that the coefficient of density, or expansion, of all liquids at corresponding temperatures is the same, and by similar reasoning this law is deducible for magnets. This is, in fact, the law to which the experiments cited above lead.

It is also worthy of notice that the temperature coefficient of density of liquids is of the same order as the temperature coefficient of intensity of ferromagnetics, just as the temperature coefficient of density of gases is of the same order as the temperature coefficient of intensity of paramagnetics.

Within the limits of this letter it is not possible to discuss these facts, but they show that certain magnetic problems may be treated by an application of van der Waals's equation with results consistent with experiment.

Manchester. J. R. ASHWORTH.

The Ratio between Uranium and Radium in Minerals.

DR. BOLTWOOD established the constancy of this ratio for all the minerals he examined (*Phil. Mag.*, April, 1905). He examined, however, no mineral in which uranium was present as phosphate, nor did he examine the then newly discovered mineral thorianite. Later, Mdlle. Gleditsch (*Comptes rendus*, cxlviii., 1451; cxlix., 267) found that the ratio radium to uranium was about

18 per cent. greater in thorianite than in Joachimsthal pitchblende, while in autunite, a phosphate of uranium, this ratio was about 20 per cent. less. She separated the radium chemically before estimating it.

This month appeared in the *Philosophical Magazine* (p. 345) a communication by Mr. F. Soddy and Miss Pirret on this subject. They find that, by determining the radium directly in the mineral, the ratio is practically the same for thorianite as for Joachimsthal pitchblende, but that in their specimen of autunite the ratio is only 44 per cent. of that of pitchblende. During the last three months I have been engaged on this problem also. I find that the ratio in thorianite from Java agrees within the limits of experimental error with that in specimens of pitchblende from Joachimsthal and from German East Africa, the latter of which is probably of primary formation. In my specimen of autunite, however (from Autun, in France), the ratio is only 27 per cent. of that of the pitchblendes. Thus, taking the ratio Ra to U in pitchblende as 1, in Mdlle. Gleditsch's specimen of autunite it is only 0·80; in Mr. Soddy and Miss Pirret's it is 0·44, and in mine 0·27.

To explain these somewhat exceptional results, it must be assumed either (1) that the Ra has been washed out of the mineral in some way, or (2) that the mineral is very young, and that therefore the Ra is not yet present in equilibrium amount.

To throw light on these points, I hope to determine the ratios uranium to ionium and to actinium in different specimens, not only of autunite, but of the family of minerals $R'(UO_2)_2(R''O_4)_2.8H_2O$ (R' = Ca, Ba, Cu; R'' = P, As), of which it is a member.

Elemental Weight Accurately a Function of the Volution of Ideal Space-symmetry Ratios.

Suffering from a malady of the eyes, I may be excused the two following errors in my communication published in Nature of July 21:—

(1) For *hex*, or the cubic line-ratio, read throughout *oct*, or the octahedral line-ratio; and for *oct* similarly read throughout *hex*.

(2) In the table at the end, No. 6, read 1·00766 as the mean, in place of 1·00765, the product in this instance (No. 4 in the references to the general formula) deviating by 0·00001 from the experiment; in the other cases the figures are exact.

Aberdovey, North Wales.

The Jamaica Earthquake.

May I point out that in the review of "Recent Earthquake Investigations" (Nature, August 11, p. 165), the date of the Jamaica or Kingston earthquake (where the loss of life was 800, and of property about 2,010,000*l*.) is wrongly stated? It took place on January 14, 1907, and not on June 14, 1906.

Boscombe, August 12.

CHOLERA AND ITS CONTROL.

Nothing is more striking, even to the casual observer, than the change that has taken place in the attitude of the public, no less than of those who have charge of the public health, towards those great epidemic outbreaks that swept Europe up to the end of the eighteenth century "and after." Until the Great Fire of London in 1666—indeed, until the rise of the great school of sanitary reformers of whom Chadwick and Simon may be taken as types—panic and despair were the predominant emotions aroused in the presence of plague, cholera, and the like. With a knowledge of the results of what could be done by the adoption of efficient sanitary measures, these two paralysing influences were gradually rendered less effective, especially as the call to preventive and curative work could be made to divert men's minds from brooding and evil anticipation. Men then realised how much could be done to ameliorate the conditions of communities attacked by these diseases, and how successful were the preventive measures adopted as regards transference not only from community to community, but from individual to individual, with the result that organisation took the place of panic and hope succeeded on despair. Still, men were working in the dark, and the mystery enshrouding the mode of spread of disease was profound until Pasteur, Koch, Lister, and their many disciples gradually evolved from the chaos of theory, fact, and fancy the germ-theory of disease, and isolated from the welter of organisms by which the patient was surrounded the one that in each case appeared to be the specific cause of the disease.

In no case is this more marked than in that of cholera, and at the present time one may see in different parts of Europe reproduced different phases of the history of the evolution of our methods of dealing with cholera epidemics at different periods. In Russia and in some parts of Italy, where fatalism and apathy prevail, and where sanitary science has not yet reared its head, cholera still arouses panic, only to be followed by the lethargy of despair. In other parts of Europe efforts—in many cases very inadequate—are made to combat the spread of the disease, whilst in northern Europe, including such places as Amsterdam and London, the announcement that cholera may invade the country, or that it has already gained a foothold, simply means a call to renewed sanitary efforts directed by intelligent experience and skill, which will prevent the disease from entering the country except as carried by isolated patients, and the treatment of patients in such fashion that there will be no further extension beyond a very limited area.

At the present juncture, when cholera may spread from Russia, Italy, Roumania, or elsewhere, the crisp instructions issued to port medical officers no less than timely account of the outbreak of cholera in Rotterdam last year about this time (see the *Times*, August 19), should give comfort and courage, both to those who have to deal with cholera in our ports, and to those who at one time would inevitably have been attacked in large numbers. Between August 20, 1909 (when cholera was found in three children in one family, who died suddenly with the clinical symptoms of cholera, the nature of the disease being at once confirmed by full bacteriological examination) and September 11, what might have expanded into a great epidemic in Rotterdam began and was crushed. The facilities for the spread of the diseases are perhaps greater in Rotterdam than in any other seaport town in the world, but by careful isolation, not only of the patient, but of "contacts," *i.e.* people who have come in contact with the patients at any time after the outbreak of the disease, in "isolation" wards, and "observation" sheds, by warning the people against the use of unfiltered water, the eating of green fruit, and excessive indulgence in the use of alcoholic liquors, the epidemic was cut short. Fines and imprisonment were awarded to those who interfered in any way with the authorities in carrying on their work, either by obstructing them or by failing to notify cases where the illness showed any symptoms of cholera. Careful observation of suspected cases, disinfection of houses, bed linen, clothing, of patients and contacts alike, were all resorted to; but, on the other hand, all who helped were well treated, receiving whatever wages they would have earned normally; indeed, we are told, they were so well treated generally that "many presented themselves as contacts in the hope of receiving food, clothing, and wages without working." It may be said that these methods were, on one hand, harassing, and, on the other, expensive; but as compared with the work and expense involved in outbreaks such as at one time or another have attacked our north European ports, the work and expense involved are absolutely trifling.

All this, of course, is exceedingly reassuring, but we have, on the other hand, as the outcome of our knowledge of the life-history of the cholera bacillus and its relation to the human subject, a fact which, disregarded, may be a source of great danger, though, knowing of its existence, precautionary measures may be taken which may render it harmless. Of 108 patients, presumably "contact patients," or patients who had recovered, examined at Rotterdam in 1909, nearly 4 per cent. were found to be bacilli-carriers, corresponding to the so-called typhoid-carriers which, only recently recognised, seem to play such an important part in the dissemination of the typhoid fever germ. The cholera bacillus was found in these carriers for periods of from five to twelve days after they came under observation. It is pointed out that, this being the case, out of more than 100 people leaving a cholera-infected port four (approximately), according to the above statistics, may carry these germs for twelve days, so that any port within twelve days' distance at which these carriers land might be infected by cholera. How far this observation accords with the experience of port officials it is impossible to say at present, but no doubt the matter will be carefully gone into now that attention has been directed to it.

A very interesting outcome of the curative treatment of the cases of cholera that occurred in the Rotterdam outbreak is that, although the epidemic death-rate in Holland during 1909 was about 45 per cent., the death-rate in the municipal hospitals, where special treatment was carried out, was only 13 per cent. Here the doctors resorted to the hypodermic injection of a normal saline solution, sometimes in quantities of several quarts a day, the effect of this mild saline solution, as pointed out by the *Times* correspondent, being not only a replacing of the moisture which the system loses as the result of the extreme watery diarrhœa, but "a direct stimulation of the heart and also an indirect stimulation of the heart by diluting the blood and thus reducing friction."

The whole treatment, both preventive and curative, of cholera is the outcome of modern methods of medical research, a fact that may be commended to those who, either through prejudice or ignorance, or both, would limit the study of bacteriology and experimental medicine to the field the bounds of which are those of their own narrow vision.

MALARIA PROPHYLAXIS IN INDIA.[1]

"A PROBLEM of Imperial magnitude." "Epidemics of smallpox, cholera, and plague are grievous afflictions, but neither singly nor even collectively are they responsible for so much economic inefficiency, and what is worse, actual human misery, as the recurrent scourge of malaria." These words of the Viceroy and the Lieutenant-Governor of the Punjab respectively impress us with the magnitude and seriousness of the problem that the conference had to consider. If we attempt to translate these words into figures, we are met with difficulties, owing to the fact that the registrar of deaths in India is often the ignorant village chowkidar, but as a rough approximation, it may be assumed that the mean death-rate is about 5 per 1000, *i.e.* over a million deaths annually throughout the country as a whole; whereas in the jails, owing to the care with which prisoners are treated, the mean death-rate from malaria is only 1 per 1000.

But even if the figures for the country as a whole be correct, an analysis of them does not reveal where the real mischief lies. If we assume, for example, that we know the malarial death-rate of a particular town or district the figures available still do not show us whether, as not uncommonly is the case, some parts of the town or district may not be quite free from malaria. It is evident, then, if prophylactic measures are to be applied economically and from financial considerations, this is a prime necessity: one of the first and most important steps must be to determine accurately what areas are malarial, or are so to such an extent as materially to affect the whole of the inhabitants; for it is obviously unnecessary to apply prophylactic measures to those areas which do not need them; but unfortunately there appears to be evidence that this has already been done, not to mention the "fatuous" instance recorded of oiling drains, under instructions, where minute examination showed that no anopheline larvæ existed. But on the other hand, there is already work waiting to be done. What is the nature of this work, and how is it to be done?

It is these questions that mainly occupied the attention of the delegates to the conference. It was pointed out that a multitude of different conditions exist in India, but that small villages surrounded by swamps are in the enormous majority, and again it was stated that the mitigation of malaria in India is chiefly the problem of its mitigation in small villages. For scattered populations, small villages, and rural areas we have the opinion of Major Ross quoted that we must generally fall back upon quinine, yet, rightly, the conference put mosquito destruction in the forefront of its policy, for no doubt—and this is also Ross's opinion—this is the fundamental method; the question is, to what extent is it financially possible?

The resolutions of the conference on this point are expressed in an apparently contradictory sentence. They state "that it will not be possible to protect rural areas by any scheme of drainage which is financially practicable, but it has been found that in some highly malarious tracts the level of subsoil water has been materially lowered with great permanent benefit by drainage operations, the cost of which was not prohibitive." This question of drainage was discussed at length by the conference, and very contradictory views were expressed, not only as to its practicability owing to expense, but as to its benefit, evidence being adduced to show that even in well-drained areas there had, in some cases, been no reduction in malaria.

It is a somewhat discouraging fact that no instance of a drainage scheme with successful result was put before the conference, but that already many unrecorded failures have occurred. It seems to us a matter of importance, then, to inquire into the cause of these failures, so as to ascertain if anything was left undone that could now be better done. Ill thought-out schemes are not uncommon. We ourselves know of a case where a large, shallow tidal area of water, quite free from anophelines, was converted into an ideal breeding-ground by partial filling with earth and by the consequent formation of many hundreds of pools. The danger, too, was pointed out of draining a permanently flooded area, whereby a comparatively healthy was converted into an unhealthy tract, with numerous pools in the rainy season. Some difference of opinion was expressed as to the effect

[1] Proceedings of the Imperial Malaria Conference held at Simla in October, 1909. Pp. vi+107. (Simla: Government Central Branch Press, 1910.

of a high subsoil water on the malaria rate, but it was eventually agreed that "pukka" surface drainage and the lowering of high subsoil water level were anti-malarial measures of primary importance.

It is clear, then, that although failures are on record, and although finance may be a great difficulty, the permanent policy which is adopted is to drain, and, moreover, large drainage schemes may not always be prohibitive from their expense, as the sale of the land re-drained may defray the cost. Any particular scheme must, however, be well thought out, *after*—and this, in our opinion, is essential—the extent of malaria in the particular area has, as far as possible, been accurately estimated, and with the help of sanitary engineers the conditions determining the mortality minutely investigated. Then, and then only, can the effect of the scheme be accurately gauged in all its bearings, and "the devastating flood of recommendations" be checked by concrete facts.

We are, perhaps, in the habit of regarding malaria as an endemic rather than an epidemic disease, but a study of the conditions in India shows clearly that it has indeed terrible epidemic manifestations, such as occurred in the Punjab in 1908. We cannot discuss here the cause of these epidemics, but refer those interested to the report itself. We mention them here because it was said that if we could check epidemic "fulminant" malaria "we should have removed the most urgent and distressing effect of this disease, and those manifestations which the people themselves are most impressed by." A study of this question of epidemics impresses on us more than anything the magnitude of the problem to be dealt with, and the urgent need for re-study of the many problems of endemic and epidemic malaria. With regard to these epidemics, the opinion was expressed that they could probably be predicted, and that the only possible way of dealing with them was by the use of quinine.

The importance of quinine as a prophylactic measure cannot be overrated. We have the fact that this is the main method adopted by the Italians; we have the experience of Canada as related by Prof. Osler; the "marked success" of this method on the Panama Canal; and, indeed, we have the striking fact that the only successful prophylactic experiment presented to the conference was that carried out in the Punjab jails, where, by the administration of 15 grains of quinine once a week to each prisoner, the malaria death-rate was, with one exception, reduced to the lowest figure on record, and this during the great epidemic of 1908. That the quinine question, like the drainage question, requires very careful study, the papers read at the conference show. We hope, too, that the period of rivalry, if not of actual animosity, between the advocates of drainage and quinine has passed, though it must surely be admitted by those who are impartial, that quinine has at least one advantage, that it can be applied at once in many cases where drainage is completely impossible. The difficulties of the administration of quinine in India cannot, however, be overlooked.

We would conclude by pointing out the need also for "minor" measures, if we might call them so. An extended study is necessary of the numerous enemies of larvæ—fish, and a variety of predaceous insects, &c.—and of the complete inhibitory effect on larvæ of weeds such as Lemna. We would venture to suggest the appointment of one or more officers to study solely the "bionomics" of the mosquito in all its aspects. We would also urge the appointment of officers for the study of the various malarial problems already alluded to. We think, too, that officers should visit Italy to study quinine prophylaxis there; and that the methods advocated by Major Ross in Mauritius, and those carried out in Panama, should also be studied on the spot.

Finally, there remains one method no less difficult, but one essential to the success of all the others, and that is the education of the people. That the Government has a many-sided and difficult problem before it is clear, but the problem has now been systematically taken up, and we feel confident that when the next malaria conference meets progress will be reported.

KENTISH BIRDS.[1]

THE latest book on the "Birds of Kent"—the third to appear in recent years—is entitled, very appropriately, a history of the birds of the county. For the author, who has been sixteen years preparing this work, has given especial attention to the present and past status of all those species the distribution of which within the county is not quite general, and of those which have become rarer or more common, or have begun or ceased to breed within what we may term historic times, that is, since Kentish birds were first noticed by the older writers; and he has most carefully worked out chronologically the histories of fading and vanished species, as, for instance, the chough, raven, harrier, buzzard, kite, avocet, &c. In this connection we may, however, point out that too much importance must not be attached to the use of the word chough in Shakespeare's description of the cliff at Dover,

"The Crows and Choughs that wing the midway air,"

for there is evidence to show that the older writers must have often meant jackdaws when they wrote choughs. The name chough, indeed, seems to have been originally as generic as pie; and just as they distinguished the mag-pie and the jay-pie, so in time they distinguished the less-known chough as the Cornish chough. Happily, this history is not obliged to confine itself to dealing with the decreases of all the more interesting species, but can detail the increases of some, and point out the gratifying fact of some kinds of wild ducks and other birds breeding in increasing numbers. Of that little wader which has always been associated with the county—and may be called *the* county bird—viz. the Kentish plover, it is extremely satisfactory to read of the steady increase in the number of breeding pairs of late years. Here again we have an exhaustive and valuable article. Very interesting details, too, are given of the nesting of the golden oriole in four localities and in some of them for several years in succession. The present status of the Sandwich tern is set forth, and of the Dartford warbler (the third bird the name of which connects it with Kent) we learn with regret that it is now extinct in the county, its history therein being admirably drawn up. Exact information on these points has been wanting hitherto.

In his accounts of the different species, the author has found it necessary, in order to treat adequately of their history, status, distribution, migratory movement, and economic aspects, to confine his remarks strictly to these questions, and to omit all references to plumages, songs, general and nesting habits, and anecdotes, except in so far as these affect the other questions or offer peculiarities of themselves, or bear some particular relation to the environment of the species in the county. Even so the volume is bulky,

[1] "A History of the Birds of Kent." By Norman F. Ticehurst. Pp. lvi + 568. (London: Witherby and Co., 1909.) Price 21s. net.

and if the omission of these lighter matters make the book less fascinating to read than some others, it detracts nothing from its solid worth. Beginning with a bibliography, the volume contains an introduction of twenty-seven pages, dealing with the topography, geology, rivers, vegetation, avifauna, migration, museums, and collections of and in the county, and of the former authors on the subject. Then follows the detailed account of each species on the lines indicated. Excluding forty-two "doubtful species," which are included in square brackets, these number 312; 107 birds breed regularly in Kent, thirteen have bred only once or on very rare occasions, and fifteen formerly bred and have ceased to do so.

Kent has of late years produced an extraordinary number of rare birds, accidental visitors to these shores, several of them having been "new" to the British list; and in reading the pages of this volume one is impressed with the enormous importance in the compilation of a long county list of rare birds of the existence on the spot of a bird-stuffer always on the look-out for a rare bird, and ready to offer it for the inspection of the trained ornithologist; for it is to be noticed that nearly all these rarities which have apparently been pouring like a stream upon the shores of Kent in the last few years have passed through the hands of one bird-stuffer. Another point which will strike the reader is the sharp eye for a rare bird possessed by some of the Kentish men—more than one great rarity has been secured by shepherds, and most of them by people who were ready to part with them—for we should be loth to think that these gunners shoot all and sundry that come within range on the chance of getting a good bird. At the same time, this apparent habit of men with guns patrolling the county during May and other parts of the close season is a little disquieting, and seems to require attention. Not that we suggest for one moment that the shooting of these stray wanderers far out of their usual range of distribution—does a tittle of harm to the respective species, or that their reaching the hands of the critical ornithologist serves any but a good purpose. But at the same time the habit—unchecked, it would appear of shooting on marsh and shore in the breeding season is essentially a bad and harmful one, and in the case of irresponsible people may easily lead to the death of breeding wildfowl or waders.

Among the many wonders of migration oversea is the fact disclosed in this volume of rare birds from remote countries arriving, not only singly, but in pairs and small parties. Thus two snow-finches (a sedentary species living in the Alps) were shot from a party of five; three white-winged larks observed together, and all secured, and three black larks (new to our list) out of five. So, too, sandpipers from America come not only singly, pairs of the solitary and spotted sandpipers being here recorded. In some years there has been quite an American invasion. In July, 1908, examples of the solitary, pectoral, and Bartram's sandpiper occurred; and 1906 produced both Bonaparte's and the pectoral sandpipers.

The "Hoppen Pits," Dungeness. Breeding Haunt of Black-headed Gulls, Moor-hens, Reed-warblers, &c. From "A History of the Birds of Kent."

The twenty-four plates comprise reproductions of the plates in old books of Kentish specimens, some modern Kentish rarities, and nesting sites and bits of Kentish scenery, the typical haunts in the county of various species. These are very pleasing and appropriate to the objects of the book. By permission of the publishers we are enabled to reproduce one of the illustrations. There is also a good map at the end of the volume, which is nicely got up and well printed on good unglossed paper, so that, despite its bulk, the book is not very heavy.

ON AND OFF DUTY IN ANNAM.[1]

THIS is the work of an Englishwoman, who accompanied her husband, a doctor in the French Colonial Service, to Nhatrang, on the coast of Annam. On landing in Saigon, the capital of Cochin China, she recounts her impressions of the city in terms much more favourable than one would

FIG. 1.—A Well-made Moi Dwelling. From "On and Off Duty in Annam."

expect who had visited the place in its early stages of development. It was then a scattered, sickly settlement; it is now "the Paris of the East," with its wide, well-appointed boulevards and imposing public buildings, the Governor's palace, cathedral, theatre, and hotels, after the best models in Europe. All the more praise to the Government for the transformation of this once swampy wilderness into probably the fairest city in further Asia, equipped with all the latest scientific appliances in effective operation. Its Pasteur Institute has done admirable work in arresting the ravages of plague, cholera, and diseases common to the tropics. The author and her husband were sent to Nhatrang, where the doctor was appointed assistant to the president of the Pasteur Institute, Dr. Yersin, who was one of Pasteur's first pupils, and justified his being chosen to carry out colonial work by his original discoveries, and his energy successfully displayed in other directions.

The author's notes on the native dread of the European treatment of disease are piquant, and enlivened by her keen sense of humour. Their superstitious treatment of the sick is in itself a plague, accountable for greatly increasing the death-rate. This lady's efforts in founding a home in this distant colony will fascinate the reader used to all the comforts and amenities of the West. Her servants had to be taught the elementary principles of truth and cleanliness, and to adopt her point of view regarding honesty, but she had other worries provided by the inroads of destructive insects that had to be dealt with. Her success in utilising the most unpromising material, and creating a pleasant home are worthy of all praise. The cost of living in this region, under the eye of a trained economist, compares favourably with that of the West. She found seven shillings a week sufficient allowance for the cook, who had to provide "three courses for lunch and the same for dinner." This may induce some of the "hard hit" at home to emigrate to the hospitable shores of Annam.

The manners and customs of the Annamites, which are ably set forth, may stem the tide of settlers flowing Eastward. Be that as it may, the author's pictures of life in this region are not without attraction.

The history of Annam is passed in review in this interesting work, and the part played by the aborigines, whose country she explored when off duty. Government and religion are also discussed. But in this vast section of eastern Asia some weighty problems await solution regarding the different races that people its area, and the religions which they follow.

Cambodia, the latest acquisition of France, is touched upon with a light hand, and in some respects it is the most important of her Eastern possessions. It was at one time an extensive and powerful kingdom, inhabited by a highly civilised race of men, whose stone temples, cities, and palaces remain to bear witness to their skill as builders, and to their knowledge of art. In the last and greatest temple reared, Nakhon Wat, one has evidence that this was an early stronghold of Brahmanism, a Far Eastern outpost of the faith. In its outer galleries, sculptured in low relief, half life-size, on the stone walls a series

FIG. 2.—The Verandah of the Pasteur Institute. From "On and Off Duty in Annam."

of illustrations meant for all time of the chief episodes of India's sacred epics, the Ramánayána, and Mahábhárata, in which the design, craftsmanship, and drawing are so excellent as to suggest Western influence. There is no Brahmanical temple in India so vast and imposing. Notices of Cambodia are found in the Chinese annals of the Tsin, Sui, and Tang

[1] "On and Off Duty in Annam." By Gabrielle M. Vassal. Pp. xi + 283 (London: William Heinemann, 1910.) Price 10s. net.

dynasties, which throw some light on the early history of this region.

The author describes the ancient temple at Nhatrang, stone built, with inscriptions in primitive Pali, similar to those found in Nakhon Wat, and other monuments scattered over a vast area.

In conclusion, the book covers a wide field of interest, and is a welcome addition to the literature of further Asia. J. THOMSON.

LAKE CHAD.[1]

THE first volume gives the geographical results of the mission presided over by Captain Tilho (which undertook, in connection with British delegates, a delimitation of the Anglo-French frontier in the region of Lake Chad and northern Nigeria). The main purport of this volume is the survey and delineation of that extraordinarily puzzling feature in African geography, Lake Chad—a "lake" described by Captain Tilho as being nothing but an immense marsh with variable stretches of open water nowhere more than 12 feet deep.

Probably the first definite mention of Lake Chad (under the name of Zad) occurs in the writings of Frederick Hornemann, at the very close of the eighteenth century. (Hornemann, who was taken into the employ of the English African Association, and sent by them to reveal this lake and also the central course of the Niger, is believed to have reached the Niger and to have died in the Nupe country about 1800.) But rumours of a great sheet of water in the heart of Africa, beyond the Sahara Desert, had probably reached the Romans in the first century of the the Christian era, through their connection with Tunis, Tripoli, and Fezzan, and these stories were reflected in the conjectured Libya Palus of Claudius Ptolemæus, who wrote in the middle of the second century. When the Arabs and Moors had become thoroughly acquainted with the geography of the Sudan they revived these traditions, but mixed them up with both the Niger and the Nile systems.

As a matter of fact, the basin of Lake Chad is curiously on the balance between the watersheds of the Nile and of the Niger. The work of other and earlier French expeditions (especially that of Dr. Auguste Chevalier) which preceded that of Captain Tilho has put before us evidence of a faunistic and geological character which prompts the supposition that Lake Chad is the very last vestige (shrinking annually, one might say) of a vast, *shallow*, inland sea, which covered much of the region north, east, and, above all, west of Lake Chad, of the basin of the Niger north of the mountains, and probably communicated with the sea along the basin of the Senegal River. Whether there was any north-eastern outlet towards the Nile basin is more doubtful. Looking at the most recent map of Africa in relief, it would seem more probable that there has been for ages a bridge of high land through the Tibesti country which has connected southern Tunis with Central Africa, and separated the Niger-Chad basins from that of the Nile; but it is more likely that down to the close of the Secondary epoch, or even at the very beginning of the Tertiaries, there may have been a connection between the Chad-Shari basin and that of the Congo. Nearly the whole of the Congo basin was, down to a relatively recent period, a vast freshwater lake. A rise of ground so slight as scarcely to be perceptible to the traveller separates at the present day the basin of the Shari River from that of the Mubangi-Wele, which, of course, marks the existing limits to the north of the former Congo Sea, that sea which in Tertiary times forced its present narrow outlet through the Crystal Mountains into the southern Atlantic. Many arguments for the justification of these hypotheses (as also for arguing the relatively early detachment of the Congo Sea from that of the Sahara) may be found in the remarkable works of Mr. G. A. Boulenger on the fresh-water fishes of Africa. From this same source, again, may be derived further arguments for the relatively recent existence of the Chad-Niger Sea, and perhaps also for the close geographical connection between that vast area of fresh water and the great lake which formerly filled up much of the Bahr-al-Ghazal-and-Upper-Nile regions, a lake represented at the present day by the Sudd region.

Other French expeditions dealing with the country between Lake Chad and the Mubangi-Congo have established the existence (it is said) of the manati in the Shari River, and, above all, in the isolated lakes and pools to the north-east of that stream. The manati is also stated to be found in the Niger River between Sego in the west and Yauri in the east. If this is really the case, it is further evidence for the existence and the relatively recent drying-up of this vast fresh-water Sahara Sea; for the manati is a Sirenian mammal the nearest relations of which are found fossil in lower Egypt, in the West Indies, and in Florida. The manati is still found as a living animal in the estuaries and broader rivers of West Africa, but it would be exceedingly difficult for it to reach the Upper Niger over the Busa Rapids, though it might, and perhaps does, pass up the river Benue, and thus reach the Shari by way of the Tuburi marshes. (The manati is not found in the Upper Congo.) With regard to these Tuburi marshes, we have here a very interesting problem to discuss. Another French scientific expedition established not long ago the feasibility of passing from the Upper Benue by canoe through the Tuburi marshes into the Logun River, and thus into the Shari and Lake Chad. Its leader (Lieut. Faure) has proved that at the height of the rainy season of that particular year there was continuous water communication between the mouth of the Niger and Lake Chad, so that Lake Chad was then nothing but a backwater of a river system in Central Africa which sent a superfluity of its waters to the Benue and the Niger.

Captain Tilho's work, however, though it touches on some of these hydrographical problems, deals mainly with the configuration of Lake Chad, in the volume under review. It shows that the average depth of the lake is only 1 metre 50 cm. (say 4 feet 10 inches), and in the great stretches of open water scarcely more than about 3 metres (say 10 feet). It is simply a vast swamp joining the waters of the Komadugu, which enters the Chad on the north-west, with the floods of the Shari coming in on the south-east. During the three years of study devoted by this mission, the only area of open water remaining in the Chad was quite outside British political limits, and lay to the north and north-west of the Shari delta. The rest of the lake surface was either completely dry land (north of the Komadugu River) or it consisted in the east of an archipelago of almost innumerable islands interspersed with lagoons, pools, and navigable creeks. Where Denham saw the waters of Lake Chad at Ngigmi in 1822 there may be a few tiny pools or a small area of moist ground, but the rest of the northern third of the lake has become absolutely dry land.

No doubt to the later expeditions of Barth and Vogel the surface of open water in Lake Chad was

[1] République Francaise. Ministère des Colonies. "Documents scientifiques de la Mission Tilho" (1906–9). First Volume. Pp. lx + 412 and Cartes. (Paris, Imprimérie nationale, 1910.)

already much restricted and blocked with swamp vegetation. There has been not only partial desiccation due to a lessening in the rainfall of West Central Africa, but also a raising of the lake level by the excessive growth of marsh vegetation—papyrus, reeds, rushes, grasses, and the ambatch tree. The water of Lake Chad would also seem to be increasing in salinity, which, however, does not appear to interfere with the growth of vegetation. On the contrary, when every now and then (according to the stories of the natives) the lake is partially recreated by floods from the Shari and the Komadugu and the water becomes fresh, the vegetation tends to disappear, partly by its being drowned, and partly because the water has lost some element suited to its growth.

Some further geographical information is given as to the Bahr-al-Ghazal Channel, or Soro, as it should preferably be called (in order not to confuse it with the name of the western basin of the Nile). This would seem to have been an ancient outlet of the flooded Chad, which carried these waters along a definite channel towards the north-east into the Bodele depression. Another possible *déversoir* of Lake Chad exists still in Lake Fitri, far away to the south-east, which this mission showed still to possess an area of open water of nearly 150 square miles.

H. H. JOHNSTON.

NOTES.

WE have received a programme of the International Congress on Radiology and Electricity to be held at Brussels on September 13–15. Among the important matters to be brought forward is the question of radium standards and nomenclature. The congress will be divided into three sections. In the first section, general questions of terminology and methods of measurement in radio-activity and subjects connected with ionisation will be discussed. The second section will be devoted to subjects relating to the fundamental theories of electricity, the study of radiations (including spectroscopy, the chemical effects of radiations, and allied subjects), radio-activity, atomic theory, and cosmical phenomena, such as atmospheric electricity and the radio-activity of the atmosphere. The third section is biological, and will be devoted to the consideration of the effects of radiations on living organisms. This section will deal with purely biological subjects, as well as the use and application of various radiations for medical purposes. A long list of papers already promised is given in the programme, as well as a list of members up to date. A special exhibit of apparatus relating to the work of members is to be held in connection with the congress, and members are invited to forward exhibits to the Physical Laboratory of the University of Brussels. A number of excursions have already been arranged to take place after the congress, and special facilities will be granted to members on the Belgian and French railways. Intending members should communicate with Dr. J. Daniel at Ostende, rue Wellington 28.

THE preliminary programme of the twenty-fifth congress of the Royal Sanitary Institute, to be held in Brighton on September 5–10 under the presidency of Sir John A. Cockburn, K.C.M.G., has now been issued. Dr. A. Newsholme (Principal Medical Officer, Local Government Board) will deliver the lecture to the congress on "The National Importance of Child Mortality." Dr. Alex. Hill will deliver the popular lecture on "The Bricks with which the Body is Built." In connection with the congress, a health exhibition of apparatus and appliances relating to health and domestic use will be held as practical illustration of the application and carrying out of the principles and methods discussed at the meetings. The congress will include general addresses and lectures, and there will be two section meetings for two days each, dealing with:—Section i., sanitary science and preventive medicine, *president*, Prof. E. W. Hope; Section ii., engineering and architecture, *president*, Mr. H. Rofe. Eight special conferences will be held, dealing respectively with municipal representatives; port sanitary authorities; medical officers of health; engineers and surveyors to county and other sanitary authorities; veterinary inspectors; sanitary inspectors; women on hygiene; and hygiene of childhood.

THE death is announced, at seventy-five years of age, of Prof. F. von Neumann, who from 1876 until 1909 held the chair of political economy at the University of Tübingen.

WE regret to see the announcement of the death of Dr. Louis Olivier, at fifty-six years of age. Dr. Olivier was the founder and editor of our esteemed contemporary the *Revue générale des Sciences*, which ever since it first appeared, twenty years ago, has taken a leading place among the scientific periodicals of the world.

THE International Horticultural Exhibition of 1912 will be held in the grounds attached to the Royal Hospital, Chelsea. These beautiful grounds were laid out by Sir Joseph Paxton, and they are well adapted for the purposes of a horticultural exhibition. The area leased to the exhibition authorities is approximately twenty acres, and nearly sixteen will be directly available for the accommodation of the exhibits. In the remaining portion, which includes some shrubberies, there are many fine specimen trees.

THE following news of north polar exploration has been sent to London by the manager of the Nordenfjeldske Steamship Company of Trondhjem:—*Kong Harold* has returned from polar ice. Reached 80° 10′, within 10° Pole. Met *Fram* expedition at Spitsbergen. *Fram* has discovered volcano and hot springs Wood Bay; beach covered with lava. Zeppelin has taken possession of tract of land at King's Bay, and has named it Zeppelinshafen.

IT is reported by the Polar Sea yacht *Laura*, which arrived at Tromsö on August 17 from East Greenland, that the expedition ship *Alabama*, belonging to the Danish explorer Captain Mikkelsen, was crushed by the ice at the end of March last. The crew were saved, and wintered on Shannon Island. The Copenhagen correspondent of the *Morning Post* states that Captain Mikkelsen with Mr. Iversen, who started from Shannon Island on March 3, are trying to reach Cape York, on the western coast of Greenland, travelling by way of Peary Channel and the inland ice. If insurmountable difficulties are encountered, they can return to Shannon Island, where a house, in which there are provisions sufficient for two years, has been built. On August 7 Captain Mikkelsen and his companion had not yet returned, and it is supposed that they continued their way through the Peary Channel to Cape York, or that they are returning along the east coast, having spent the summer there.

THE Anthropological Society of Paris, in the last issue of its *Bulletins et Mémoires*, gives a report of the meeting, attended by leading anthropologists from all parts of Europe, to commemorate the fiftieth anniversary of its foundation. An interesting feature in the report is a series of papers contributed by the foreign delegates describing the progress of research in the various parts of Europe. As representative of the Royal Anthropological

Institute, Prof. W. Ridgeway sketched the results attained in this country during the last fifty years. Describing the refusal of the Prime Minister of a grant in aid of the proposed Bureau of Anthropology, who at the same time admitted that a knowledge of the science was indispensable for our Indian and Colonial administrators, he added:—"If, then, in the United Kingdom we have not done all that we ought to extend the study of man, I beg you to remember that the Anthropological Institute has to depend upon the subscriptions of its members. Your distinguished society has long been recognised as of public utility by the State."

In *Folk-lore* for June Mr. Andrew Lang discusses the strange myth of Theseus and the Minotaur. He argues that the fact of human sacrifice in Minoan times is not established, and that the suggestion that Minos, like the priest kings described by Prof. J. G. Frazer, had to fight for his life at stated periods, rests upon a passage in Homer which cannot bear that meaning. He concludes that the historic fact in the Attic myth is the sending of Attic captives into the Cretan bull-ring, where boy and girl acrobats played perilous tricks with bulls, as often depicted in Cretan art. The rest of the myth is a common *marchen* localised.

In a recent number of the Journal of the Royal Society of Arts, a paper by Mr. H. Gibson is reprinted, embodying the investigations made by Mr. H. P. Slade of the dew-ponds on the Thorpe Downs, Berkshire. The result is to show that dew contributed nothing to the water supply, which appears to be entirely the consequence of rainfall. Dew, in fact, is only scantily deposited on such high grounds owing to draughts of air, which cause rapid re-evaporation. As the temperature of the water was found to be at night much lower than that of the surrounding air, the author believes that the possibility of dew condensation is disproved. He concludes that a catchment area consisting of galvanised corrugated iron stretched upon a wooden frame, with a roofed reservoir to collect and store the rainfall, would be more economical and sanitary, as a souce of water supply, than the most ingenious dew-pond ever constructed.

Information has been received by the *Times* that the new direct wire connecting Montreal with the Bamfield Creek cable station has been completed by the Canadian Pacific Railway, and was handed over to the Pacific Cable Board on Monday. The longest cable in the world (3458 nautical miles) is thus connected with a land line 3000 miles in length, and communication between Fanning Island (long. 159 W., lat. 3 N.) and Montreal (long. 75 W., lat. 45 N.) will be effected with only one retransmission. The Pacific Cable Board expects, as a result of this new arrangement, to be able to reduce the average time in transmission between Australasia and London by fifteen minutes.

A fifth report on research work carried out for the Metropolitan Water Board by Dr. Houston, director of water examination, has been issued. One important section contains the results of the examination of *raw* Thames and Lea water for the presence of the typhoid and Gartner bacilli. The total amount of water dealt with was 12 litres, averaging 62,688 microbes per cubic centimetre. From this vast number of bacteria, one was isolated having all the characters of a typhoid bacillus; another corresponded to the Gartner bacillus. If present, therefore, these microbes must be extremely scanty in the raw waters, for control experiments carried out with the raw waters artificially inoculated with these organisms showed that the methods employed sufficed to reveal a very small infection. Another search was for Morgan's bacillus No. 1, supposed to be a cause of summer diarrhœa of infants, but it was not found in the raw waters.

In the *Irish Naturalist* for August, Dr. A. R. Jackson records from Ireland a spider, *Erigone capra*, new to the fauna of the British Isles.

In the paragraph on the local forms of musk-ox in our last week's issue (p. 211), the statement that the range of the species extends to the west of the Mackenzie applies only to a past epoch.

To the August number of the *Naturalist* Mr. Sheppard contributes an illustrated article on Neolithic implements from Bridlington, where there appear to have been four sites for their manufacture, one of which occurs near Danes' Dyke, the ancient earthwork stretching across Flamboro' Head. All the implements are made from black flint, quite different from the local grey flint. Some of the specimens recently obtained, more especially a so-called sickle, are stated to be of unusual types.

To the Proceedings of the Philadelphia Academy for April Mr. J. P. Moore contributes the second part of an article on polychætous annelids dredged off the Californian coast by the *Albatross* in 1904. In the Polynoidæ twelve species are described as new, while four previously known from Japan are for the first time recorded from the American side of the Pacific. The other groups discussed are the Aphroditidæ and Segaleonidæ, of which new forms, including a new genus, are also described.
