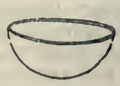
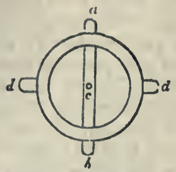
We shall illustrate the mode of fabricating loam moulds, by a simple case, such as that of a sugar-pan. *Fig.* 992 is the pan. There is laid upon the floor of the foundry an annular platform of cast iron, *a*, *b*, *fig.* 993; and upon its centre *c*, rests the lower extremity of a vertical shaft, adjusted so as to turn freely upon itself, while it makes a wooden pattern *e f*, *fig.* 994, describe a surface of revolution identical with the internal surface reversed of the boiler intended to be made. The outline *e g*, of the pattern is fashioned so as to describe the surface of the edge of the vessel. Upon the part *a*, *d*, *b*, *d*, *fig.* 993, of the flat cast-iron ring, there must next be constructed, with bricks laid either flat or on their edge, and clay, a kind of dome, *h i k*, *fig.* 994, from two to four inches thick, according to the size and weight of the piece to be moulded. The external surface of the brick dome ought to be everywhere two inches distant at least, from the surface described by the arc *e f*. Before building up the dome to the point *i*, coals are to be placed in its inside upon the floor, which may be afterwards kindled for drying the mould. The top is then formed, leaving at *i*, round the upright shaft of revolution, only a very small outlet. This aperture, as also some others left under the edges of the iron ring, enable the moulder to light the fire when it becomes necessary, and to graduate it so as to make it last long enough without needing more fuel, till the mould be quite finished and dry. The combustion should be always extremely slow.

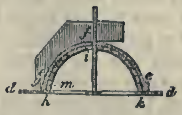
992



993



994



Over the brick dome a pasty layer of loam is applied, and rounded with the mould *g*, *e*, *f*; this surface is then coated with a much smoother loam, by means of the concave edge of the same mould. Upon the latter surface, the inside of the sugar-pan is cast; the line *e g* having traced, in its revolution, a ledge, *m*. The fire is now kindled, and as the surface of the mould becomes dry, it is painted over by a brush with a mixture of water, charcoal-powder, and a little clay in order to prevent adhesion between the surface already dried and the coats of clay about to be applied to it. The board *g e f* is now removed, and replaced by another, *g′ e′ f′*, *fig.* 995, whose edge *e′ f′* describes the outer surface of the pan. Over the surface *e f*, a layer of loam is applied, which is turned and polished so as to produce the surface of revolution *e′ f′*, as was done for the surface *e f*; only in the latter case, the line *e′ g′* of the board does not form a new shoulder, but rubs lightly against *m*.

The layer of loam included between the two surfaces *e f*, *e′ f′* is an exact representation of the sugar-pan. When this layer is well dried by the heat of the interior fire, it must be painted like the former. The upright shaft is now removed, leaving the small vent-hole through which it passed to promote the complete combustion of the coal. There must be now laid horizontally upon the ears of the platform *d d*, *fig.* 993, another annular platform *p q*, like the former, but a little larger, and without any cross-bar. The relative position of these two platforms is shown in *fig.* 997. Upon the surface *e′ f′ fig.* 996, a new layer of loam is laid, two inches thick, of which the surface is smoothed by hand. Then upon the platform *p q*, *fig.* 997, a brick vault is constructed, whose inner surface is applied to the layer of loam. This contracts a strong adherence with the bricks which absorb a part of its moisture, while the coat of paint spread over the surface *e′ f′*, prevents it from sticking to the preceding layers of loam. The brick dome ought to be built solidly.

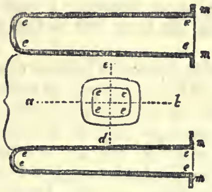
995

996

997

The whole mass is now to be thoroughly dried by the continuance of the fire, the draught of which is supported by a small vent left in the upper part of the new dome; and when all is properly dry, the two iron platforms are adjusted to each other by pin points, and *p q* is lifted off, taking care to keep it in a horizontal position. Upon this platform are removed the last brick dome, and the layer of loam which had been applied next to it; the latter of which represents exactly by its inside the mould of the surface *e′ f′*, that is, of the outside of the pan. The crust contained between *e f* and *e′ f′* is broken away, an operation easily done without injury to the surface *e f*, which represents exactly the inner surface of the pan; or only to the shoulder *m*, corresponding to the edge of the vessel. The top aperture through which the upright shaft passed must be now closed; only the one is kept open in the portion of the mould lifted off upon *p q*; because through this opening the melted metal is to be poured in the process of casting. The two platforms being replaced above each other exactly, by means of the adjusting pin-points, the mould is completely formed, and ready for the reception of the metal.

998



999

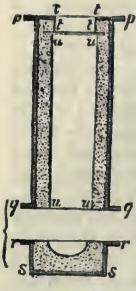
When the object to be moulded presents more complicated forms than the one now chosen for the sake of illustration, it is always by analogous processes that the workman constructs his loam moulds, but his sagacity must hit upon modes of executing many things which at first sight appear to be scarcely possible. Thus, when the forms of the interior and exterior do not permit the mould to be separated in two pieces, it is divided into several, which are nicely fitted with adjusting pins. More than two cast-iron rings or platforms are sometimes necessary. When ovals or angular surfaces must be traced instead of those of revolution, no upright shaft is used, but wooden or cast-iron guides made on purpose, along which the pattern cut-out board is slid according to the drawing of the piece. Iron wires and claws are often interspersed through the brick-work to give it cohesion. The core, kernel, or inner mould of a hollow casting is frequently fitted in when the outer shell is moulded. The case of a gas-light retort, *fig.* 998, will illustrate this matter. The core of the retort ought to have the form *e e e e*, and be very solid, since it cannot be fixed in the outer mould for the casting, except in the part standing out of the retort towards *m m*. It must be modelled in loam, upon a piece of cast iron called a *lantern*, made expressly for this purpose. The lantern is a cylinder or a truncated hollow cone of cast iron, about half an inch thick; and differently shaped for every different core. The surface is perforated with holes of about half an inch in diameter. It is mounted by means of iron cross-bars, upon an iron axis, which traverses it in the direction of its length. *Fig.* 999, represents a horizontal section through the axis of the core; *g h* is the axis of the lantern, figured itself at *i k k i*; *o i i o* is a kind of disc or dish, perpendicular to the axis, open at *i i*, forming one piece with the lantern, whose circumference *o o* presents a curve similar to the section of the core, made at right angles to its axis. We shall see presently the two uses for which this dish is intended. The axis *g h* is laid upon two gudgeons, and handles are placed at each of its extremities, to facilitate the operation in making the core. Upon the whole surface of the lantern, from the point *h* to the collet formed by the dish, a hay cord as thick as the finger is wound. Even two or more coils may be applied, as occasion requires, over which loam is spread to the exact form of the core, by applying with a hand a board, against the dish *o o*, with its edge cut out to the desired shape; as also against another dish, adjusted at the time towards *h;* while by means of the handles a rotatory movement is given to the whole apparatus.

The hay interposed between the lantern and the loam, which represents the crust of the core. aids the adhesion of the clay with the cast iron of the lantern, and gives passage to the holes in its surface, for the air to escape through in the casting.

When the core is finished, and has been put into the drying stove, the axis *g h* is taken out, then the small opening which it leaves at the point *h*, is plugged with clay. This is done by supporting the core by the edges of the dish, in a vertical position. It is now ready to be introduced into the hollow mould of the piece.

This mould, executed in baked sand, consists of three pieces; two of which, absolutely similar, are represented, *fig.* 1000, at *p q*, the third is shown at *r s*. The two similar parts *p q*, present each the longitudinal half of the nearly cylindrical portion of the outer surface of the gas retort; so that when they are brought together, the cylinder is formed; *r s* contains in its cavity the kind of hemisphere which forms the bottom of the retort. Hence, by adding this part of the mould to the end of the two others, the resulting apparatus presents, in its interior, the exact mould of the outside of the retort; an empty cylindrical portion *t t*, whose axis is the same as that of the cylinder *u u*, and whose surface, if prolonged, would be everywhere distant from the surface *u u*, by a quantity equal to the desired thickness of the retort. The diameter of the cylinder *t t* is precisely equal to that of the core, which is slightly conical, in order that it may enter easily into this aperture *t t*, and close it very exactly when it is introduced to the collet or neck.

1000



1001

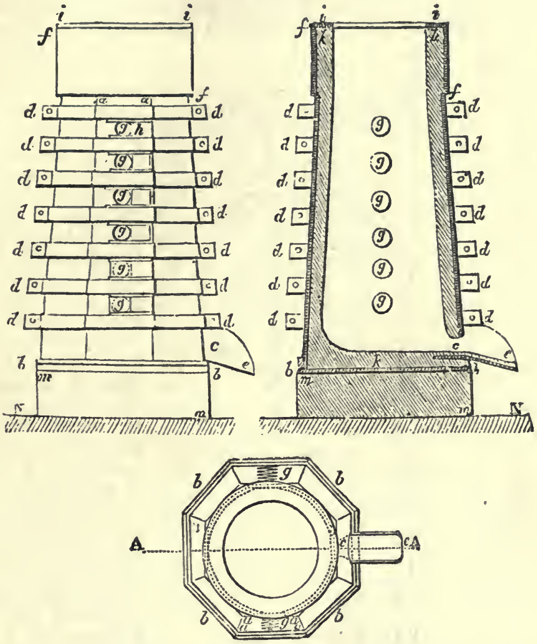
The three parts of the mould and the core being prepared, the two pieces *p q*, must first be united, and supported in an upright position, then the core must be let down into the opening *t t*, *fig.* 1001. When the plate or disc *o o* of the core is supported upon the mould, we must see that the end of the core is everywhere equally distant from the edge of the external surface *u u*, and that it does not go too far beyond the line *q q*. Should there be an inaccuracy, we must correct it by slender iron slips placed under the edge of the disc *o o*; then by means of a cast-iron cross, and screw bolts *v v*, we fix the core immovably. The whole apparatus is now set down upon *r s*, and we fix with screw bolts the plane surface *q q* upon *r r*; then introduce the melted metal by an aperture *z*, which has been left at the upper part of the mould.

When, instead af the example now selected, the core of the piece to be cast must go beyond the mould of the external surface, as is the case with a pipe open at each end, the thing is more simple, because we may easily adjust and fix the core by its two ends.

In casting a retort, the metal is poured into the mould set upright. It is important to maintain this position in the last two examples of casting; for all the foreign matters which may soil the metal during its flow, as the sand, the charcoal, gases, scoriæ, being less dense than it, rise constantly to the surface. The hydrostatic pressure produced by a high gate, or filling-in aperture, contributes much to secure the soundness and solidity of the casting. This gate piece being superfluous, is knocked off almost immediately after, or even before the casting cools. Very long, and somewhat slender pieces, are usually cast in moulds set up obliquely to the horizon. As the metal shrinks in cooling, the mould should always be somewhat larger than the object intended to be cast. The iron founder reckons in general upon a linear shrinkage of a ninety-sixth part; that is one-eighth of an inch per foot.

Melting of the cast iron.—The metal is usually melted in a cupola furnace, of which the dimensions are very various. *Fig.* 1002 represents in plan, section, and elevation, one of these furnaces of the largest size; being capable of founding 5 tons of cast iron at a time. It is kindled by laying a few chips of wood upon its bottom, leaving the orifice *c* open, and it is then filled up to the throat with coke. The fire is lit at *c*, and in a quarter or half an hour, when the body of fuel is sufficiently kindled, the tuyère blast is set in action. The flame issues then by the mouth as well as the orifice *c*, which has been left open on purpose to consolidate it by the heat. Without this precaution the sides, which are made up in argillaceous sand after each day's work, would not present the necessary resistance. A quarter of an hour afterwards, the orifice *c* is closed with a lump of moist clay, and sometimes, when the surface is to contain a great body of melted metal, the clay is supported by means of a small plase of cast iron fixed against the furnace. Before the blowing-machine is set a-going, the openings, *g g g* had been kept shut. Those of them wanted for the tuyères are opened in succession, beginning at the lowest, the tuyères being raised according as the level of the fused iron stands higher in the furnace. The same cupola may receive at a time from one to six tuyères, through which the wind is propelled by the centrifugal action of an excentric fan or ventilator. It does not appear to be ascertained whether there be any advantage in placing more than two tuyères facing each other upon opposite sides of the furnace. Their diameter at the nozzle varies from 3 to 5 inches. They are either cylindrical or slightly conical. A few minutes after the tuyères have begun to blow, when the coke sinks in the furnace, alternate charges of coke and pig-iron must be thrown in. The metal begins to melt in about 20 minutes after its introduction; and successive charges are then made every 10 minutes nearly; each charge containing from 3 cwts. to 5 cwts. of iron, and a quantity proportional to the estimate given below. The amount of the charges varies of course with the size of the furnace, and the speed required for the operation. The pigs must be previously broken into pieces weighing at most 14 or 16 lbs. The vanes of the blowing fan make from 625 to 650 turns per minute. The two cupolas represented in *fig.* 1003, and another alongside in the plan, may easily melt $6\frac{1}{2}$ tons of metal in $2\frac{3}{4}$ hours; that is $2\frac{1}{3}$ tons per hour. This result is three or four times greater than what was formerly obtained in similar cupolas, when the blast was thrown in from small nozzles with cylinder bellows, moved by a steam-engine of 10 horse-power.

1002



In the course of a year, a considerable foundry like that represented in the plan, *fig.* 991, will consume about 300 tons of coke in melting 1,240 tons of cast iron; consisting of 940 tons of pigs, of different qualities, and 300 tons of broken castings, gate-pieces, &c. Thus it appears that 48 lbs. of coke are consumed for melting every 2 cwts. of metal.

Somewhat less coke is consumed when the fusion is pushed more rapidly, to collect a great body of melted metal for casting heavy articles; and more is consumed when, as in making many small castings, the progress of the founding has to be slackened from time to time; otherwise, the metal would remain too long in a state of fusion, and probably become too cold to afford sharp impressions of the moulds.

It sometimes happens that in the same day, with the same furnace, pieces are to be cast containing several proportions of different kinds of iron; in which case, to prevent an intermixture with the preceding or following charges, a considerable bed of coke is interposed. Though there be thus a little waste of fuel, it is compensated by the improved adaptation of the castings to their specific objects. The founding generally begins at about 3 o'clock P.M., and goes on till 6 or 8 o'clock. One founder aided by four labourers for charging, &c., can manage two furnaces.

The following is the work of a well-managed foundry in Derby.

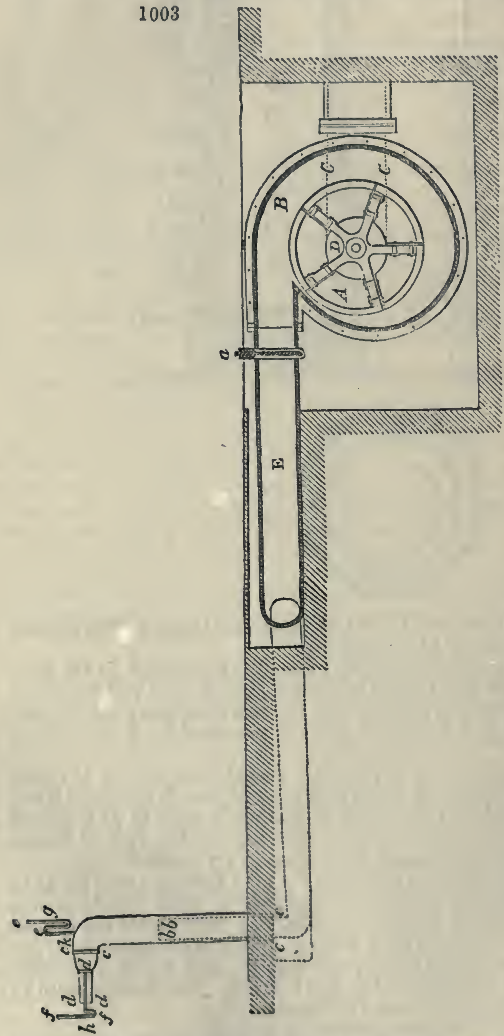
200 lbs. of coke are requisite to melt, or bring down (in the language of the founder), 1 ton of cast iron, after the cupola has been brought to its proper heat, by the combustion in it of 9 baskets of coke, weighing, by my trials, 40 lbs. each = 360 lbs.

The chief talent of the founder consists in discovering the most economical mixtures and so compounding them as to produce the desired properties in the castings. One piece, for example, may be required to have great strength and tenacity to bear heavy weights or strains; another must yield readily to the chisel or the file; a third must resist sudden alternations of temperature; and a fourth must be pretty hard.

The filling-in of the melted metal is managed in two ways. For strong pieces, whose moulds can be buried in the ground at 7 or 8 yards' distance from the furnace, the metal may be run in gutters, formed in the sand of the floor, sustained by plates or stones. The clay plug is pierced with an iron rod, when all is ready.

When from the smaller size, or greater distance of the moulds, the melted metal cannot be run along the floor from the furnace, it is received in cast-iron pots or ladles, lined with a coat of loam. These are either carried by the hands of two or more men, or transported by the crane. Between the successive castings, the discharge hole of the furnace is closed with a lump of clay, applied by means of a stick, having a small disc of iron fixed at its end.

1003



After the metal is somewhat cooled, the moulds are taken asunder, and the excrescences upon the edges of the castings are broken off with a hammer. They are afterwards more carefully trimmed or chipped by a chisel when quite cold. The loss of weight in founding is about 6½ per cent. upon the pig iron employed. Each casting always requires the melting of considerably more than its own weight of iron. This excess forms the gates, false seams, &c.; the whole of which being deducted, shows that 1 cwt. of coke is consumed for every 3 cwts. of iron put into the furnace; for every 138 cwts. of crude metal, there will be 100 cwts. of castings, 32 of refuse pieces, and 6 of waste.

Fig. 1002, *Cupola furnace*, requires a little further description. It is 3 feet wide within, and 13½ feet high. *m m*, solid body of masonry, as a basis to the furnace.

b b, octagonal platform of cast iron, with a ledge in which the plates *a a a a* are engaged.

a a, eight plates of cast iron, 1 inch thick, absolutely similar; only one of them is notched at its lower part in *c*, to allow the melted metal to run out, and two of the others have six apertures, *g g g*, &c. to admit the tuyères.

c, orifice for letting the metal flow out. A kind of cast-iron gutter, *e*, lined with loam, is fitted to the orifice.

d, hoops of hammered iron, 4½ inches broad; ½ inch thick for the bottom ones; and ¼ inch for the upper ones. The intermediate hoops decrease in thickness from below upwards between these limits.

e, cast-iron gutter or spout, lined with loam, for running off the metal.

f f, cylindrical piece of cast iron, for increasing the height and draught of the furnace.

g, side openings for receiving the tuyères, of which there are six upon each side of the furnace. Each of them may be shut at pleasure, by means of a small cast-iron plate, *h*, made to slide horizontally in grooves sunk in the main plate, pierced with the holes *g g*.

k k, interior lining of the surface, made of sand, somewhat argillaceous, in the following way:—After having laid at the bottom of the furnace a bed of sand a few inches thick, slightly sloped towards the orifice of discharge, there is set upright, in the axis of the cupola, a wooden cylinder of its whole height, and of a diameter a little less than that of the vacant space belonging to the top of the furnace. Sand is to be then rammed in so as to fill the whole of the furnace; after which the wooden cylinder is withdrawn, and the lining of the sand is cut or shaved away, till it has received the proper form.

This lining lasts generally five or six weeks, when there are six meltings weekly.

i i, cast-iron circular plate, through which the mouth of the furnace passes for protecting the lining in *k* during the introduction of the charges.

N N, level of the floor of the foundry. The portion of it below the running-out orifice consists of sand, so that it may be readily sunk when it is wished to receive the melted metal in ladles or pots of large dimensions.

The fan distributes the blast from the main pipe to three principal points, by three branch tubes of distribution. A register, consisting of a cast-iron plate sliding with friction in a frame, serves to intercept the blast at any moment, when it is not desirable to stop the moving power. A large main pipe of zinc or sheet iron is fitted to the orifice of the slide valve. It is square at the beginning, or only rounded at the angles; but at a little distance it becomes cylindrical, and conducts the blast to the divaricating points. There, each of the branches turns up vertically, and terminates at *b b*, *fig.* 1003, where it presents a circular orifice of 7½ inches. Upon each of the upright pipes *b*, the one end of an elbow-tube of zinc *c c c*, *fig.* 1003, is adjusted rather loosely, and the other end receives a tuyère of wrought iron *d d*, through the intervention of a shifting hose or collar of leather *c c d*, hooped with iron wire to both the tube and the tuyère. The portion *c c c* may be raised or lowered, by sliding upon the pipe *b*, in order to bring the nozzle of the tuyère *d d*, to the requisite point of the furnace. The portion *c c c* may be made also of wrought iron. A power of 4 horses is adequate to drive this fan, for supplying blast to 3 furnaces.

The founders have observed that the efflux of air was not the same when blown into the atmosphere as it was when blown into the furnaces; the velocity of the fan, with the same impulsive power, being considerably increased in the latter case. They imagine that this circumstance arises from the blast being sucked in, so to speak, by the draught of the furnace, and that the fan then supplied a greater quantity of air.

The following experimental researches show the fallacy of this opinion. Two water siphons, *e e e*, *f f f*, made of glass tubes, one-fifth of an inch in the bore, were inserted into the tuyère, containing water in the portions *g*, *h*. The one of these *manometers* for measuring the pressure of the air was inserted at *k*, the other in the centre of the nozzle. The size of this glass tube was too small to obstruct in any sensible degree the outlet of the air. It was found that when the tuyères of the fan discharged into the open air, the expenditure by a nozzle of a constant diameter was proportional to the number of the revolutions of the vanes. It was further found, that when the speed of the vanes was constant, the expenditure by one or two nozzles was proportional to the total area of these nozzles. The following formulæ give the volume of air furnished by the fan, when the number of turns and the area of the nozzles are known:—

$$\text{Volume} = \frac{25{\cdot}32\ S\,n}{1{\cdot}000{,}000} \qquad (1)$$

$$\text{Volume} = \frac{0{\cdot}86'6'7\ S\,n}{1{,}000{,}000} \qquad (2)$$

The volume is measured at 32° Fahr., under a pressure of 29·6 inches barom.

S = the total area of the orifices of the tuyères in square inches.

n = the number of turns of the vanes in a minute.

After measuring the speed of the vanes blowing into the atmosphere, if we introduce the nozzle of discharge into the orifice of the furnace, we shall find that their speed immediately augments in a notable degree. We might, therefore, naturally suppose that the fan furnishes more air in the second case than in the first; but a little reflection will show that it is not so. In fact, the air which issues in a cold state from the tuyère encounters instantly in the furnace a very high temperature, which expands it, and contributes, along with the solid matters with which the furnace is filled, to diminish the facility of the discharge, and consequently to retard the efflux by the nozzles. The oxygen gas consumed is replaced by a like volume of carbonic acid gas, equally expansible by heat. Reason leads us to conclude that less air flows from the nozzles into the furnace than into the open atmosphere.

The increase in the velocity of the vanes takes place precisely in the same manner, when after having made the nozzles blow into the atmosphere, we substitute for these nozzles others of a smaller diameter, instead of directing the larger ones into the furnace. Hence we may conceive that the proximity of the charged furnace acts upon the blast like the contraction of the nozzles. When the moving power is uniform, and the velocity of the vanes remains the same, the quantity of air discharged must also be the same in the two cases.

Two tuyères, one 5 inches in diameter, the other 4½, and which, consequently, presented a total area of 35½ square inches, discharged air into one of the furnaces, from a fan whose vanes performed 654 turns in the minute. These two nozzles being briskly withdrawn from the furnace, and turned round to the free air, while a truncated pasteboard cone of 3½ inches diameter was substituted for the nozzle of 4½ inches, wherein the area of efflux was reduced to 29·3 square inches, the velocity of the vanes continued exactly the same. The inverse operation having been performed, that is to say, the two original nozzles having been smartly replaced in the furnace, to discover whether or not the moving power had changed in the interval of the experiment, they betrayed no perceptible alteration of speed. From the measures taken to count the speed, the error could not exceed three revolutions per minute, which is altogether unimportant upon the number 654.

It follows, therefore, that when the vanes of the fan have the velocity of 654 turns per minute, the expenditure by two nozzles, whose joint area is 35½ square inches, both blowing into a furnace, is to the expenditure which takes place, when the same nozzles blow into the air, as 35·5 is to 29·3; that is, a little more than ⅘ths.

If this be, as is probable, a general rule for areas and speeds considerably different from the above, to find the quantity of air blown into one or more furnaces by the fan, we should calculate the volume by one of the above formulæ (1) or (2), and take ⅘ths of the result as the true quantity.

The fan A C, represented (*fig.* 1003), is of the best excentric form, as constructed by Messrs. Braithwaite and Ericsson. D is the circular orifice round the axis by which the air is admitted; and C C B is the excentric channel through which the air is wafted towards the main discharge pipe E. See Ventilation.

FOUNTAIN. A stream of water rising through the superficial strata.

FOWLER'S SOLUTION. A solution of arsenite of potash used in pharmacy.

FOXGLOVE. The *Digitalis purpurea*, a common British plant, belonging to the natural order *Scrophulariaceæ*. The leaves and other parts contain a poisonous principle called *digitaline*. In small doses foxglove is used as a diuretic and for lessening the action of the heart, but in larger doses it altogether stops the circulation. The vulgar name *foxglove* is said to be a corruption of *folk's-glove* (fairy's glove), in allusion to the shape of the flower.

FOXING, is a term employed by brewers to characterise the souring of beer, in the process of its fermentation or ripening.

FRACTIONAL DISTILLATION. A process of distillation, in which, by regulating the heat, fluids possessing different degrees of volatility are separated from each other. See Naphtha, Boghead.

FRACTURE OF MINERALS. The fracture of minerals has been grouped under the following heads, there being very few variations from them :—

1. *Conchoidal;* from *concha*, like *a shell*, when a mineral breaks with curved concavities; example, flint.

2. *Even;* when the surface of fracture is not rough, and has no small elevations and depressions.

3. *Splintery;* when the broken surface exhibits protruding points.

4. *Hackly;* when the elevations are sharp or jagged, as iron.

FRAME, *a mining term.* See Dressing of Ores.

FRANCOLITE. A variety of apatite. See Apatite.

FRANGULIN. A yellow crystalline substance obtained from the bark of the *Rhamnus frangula.*

FRANKFORT BLACK is a black used in copper-plate printing. It is said to be a charcoal obtained from grape and vine lees, peach kernels, and bone shavings. It is doubtful whether the finest black is not a soot produced from the combustion of some of these bodies. The preparation is, however, made much of a mystery.

FRANKINCENSE. The spontaneous exudations of the *Abies excelsa*, the *Norway spruce fir.* East Indian frankincense is said to be derived from certain species of *Boswellia.*

FRANKLINITE. A mineral related to magnetic iron-ore, crystallising in regular octahedra of an iron-black colour and metallic lustre. When scratched, it affords a dark reddish-brown streak. Its spec. grav. is 5·05 to 5·16. Franklinite is a combination of the sesquioxides of iron and manganese, with protoxide of zinc. The following figures give the mean of several recent analyses by Mr. F. C. Van Dyck ('Geology of New Jersey, 1868'); the excess in these analyses is probably due to the oxidation of the iron, which appears to exist partly in the state of protoxide; the magnetic properties of this species have also been attributed to the presence of protoxide of iron:—

	I	II
Sesquioxide of iron	68·3	74·8
Oxide of zinc	24·8	21·7
Red oxide of manganese	10·5	7·8
	103·6	104·3

I. From Stirling Hill Mine, N. J. II. From Mine Hill, N. J.

These are the two principal localities of franklinite. It occurs associated with red oxide of zinc (spartalite) and silicate of zinc (willemite) in metamorphic limestones of Silurian age. At Stirling Hill it forms the main constituent of the irregular deposit known as the 'Franklinite Vein.'

Franklinite was at first employed for the production of zinc; but for that purpose it did not answer commercially. It was then employed in combination with iron, and Major Farrington of New Jersey thus speaks of it:—'Many experiments have been made under my superintendence upon the ores of franklinite, and I have also witnessed several others of an interesting character made by other parties in mixing franklinite with pig iron in the puddling furnace, and also a mixture of franklinite-pig with other irons in their conversion to wrought iron. The result in all cases has been a great improvement in the quality of iron as manufactured. The most marked and, as I consider, the most valuable result is obtained by using from 10 to 15 per cent. of the weight of pig iron to be puddled with pulverised franklinite ore in the furnace at each heat. Iron of the most inferior quality when thus treated is converted into an article of No. 1 grade. The volatile nature of zinc at a high temperature, combining with the sulphur, phosphorus, and other volatile constituents of the coal, or that may be in the iron, being carried off mechanically, I consider is one of the causes of the improvement; the manganese also of the ore combines with silica at a high temperature, and pig iron that contains silica is thus freed from it. The great advantage to be obtained by using the pulverised ore in the puddling furnace is, that a high grade of iron may be made; and where re-heating has been hitherto deemed indispensable, one heating is found sufficient for such uses as wire billets, nuts, bolts, horseshoe iron, and nails. A particular selection of fuel is not required, coke and charcoal can be dispensed with, and bituminous or anthracite coal used.'

Franklinite is now employed by the New Jersey Zinc Company for the production of zinc, which is converted into oxide, whilst the cindery residues are smelted for Spiegeleisen. See Iron.

FREESTONE. A term used to denote any stone which is capable of being worked freely in every direction, and, which has no tendency to break in one direction more than another. In the counties of Wicklow and Dublin, and also in Cornwall, the term is applied to granite which works freely.—H.W.B.

FREEZING. (*Congélation*, Fr.; *Gefrierung*, Ger.) The three general forms, solid, liquid, and gaseous, under one or other of which all kinds of matter exist, are referrible to the influence of heat, modifying, balancing, or subduing the attraction of cohesion. Nearly every solid may be liquefied, and every liquid may be vaporised, by a certain infusion of heat, whether this be regarded as a moving power, or an elastic essence. The converse of this proposition is equally true; for many gases, till lately styled permanent, may be liquefied, nay, even solidified, by diminution of their temperature, either alone, or aided by a sufficient mechanical condensation, to bring their particles within the sphere of aggregative attraction. When a solid is transformed into a liquid, and a liquid into a gas or vapour, a quantity more or less considerable of heat is absorbed, or becomes latent, to use the term of Dr. Black. When the opposite transformation takes place, the heat absorbed is again emitted, or what was latent becomes sensible. See Heat for the more recent hypotheses.

The production of cold is a curious and interesting branch of physical inquiry. A few general laws may be distinctly named.

If a solid body suddenly liquefies, without the application of external heat, it abstracts from the surrounding bodies the heat necessary for its liquefaction.

When a salt is dissolved in water cold is produced.

If a liquid vaporises, the vapour is produced at the expense of the heat of some neighbouring body.

When spirits of wine, or ether, is thrown on the body, a sensation of coldness is produced from the vaporising liquids robbing the body of heat.

By placing water in a porous vessel, and exposing it to the sun, it becomes very cold. The solar heat-rays occasion a rapid evaporation of the water which has filtered through the pores of the vessel, and some heat is taken by the process from the fluid in the interior.

If air is allowed suddenly to expand, it takes heat from the surrounding bodies, or produces cold.

Sir John Herschel some years since recommended the following method for obtaining at moderate cost large quantities of ice:—

A steam-engine boiler was to be sunk into the earth and the quantity of water which it was desired to freeze placed in it. By means of a condensing pump, several atmospheres of air were forced into the boiler, and then everything was allowed to remain for a night, or until the whole had acquired the temperature of the surrounding earth. Then, by opening a stop-cock, the air expanding escaped with much violence, and the water being robbed of its heat to supply the expanding air, the temperature of the whole was so reduced, that a mass of ice was the result.

The most familiar method of producing intense cold is by means of freezing mixtures. A great number of these were invented by Mr. Walker; the principal results are contained in the following tables:—

I.—Table, consisting of Frigorific Mixtures, having the power of generating or creating cold without the aid of ice sufficient for all useful and philosophical purposes, in any part of the world at any season.

Frigorific Mixtures without Ice.

MIXTURES		Thermometer sinks	Deg. of cold produced
Nitrate of ammonia . . . Water	1 part 1	From + 50° to + 4°	46°
Chloride of ammonium . Nitrate of potash . . . Water	5 parts 5 16	From + 50° to + 10°	40
Chloride of ammonium . Nitrate of potash . . . Sulphate of soda . . . Water	5 parts 5 8 16	From + 50° to + 4°	46
Sulphate of soda . . . Diluted nitric acid . .	3 parts 2	From + 50° to − 3°	53
Nitrate of ammonia . . Carbonate of soda . . Water	1 part 1 1	From + 50° to − 7°	57
Phosphate of soda . . Dilute nitric acid . . .	9 parts 4	From + 50° to − 12°	62
Sulphate of soda . . . Hydrochloric acid . .	8 parts 5	From + 50° to − 0°	50
Sulphate of soda . . . Dilute sulphuric acid . .	5 parts 4	From + 50° to + 3°	47
Sulphate of soda . . . Chloride of ammonium . Nitrate of potash . . . Dilute nitric acid . . .	6 parts 4 2 4	From + 50° to − 10°	60
Sulphate of soda . . . Nitrate of ammonia . . Dilute nitric acid . .	6 parts 5 4	From + 50° to − 40°	64

II.—Table consisting of Frigorific Mixtures, composed of ice, with chemical salts and acids.

Frigorific Mixtures with Ice.

MIXTURES		Thermometer sinks		Deg. of cold produced
Snow, or pounded ice . . Chloride of sodium . .	2 parts 1	From any temperature	to −5°	*
Snow, or pounded ice . . Chloride of sodium . . Chloride of ammonium .	5 parts 2 1		to −12°	*
Snow, or pounded ice . . Chloride of sodium . . Chloride of ammonium . Nitrate of potash . . .	24 parts 10 5 5		to −18°	*
Snow, or pounded ice . . Chloride of sodium . . Nitrate of ammonium . .	12 parts 5 5		to −25°	*
Snow . . . . . . Dilute sulphuric acid . .	3 parts 2	From +32° to −23°		55
Snow . . . . . . Hydrochloric acid . .	8 parts 5	From +32° to −27°		59
Snow . . . . . . Dilute nitric acid . . .	7 parts 4	From +32° to −30°		62
Snow . . . . . . Chloride of calcium . .	4 parts 5	From +32° to −40°		72
Snow . . . . . . Cryst. chloride of calcium .	2 parts 3	From +32° to −50°		82
Snow . . . . . . Potash	3 parts 4	From +32° to −51°		83

N. B.—The reason for the omissions in the last column of the preceding table is, the thermometer sinking in these mixtures to the degree mentioned in the preceding column, and never lower, whatever may be the temperature of the materials at mixing. To produce these results in a satisfactory manner, it is necessary to cool, previously to the experiments, the vessels in which the mixtures are made.

A very intense cold may be obtained from the evaporation of a mixture of solid carbonic acid and sulphuric ether, by which a temperature of 166° Fahr. below the freezing point of water is produced. By means of this intense cold, assisted by mechanical pressure several of the gaseous bodies have been condensed into liquids, and in some instances solidified.

Natterer has obtained a temperature as low as −220° Fahr. by evaporation *in vacuo* of a mixture of liquid nitrous oxide and bisulphide of carbon.

The following process for producing cold has been patented in this country:—

In a reservoir, or what may with propriety be called a boiler, was placed a quantity of sulphuric ether. This reservoir was placed in a long vessel of saline water, this fluid by the arrangement being made to flow from one end of the trough to the other, that is to and from the reservoir. In this water was placed a number of vessels, the depth and breadth of the trough, but of only two inches in width, and these were filled with the water to be frozen.

A steam-engine was employed to pump the air from the reservoir; this being done, of course the ether boiled, and the vapour of the ether was removed by the engine as fast as it was formed. The heat required to vaporise the ether was derived from the saline water in the trough, and this again took the heat from the water in the cells; thus eventually every cell of water was converted into ice. The ether was, after it had passed through the engine, condensed by a refrigeratory of the ordinary kind. The statement made by the patentee was very satisfactory, as it regarded the cost of production. An apparatus of this kind is of course intended for hot countries only, where ice becomes actually one of the necessaries of life.

A peculiar physical fact connected with the freezing of water has been made available to some important uses. Water in freezing really rejects everything it may contain—even air, and hence solid ice is actually *pure* water. This may be easily proved. Make a good freezing mixture, and place some water in a flask, and while it is undergoing consolidation by being placed in the frigorific compound, gently agitate it with a feather. Now, if the water contains spirit, acid, salt, or colouring matter, either of them are alike rejected, and the solid obtained, when washed from the matter adhering to its surface, is absolutely pure solid water.

This philosophic fact, although it has only been subjected to examination within the last few years, has long been known.

Byron, in his 13th canto of 'Don Juan,' has the following allusion to it:—

> "I'll have another figure in a trice:—
> What say you to a bottle of champagne?
> Frozen into a very vinous ice,
> Which leaves few drops of that immortal rain,
> Yet in the very centre, past all price,
> About a liquid glassful will remain;
> And this is stronger than the strongest grape
> Could e'er express in its expanded shape."

The old nobles of Russia, when they desired a more intoxicating drink than usual, placed their wines or spirit in the ice of their frozen rivers, until all the aqueous portion was frozen; when they drank the ardent fluid accumulated in the centre. This plan has been employed also for concentrating lemon-juice and the like.

The manufacture of ice by machinery is one of the many interesting applications of science, and this has now become a practical trade. In 1851 M. Rezet, of Rouen, volatilized ether in a close vessel by exhausting the air from its surface. After the air, the ether-vapour itself was exhausted by a pump, then condensed by the aid of cold water, and forced back into the same vessel, by which a continual absorption of caloric from the surrounding bodies was effected, and a continual refrigeration obtained as long as the circulation of ether was kept up by working the pump.

Harrison's ice-making machine, and its improved form by Mr. Siebe, is a particular application of the exhausting air-pump. The working of the process is as follows:—A quantity of sulphuric ether, contained in a close vessel surrounded by a current of salt water, is made to pass rapidly into a state of vapour by the action of a large air-pump driven by steam-power; the necessary amount of heat requisite to effect this change in the ether is abstracted from the surrounding salt water casing, which is thus cooled to a temperature below the freezing point of water, and is then made to circulate through a box, containing the water to be frozen, in tin moulds arranged on a travelling frame, which moves in a direction contrary to the refrigerating current. The ether-vapour removed at every stroke of the pump is passed over to a condenser, where it reassumes the liquid form, and is returned to the evaporating vessel.

It will be seen that the principle in the machines of Harrison, Rezet, and Siebe is the same. The machine invented by M. Carré appears to be much more effective.

Messrs. Carré and Co.'s ice-making machines are of two kinds, one being continuous, and the other intermittent in action; but the principle involved is the same in both cases, viz., the production of cold by the volatilisation of a gas which is easily liquefiable, and at the same time in a high degree soluble in water. The smaller, or intermittent apparatus consists essentially of a pair of distilling and condensing vessels, united together by an air-tight joint, and capable of resisting an internal pressure of 150 lbs. to the square inch. The distilling vessel is filled with a watery solution of ammonia, at the maximum point of saturation. By the application of heat, the ammoniacal gas is driven off, and passes over into the receiver or condensing vessel, where it is soon liquefied by the constantly increasing pressure of the gas given off by the watery solution, a pressure of 97 lbs. to the square inch being sufficient to effect the liquefaction of the gas, when the temperature of the vapour does not exceed 50° Fahr. When the condenser is filled with pure fluid ammonia, the distilling vessel is removed from the fire, and is immersed in a vessel of water at the ordinary temperature of the air. By this means the water remaining in the distilling vessel is slightly cooled, and it immediately redissolves the column of ammoniacal gas standing above it, a vacuum is formed, and the liquefied gas immediately begins to distil back and redissolve. The heat necessary to effect this redistillation is abstracted from the water to be frozen, which is contained in a cylindrical mould, placed in the internal tube of the annular condensing vessel. The time required for producing 1 lb. of ice in the smallest size of the portable apparatus is 55 minutes; 25 minutes being required for the preliminary, and 30 minutes for the reverse distillation; it is during the latter period that the ice is produced. About four pounds of ice are produced for every pound of fuel consumed in the preliminary distillation.

The continuous apparatus is more complicated in construction; it consists of a boiler or distilling vessel, with the addition of a rectifier, formed of a series of horizontal tubes in which the gas is freed from the last trace of water by a current of weak ammonia water circulating in the opposite direction. From the rectifier the gas passes to a serpentine tube, forming part of the boiler, and thence into the condenser, a series of tubes cooled by a current of water to 60° Fahr. Here the gas is liquefied, and is driven over by the pressure in the boiler into a regulator, from which it passes into the freezing vessel, also formed of a series of spiral tubes, which are surrounded by a solution of chloride of calcium; the moulds containing the water to be frozen are placed in a vibrating frame, in order to cause the ice to form more rapidly. The return current of ammoniacal gas from the freezing vessel is passed over by an exhausting pump into a receiver, where it is redissolved in the spent water drawn from the boiler. The ice produced in the continuous apparatus varies between eight and fifteen times the weight of the fuel consumed: about a gallon of condensing water is required for every pound of ice produced. For some further matters connected with this peculiar condition, see WATER.

FREIBERGITE. An argentiferous fahlerz. See FAHLERZ.

FREIESLEBENITE. A sulphide of silver, lead, and antimony. See SILVER.

FRENCH BERRIES. The berries of the *Rhamnus catharticus*, and other species of the Buckthorn. The true French berries, which should be four-seeded, belong to the first named; all the two-seeded berries are obtained from other and inferior kinds. See BUCKTHORN.

FRENCH CHALK. A steatite; a soft magnesian mineral.

FRENCH POLISH. There are numerous methods given for the preparation of this polish; one of the best is probably the following: 1½ lb. of shell lac dissolved in a gallon of spirits of wine without heat. Another recipe is 12 ounces of shell lac, 2 ounces of gum elemi, and 3 ounces of copal to 1 gallon of spirits of wine.

FRENCH PURPLE. Amongst the most important of the modern improvements in the preparation of colouring matter from the lichens may be mentioned the preliminary extraction of the colouring acids of the lichens by digestion with an alkali (potash or lime) and the subsequent precipitation of these acids, whereby they are completely separated from the woody matters and other impurities. Dr. Stenhouse, to whom this valuable suggestion is due, recommends manufacturers to macerate the lichens on the spot with milk of lime, and then to precipitate the clear solution by means of an acid such as hydrochloric, or acetic acid, whereby the colour-yielding acids are separated. By subjecting these acids, more or less pure, to the action of air and ammonia, products are obtained not only free from woody fibre, but exhibiting brighter and deeper colours, not to speak of the economy and facility of manipulating a much smaller bulk of material during the most important stage of the manufacture.

Archil prepared by the usual methods, notwithstanding its fine colour, has the defect of being extremely liable to change by the action of acids and alkalis, and of easily deteriorating in colour when applied to silk, wool, or animalized cotton. Recently, however, a new kind of archil has been prepared, under the name of *French Purple*, distinguished in the first place by its very pure mauve or dahlia colour, and, secondly, by being much faster than common archil, and less sensitive to the action of acids.

This beautiful colour has been introduced and is chiefly manufactured by MM. Guinon, Marnas, and Bonnet, of Lyons. It is prepared as follows:—The lecanoric, erythic, evernic acids, &c., of the lichens are extracted by digestion with ammonia; the mass is pressed, the solution precipitated by a mineral acid, and the precipitate collected, washed, and re-dissolved in ammonia by the aid of heat, whereby a solution is obtained which, on exposure to the air at a temperature of 19° or 20° C., gradually assumes a very bright red colour. As soon as the tint has acquired sufficient intensity the liquid is introduced into shallow basins, and very slowly evaporated at a temperature between 40° and 60° C., care being taken not to exceed the latter limit. By this evaporation in contact with the air the liquid after a few days acquires a very deep violet colour, which undergoes no further change even by the action of acids. The violet solution, super-saturated with a strong acid, yields a copious flocculent precipitate of a very fine and rich garnet colour, which when collected on a filter, and washed to remove the saline mother liquid, constitutes French purple.

The dye thus prepared has not, however, attained the highest degree of beauty and purity of which it is susceptible. When used directly for dyeing wool or silk (for which purpose it does not require the aid of mordants, the colouring matter being simply dissolved in ammonia, and the solution diluted with the proper quantity of water), it imparts to them a violet colour having a reddish cast.

To obtain the dye in a state of greater purity it is converted into a lime or alumina lake. For this purpose the ammoniacal solution is precipitated with chloride of calcium or with alum; the red colouring matter then remains almost wholly in solution, and the lakes are collected, carefully washed with cold water, and dried at a gentle heat. They then present a violet or bluish aspect, and acquire a coppery lustre by friction.

French purple is generally sent into the market in the form of lime lake. To render it available for dyeing, the lake is decomposed and the colouring matter set free. For this purpose the lake is reduced to an impalpable powder, which is boiled with oxalic acid to separate the lime, and the colouring matter then dissolved out by ammonia. The lake may also be directly decomposed by boiling it with carbonate of ammonia. For printing, the lake is dissolved in acetic acid, and the solution mixed with alcohol and thickened.

In this manner, very fine and pure mauve and dahlia tints are obtained, especially on silk, without the use of mordants, properly so called. French purple, moreover, mixes easily with other colouring matters, such as ultramarine, indigo, carmine, cochineal, aniline red, &c., producing the most varied and delicate tints.

Recently, however, the manufacture of French purple has diminished in importance by the competition of the coal-tar purple. The upshot of this struggle will depend on the relative beauty and purity of the tints obtained, and on their comparative cost: for, so far as regards fastness and resistance to the influence of light, French purple is superior to aniline purple. See Watts's 'Dictionary of Chemistry.'

FRENCH TUB. A dyer's term for a mixture of protochloride of tin and logwood, called also 'plum tub.'

FRICTION. The resistance to motion which depends on the structure of the surfaces in contact. Friction is usually divided into two kinds: *sliding friction* and *rolling friction.* The questions involved in the consideration of friction are purely engineering, and cannot therefore be treated here. One very important element may, however, be named, as showing the importance of exact science in connection with the improvements in mechanics. By friction *heat* is evolved. It is found by accurate experiment, that the *quantity of heat evolved is exactly sufficient to reproduce the effort caused in overcoming the friction.—Joule and Thomson.*

FRIEZE. (*Frise,* Fr.; *Frisa,* Sp.) The nap on woollen cloth; hence it is applied to a coarse kind of woollen cloth or stuff with a nap on one side. See BAIZE.

FRIT. See ENAMEL and GLASS.

FRITTING. It was formerly the practice in glass-making to heat the glass-mixture to such an extent that an incipient fusion, or caking-together, commenced, during which the silica began to act upon the bases, the carbonic acid was partially expelled, and a *frit* was produced. The *Schmelz* of the Austrian and Bohemian glass-houses is a true *frit,* or an imperfectly-melted mixture, composed of lixiviated ashes and sand. See GLASS.

FRUIT. The fruit of a plant consists essentially of the matured ovary enclosing the seeds, or ripened ovules. But in many cases other parts of the flower enter into the composition of the fruit; in the apple, for example, the calyx adheres to the ovary, and, becoming succulent, forms the greater portion of the fruit. Few vegetable structures are more liable to be misunderstood than the fruit; many parts of a plant being popularly called fruit which have no scientific claim to the name, whilst many structures which are truly fruit in botanical language would not be generally recognised as such. The common idea of a soft succulent structure, like the berry and the drupe, is by no means necessary to the constitution of a fruit, many kinds of fruit, such as the nut and the capsule being dry and more or less hard. Among umbelliferous plants, the structures commonly called 'seeds,' such as aniseed, caraway seeds, coriander seed, &c., are true fruits; the external envelope, or seed-vessel, being firmly adherent to the enclosed seed. So too the grains of cereals are fruits, the albuminous seed being closely invested in a thin membranous coat, or pericarp.

Fruits not only furnish articles of diet—in some cases of great importance, as the date and the bread-fruit—but some of them yield oil—olive-oil and palm-oil, for example—whilst others possess a strong integument from which useful vessels are prepared, such as the gourds and calabashes.

FUCHSINE. See ANILINE RED.

FUCHSITE. A green micaceous mineral, containing chromium, found in the Tyrol.

FUCUS. A genus of sea-weeds. In the *Fucus serratus* and *F. ceramoides* silver has been detected: Malaguto has stated to the extent of $\frac{1}{100000}$, in the ashes of these plants. It has also been stated that these and some other plants contain lead and copper.

FUCUSINE and **FUCUSOL.** Two substances obtained by Dr. Stenhouse, by acting with sulphuric acid on certain species of *Fucus*.

FUD, or *Woollen Waste*, is the refuse of the new wool taken out in the scribbling process, and is mixed with the mungo for use. See MUNGO.

FUEL. (*Combustible*, Fr.; *Brennstoff*, Ger.) Such matters as are used for the economical production of fire. Wood, Turf, Coal, are familiar examples. Fuels differ in their nature, and in their power of giving heat, and consequently in their properties of developing heat when undergoing combustion. It is therefore important to understand the principle upon which depends the value of a particular fuel.

With the philosophy of the question we are scarcely called upon to deal in the present volume. A few remarks may not, however, be entirely out of place, and they may serve to guide the reader in his consideration of the production of heat by combustion—which is the only means of production with which we have to deal.

In his 'Novum Organum' Bacon writes: 'Heat is an expansive motion whereby a body strives to dilate and stretch itself to a larger sphere or dimension than it had previously occupied. This difference is most observable in flame—when the smoke or thick vapour manifestly dilates and expands into flame. . . . *Heat is a motion*, expansive, restrained, and acting in its strife upon the smaller particles of bodies. But the expansion is thus modified—while it expands in all ways, it has at the same time an inclination upwards—but the struggle in the particles is modified also, it is not sluggish, but hurried and with violence.'—*Bacon's Works*, Spedding's Translation, vol. iv.

Count Rumford's paper read before the Royal Society, January 25, 1798, entitled, 'An Enquiry concerning the Source of the Heat which is excited by Friction,' contains the results of his experiments made at Munich on the boring of brass cannon. He shows that by friction so much 'heat was generated' that the water in which the cannon during the operation of boring was placed, gained heat so rapidly that 'at two hours and twenty minutes it was 200°, and at two hours and thirty minutes it *actually boiled*.' He finds by careful estimates that the total heat produced was sufficient to raise 26·58 lbs. of ice-cold water to its boiling point, or through 180° F.; and that this heat is equal to that given out by the combustion of 2303·8 grains (or $4\frac{8}{10}$ oz. troy) of wax. Considering this interesting subject Count Rumford asks, 'What is heat? Is there any such thing as an *igneous fluid*? Is there anything that can with propriety be called *caloric*?' He then continues, 'We have seen that a very considerable quantity of heat may be excited by the friction of two metallic substances, and given off in a constant stream or flux in *all directions*, without interruption or intermission, and without any signs of diminution or exhaustion. . . . It is hardly necessary to add, that anything which any insulated body or system of bodies can continue to furnish without limitation cannot possibly be a material substance; and it appears to me to be extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated in those experiments, except it be *motion*.'

Locke says, 'Heat is a very brisk agitation of the insensible parts of the object which produces in us that sensation from whence we denominate the object heat; so what in our sensation is *heat*, in the object is nothing but *motion*.'

Sir H. Davy wrote in 1812: 'The immediate cause of the phenomena of heat, then, is motion, and the laws of its communication are precisely the same as the laws of the communication of *motion*.'

These are the views entertained by those who do not believe heat to be matter. The *dynamical*, or as it is often called, the *mechanical theory*, of heat, assumes all heat to be a *motion of the ultimate particles of matter*.

The material hypothesis of heat, which held possession of the minds of most experimental philosophers—especially of Lavoisier and of Black—embraced the view which is well expressed by Gmelin in his 'Hand-book of Chemistry.' He says: 'Heat is *the substance* whose entrance into our bodies causes the sensation of warmth, and its egress the sensation of cold.' That is, heat was regarded as an infinitely subtile agent—a positive entity—which interpenetrated matter, in which it lay hidden, or latent, until it was by some exciting powers disturbed. This differs little, if anything, from the hypothesis of an all-pervading ether, which, being disturbed, produces one or the other of the so-called physical forces.

Heat can be produced by the effect of *gravitation*—a falling body, for example—but for all practical purposes water is really the only body we can employ to produce the motion necessary for the production or development of heat. A cataract or a river may be regarded as a constant means of obtaining the required motion. But this water has been lifted from the sea-level by the action of the solar heat, which has been produced in the sun, by, it would appear, the actual combustion of some material substances. Therefore, the heat which we obtain by the influence of the motion produced by the gravitating power of water, is really due to the emission of heat from the sun. By the influence of *Life*—vital force—we may produce motion and heat; but here again, as life is dependent upon solar heat, we have to look to the sun as its source. *Electricity* is another agent by means of which heat can be developed, but this power has a similar origin, in all probability, to heat itself. *Chemical action* in a vast number of cases produces the disturbance which is manifested as heat; and the combustion of all kinds of fuel may be considered to be but examples of chemical change. It is the operation especially of this source of heat, which we have to consider.

All the substances used by man for the production of Fire are chiefly of vegetable origin, as wood, peat, turf, and coal. Some few may possibly be derived from the animal kingdom, as some of the native bitumens. But either vegetable or animal fuel has originally gathered its heat from the sun—in the process of growth—and it has held that heat stored until a peculiar disturbance has liberated it for the use of man.

Numerous excellent experiments have been made for the purpose of determining with exactness the heating values of fuels of different kinds. Lavoisier and Laplace, in an extensive examination carried out by them, used their well-known *Calorimeter*, by which they determined the value of the heat by the quantity of ice melted in a given time. Count Rumford subsequently measured the quantity of heat by the increase of temperature in a given quantity of water. The quantity of heat which will melt 1 lb. of ice at 0° Cent. being just sufficient, according to Laplace, to raise the temperature of a pound of water to 75° Cent. or, according to the experiments of Regnault to 79° Cent. Clement and Desormes have also shown, that an equal weight of aqueous vapour, whatever may be its temperature and tension, is always produced by one and the same amount of heat.

As far as we can within the limits of the present work, we shall endeavour to present a full practical view of the subject, giving each class of fuels under their several heads.

1. *Wood*, which is divided into hard and soft. To the former belong the oak, the beech, the alder, the birch, and the elm; to the latter, the fir, the pine of different sorts, the larch, the linden, the willow, and the poplar.

Under like dryness and weight, different woods are found to afford very different degrees of heat and combustion. Moisture diminishes the heating power in three ways: by diminishing the relative weight of the ligneous matter, by wasting heat in its evaporation, and by causing slow and imperfect combustion. If a piece of wood contain, for example, 25 per cent. of water, then it contains only 75 per cent. of fuel, and the evaporation of that water will require $\frac{1}{28}$th part of the weight of the wood. Hence the damp wood is of less value in combustion by $\frac{8}{28}$ or $\frac{2}{7}$ than the dry. The quantity of moisture in newly-felled wood amounts to from 20 to 50 per cent.; birch contains 30, oak 35, beech and pine 39, alder, 41, fir 45. According to their different natures, woods which have been felled and cleft for 12 months contain still from 20 to 25 per cent. of water. There is never less than 10 per cent. present, even when it has been kept long in a dry place, and though it be dried in a strong heat, it will afterwards absorb 10 or 12 per cent. of water. If it be too strongly kiln-dried, its heating powers are impaired by the commencement of carbonisation, as if some of its hydrogen were destroyed.

The following Table, compiled from the researches of Count Rumford, will place these points clearly before us:—

One pound of the following woods when burnt will heat:	Pounds of water from 0° to 100° C.		
	Ordinary condition	Slightly dried	Strongly dried
Lime tree	34·708	38·833	40·131
Beech	33·798	...	36·746
Elm	30·205	...	34·083
Oak	25·590	29·210	29·838
Ash	30·666	33·720	35·449
Sycamore	...	...	36·117
Fir	30·322	34·000	37·379
Poplar	34·601	...	37·161

From every combustible the heat is diffused either by radiation or by direct communication to bodies in contact with the flame. In a wood fire the quantity of radiating heat is, to that diffused by the air, as 1 to 3; or it is one-fourth of the whole heating power.

II. *Charcoal.*—The different charcoals afford, under equal weights, equal quantities of heat. We may reckon, upon an average, that a pound of dry charcoal is capable of heating 75 pounds of water from the freezing to the boiling point; but when it has been for some time exposed to the air, it contains at least 10 per cent. of water, which is partially decomposed in the combustion into carburetted hydrogen, which causes flame, whereas pure dry charcoal emits none.

Winkler gives the following as the results obtained by him with charcoal from various sources:—

Charcoal from:	Pounds of water heated from 0° to 100° Cent. by 1 pound of charcoal	Air required by perfect combustion	Pounds of lead reduced by 1 pound of charcoal
Poplar	On an average 75·7.	On an average 293·5 cubic feet at 19° Cent.	33·56
Sycamore			33·23
Fir			33·51
Ash			33·23
Birch			33·71
Oak			33·74
Elm			33·26
Willow			33·49
Pine			33·53

A cubic foot of charcoal from soft wood weighs upon an average from 8 to 9 pounds, and from hard wood 12 to 13 pounds; and hence the latter is best adapted to maintain a high heat in a small compass. The radiating heat from charcoal fires constitutes one-third of the whole emitted. See Charcoal.

The following Table gives the approximate values of given weights of wood.

According to Landet, 'Polyt. Centr. 1854,' the value of fuel bought by volume corresponds to the product of the absolute heating power of fuel into the weight of a certain volume.

These two factors have the following value with various kinds of fuel:—

Kind of Fuel	Absolute heating power	Weight of 1 cubic mètre in kilos.
Holm oak (wood in large pieces or logs)	10,000	380
Red beech (logs)	9,941	380
Oak, both varieties in mixture (logs)	9,763	371
White beech (logs)	9,490	370
Oak (logs)	9,448	359
White beech (pieces and stumps in mixture)	9,392	338
Birch (logs)	9,260	381
Birch (pieces and stumps, &c., in mixture)	9,224	332
Birch (stumps)	8,836	318
Pine (stumps)	8,587	312
Oak (both varieties in mixture)	8,342	317
Red beech (stumps)	8,214	314
Alder (log-wood)	8,127	293
Alder (pieces and stumps in mixture)	8,070	291
White beech (stumps)	8,030	313
Red beech (branches)	7,953	304
Pine (branches)	7,898	287

III. *Turf or peat.*—One pound of this fuel will heat, according to its quality, from 18 to 42 pounds of water from freezing to boiling. Its value depends upon its compactness and freedom from earthy particles; and its radiating power is to the whole heat it emits in burning as 1 to 3.

According to Berthier, the following results were obtained from peat:—

Source of the Peat.	Pounds of water heated by 1 pound of peat from 0° to 100° Cent.
From Troyes	18·1
„ department de la Somme	27·9
„ „ de la Marne	29·2
„ „ de la Vosges	34·9
„ „ des Landes	34·6

Winkler gives 26·9 as the evaporative power of the worst Hanoverian peat, and 42·6 as that of the best.

Peat obtained from the Bog of Allen gave, according to Griffith (the discrepancies between the results we do not understand):—

	Pounds of water heated from 0° to 100° Cent.
Upper peat	62·7
Lower peat	56·6
Pressed peat	28·0

See PEAT.

IV. *Coal.*—The varieties of coal are almost indefinite, and give out very various quantities of heat in their combustion. The carbon is the heat-giving constituent, and it amounts, in different coals, to from 75 to 95 per cent. One pound of good coal will, upon an average, heat 60 pounds of water from the freezing to the boiling point. Small coal gives out three-fourths of the heat of the larger lumps. The radiating heat emitted by burning pitcoal is greater than that by charcoal.

V. *The Coke of Coal.*—The heating power of good coke is to that of pitcoal as 75 to 69. One pound of the former will heat 65 pounds of water from 32° to 212°; so that its power is equal to nine-tenths of that of wood charcoal.

Berthier gives as the results of his trials:—

	Pounds of water heated by 1 pound of coal from 0° to 100° C.
Dowlais coal	72·0
Glamorgan „	70·7
Newcastle „	70·0
Derbyshire „	61·6
Lancashire „ (cannel)	53·2
Durham „	71·6
Coke (St. Etienne)	65·6
Do. gas from Paris	50·3

VI. *Carburetted Hydrogen or Coal Gas.*—One pound of this gas, equal to about 24 cubic feet, disengages in burning as much heat as will raise 76 pounds of water from the freezing to the boiling temperature.

In the following table the fourth column contains the weight of atmospheric air, whose oxygen is required for the complete combustion of a pound of each particular substance:—

Species of combustible	Pounds of water which a pound can heat from 0° to 212°	Pounds of boiling water evaporated by 1 pound	Weight of atmospheric air at 32°, to burn 1 pound
Perfectly dry wood	35·00	6·36	5·96
Wood in its ordinary state	26·00	4·72	4·47
Wood charcoal	73·00	13·27	11·46
Pitcoal	60·00	10·90	9·26
Coke	65·00	11·81	11·46
Turf	30·00	5·45	4·60
Turf charcoal	64·00	11·63	9·86
Carburetted hydrogen gas	75·00	13·81	14·58
Oil Wax Tallow	78·00	14·18	15·00
Alcohol of the shops	52·60	9·56	11·60

The quantity of air stated in the fourth column, is the smallest possible required to burn the combustible, and is greatly less than would be necessary in practice, where much of the air never comes into contact with the burning body, and where it consequently never has the whole of its oxygen consumed. The heating power stated in the second column is also the maximum effect, and can seldom be realised with ordinary boilers. The draught of air usually carries off at least one-seventh of the heat, and more if its temperature be very high when it leaves the vessel. In this case it may amount to one half of the whole heat, or more; without reckoning the loss by radiation and conduction, which however may be rendered very small by enclosing the fire and flues within proper non-conducting and non-radiating materials.

It appears that, in practice, the quantity of heat which may be obtained from any combustible in a properly-mounted apparatus, must vary with the nature of the object to be heated. In heating chambers by stoves, and water boilers by furnaces, the effluent heat in the chimney, which constitutes the principal waste, may be reduced to a very moderate quantity, in comparison with that which escapes from the best constructed reverberatory hearth. In heating the boilers of steam-engines, one pound of coal is reckoned adequate to convert 7½ lbs. of boiling water into vapour; or to heat 41¼ lbs. of water from the freezing to the boiling point. One pound of fir of the usual dryness will evaporate 4 pounds of water, or heat 22 lbs. to the boiling temperature; which is about two-thirds of the maximum effect of this combustible. According to Watt's experiments upon the great scale, one pound of coal can boil off with the best built boiler, 9 lbs. of water; the deficiency from the maximum effect being here $\frac{10}{57}$, or nearly one-sixth. *See the Tables at the end of this article.*

In many cases the hot air which passes into the flues or chimneys may be beneficially applied to the heating, drying, or roasting of objects; but care ought to be taken that the draught of the fire be not thereby impaired, and an imperfect combustion of the fuel produced. For, at a low smothering temperature, both carbonic oxide and carburetted hydrogen may be generated from coal, without the production of much heat in the fireplace.

Calorimeters.—To determine exactly the quantity of heat disengaged by any fuel in the act of burning, three different systems of apparatus have been employed: 1, the calorimeter of Lavoisier and Laplace, in which the substance is burned in the centre of a vessel whose walls are lined with ice, and the amount of ice melted measures the heat evolved; 2, the calorimeter of Watt and Rumford, in which the degree of heat communicated to a given body of water affords the measure of temperature; and 3, by the quantity of water evaporated by different kinds of fuel in similar circumstances.

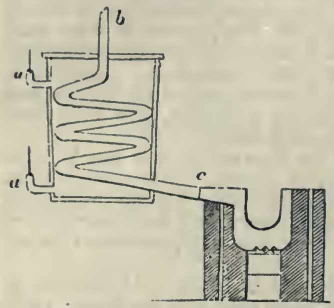
Lavoisier's.—The first and most celebrated, though probably not the most accurate apparatus for measuring the quantity of heat transferable from a hotter to a colder body, consisted of three concentric cylinders of tin plate, placed at certain distances asunder; the two outer interstitial spaces being filled with ice, while the innermost cylinder received the hot body, the subject of experiment. The quantity of water discharged from the middle space by the melting of the ice in it, served to measure the quantity of heat given out by the body in the central cylinder. A simpler and better instrument on this principle would be a hollow cylinder of ice of proper thickness, into whose interior the hot body would be introduced, and which would indicate by the quantity of water found melted within it the quantity of heat absorbed by the ice. In this case the errors occasioned by the retention of water among the fragments of ice packed into the cylindric cell of the tin calorimeter, would be avoided. One pound of water at 172° F., introduced into the hollow cylinder described, will melt exactly one pound of ice; and one pound of oil heated to 172° will melt half a pound. One constant source of error in this instrument is the *regelation* of the water from the liquified ice in passing through the ice, which still maintains a temperature below 32° F.

Meyer's Method of Refrigeration, contrived at first by Meyer, was brought to great perfection by Dulong and Petit. It rests on the principle, that two surfaces of like size, and of equal radiating force, lose in like times the same quantity of heat when they are at the same temperature. Suppose, for example, that a vessel of polished silver, of small size, and very thin in the metal, is successively filled with different pulverised substances, and that it is allowed to cool from the same elevation of temperature; the quantities of heat lost in the first instant of cooling will be always equal to each other; and if for one of the substances, the velocity of cooling is double of that for another, we may conclude that its capacity for heat is one half, when its weight is the same; since by losing the same quantity of heat, it sinks in temperature double the number of degrees.

The Method of Mixtures.—In this method two bodies are always employed: a hot body, which becomes cool, and a cold body, which becomes hot, in such manner that all the heat disengaged by the former is expended in heating the latter. Suppose, for example, that we pour a pound of quicksilver at 212° F., into a pound of water at 32°; the quicksilver will cool and the water will heat, till the mixture by stirring acquires a common temperature. If this temperature was 122°, the water and mercury would have equal capacities, since the same quantity of heat would produce in an equal mass of these two substances equal changes of temperature, viz., an elevation of 90° in the water and a depression of 90° in the mercury. But in reality, the mixture is found to have a temperature of only 37½°, showing that while the mercury loses 174½°, the water gains only 5½°; two numbers in the ratio of about 32 to 1; whence it is concluded, that the capacity of mercury is $\frac{1}{32}$ of that of water. Corrections must be made for the influence of the vessel and for the heat dissipated during the time of the experiment.

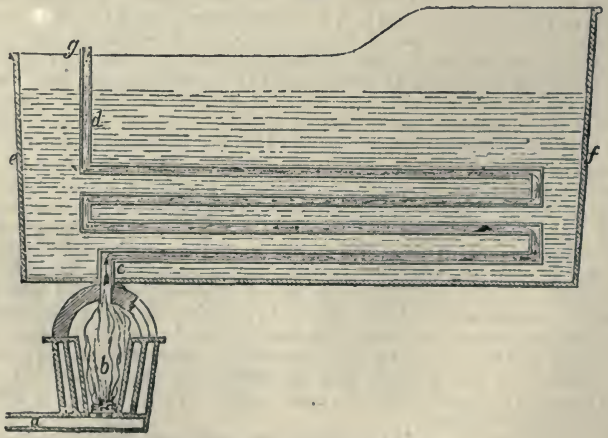
If our object be to ascertain the relative heating powers of different kinds of fuel, we need not care so much about the total waste of heat in the experiments, provided it be the same in all; and therefore they should be burned in the same furnace, and in the same way. But the more economically the heat is applied, the greater certainty will there be in the results. The apparatus, *fig.* 1004, is simple and well adapted to make such comparative trials of fuel. The little furnace is covered at top, and transmits its burned air by *c*, through a spiral tube immersed in a cistern of water, having a thermometer inserted near its top, and another near its bottom, into little side orifices, *a a*, while the effluent air escapes from the upright end of the tube *b*. Here also a thermometer-bulb may be placed. The average indication of the two thermometers gives the mean temperature of the water. As the water evaporates from the cistern, it is supplied from a vessel placed alongside of it. The experiment should be begun when the furnace has acquired an equability of temperature. A throttle valve at *c* serves to regulate the draught, and to equalise it in the different experiments by means of the temperature of the effluent air. When the water has been heated the given number of degrees, which should be the same in the different experiments, the fire may be extinguished, the remaining fuel weighed, and compared with the original quantity. Care should be taken to make the combustion as vivid and free from smoke as possible.

1004



The following calorimeter, founded upon the same principle as that of Count Rumford, but with certain improvements, may be considered as an equally correct instrument for measuring heat with any of the preceding, but one of much more general application, since it can determine the quantity of heat disengaged in combustion, as well as the latent heat of steam and other vapours.

1005



Scale about ½ inch to the square foot.

It consists of a large copper bath, *e, f* (*fig.* 1005), capable of holding 100 gallons of water. It is traversed four times, backwards and forwards, in four different levels, by a zig-zag horizontal flue or flat pipe *d*, *c*, nine inches broad and one deep, ending below in a round pipe at *c*, which passes through the bottom of the copper bath *e*, *f*, and receives there into it the top of a small black-lead furnace *b*. The innermost crucible contains the fuel. It is surrounded at the distance of one inch by a second crucible, which is enclosed at the same time by the sides of the outermost furnace; the strata of stagnant air between the crucibles serving to prevent the heat from being dissipated into the atmosphere round the body of the furnace. A pipe *a*, from a pair of cylinder double bellows, enters the ash-pit of the furnace at one side, and supplies a steady but gentle blast, to carry on the combustion, kindled at first by half an ounce of red-hot charcoal. So completely is the heat which is disengaged by the burning fuel absorbed by the water in the bath, that the air discharged at the top orifice *g* has usually the same temperature as the atmosphere.

The vessel is made of copper, weighing 2 lbs. per square foot; it is 5½ feet long, 1½ wide, 2 deep, with a bottom 5½ feet long, and 1¾ broad, upon an average. Including the zig-zag tin plate flue, and a rim of wrought iron, it weighs altogether, 85 lbs. Since the specific heat of copper is to that of water as 94 to 1,000, the specific heat of the vessel is equal to that of 8 lbs. of water, for which, therefore, the exact correction is made by leaving 8 lbs. of water out of the 600 or 1,000 lbs. used in each experiment.

In the experiments made with former calorimeters of this kind, the combustion was maintained by the current or draft of a chimney open at bottom, which carried off at the top orifice of the flue a variable quantity of heat, very difficult to estimate.

When the object is to determine the latent heat of steam and other vapours, they may be introduced through a tube into the top orifice *g*, the latent heat being deduced from the elevation of temperature in the water of the bath, and the volume of vapour expended from the quantity of liquid discharged into a measure glass from the bottom outlet *c*. In this case, the furnace is of course removed.

The heating power of the fuel is measured by the number of degrees of temperature which the combustion of one lb. of it raises 600 or 1,000 lbs. of water in the bath,—the copper substance of the vessel being taken into account.

It must be borne in mind that a coal which gives off much unburnt carburetted hydrogen gas does not afford so much heat, since in the production of the gas a great deal of heat is carried off in the latent state.

The economy of fuel, as exhibited in the celebrated pumping engines of Cornwall, will be dealt with under the proper head. See STEAM ENGINE. And in reference to the ordinary uses of fuel for domestic and other purposes, see STOVES.

Prof. T. S. Hunt, in the 'Canadian Naturalist,' July 1861, gives the results of the analyses by various chemists, taken chiefly from Bischof's 'Chemical Geology,' showing the relative proportions of the elements in wood, peat, coal, asphalte, and petroleum.

He states that 'the nitrogen, which in most cases was included with the oxygen in the analysis, has been disregarded, and the oxygen and hydrogen, for the sake of comparison, have been calculated for twenty-four equivalents of carbon.'

1. Vegetable fibre or cellulose	C^{24}	H^{20}	O^{20}
2. Wood, mean composition . . .	C^{24}	$H^{18\cdot4}$	$O^{16\cdot4}$
3. Peat (Vaux)	C^{24}	$H^{14\cdot4}$	O^{10}
4. ,, (Regnault)	C^{24}	$H^{14\cdot4}$	$O^{9\cdot6}$
5. Brown Coal (Schrötter)	C^{24}	$H^{11\cdot3}$	$O^{10\cdot6}$
6. ,, ,, (Woskresensky) . . .	C^{24}	H^{13}	$O^{7\cdot6}$
7. Lignite (Vaux)	C^{24}	$H^{11\cdot3}$	$O^{6\cdot4}$

Most persons interested in the uses of coal for manufacturing purposes will be able to calculate readily the value of any of those coals as fuel.

The following Table will show in a yet more satisfactory manner the value of varieties of coal as fuel.

Report of Trials of Coals at Woolwich Dockyard, between February 9, 1848, *and March* 31, 1858.

Description of the Fuel tried	Number of Trials from which the Average Results are deduced	Pounds of Water evaporated to 1 lb. Coal consumed, calculated from 100° constant Temperature of the Feed Water	Cubic Feet of Water evaporated per Hour, calculated from 100° constant Temperature of the Feed Water	Percentage of Clinker	Percentage of Ash	Percentage of both Clinker and Ash	Smoke

The calorific values of a selected variety of coals, as tried under circumstances considered the most favourable for the development of heat, will be found in the Table at top of next page; the result being given in a somewhat different form from the result in the preceding Tables. See COAL; COKE.

On Liquid Fuel.—The proposal to substitute for the coal now used as fuel in steam-vessels some kind of liquid combustible, arose from the discovery of vast quantities of petroleum in America; and it was that material which was in the first instance recommended as the substitute for coal. A commission appointed in America to investigate the subject reported that petroleum was beyond doubt more than twice as effective as anthracite coal in the production of steam, and that steam could, by the use of this material, be produced in less than half the usual time.

It was an inference by no means unnatural that, if this were the case, and if coal could be superseded by this material as the fuel of steam-vessels, a very great portion of the space required in merchant steamers for the stowage of coal would be rendered available for more profitable cargo; that steam-packets might become independent of coal depôts at various points of their passage; and that ships of war would be enabled to keep the sea for a very much longer time than they now do with coal. Any prospect of such advantages as these being attainable might reasonably have been expected to justify a more thorough and searching investigation of this subject than it has yet received in this country.

Name or Locality of Coal	Actual Number of lbs. of Water converted into Steam by 1 lb. of Coal	Number of lbs. of Water converted into Steam by the Coke left by the Coal	Total Number of lbs. of Water convertible into Steam by 1 lb. of the Coal	Amount of Ammonia corresponding to the Nitrogen contained in the Coal	Amount of Sulphate of Ammonia corresponding to the Nitrogen contained in the Coal

Besides petroleum, several other analogous materials have been proposed as substitutes for coal; for instance, the oil obtained by distilling particular kinds of coal, or the shale which occurs in coal formations, and more recently the oil known as 'dead oil,' which is one of the products obtained in rectifying the coal-tar of gas works. All these materials resemble each other closely in being composed chiefly of carbon and hydrogen, which are, in various proportions, the combustible and heat-producing constituents of all kinds of fuel. For the application of these materials and of liquid fuel generally, various methods have been proposed. It is desirable to consider in the first place, what is the evaporative power of these materials respectively, since that is a very important point to determine in regard to the question as to the relative merits of these different kinds of fuel.

The following table gives several examples of the total evaporative powers of some kinds of fuel, as calculated from their chemical composition:—

	C.	H.	O.	A.	E.	Evap. due to	
						C.	$H.—\frac{O}{8}$
Charcoal	·93	0	0	11·5	14·0	14·0	0
Coke	·88	0	0	10·6	13·2	13·2	0
Rock-oils $C^{18} H^{20}$	·84	·16	0	15·75	22·7	12·7	10·0
Rock-oils $C^{26} H^{28}$	·85	·15	0	15·65	22·5	12·66	9·84
Coal	·87	·05	·04	12·1	15·9	13·05	2·85
,,	·85	·05	·06	11·7	15·5	12·75	2·75
,,	·75	·05	·05	10·6	14·1	11·25	2·85
Peat, dry	·56	·06	·31	7·7	10·0	8·5	1·5
Wood ,,	·50	·05	·40	6·0	7·5	7·5	0

The first line refers to charcoal; the second to coke of average quality; the third and fourth lines give two examples of hydrocarbons, which comprise between them the chief ingredients of rock-oil. Lines 5, 6, and 7 give a few examples of coal. They differ from the kinds of fuel previously mentioned, in having some oxygen in them, which somewhat lessens the evaporative power. Here, too, the units of evaporation due to carbon and to hydrogen are distinguished; for example, line 6 shows 12¾ units of evaporation due to carbon, and 2¾ due to hydrogen. Then follow some results for peat and for wood, on which we need not enlarge. In the third, fourth, and fifth columns are stated the proportions of the chemical constituents, ranging for the rock-oils, between 84 per cent. of carbon to 16 of hydrogen, and 85 per cent. of carbon to

15 of hydrogen. The fifth column gives the net weights of air required for the oxidation of the fuel. In the sixth column the theoretical evaporative powers are set down: for rock-oils they are from 22·7 to 22·5, or, in round numbers, we may say 22½. In two additional columns are some figures to show how much evaporation is due to carbon and how much to hydrogen. In rock-oils those quantities are 12½ due to the carbon, and 10 to the hydrogen, out of the 22½ units of evaporation.

It is to be observed that the examples given in this table, which are only a few selections out of much more voluminous data, are all taken from good specimens. But it may be taken as the result of practical experience that the evaporative power of bad specimens of fuel from a particular district is about two-thirds that of good. This applies particularly to coal. The difference is chiefly due to refuse or ash. But it does not apply to mineral oils, because they can hardly contain anything else but combustible matter. They do not contain ash; they do not contain earthy matter. The statement, then, about qualities of fuel which have only two-thirds of the total evaporative power of those set down in the table, applies to coal and peat; but it does not apply to mineral oils.

We have gone at some length into the principles of the total evaporative power of different sorts of fuel, because it is of great practical importance to understand them. They show the theoretical limit towards which practice approaches in the course of improvement, but which practice cannot surpass nor even attain: the knowledge of those principles prevents people, on the one hand, from forming too small an estimate of the results which may be got from the economical use of fuel; and on the other hand from indulging in exaggerated estimates of those results. It shows us, indeed what is the actual waste, when we know the result attained in practice: it enables us to judge how far that result falls short of theoretical perfection, and what room there is for further economy by means of improvements.

The late Dr. W. J. Macquorn-Rankine, from whose work on 'The Economy of Fuel' we are about to quote, writes thus with regard to mineral oil:—

'I may make the following observations on what we may look forward to as the probable result of the introduction of such classes of fuel as mineral oil as substitutes for coal. Coal is a very complex kind of fuel. To ensure the best possible economy in the use of it requires the fulfilment of many different conditions, some of which conflict with each other. We have to burn fixed carbon, and we have to burn the gas that is disengaged from the coal. We may burn one very efficiently, and not burn the other. It is extremely difficult to manage the introduction of air, so that there shall at once be no risk of a deficiency of air, which causes imperfect combustion, and gives bad economy in one way; or a surplus of air, which carries heat to waste up the chimney, and causes bad economy in another way. On the one hand, we are exposed to the risk, from any little fault of construction or management of the furnaces, of the hydrogen going off unburned, and of its carrying off a large portion of the carbon unburned also. On the other hand, we are exposed to the risk of solid carbon being imperfectly burned, and going off as carbonic oxide. The contrivances for diminishing the causes of waste are somewhat difficult and complex to apply in practice; and above all, too much depends upon the skill of the fireman or stoker. We may say almost everything depends upon the way the furnace is managed. The very best furnaces, the very best boilers that were ever contrived, may be made extremely wasteful by a careless stoker. On the other hand, in using mineral oils, we are somewhat in the position of the chemist who has got a good burner for burning coal-gas. We have to contrive a suitable apparatus for introducing that oil into the furnace in such a way that it shall be thoroughly mixed with air—whether in the state of vapour, or in the state of fine spray, with or without the assistance of some porous substance to act as a wick. A steam-jet seems to be the most efficient apparatus for that purpose. Then if our apparatus is properly contrived and properly constructed, and works in the right manner and produces complete combustion at first, there is no reason to suppose that it will ever act badly if treated with ordinary care.

'It would seem to be no difficult matter with fuel of that sort to diminish the waste of heat through imperfect combustion to nothing, and the waste of heat through hot gases going up the chimney to something very small indeed. In fact, such an efficiency as 90 per cent. of the total evaporative power being realised, instead of being a very extraordinary thing, may be looked for as a very ordinary thing; so that, taking the theoretical evaporative power of some hydrocarbon compounds at 22½, we ought not to be surprised that, even with rude apparatus, in a merely experimental state, we get an evaporation of 19 or 20 times the weight of the fuel—say 19, at all events. I believe that has been realised in experiments that have been made, and that are now being continued.

'There is another phenomenon as to which I may say something—the mode of operation of steam-jets in cases of this kind. There can be no doubt that one use of the steam-jet is the mechanical action to which I have frequently referred—the thorough mixing of the gaseous fuel with the oxygen required for the purpose of combustion—the churning of the particles all together, so that they shall be brought thoroughly into contact. There may be another mode of operation of steam—a chemical action whose effect is to prevent the deposition of unconsumed carbon from gaseous fuel. All hydrocarbons have a tendency when raised to a high temperature to deposit the carbon, unless it be instantly burned. We see that in the smoke that a flame tends to give out, if there is anything to prevent immediate and free access of oxygen to the carbon. Now it is possible that besides its mechanical action, the steam-jet may also have a chemical action of the following kind:—The oxygen of the steam combines with the carbon of the hydrocarbon fuel, and the hydrogen of both is set free; there is a mixture thus produced of carbonic oxide and of hydrogen, which is sure to be completely burnt as soon as a sufficient quantity of air gets access to it, and thus the deposit of unconsumed carbon is entirely prevented.'

Dr. Paul, in a paper communicated to the Society of Arts, has the following valuable remarks upon the combustion of mineral oils:—

'The volumes of the air-supply and combustion-products for the extreme cases of carbon and hydrogen are as follow:—

	Air-Supply at 60° F.			Combustion-Products at 660° F.	
	lb.	lbs.	Cubic feet	lbs.	Cubic feet
Carbon . . .	1	24	320	25	630
Hydrogen . .	1	69	960	70	2044

'In the combustion of carbon there is no expansion of volume in the combustion-product, except that due to the heat generated, which would render the volume at the temperature of combustion (2,522° F.) rather more than six times that of the air supplied. By the transfer of heat to the boiler, to such an extent as to reduce the temperature to 660° F., the volume would be reduced again to about 630 cubic feet per pound of carbon burnt.

'In the combustion of hydrogen the supply of air required is about three times as large as that required in the combustion of an equal weight of carbon. There is also an expansion of the combustion-products, independent of the heat generated, and amounting to one-half the normal volume of the hydrogen burnt. The expansion due to heat is also greater than in the combustion of carbon, on account of the greater amount of heat generated, so that the volume of the furnace-gas at the temperature of combustion (2,791° F.) would be about 6½ times that of the air supplied, and the volume of gas discharged into the chimney would be about 3½ times as great as in the combustion of an equal weight of carbon. This larger quantity of gas will, however, contain nearly 4 times as much effective heat as that resulting from the combustion of an equal weight of carbon, and its temperature will be about 270° higher, so that in this respect the use of fuel containing a large amount of hydrogen, provided it can be perfectly and readily burnt, presents an advantage as compared with fuel consisting almost entirely of carbon. Rather more than one-fourth of a pound of hydrogen would give as much effective heat as one pound of carbon with a somewhat smaller volume of combustion-products. The extent to which this advantage affects the value or efficiency of fuel will, of course, depend on the amount of hydrogen it contains. Since no hydrocarbon available as fuel contains more than 15 per cent. of hydrogen, the actual evaporative efficacy of such a material, when used under the ordinary conditions, cannot, at the utmost, be more than about 40 per cent. greater than that of an equal weight of carbon. This, assuming it to be perfectly burnt, and the arrangement of boiler flues or tubes, &c., to be favourable for the transfer of heat, is the maximum effect to be looked for according to the data already given.

'The amount of hydrogen in petroleum is probably larger than in any of the other hydrocarbons proposed to be used as fuel, and that contains, on the average, about 13 per cent. In coal and shale oil the amount of hydrogen is less. Consequently, the evaporative efficacy of these materials, as compared with carbon, would not reach the above limit of 40 per cent. in excess. The ratio between these materials and ordinarily good coal is much about the same in regard to evaporative efficacy, since the hydrogen contained in coal compensates for the oxygen and ash it contains, unless the amount of these is very considerable.

'The following tables show the relation between the total heat of combustion and the available heat of hydrocarbons, containing respectively 14 and 25 per cent. of hydrogen, also the amounts of heat consumed in the furnace-gas, and the mode in which it is disposed of:—

'One pound of hydrocarbon, containing 14 per cent. of hydrogen, yields about 31 lbs. of furnace-gas, consisting of:—

	Furnace-Gas	Quantities of Heat in Furnace-Gas	Equivalent Evaporation of Water	
			at 212°	at 60°
	lbs.	heat units	lbs.	lbs.
Carbonic acid gas	3·16	411		
Water vapour	1·26	359		
Nitrogen gas	11·45	1,683		
Surplus air	14·37	2,124	2·2	
	30·74	4,577	4·8	
Total heat of combustion		21,154		
Latent heat of water vapour		1,217	1·3	
Available heat		19,937		
Waste heat of furnace-gas		4,577	4·8	
Effective heat		15,630	15·8	13.5
Theoretical evaporative power		...	21·9	
Relative evaporative efficacy as compared with carbon or coal = 1	1·39			

'One pound of hydrocarbon, containing 25 per cent. of hydrogen, yields about 36 lbs. of furnace-gas, containing:—

	Quantities	Quantities of Heat in Furnace-Gas	Equivalent Evaporation of Water	
			at 212°	at 60°
	lbs.	heat units	lbs.	lbs.
Carbonic acid gas	2·75	358		
Water vapour	2·25	641		
Nitrogen gas	13·39	1,968		
Surplus	17·39	2,483	2·6	
	35·78	5,450	5·6	
Total heat of combustion		26,283		
Latent heat of vapour		2,174	2·2	
Available heat		24,109		
Waste heat of furnace-gas		5,450	5·6	
Effective heat		18,659	19·3	16·6
Theoretical evaporative power		...	27·1	
Relative evaporative efficacy as compared with carbon or coal = 1	1·69			

'I am not aware of any liquid hydrocarbon applicable as fuel, which contains so much as 25 per cent. of hydrogen, so that an evaporative effect of about 16 lbs. of steam per pound of hydrocarbon burnt must be regarded as the maximum result to be attained with such material used as fuel. By burning these hydrocarbons with only just enough air for combustion, or half the quantities assumed to be supplied in the above estimations, the effect capable of being realised would be from 13 to 14 per cent. greater than in the case stated above, or about 18 lbs. of steam per pound of hydrocarbon containing 14 to 15 per cent. of hydrogen.

'The plan of using liquid fuel, which so far as I am aware has proved the most advantageous, is one which does, to some extent at any rate, secure the advantage to be gained by forcing air into the furnace. According to this plan the oil is supplied to the furnace through a small pipe, together with a jet of high-pressure steam, by which it is converted into spray, much in the same manner as, in the toy known as the perfume-vaporiser, a liquid is blown out of a bottle by a current of air. The steam-jet at the same time induces a current of air which mixes with the oil spray and supports its combustion. This is the arrangement used by Messrs. Field and Aydon, and it appears to work exceedingly well, effecting a very perfect combustion of the oil. The oil I have seen used in this way was the dead oil, or creosote oil, which is a refuse product in the refining of gas-tar. It possesses characters which render it much preferable to petroleum, or to the oil obtained by distilling coal at a low heat, for use as liquid fuel. In the first place, its density being greater than that of water—the gallon weighing about 12 lbs.—it takes less space for stowage than petroleum or coal-oil, the gallon of which weighs only from 8 to 8½ lbs. For the same reason it would not be so dangerous as the lighter oils in case of accident; for instead of floating on the surface of water and burning, it would sink harmlessly. Again, its very high boiling point, approaching to a red heat, and the great density of its vapour as compared with that of petroleum or coal-oil, are great advantages as regards risk of explosion in consequence of the oil-vapour becoming mixed with air and then catching fire. This could hardly take place with the dead oil, except at a very high temperature, while petroleum readily gives off vapour to the air at a moderate degree of heat.

'The use of this oil as fuel presents great advantages for gas-tar distillers, with whom it is a troublesome waste product. If it should come into demand as steam-fuel its value would of course rise above that of coal, to an extent proportionate to its greater efficacy and any other advantages resulting from its application as steam fuel. Such an application might therefore be a great advantage to gas companies.

'Unfortunately the quantity of this oil which is available is very small as compared with the requirements of steam navigation, probably not amounting to 100,000 tons a year in the whole country, and therefore its application must be very limited.

'In order now to arrive at some estimate of the advantage to be gained in a steam vessel, either in point of weight to be carried, or space occupied by liquid fuel as compared with coal, it is evident that 100 tons of petroleum, or coal-oil, would do the work of about 140 tons of good coal. But as coal is rarely burnt in such a way as to be rendered useful to its full capability, and as there is always a considerable waste in the shape of dust and cinders, which would not be the case with liquid fuel, a further allowance must be made for this. Assuming that one-fifth of the coal is wasted in this way, then the equivalent of 100 tons of oil would be 175 tons of coal, for taking the density of the oil as ·850, it would occupy about the same space as an equal weight of coals, or at the rate of about 53 lbs. per cubic foot. This difference would enable a vessel capable of carrying coal for 12 days' steaming, to carry oil for 21 days. In burning this oil there would be a saving of labour in stoking, and as it would not give any ashes, a great deal of trouble would be saved in that way.

'These results differ widely from the statements which have been made in reference to the relative efficiency of oil and coal, according to which it has been represented that one ton of oil was equal to from 4 to 5 tons of coal, and that in regard to stowage-room the saving was more than nine-tenths in bulk. I am not aware of any evidence having yet been brought forward, such as would call for, or justify, the abandonment of those well-established principles by which the heating power and efficacy of fuel is determined, as above stated.

'Mr. Trickett, the engineer-in-chief of the dockyard, gives, as the highest evaporative effect obtained with petroleum, 11·63 lbs. of water converted into steam per pound of oil burnt. In this case, however, the combustion was imperfect. But in the most successful trials with coal-oil and shale-oil, when very little smoke was given off, the evaporative effect was about 18 lbs. of steam produced per pound of oil burnt. In this case some deduction is required to be made for the steam applied as a blast to the fire, but the amount was not ascertained. This result was also obtained under peculiarly favourable circumstances as regards the proportion of heating surface of the boiler to the rate of evaporation.

'In regard to the supply of material capable of being used as liquid fuel, it is necessary to make a few remarks. First, as regards petroleum, I imagine it is now generally acknowledged that this material in its natural state is not well adapted for the purpose. In that state it contains a large amount of very volatile hydrocarbon, which, even at the ordinary temperature, vaporises by contact with air, and the mixture of this vapour with air is explosive. At the temperature of a steam vessel's stokehole this vaporisation would take place more readily, and if there were any leakage in the supply pipes or tanks, disastrous consequences might ensue. In order to remove this objection to the use of petroleum as liquid fuel, the more volatile portion of it must be separated by distillation, and that operation, when carried far enough to render the oil fit for use with safety, would reduce the quantity to about one-third.

'Another objection to petroleum in its natural state is its bulkiness, the gallon weighing only about 8 lbs. This is to some extent removed by the distillation; and by the reduction of the quantity to one-third, an oil is obtained which weighs about 8½ lbs. per gallon.

'According to the latest returns, the total production of petroleum in America—which is out of all proportion the most abundant source of this material—amounts to about 360,000 tons a year. It would be mere speculation to offer any opinion as to whether this rate of production is the maximum which is attainable, or as to the time it may continue; but the prevailing impression is that the sources from which this supply originates are subterranean accumulations, and, therefore, not to be depended on beyond a certain limit. The experience of oil-winning in America has confirmed this view, for it has been found that the wells which were at first what are termed "flowing wells," *i.e.*, yielding their oil spontaneously, have gradually ceased to flow; and that after pumping has been resorted to for bringing the oil to the surface, even that means gradually declined in its effect. It would, therefore, be unwise to rely upon the supply of petroleum as affording material for fuel.' See the articles Naphtha; Petroleum; Shale Oils.

Patent Fuel. Under this name a great many attempts have been made to utilise waste material. In countries where charcoal is abundant, charcoal-dust mixed with pitch has been employed, and attempts have been made to utilise the immense quantities of saw-dust produced in the north of Europe, by mixing it with clay and tar. Passing over the several kinds of artificial fuel which have been made on the Continent, the productions of this character made in this country must be described.

Wylam's patent fuel is small coal and pitch, moulded together into bricks by pressure. The pitch is obtained, by the distillation of coal-tar from which naphtha and a peculiar oil are separated, leaving the pitch. This pitch is ground fine and mixed with small coal, and in this state is passed, by a very ingenious application of the Archimedean screw, through a retort maintained at a dull red heat, by which it is softened for being moulded, which is effected by a kind of brick-making machine under enormous pressure.

Warlich's patent fuel is similar in character, but he adds a little common salt or alum to prevent the evolution of too much smoke, and the fuel bricks are subjected to a temperature of 400° F. for eight hours, by which the more volatile constituents are driven off.

Wood's fuel is prepared by mixing small coke or coal in a heated state with tar or pitch in a common pug-mill, after which it is moulded in the ordinary manner.

Bessemer's process consists merely in exposing coal-dust to a temperature of 600° F. By this the bituminous matter of the coal becomes softened, and the whole can be pressed into a firm block.

Grant's patent. This fuel is composed of coal-dust and coal-tar pitch: these materials are mixed together, under the influence of heat, in the following proportions:—20 lbs. of pitch to 1 cwt. of coal-dust, by appropriate machinery, consisting of crushing-rollers for breaking the coal in the first instance sufficiently small that it may pass through a screen, the meshes of which do not exceed a quarter of an inch asunder; 2ndly, of mixing-pans or cylinders, heated to the temperature of 220°, either by steam or heated air; and 3rdly, of moulding machines, by which the fuel is compressed, under a pressure equal to five tons, into the size of a common brick; the fuel bricks are then whitewashed, which prevents their sticking together, either in the coal bunkers or in hot climates. The advantages of this artificial fuel over coal may be stated to consist, first in its efficacy in generating steam; secondly, it occupies less space, that is to say, 500 tons of it may be stowed in an area which will contain only 400 tons of coal; thirdly, it is used with much greater ease by the stokers or firemen than coal, and it creates little or no dirt or dust, considerations of some importance when the delicate machinery of a steam-engine is considered; fourthly, it produces a very small proportion of clinkers, and thus it is far less liable to choke and destroy the furnace bars and boilers than coal; fifthly, the ignition is so complete that comparatively little smoke, and only a small quantity of ashes, are produced by it; sixthly, from the mixture of the patent fuel, and the manner of its manufacture, it is not liable to enter into spontaneous ignition.

A great many other persons have either patented processes for the preparation of artificial fuel, or published suggestions. These are so nearly alike that a few of them only require any notice.

Cobbold agitates peat in water to separate the earthy matter, and then allows the peat to subside, and consolidates it.

Godwin makes brick of mud or clay with pitch or coal.

Oram employs tar, coals, and mud.

Hill takes the residuary matter after the distillation of peat, and mixes it with pitch.

Holland mixes lime or cement with tar and small coals.

Ransome cements small coal together by a solution of silicate of soda.

From the Admiralty Coal Inquiry's Report we obtain the following analyses of several of the more important artificial fuels:—

Name of Fuel	Specific Gravity of Fuel	Carbon	Hydrogen	Sulphur	Oxygen	Ash
Warlich's	1·15	90·02	5·56	1·62	...	2·91

In connection with the consideration of the values of Fuel, as producers of mechanical power, the *Economiste Français* has published an article in which it examines the improvements that may be introduced into motive machines by the application of the science of the mechanical theory of heat. The writer thinks that the science itself is sufficiently advanced to afford important practical results, and, in support of that view, names the recent work of M. Léon Pochet, *La Nouvelle Mécanique Industrielle.*

Every thermal machine, which has for its object the conversion of heat into mechanical power, approaches perfection exactly in relation to the amount of heat which it transforms; this transformation has a maximum limit which cannot possibly be passed, but the machines at present in use are far from attaining the degree of perfection indicated by the theoretical limit. By calculating the heat necessary for converting water into steam at the proper temperature, in a supposed perfect machine, the consumption of fuel amounts to 0·17 kilogramme (of 2·204 avoirdupois lbs. of 7,000 grains) per horse-power per hour (see Horse Power); while the consumption of engines in industrial use is as follows:—The most perfect engines of large power, one kilogramme; those of moderate power, two; and small machines, four to six kilogrammes. This statement shows that many improvements are still to be looked for in our motive engines: and we may enquire in what direction and with what results the endeavour towards such amelioration has been pursued of late, with a special view to the economy of combustion.

The power of a boiler is measured by the weight of steam produced per hour for a given amount of heating surface, and its working power by the weight of steam produced by a given weight of fuel, for a boiler may give a large quantity of steam per unit of surface and by time, and yet utilise but a small portion of the heat emitted by the fuel. Thus, engineers are occupied at the present time with the question of the disposition of steam generators; the types employed in industry vary infinitely in their details, but they may all be referred to one or other of the seven heads following:—1. Waggon-head boilers; 2. Cylindrical boilers with exterior furnaces; 3. Cylindrical boilers with interior furnaces; 4. Boilers with hot-water tubes; 5. Tubular boilers; 6. Boilers with circulating arrangement; 7. Marine boilers.

According to the results of a considerable number of experiments made with various forms of apparatus, the weight of steam produced by a kilogramme of fuel oscillates between 4·30 (boiler with two lateral hot-water tubes, experimented on by M. Chavés on the Northern Railway of France) and 10·84 to 11·30 (cylindrical boiler, with a Wye-Williams' superheater), the exceptional limit yet arrived at. These figures, which indicate the economic value of each system, depend upon a great number of conditions, amongst which it must be remembered that the experience and care of the stokers are not the least important. From the economical point of view, little or no progress has taken place in boilers since the time of Watt. The old Cornish and London boilers gave about eight kilogrammes of steam for one kilogramme of fuel: modern apparatus only attain this result exceptionally. This arose in great part from the care with which the first boilers were constructed; precautions were taken in them to avoid loss of heat, which have unfortunately been neglected of late. The necessity for economising space aggravated the effects of this negligence. In diminishing the length of the boilers that of the flues was also lessened, and consequently the gases were allowed to escape at a higher temperature than before. What was gained in space was thus lost in economy.

In the present state of the art of construction, the maximum result to be looked for, under ordinary circumstances, from a good boiler, is that of seven kilogrammes of steam per kilogramme of coal of average quality, producing ten per cent. of cinders. In fixing at 8,000 units the heat disengaged by the combustion of a kilogramme of pure coal, we recognise the fact that the utilisation of boilers corresponds with a fraction equal to about fifty-seven per cent. More than a third of the heat is lost in our best steam generators. The care of a good stoker may easily augment the result by ten per cent.

Although this portion of our steam apparatus seems susceptible of notable improvements, still if we consider the stationary conditions of caloric effect since Watt's time, it would seem that these improvements are exceedingly difficult to bring about. The Siemens' furnaces appear to be the only apparatus introduced with the object of economising fuel, which deserve special notice; but their application is necessarily restricted to fixed engines.

Steam once produced, the next thing is to turn it to account, and in this case we can scarcely look for improvement in future but from amelioration in the details of the apparatus—and industry has almost arrived at perfection in this respect—steam-engines which consume a kilogramme of coal per horse-power effective and per hour, are not far removed from it.

It has been sought to replace steam in thermal engines by other vapours or by gas.

Trembley's engine, tried in 1840, and adopted for a boat which ran regularly between Marseilles and Algiers, was worked with steam and the vapour of ether. Sulphuric ether boils at a temperature of 37° Cent.; condensed steam preserves sufficient heat to convert ether into vapour which, by its expansion, adds a certain amount of power to that already produced. This experiment, however, was not successful, and the engines constructed upon this system were considered extremely dangerous. The substitution of chloroform for ether, proposed by M. Lafond, of the French Navy, was not more satisfactory.

Capt. Ericson, in his engine, which was remarkable from a theoretical point of view, constructed about 1852, appears to have been the first inventor who succeeded in utilising atmospheric air in thermic engines. But although his apparatus has been employed in America, under various circumstances, and especially for vessels, the hot-air engine, whether on the system of Ericson, Franchot, Lemoine (of Rouen), Belou or others, has not yielded really practical results or rendered any real service. It is well known that the effects of hot-air engines should far exceed those of good steam-engines. Our best motors actually consume, as already stated, a kilogramme of coal per horse per hour; if we admit that the heating apparatus of a hot-air engine transmits two-thirds of the heat developed in the furnace, that the mechanism utilises 60 per cent. of the possible mechanical power, and that the coal produces only 7,500 units of heat; lastly, if we estimate the absolute theoretical effect at 0·50, the consumption of a hot-air engine will, under these circumstances, be equal to 0·424 per horse per hour—a very reduced amount. It would be to despair of human ingenuity not to believe that such a result will some day be obtained. See Air Engine.

FULGURATION designates the sudden brightening of the melted gold and silver in the cupel of the assayer, when the last film of vitreous lead and copper leaves their surface.

FULLER'S EARTH. (*Terre à foulon, Argile smectique*, Fr.; *Walkererde*, Ger.) In geology this term is applied to the clayey deposit which intervenes between the calcareous strata commonly known as the Bath or Great Oolite, and the Inferior Oolite. A sandy argillaceous earth is met with in the upper part of the clay in question, to which the name Fuller's earth was given from its adaptability for *fulling* or cleansing cloth, when first woven, from grease or other impurities. The term thus limited originally to a particular stratum was subsequently applied to the entire formation by Dr. William Smith in his classification of the British strata, and has ever since retained its place in geological nomenclature. The fuller's earth above mentioned was formerly procured in considerable quantities from the Downs, to the south of Bath, whence it was sent to the cloth factories of Gloucestershire. Of late years, however, an artificial substitute has been found in a chemical preparation, and the demand for the natural production has decreased so far, that little or none of it is now procured in the West of England. The fuller's earth of Reigate is found in strata of a much more recent date than those alluded to above, and forms a part of the Lower Greensand. See Greensand.

From Reigate 12,000 tons of dried fuller's earth are raised annually. There are two varieties, called the blue and yellow; their analyses are respectively—

	Blue	Yellow
Alumina	18	11
Silica	42	44
Lime	4	5
Magnesia	2	2
Oxide of Iron	6	10
Soda	5	5

The other places from which fuller's earth has been obtained, are—Penenden Heath, Maidstone, Frome, Lonsdale, Coombe Hay, English Coombe, and Duncorn Hill in Gloucestershire, and at one locality in Bedfordshire.—H. W. B.

FULLERS' TEAZEL. *Dipsacus* (*δίψα, thirst*), so called because the bases of the leaves are, in many species, connate, so that they enclose a cavity which contains water ready to allay thirst. The fullers' teazel is the *Dipsacus fullonum*; the bracts of the head are very spiny, and are much used for carding cloth; consequently the teazel is cultivated in many parts. Many carding machines have been introduced, but the best cloth weavers still prefer the teazel for finishing their cloth.

FULLING. The art of cleansing, scouring, and pressing woollen manufactures. The object is to render them stronger and firmer. It is called also *milling*, because the cloths are scoured by a water mill.

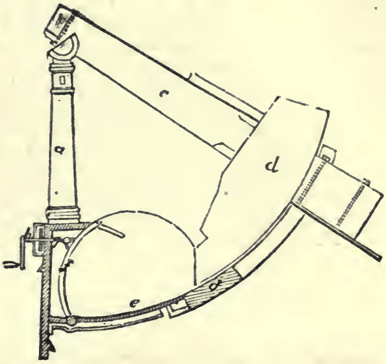
The principal parts of a fulling mill are the wheel with its trundle, which gives motion to the tree or spindle whose teeth communicate that motion to the stampers or beaters, which fall into troughs, wherein the cloth is put, with the fuller's earth.

William and Ogle introduced in 1825 some new fulling machinery, designed to act in a similar way to the ordinary stocks, in which cloths are beaten, for the purpose of washing and thickening them; but the standard and the bed of the stocks are made of iron instead of wood, as heretofore; and a steam vessel is placed under the bed, for heating the cloths during the operation of fulling, whereby their appearance is said to be greatly improved.

Fig. 1006 is a section of the fulling machine or stocks: *a*, is a cast-iron pillar, made hollow for the sake of lightness; *b*, is the bed of the stocks, made also of iron, and polished smooth, the side of the stock being removed to show the interior; *c*, is the lever that carries the beater *d*. The cloths are to be placed on the bed *b*, at bottom, and water allowed to pass through the stock, when by the repeated blows of the beater *d*, which is raised and let fall in the usual way, the cloths are beaten, and become cleansed and fulled.

A part of the bed at *e* is made hollow, for the purpose of forming a steam box, into which steam from a boiler is introduced by a pipe with a stopcock. This steam heats the bed of the stock, and greatly facilitates, as well as improves, the process of cleansing and fulling the cloths.

1006



The smoothness of the surface of the polished metal, of which the bed of the stock is constituted, is said to be very much preferable to the roughness of the surface of wood of which ordinary fulling stocks are made, as by these iron stocks less of the nap or felt of the cloth is removed, and its appearance when finished is very much superior to cloths fulled in ordinary stocks.

In the operation of fulling, the cloths are turned over on the bed by the falling of the beaters, but this turning over of the cloths will depend in a great measure upon the form of the front or breast of the stock. In these improved stocks, therefore, there is a contrivance by which the form of the front may be varied at pleasure, in order to suit cloths of different qualities; *f*, is a moveable curved plate, constituting the front of the stock; its lower part is a cylindrical rod, extending along the entire width of the bed, and being fitted into a recess, forms a hinge joint upon which the curved plate moves; *g*, is a rod attached to the back of the curved plate *f*, with a screw thread upon it; this rod passes through a nut *h*, and by turning this nut, the rod is moved backward or forward, and, consequently, the position of the curved plate altered.

The nut *h*, is a wheel with teeth, taking into two other similar toothed wheels, one on each side of it, which are likewise the nuts of similar rods jointed to the back of the curved plate *f*; by turning the central wheel, therefore, which may be done by a winch, the other two wheels are turned also, and the curved plate moved backward or forward. At the upper part of the plate there are pins passing through curved slots, which act as guides when the plate is moved.

FULMINATING MERCURY, $C^4N^2Hg^2O^4$ ($\mathbf{C^2N^2HgO^2}$). The well-known compound used for priming percussion caps. It was analysed many years ago by Liebig, and subsequently, by Gay-Lussac. Although chemists have long been acquainted with the true composition of fulminic acid, and the formula of fulminating mercury has also been rendered almost certain, no accurate analysis of the latter compound was made public until 1855, when M. Schischkoff published his celebrated paper on the fulminates. It is singular that Liebig and Schischkoff were independently engaged at the same time in investigating the products of decomposition of the fulminates. The formula of fulminic acid, and also that of fulminating mercury, had been deduced from the very accurate analyses of fulminating silver made by Gay-Lussac and Liebig. A great number of processes for the preparation of fulminating mercury have been published. The following are the best as regards economy and certainty:

1. One part of mercury is to be dissolved in 10 parts of nitric acid, sp. gr. 1·4; and the solution at a temperature of 130° F. is to be poured into 8·3 parts of alcohol, sp. gr. 0·830.—*Ure.*

2. One part of mercury is to be dissolved in 12 parts of nitric acid, of sp. gr. 1·3. To the solution (as soon as it has cooled to 55° F.). 8 parts of alcohol, sp. gr. 0·837, are to be added; the vessel containing the mixture is to be heated in boiling water

until thick white fumes begin to form. The whole is then set in a cool place to deposit the crystals of fulminate.—*Cremascoli.*

3. One part of mercury is to be dissolved in 12 parts of nitric acid, sp. gr. 1·340 to 1·345, in a flask capable of holding 18 times the quantity of fluid used. When the metal is dissolved, the solution is decanted into a second vessel containing 5·7 parts of alcohol, of 90° to 92° (*Tralles*), then immediately poured back into the first vessel, and agitated to promote absorption of the nitrous acid. In five to ten minutes gas-bubbles begin to rise, and there is formed at the bottom of the vessel a strongly refracting, specifically heavier liquid, which must be mixed with the rest by gentle agitation. A moment then arrives when the liquid becomes black from separation of metallic mercury, and an extremely violent action is set up, with evolution of a thick white vapour, and traces of nitrous acid; this action must be moderated by gradually pouring in 5·7 parts more of the same alcohol. The blackening then immediately disappears, and crystals of fulminating mercury begin to separate. When the fluid has become cold, all the fulminating mercury is found at the bottom. By this method not a trace of mercury remains in solution.—*Liebig.*

The fulminate in all these processes is to be collected on filters, washed with distilled water, and dried. The violent reaction which takes place when the solution of mercury reacts on the alcohol is essential to the success of the operation.

With regard to the economy of the above methods, it has been found that 1 part of mercury yields the following proportions of fulminate:—

1st process	1·30
2nd ,, ...	1·25
3rd ,, ...	1·53

C. G. W.

FULMINATING SILVER, $C^4N^2Ag^2O^4$ ($\mathbf{C^2N^2Ag^2O^2}$). This salt corresponds in constitution to the fulminate of mercury; it may also be prepared by analogous processes, merely substituting silver for mercury. *Preparation.*—1. 1 part of silver is to be dissolved in 24 parts of nitric acid, sp. gr. 1·5, previously mixed with an equal weight of water. To the solution is to be added alcohol equal in weight to nitric acid. *Produce,* 1·5 part of fulminating silver. 2. 1 part of silver is to be dissolved in 20 parts of nitric acid, sp. gr. 1·38. To the solution is to be added 27 parts of alcohol, sp. gr. 0·832. The mixture is to be heated to boiling, and, as soon as it shows signs of becoming turbid, it is to be removed from the fire, and a quantity of alcohol, equal in weight to the first, is to be poured in. The liquid is now to be allowed to become perfectly cold, when the fulminate will be found at the bottom of the vessel. *Produce,* equal to the silver employed. 3. 1 part of silver is to be dissolved in ten times its weight of nitric acid, sp. gr. 1·36. To the solution is to be added 20 parts of alcohol, sp. gr. 0·83. The mixture is to be treated as in the second mode of preparation, except that no more alcohol is to be added. The produce should be in fine crystals. Whichever mode of preparation be selected, it is absolutely necessary, in order to avoid fearful accidents, that the following precautions be attended to. The beakers or flasks employed must be two or three times larger than is required to hold the ingredients, for if, owing to frothing or boiling over, any of the fluid happened to find its way to the outside, and dry there, an explosion might ensue. Care must also be taken that the highly inflammable vapours given off during the preparation do not come near any flame. The salt, when formed, must be received on a filter, and well washed with cold water. It is safer to dry it spontaneously, or over oil of vitriol, for although it will endure a heat above that of boiling water before exploding, yet when warm, the slightest touch with a hard substance is often sufficient to cause a terrible detonation. A spatula of pasteboard or very thin wood should be employed to transfer it into its receptacle. Fulminating silver should not be kept in glass vessels, for fear of the salt finding its way between the cork or stopper, the slightest movement with a view of opening the vessel, being then sufficient to cause an accident. Small paper boxes are the safest to keep it in.

Fulminating silver gives a more violent detonation than the corresponding mercurial compound. The presence of roughness or granular particles on the substances with which it may be in contact assists greatly in causing it to explode.

Although giving so violent an explosion when alone, it may be burnt without danger when mixed with a large excess of oxide of copper, as in the ordinary process of organic analysis. It then gives off a mixture of two volumes of carbonic acid, and one volume of nitrogen. Gay-Lussac and Liebig made an analysis of the salt in this manner, with the annexed results:—

Experiment		Calculation		
Carbon	7·9	C^4	24	8·0
Nitrogen	9·2	N^2	28	9·3
Silver	72·2	Ag^2	216	72·0
Oxygen	10·7	O^4	32	10·7
	100·0		300	100·0

C. G. W.

FULMINIC ACID, $C^4N^2H^2O^4$ ($\mathbf{C^2N^2H^2O^2}$). The acid contained in fulminating mercury; it does not appear to exist in a free state.

FUMIGATION is the employment of fumes or vapours to purify articles of apparel, and goods or apartments supposed to be imbued with some infectious or contagious poison or fumes. The vapours of vinegar, the fumes of burning sulphur, or explosion of gunpowder, have been long prescribed and practised, but they have in all probability little or no efficacy. The diffusion of such powerful agents as chlorine gas, muriatic acid gas, or nitric acid vapour, should alone be trusted to for the destruction of morbific effluvia. See DISINFECTANTS.

FUMITORY. A bitter herb, *Fumaria officinalis.* It grows abundantly in this country, and was at one time used in medicine. The name is derived from the Latin word *fumus*, smoke, on account of its smoke-like smell. The French call it *fumeterre*, whence our name *fumitory.*

FUNGI. One of the orders into which the *Thallogenæ* are divided, comprehending the mushrooms. The fungi are cellular plants, which generally appear in the form of a more or less rounded *thallus* supported upon a stalk, and with spores or seeds on the under surface or gills, or, as it is called, the *hymenium.* Upwards of 4,000 species of fungi have been enumerated by botanists. All matter, and especially organic matter, may become productive soil for many species. The parasitic fungi are very serious agents of destruction, and the cereals and other useful plants are often entirely destroyed or rendered poisonous by their appearance. The mildew of wheat, *Puccinia graminis*; the smut, *Uredo segetum*; the bunt, *Uredo fœtida*; the ergot or cock's spur, *Spermœdia clarus*, which, without destroying the crops, renders the grain poisonous for food: the potato disease, which is intimately connected with the attack of a species of *Botrytis* (*Peronospora*) *infestans*, as are also diseases of many of the ordinary vegetables, are some of the minute and destructive kinds of fungi. Some of these parasitic fungi grow on living animals; the non-secretion of the silkworm is due to the fungus *Botrytis Bassiana.* A certain species of caterpillar is attacked by the fungus *Sphæria Sinensis*, and the animal becomes perfectly absorbed in the vegetable, and this substance is collected and used as a highly-prized drug among the Chinese. A very large class of fungi bears the name of mushroom; many of these species are edible, while others are more or less poisonous. The *Agaricus muscaria* is used by the natives of Kamtschatka and Korea to produce intoxication: of the edible kinds the *Agaricus campestris* is most used in this country as an article of food, and from it is obtained the sauce called Ketchup, or Catsup; this species is considered poisonous in Italy, while many others eaten in foreign countries are considered here unfit for food. The fairy-ring mushroom, *Agaricus pratensis*, is also an edible plant, and is used for mixing with rich sauces. The truffle, *Tuber cibarium*, is also a mushroom. The commercial value of this fungus is very great. Beyond these there are none of the fungi which have any practical uses in this country. In Rome it is stated that the yearly average of taxed mushrooms, from 1837 to 1847, was between 60,000 and 80,000 lbs. weight. The *Cyttaria Darwinii*, growing on the bark of the beech in Tierra del Fuego and in Australia; and species of the *Boletus*, especially one called native bread, *Mytittus Australis*, are much used by the respective natives as food. Some species of fungi are phosphorescent; the *Rhizomorpha*, one of these, is said to give to caves and mines where it abounds an indescribable splendour. Many of the smaller fungi are most destructive in their nature, as remarked previously. Fungous formations have been detected in our cotton goods sent to India, and the result has been most serious to our trade in these goods.

As many deaths have occurred by mistaking poisonous for edible fungi, it may be useful to point out the chief marks of distinction between the two classes. The characters have been thus contrasted by Prof. Bentley:—

Edible Mushrooms.	*Poisonous Mushrooms.*
1. Grow solitary, in dry, airy places.	Grow in clusters, in woods, and dark damp places.
2. Generally white or brownish.	Usually with bright colours.
3. Have a compact, brittle flesh.	Flesh tough, soft, and watery.

Edible Mushrooms.	*Poisonous Mushrooms.*
4. Do not change colour when cut, by action of air.	Acquire a brown, green, or blue tint, when cut and exposed to the air.
5. Juice watery.	Juice often milky.
6. Odour agreeable.	Odour commonly powerful, and disagreeable.
7. Taste not bitter, acrid, salt, or pungent.	Have an acrid, astringent, acid, salt, or bitter taste.

Further, all fungi should be avoided if insects will not touch them; if the fungi have scales or spots on their surfaces; or if they exhibit any signs of decomposition. It is said that some poisonous fungi are rendered innocuous by being cut in slices, macerated in vinegar and water for an hour, and then washed in boiling water before being dressed.

FUR. (*Fourrure*, Fr.; *Pelz*, Ger.) Fur may be strictly defined as the short fine soft hair of certain animals, growing thick on the skin, and distinguished from the hair, which is longer and coarser. The term is, however, used sometimes very loosely, and includes those skins which are covered with hair. Fur is one of the most perfect non-conductors of heat, and consequently we find the animals of the colder regions of the earth clothed with this substance, and hence man has adopted it as the warmest of clothing.

To the admirable report made by Messrs. J. A. Nicholay and James B. Bevington, on the Furs of the Great Exhibition, we are mainly indebted for the following particulars.

The Russian Sable (*Mustela zibellina*). In the reign of Henry VIII., by a law to regulate the expenses of different classes, and to distinguish them by peculiarity of costume, the use of sable was confined to the nobility above the rank of viscount. It is stated that 25,000 skins are annually collected in the Russian territories. The fur is brown, with some grey spots on the head; the darker varieties are the most valuable, a single skin of a fine dark colour being sold for as much as nine pounds, though the average value does not exceed two or three. The Russian sable is sometimes confounded with the Hudson's Bay sable, but to the furrier the former is easily distinguishable from the length and fullness, as well as the darker colour, of the fur.

Hudson's Bay Sable (*Mustela Canadensis*). As the natural colour of this skin is much lighter than the prevailing taste, it is the practice to dye many of them a darker colour, and the furs thus treated are scarcely inferior to the Russian or true sable. Not less than 120,000 skins are annually imported into this country.

Pine Marten or Baum (*Mustela abietum*). The animals producing this skin are found in extensive forests in the north of Europe. The skins are distinguished from the stone marten by the yellow colour of the throne. These skins are dyed to imitate real sable.

Stone Marten (*Mustela saxorum*). This is frequently called French sable, from the fact that the French furriers excel in dyeing this skin. The stone marten is distributed through most European countries. The under fur is a bluish white, with the top hairs a dark brown, the throat being generally a pure white, by which it is distinguished.

Fisher. These skins are larger than the sables, and the fur is longer and fuller; about 11,000 of these skins are annually brought from America. The tail, which is long, round, and gradually tapering to a point, was formerly used as the common ornament to a national cap worn by the Jew merchants of Poland.

Mink (*Mustela vison*).. There were 245,000 skins of this little animal brought to this country in 1850. The fur resembles sable in colour, but is considerably shorter and more glossy.

Ermine (*Mustela erminea*). This animal is similar in form and habit to the common weasel of this country; but in Siberia, Russia, and Norway, from whence the skins are imported, the little animal during winter becomes as white as the snowy regions it inhabits, and is esteemed the whitest fur known, though in summer its dress is a dingy brown. The tail of the skin, of which the lower half is jet black, is usually introduced as an ornament to the purely white fur. In Edward III.'s reign, the use of ermine was restricted to the royal family.

Fitch or Polecat (*Mustela putorius*), produced throughout Europe and in our own country. This animal has a soft black fur, with a rich yellow ground. The natural smell of this fur is unpleasant and difficult to overcome.

North American Skunk (*Mephitis Americana*). These skins are imported by the Hudson's Bay Company. The animal from which it is obtained is allied to the polecat of Europe. The fur is a soft black, with two white stripes running from the head to the tail. This fur is not much used in this country.

Kolinsky (*Mustela Siberica*). The Tartar sable, which is of a bright yellow colour. It is sometimes used in its natural state, but is more frequently dyed brown to imitate other sable, to which it bears a strong resemblance. It is remarkable for the uniformity of its colour, having no spot or difference of shade in any part of the body. The tail, which is of the same colour, is exclusively used for the best artist's pencils.

Musk Rat or Musquash (*Fiber zibethicus*), an inhabitant of the swamps and rivers of America. About a million skins are brought to this country annually. The fur resembles that of the beaver, and was used by hat manufacturers. The skins are also dyed by the furrier, and manufactured into many cheap and useful articles.

Nutria or Coypon (*Myopotamus coypus*). This animal is larger than, but somewhat similar to, the musquash; it inhabits the banks of rivers in Buenos Ayres and Chili. But few of these skins are now imported.

Hamster (*Cricetus vulgaris*), a native of Germany, where not less than 100,000 skins are annually collected. It has a poor, short, and coarse fur, which is almost exclusively used for cloak linings by the Greeks. The colour of the back is a reddish brown, the belly black, with a few light spots.

Perwitzky. The skin of this animal is marked like tortoise-shell; it is brought from the southern extremities of Asiatic Russia. It is chiefly used by the Russians for cloak lining.

Beaver (*Castor Americanus*). This beautiful fur is sometimes used for articles of dress. In order to prepare the skin for this appropriation, the coarse hairs are removed, and the surface cut by a very ingenious machine, somewhat similar to that used in dressing cloth. The skin thus prepared has a beautiful appearance, not unlike the costly South Sea otter, and has the advantage of durability and lightness.

Otter (*Lutra vulgaris, Lutra Canadensis*). Of the British otter about 500 skins are collected annually. The large quantity used by the Russians and Chinese is derived principally from North America.

Sea Otter (*Enhydra marina*). The sea otter has a very thick, soft, woolly fur, and is most highly prized by the Russians and Chinese, to whom most of the skins are exported. The animal is found in the North Pacific from Kamtschatka to the Yellow Sea, on the Asiatic coasts, and from Alaska to California on the American coasts.

Seal (*Phoca*). There are numerous varieties of these animals, which are found on the western coasts of these islands, and in immense numbers on the shores of Labrador, Greenland, and Newfoundland. The greater portions of the skins imported are tanned and enamelled with black varnish for ladies' shoes; other descriptions are well adapted for fur. Before they can be used as a fur, it is necessary to remove the very coarse hairs, which cover a beautifully fine and silky fur. By shaving the felt to half its natural substance, the roots of the coarse hairs are cut through, and they easily fall out, but the same effect is produced by the natural process of fermentation, which ensues when the skins are properly prepared and allowed to remain together. This fur is rarely used in its natural state, but is dyed a deep vandyke brown, when it has the appearance of the richest velvet.

Fox. Of foxes' skins brought to this country there are many varieties; the black and silver foxes (*Vulpes fulvus*, var. *argentatus*) from the Arctic regions are the most valuable. They are purchased for the Russian market, being highly prized in that country. The cross and red foxes are used by the Russians, Turks, and Greeks for cloak linings and collars. The blue and white foxes are used in this and other countries for ladies' dresses; the white foxes (*Vulpes lagopus*) are represented by arctic travellers as exceedingly numerous, and emigrating in troops over the frozen seas at the approach of the rigorous season.

Wolverine (*Gulo luscus*). The glutton of old writers. The fur is generally a dark brown, passing into a black in winter.

Bear (*Ursus*). The skin of the black bear is used for military purposes, for rugs and carriage hammercloths. The fur of the brown or Isabella bear (*Ursus Isabellinus*) has frequently been very fashionable in this country.

The skins of the hare and the rabbit scarcely require notice.

The Squirrel, especially the Siberian squirrel, is much sought for. It is said that 15,000,000 of these skins are annually collected in Russia, and of these, 3,000,000 are sent to this country.

Chinchilla (*Chinchilla lanigera*). There are two varieties of Chinchilla, the produce of South America. Our chief supply is from Buenos Ayres and Arica. The skins from the former locality are of a silvery grey. Those from Arica are the darkest and best coloured skins.

Racoon (*Procyon totor*), this fur is used for lining coats.

CAT (*Felis domesticus*). In Holland the cat is bred for its fur; it is fed on fish and carefully tended until the fur arrives at perfection.

CANADA LYNX (*Felis Canadensis*). This fur is not much used in this country, but it is prepared and exported for the American market.

Furs, Skins, and Pelts Imported.

The importance of the trade in furs and skins will be rendered evident from the preceding accounts. It would have been desirable to have separated the furs, strictly so called, from the skins, but this has not been found practicable with anything like accuracy: the returns are therefore given under the heads adopted by the Customs, which have no been continued even in this form.

Furs are subject to injury by several species of moths, whose instinct leads them to deposit their eggs at the roots of the fine hair of animals.

Linnæus mentions five species that prey upon cloth and furs, of which *Tinea pellionella*, *T. vestionella*, and *T. tapelzella* are the most destructive. No sooner is the worm hatched than it eats its path through the fur, and continues increasingly destructive until it arrives at its full growth, and forms itself a silken covering, from which, in a short time, it again emerges a perfect moth.

Another cause of the decay of fur is, the moisture to which they are frequently exposed; the delicate structure of the fine under-fur cannot be preserved when any dampness is allowed to remain in the skin. This fact is well known to the leather manufacturer, who, having wetted his skins, allows them to remain in a damp cellar for a few days, for the purpose of removing the hair, which is pulled out with the greatest facility, after remaining only one week in a moist condition. It follows from these observations, that to preserve the furs it is necessary to keep them dry, and to protect them from moths; if exposed to rain or damp, they must be dried at a moderate distance from the fire: and when put by for the summer, should be combed and beaten with a small cane, and very carefully secured in a dry brown paper or box, into which moths cannot enter. During the summer they should be examined once a month, to be again beaten and aired, if the situation in which they have been placed be at all damp. With these precautions, the most valuable furs may be preserved uninjured for many years.

FUR. A deposit incrusting the interior of boilers, kettles, and other vessels in which water has been boiled. The fur generally consists of carbonate of lime. Its formation may be prevented by adding either soda-ash (carbonate of soda) or sal-ammoniac (chloride of ammonium) to the water. The addition of a small proportion of glycerine has also been recommended.

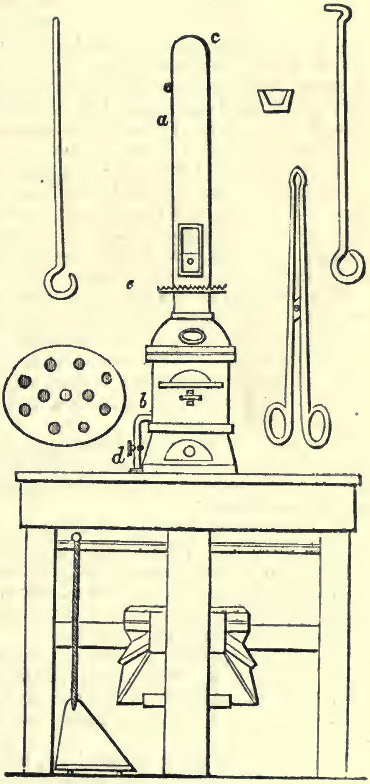
FURNACE. The construction of furnaces for the more important metallurgical operations will be found under the heads of the different metals, for the separation of which from their ores they have been employed. All the arrangements of the Blast Furnace, Puddling Furnace, and Reheating Furnace, will be found under Iron. Under the heads of Copper, Tin, Lead, Silver, Zinc, &c., will be described the furnaces used in the production of those metals.

In like manner, the several kinds of furnaces employed in Glass and other manufactures requiring the application of heat, are described in their respective places.

There remains, therefore, only one or two very ingenious forms of furnace, by which great heat can be obtained, for any purpose, to be mentioned in this place.

Furnace of Assay.—Under Assay a furnace constructed by Messrs. Anfrye and D'Arcet is mentioned, which gives some peculiar facilities and economy to the process by fire.

1007



It had originally a small pair of bellows attached to it, for raising the heat rapidly to the proper vitrifying pitch. This is not shown in the previous figure.

The furnace is $17\frac{1}{2}$ inches high and $7\frac{1}{2}$ inches wide, made of pottery or fine clay, as represented in *fig.* 1007, supported on a table having a pair of bellows beneath it. The laboratory is at *b*, the blow-pipe of the bellows at *d*, with a stopcock, and the dome is surmounted by a chimney *a c*, in whose lower part there is an opening with a sliding door for the introduction of charcoal fuel. The furnace is formed in three pieces: a dome, a body, and an ash pit. A pair of tongs, a stoking hook, a cupel, are seen on the right hand; and the plan of the stoneware grate pierced with conical holes and a poker are seen to the left.

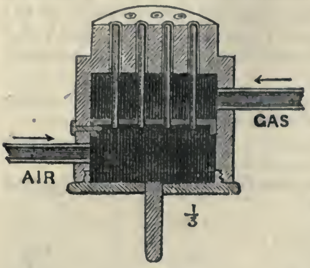
Gas Furnaces.—Gas has been employed, of late, with much advantage for heating crucibles, and many forms of burners have been introduced for the purpose of producing such jets as will yield the proper quantity of gas, and unite it with the right proportion of air, for producing the most intense heat; which can be applied in a convenient manner. The power of the burner, of whatever kind it may be, must be increased by surrounding the flame with a jacket of fire clay or some non-conducting substance, which will prevent the dissipation of heat by radiation. By attending to this a very high temperature may be produced with but a small expenditure of gas.

Griffin's Blast Gas-Furnace.—This is a more powerful apparatus, adapted for metallurgic operations, such as fusing considerable masses of metal, assaying, roasting, &c. It consists of two parts: first, of a particular form of *gas-burner*, which is supplied with gas at the usual pressure, and with a blast of common air, supplied by bellows or a blowing machine at about ten times the pressure at which the gas is supplied; and secondly, of a *furnace*, which is built up in a particular manner, round the flame produced by the gas-burner and the crucible exposed to ignition. The object of this particular construction is to accumulate and concentrate in a focus the heat produced by the gas flame, and to make it expend its entire power upon any object placed in that focus.

This apparatus can be made of various sizes, according to the amount of work required from it.

The *gas-burner* is a cylindrical iron reservoir shown in section in *fig.* 1008, which is drawn on a scale of one-third the full size. It contains two chambers, not in communication with one another. Into the upper chamber, gas is allowed to pass by the tube marked Gas. Into the lower chamber, air is forced by the tube marked Air. The upper part of this burner is an inch thick in the metal. Through this solid roof holes from 6 to 26 in number are bored for the escape of the gas. The number of holes depends, of course, upon the heating power required from the burners. The air passes from the lower chamber, through a series of metal tubes, placed in the centre of the gas-holes, and continued to the surface of the burner, so that the gas and air do not mix until both have left the gas-burner, and then a current of air is blown through the middle of each jet of gas. The bottom of the gas-burner is made to unscrew, and the division between the two chambers, which carries the air-tubes, is easily removable for the purpose of being cleaned. The gas and air pipes generally used in the inventor's experiments were each half an inch in the bore and ten inches long; the gas had usually a pressure of half an inch of water, and the blast of air about ten times that pressure. The quantity of gas used in an hour was about 100 cubic feet. The stopcock which supplied it had a bore of half an inch. The round rod represented at the bottom of the burner, *fig.* 1008, is intended to fit it to the support.

1008



When the gas is lighted and the blast of air is put on, the flame produced by the gas-burner is quite blue, and free from smoke. It is two inches in diameter and three inches high, and the point of greatest heat is about two inches above the flat face of the gas-burner. Above this steady blue flame there rises a flickering ragged flame, several inches in height, varying with the pressure of the gas. In the blue flame, thin platinum wires fuse readily.

When the gas is burning in this manner, and the apparatus is attached to flexible tubes, the burner may be inverted or held sideways, without disturbing the force or regularity of the flame, so that the flame may be directed into a furnace at the bottom, the top, or the side, as circumstances may require.

The following articles are used in building-up the gas-furnace for different experiments. They vary in size according to the volume of the crucible, or the weight of the metal to be heated:—

1. A circular plate of fire-clay, two inches thick, with a hole in the centre, exactly fitting the upper part of the gas-burner, which is made to enter into the hole three-quarters of an inch. In external diameter, this clay plate agrees with each size of the furnace.

2. A cylinder of fire-clay, of which two pieces are required to constitute the body of each furnace. In the middle of each cylinder a trial hole is made, one inch in diameter, to which a fire-clay stopper is adapted.

3. A fire-clay cylinder, closed at one end, and pierced near the open end with six holes of half an inch in diameter. The thickness of the clay is immaterial. This cylinder is three inches in diameter.

4. A circular plate of fire-clay, two and a half inches or three inches in diameter and one inch thick. Similar pieces half an inch thick are useful.

5. A cylinder of plumbago, to be used as a crucible support. It is three inches in inside diameter, one inch in height, and pierced with twelve holes of three-eighths of an inch bore.

6. A similar cylinder of plumbago, two or three inches high, pierced with twenty-four holes of three-eighths of an inch bore.

7. A thin plate of plumbago, three inches in diameter, viz. of the same diameter as the cylinder of 5 and 6. It has a small hole in the middle, and being of soft material, the hole can be easily cut or filed to suit crucibles of any desired size.

To suit the larger kind of crucibles and furnaces, cylinders are made resembling the above in form, but of greater diameter.

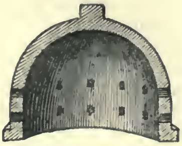
As in all cases the heating power of the gas-furnace spreads laterally and does not rise vertically, the most advisable form of the crucibles required for use in it, is *short* and *broad*, not tall and narrow, and the supporting cylinders must be shaped accordingly. No fire-bars or grates must be used to support the crucibles in this gas-furnace, because no material formed into narrow bars can sufficiently withstand its power of fusion and combustion.

8. A plumbago cylinder, or crucible jacket, two and a half inches high, two and a half inches in diameter, and a quarter of an inch thick in the walls. It has six holes of three-eighths of an inch diameter near one end.

9. A circular cover or dome (*fig.* 1009) flanged at the bottom, and having a knob or handle at the top. It is pierced with twenty-four holes of a quarter of an inch in diameter, arranged in two rows near the bottom. This dome, when of small size, is made of plumbago; when large, of fire-clay.

10. Plumbago crucibles made with a solid overhanging rim, the use of which is to suspend the crucibles over the gas-burner, by means of the cylinders Nos. 5 and 6. When the crucibles are too small to fit the cylinders, the flat-plate No. 7, is filed to fit the crucible, and is then placed on the cylinder, to whose diameter it is adapted.

1009



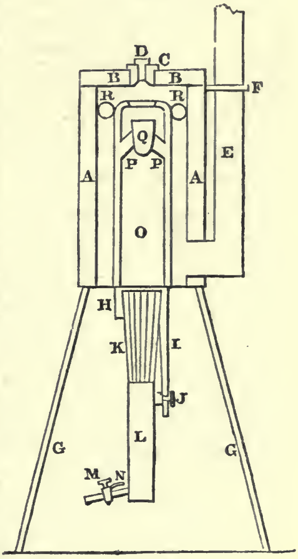
Besides these pieces of fire-clay and plumbago, it is necessary to be provided with a strong iron tripod, to sustain the furnace; an iron pan, in which to place the furnace; and a quantity of gravel, or rounded flints, not less than half an inch, nor more than one inch in diameter. These pebbles form an essential part of the gas-furnace.

Other forms of Griffin's gas-furnace will be found fully described in Watts's 'Dictionary of Chemistry.' See also Mr. Griffin's description of a gas-furnace for attaining a white heat without the aid of a blowing-machine, in Journ. of Chemical Soc., 1870, p. 280.

Mr. George Gore has patented a gas-furnace of great power, which he thus describes (*fig.* 1010):—A is a cylinder of fire-clay about nine inches high and six inches diameter, open at both ends, with a hole in its side near the bottom to lead into the chimney; it is covered by a moveable plate of fire-clay, B, with a hole in its centre for introduction or removal of the crucible, &c.; this hole is closed by a perforated plug of clay, C, for access to the contents of the crucible, and that again is closed by another clay stopper D. E is a chimney of sheet iron about five or six feet high, kept upright by a ring of iron, F, attached to the top of the furnace. The fire-clay cylinder is enclosed in a sheet-iron casing with a bottom of iron, to which are fixed three iron legs, G. An iron tube H, with a prolongation I, supports by means of the screw, J, the burner K, and its tube L, which is open at both ends. Gas is supplied to the burner by means of the tag, M, which has a small index, N, attached to it for assistance in adjusting the gas. Inside the larger cylinder is another fire-clay cylinder or cupola, O, with open ends, and with three projections of fire-clay, P, for supporting the crucible, Q; it is kept steady by means of three fire-clay marbles, R. The gas-burner is a thin metal cylinder, deeply corrugated at its upper end, with the corrugations diminishing to nothing at its lower end.

The action of this furnace is as follows:—Gas is admitted to the open tube, L, by the tap, M; it there mixes with air to form a nearly explosive mixture, which ascends through the burner, and burns in the clay cylinder, O, being supplied with the remainder of air necessary to complete combustion through the tube H, to the outer surface of the flame, by means of the spaces between the corrugations. The flame and products of combustion pass up through the cylinder O, and then downwards outside it to the chimney, the focus of greatest heat being at Q.

1010



It is important in using this furnace that the burner is placed quite in the centre of the bottom of the tube O; also that a crucible of not too large or not too small dimensions be selected. The most suitable way of supporting a smaller crucible is by placing it in a larger one that has had its upper parts broken off. If desirable, a little clay luting may be placed round the top edge of the iron casing to exclude air entering between it and the cylinder; also a little thin clay luting upon the part of the bottom of the furnace where the inner cylinder, O, rests.

In lighting the furnace, the plugs C and D are removed, a light held *inside* the opening, and the gas turned on full. Should the flame blow down to the bottom of the tube, L, on lighting (which, however, rarely occurs unless the furnace is already hot), the gas must be turned off, and the bottom of L momentarily closed whilst lighting the gas as before. Should the flame not burn down to the burner, but only burn at the orifice in the clay plate, B, it must at once be extinguished and relighted, otherwise some of the gaseous mixture will pass into the chimney unburned, and subsequently ignite and cause an explosion. A large flame now issues from the top orifice, and is white if too much gas is on, and chiefly violet or red with the proper quantity; it should now be coarsely adjusted until these appearances are presented. The annular plug, C, should now be inserted, which will compel it to pass downwards to the chimney, and as soon as the small remaining flame, now issuing, disappears or nearly disappears, as it will in a few seconds, the small stopper, D, should also be inserted. In lieu of this, the large flame may be deflected against the chimney by means of a piece of sheet-iron until it withdraws inwards as before mentioned; two plugs may then be reinserted. The gas-tap may now be partly adjusted. The crucible should be placed in the furnace after the act of lighting the gas, but not immediately after if the furnace is cold, or explosions may occur by unburned gaseous mixture passing the crucible into the chimney and igniting afterwards. After about five minutes the gas should be slowly adjusted, until a sound is heard inside like a series of small explosions. This sound is sometimes not very distinct, especially at high temperatures, and therefore requires a little experience in the use of the furnace in order to be detected. It is, however, a chief guide in determining the proper amount of gas, and should therefore be carefully studied. To assist in adjusting the gas, it will be found very useful to place a small piece of looking-glass beneath the tube, L, and to adjust the gas-tap until the flame between the burner and crucible appears wholly violet or slightly white; but this test is liable to fallacy if employed when the gas is just lighted, because the coldness of the part makes the flame much whiter than it otherwise should be. It is also fallacious, the flame appearing whiter than it really is when the crucible is very hot. It is, however, of great assistance, especially at intermediate temperatures. A rough deposit upon the outer edge of the crucible indicates an excess of gas: the deposit is carbon. Less gas is required with a crucible in the furnace than without one; also less is required when the small hole at the top of the furnace is open than when it is closed; and less is also required when the furnace is cold than after it has been lighted some time, because the draught gradually increases and draws in more air. After having accurately adjusted the gas, no further attention to the furnace is requisite.

Having once found the proper adjustment of gas under certain known conditions, it is well to notice the position of the index-pointer, N, in order to be able at once to adjust it to about the right point on other occasions.

Under ordinary circumstances, during daylight, I have found it best to set the gas nearly full on at first, and fully on at about five minutes afterwards, when the draught has become more powerful; but during twilight, when the supply of gas from the gas-works is more free, I have set the index-pointer at the numbers 2½ or 3. The gas should be supplied by a pipe of not less than three-eighths of an inch bore, with a main pipe of half an inch; but all depends upon the pressure of gas at the particular locality, which is very variable. The consumption of gas varies from thirty to forty cubic feet per hour, the value of which is about twopence.

The top of the chimney should be placed in a position where the products of combustion can pass freely away. If it is placed in an opening or pipe leading to another chimney, care must be taken not to have the draught too powerful, otherwise the heat will be drawn more into the chimney, and the supply of gas in the daytime may be found rather deficient. The furnace will act satisfactorily, though less powerfully, with the chimney standing in an open room without any special outlet for the products of combustion, provided the full height (6 feet) of chimney is employed. Under other circumstances I have generally used a chimney 4½ or 5 feet high.

This furnace will produce what is generally called 'a white heat;' it will readily melt half a pound of copper, or six ounces of cast iron. I have melted these quantities in it: it will melt as large a quantity of those substances as the largest sized crucible that can be introduced into it will contain, sufficient space being reserved around the crucible for draught. It requires from twenty to thirty minutes to acquire its highest temperature, and then *the entrance part of the chimney exhibits a faint red heat in daylight.* If it exhibits much more than this, the draught is too powerful, and if less, there is not sufficient gas.

When the small hole, D, is open, some air is drawn in that way, and less air passes up with the gas through the tube O, but the cold air does not much diminish the temperature of the crucible, because it combines with the excess of gas now passing over the edge of the inner cylinder; it, however, renders the flame round the crucible white by deficiency of air, and this should be partly corrected by lessening the gas. An excess of either gas or air renders the surface of melted copper dull.

When it is desirable to perfectly avoid contact of air with the fused substance during manipulation, a narrow crucible should be employed, and a thin and narrow ring of fire-clay should be placed upon the top of the tube O, to contract its opening; the flame then closes completely over the top of the crucible, and prevents access of air. A proper adjustment of gas, together with exclusion of air in this manner, enables a perfectly bright surface of melted copper, or even tin, to be continuously maintained, from which the images of parts above are clearly reflected. The clay ring may be withdrawn by lifting the plate B. A less perfect exclusion of air may be obtained by employing a narrow crucible placed rather low down in its support. A small iron dish should be placed beneath the tube L to receive any melted substance that may fall. The chief conditions of success in the use of this furnace are *sufficient gas, a suitable degree of draught*, and *proper regulation of gas to air*.

Several very ingenious furnaces for use in the laboratory or assay office are fully described in Watts's 'Dictionary of Chemistry.' See GAS-FURNACE.

FUR-SKIN DRESSING. Fur-skins are usually dressed by placing them in their dried state in closed tubs with a little salt butter, where they undergo a treading operation with men's feet until they are sufficiently soft, and bend easily. The skins if large are sewn up, the fur being turned inwards; but if small skins, such as ermine, are being dressed, they require no sewing. This sewing is preparatory to the greasing with butter or lard, and is intended to protect the fur from the grease, and to promote the softening in the succeeding treading operation. The skins are next wetted, and their flesh is removed; or they are fleshed. See CURRYING. They are again subjected to treading in tubs containing sawdust, that from mahogany being preferred; and afterwards in tubs containing plaster of Paris, or whitening, sprinkled between the skins. The main object of this is to remove the grease which has been used in the previous processes. They are then beaten with a stick and combed; when the dressing is completed. M. Pierre Thirion proposed to soften the skins, not by treading, but by beating stocks, of a construction like the fulling mill. They are next sewn up, and again filled in a strong vessel, where they are forced upwards by the beaters, turned over and over, and thus speedily softened. They are now fleshed, and then returned to the beating stocks, and mahogany or other sawdust is sprinkled upon the fur, before the beating is renewed. They are next placed in a heated barrel, furnished within with radial pins for turning the goods over and over, in order that they may be acted upon by various dry substances, which are thrown into the barrel, and absorb the fat from the skins. Through the hollow shaft of the barrel, steam is introduced, which heats the skins, softening the fat, which is then absorbed by sand, flour, or any other desiccative powder. It is proper to take the skins out of the barrel, from time to time, to comb them. Such as have been sufficiently acted upon may then be set aside. They are lastly freed from the dust by being subjected to a grated cylinder in a state of rotation, and then combed by hand.

FUSE. See FUZE.

FUSEES. A name given to a kind of lucifer-match which does not flame; this match is used exclusively by the smokers of tobacco. Bode of Vienna introduced them. A granule of powder, made of the same composition as the ordinary lucifer match, is placed at the end of a match, and a mixture of charcoal and nitrate of potash surrounds it. The granule is ignited by friction, and this fires the other mixture, which burns like quick-match.

FUSEL OIL. During the rectification of corn or grape spirits there is always separated a fiery fœtid oil of nauseous odour and taste. It is this substance which is the cause of the unpleasant effects which are produced upon most persons by even a small quantity of insufficiently-rectified whiskey or brandy. Any spirit which produces milkiness on the addition of four or five times its volume of water may be suspected to contain it. By repeated rectification every trace may be removed.

Fusel oil invariably consists of one or more homologues of the vinic alcohol, $C^4H^6O^2$ ($\mathbf{C^2H^6O}$), mixed with variable quantities of the latter substance and water. The nature of fusel oil varies much with the source from whence it is obtained. That which is ordinarily sold in this country for the purpose of yielding pear essence consists mainly of the amylic alcohol, $C^{10}H^{12}O^2$ ($\mathbf{C^5H^{12}O}$), mixed with from one-fourth to one-fifth of spirit of wine.

The progress of organic chemistry has been greatly assisted by the researches which have been made upon fusel oil, almost all the amylic compounds hitherto obtained having been directly or indirectly obtained from it.

To obtain fusel oil in a state of purity it is necessary, in the first place, to rectify it fractionally. By this means it will be found that much alcohol can be removed at once. If a great quantity of water and very little vinic alcohol be present, the simplest mode of purification is to shake it with water, by which means common alcohol is removed in solution, while the amylic alcohol, owing to its comparative insolubility, may be easily separated by the tap-funnel. After drying over chloride of calcium, it is to be again rectified once or twice, only that portion distilling at about 269°·6 Fahr. (132° Cent.) being received. The product of this operation is pure amylic alcohol, from which an immense number of derivations of the amylic series can be obtained. By treatment with sulphuric acid and bichromate of potash it is converted into valerianic acid. In this manner all the valerianic acid, now so much employed in medicine, is prepared. By distilling amylic alcohol with sulphuric acid and acetate of potash, we obtain the acetate of amyle, commercially known as jargonelle-pear essence.

The foreign fusel oils obtained from the grape-marc contain several homologues higher and lower in the series than the amylic alcohol. In fact, it would appear that during the fermentation of grapes there are formed, not only alcohols, but ethers and acids.

M. Chancel, by repeatedly rectifying the dehydrated and more volatile portions of the residues of the distillation of grape-marc alcohol, succeeded in isolating a fluid boiling at 205° Fahr. This proved to be true propionic alcohol. M. Wurtz has also been able to obtain the butylic alcohol by rectifying certain specimens of potato oil.

All fusel oils are not so complex. The author of this article has repeatedly examined specimens of English and Scotch fusel oil, which did not contain anything save the ethylic and amylic alcohols, accompanied by small portions of the acids, which are procured by their oxidation. M. Chancel has given the following equations, which explain the manner in which saccharine matters break up into homologous alcohols under the influence of ferments. I have reduced the unitary notation employed by him into the ordinary formulæ used in this country, in order to render the relations as clear as possible to the reader.

$$\underbrace{2C^{12}H^{12}O^{12}}_{\text{Glucose.}} = 8CO^2 + \underbrace{4C^4H^6O^2}_{\text{Alcohol.}}.$$

$$2C^{12}H^{12}O^{12} = 8CO^2 + C^4H^6O^2 + \underbrace{2C^6H^8O^2}_{\text{Propionic alcohol.}} + 2HO.$$

$$2C^{12}H^{12}O^{12} = 8CO^2 + \underbrace{2C^8H^{10}O^2}_{\text{Butylic alcohol.}} + 4HO.$$

$$2C^{12}H^{12}O^{12} = 8CO^2 + C^6H^8O^2 + \underbrace{C^{10}H^{12}O^2}_{\text{Amylic alcohol.}} + 4HO.$$

M. Chancel appears to consider the last equation as indicating the necessity of propionic alcohol being always formed wherever amylic alcohol is generated; but this is not in accordance with the results of those chemists who have examined crude amylic alcohol repeatedly for propionic alcohol, but without finding any. The formation of these interesting homologues appears therefore to depend upon special circumstances connected with the fermentation.

The caproic alcohol is also contained in certain varieties of fusel oil.

In order to assist those who may wish to examine the fluid alluded to, the following table of the physical properties of the alcohols, up as high as the caproic, has been inserted:—

Table of the Physical Properties of some Homologous Alcohols found in Fusel Oils.

Name	Observers	Formula		Boiling point	Specific Gravity	Vapour Density	
						Experiments	Calculation
Methylic .	Dumas and Peligot	$C^2H^4O^2$	CH^4O	152°	0·7980 at 68°	1·120	1·1072
Ethylic .	Gay-Lussac . .	$C^4H^6O^2$	C^2H^6O	172°	0·7938 at 60°	1·618	1·5916
Propionic .	Chancel . . .	$C^6H^8O^2$	C^3H^8O	205°	..	2·020	2·0760
Butylic .	Wurtz . . .	$C^8H^{10}O^2$	$C^4H^{10}O$	234°	..	..	2·5804
Amylic .	Balard and Dumas	$C^{10}H^{12}O^2$	$C^5H^{12}O$	270°	0·8184 at 59°	3·147	3·0448
Caproic .	Faget . . .	$C^{12}H^{14}O^2$	$C^6H^{14}O$	304°	0·8330 at 32°	3·530	3·5292

Fusel oil, in addition to these homologous alcohols, contains fatty acids. The following list contains the acids found in fusel oil, with the name of the observer:—

Name of Acid	Formula		Observer
Formic	$C^2H^2O^4$	$\mathbf{CH^2O^2}$	Wetherill
Acetic	$C^4H^4O^4$	$\mathbf{C^2H^4O^2}$	Kent
Valerianic	$C^{10}H^{10}O^4$	$\mathbf{C^5H^{10}O^2}$	Kent
Caproic	$C^{12}H^{12}O^4$	$\mathbf{C^6H^{12}O^2}$	Wetherill
Œnanthylic	$C^{14}H^{14}O^4$	$\mathbf{C^7H^{14}O^2}$	Mulder, Wetherill
Caprylic	$C^{16}H^{16}O^4$	$\mathbf{C^8H^{16}O^2}$	Wetherill
Capric	$C^{20}H^{20}O^4$	$\mathbf{C^{10}H^{20}O^2}$	Rowney
Margaric	$C^{34}H^{34}O^4$	$\mathbf{C^{17}H^{34}O^2}$	Kolbe

When 15 per cent. of fusel oil is found in alcohol it is admitted duty free; the determination of this is, therefore, a question of considerable importance. The method in use in the London Custom House for the determination of alcohol in fusel oil consists in shaking the liquid to be tested with an equal volume of water, and allowing it to stand twelve hours; at the expiration of which time it is found separated into two layers, the fusel oil being at the top. The specific gravity of the lower layer is taken, and from this the amount of proof spirit is calculated. This, Dr. Ulex says, leads to very false results, since crude fusel oil contains also ethylic, propylic, butylic, and amylic alcohol, which are variously soluble in water. He recommends the separation by fractional distillation, and the use of saturated solutions of sodic chloride (chloride of sodium). He places 100 c. c. of the fusel oil to be tested in a retort, and distils off 5 c. c., and shakes this with an equal quantity of a saturated salt solution. If, on standing, one half or more of the liquid is fusel oil we may be sure it contains less than 15 per cent. of proof spirit, which renders it free of duty in England. If less separates, shake some of the liquor with an equal quantity of brine, and allow it to stand; after separating, distil the spirit from the salt solution and determine.

Fusel oil has been patented as a solvent for quinine, but its odour, and more especially that produced by its oxidation, so persistently adheres to anything with which it has been in contact, that great care is requisite in the purification. It is remarkable, that at the first instant of smelling most specimens of fusel oil, the odour is not unpleasant, but in a very few seconds it becomes exceedingly repulsive, and provokes coughing.—C. G. W.

FUSIBILITY. That property by which solids assume the fluid state under the influence of heat. With a few exceptions, such as carbon and some organic bodies, all substances appear capable of assuming the fluid state. Although we do not appear to have actually fused charcoal by means of the voltaic battery, the diamond has been fused and converted from a crystalline gem into a mass of opaque coke.

Thénard has thus grouped the metals:—

1. Fusible below a red heat: *Mercury, potassium, sodium, tin, bismuth, lead, tellurium, arsenic, zinc, antimony, cadmium.*

2. Infusible below a red heat: *Silver, copper, gold, cobalt, iron, manganese, nickel, palladium, molybdenum, uranium, tungsten, chromium, titanium, cerium, osmium, iridium, rhodium, platinum, columbium.*

Pouillet has, in his admirable treatise on Heat, given the following table of the fusing points of various substances:—

Names	Centigrade
Mercury	— 39
Oil of Turpentine	— 10
Ice	0
Tallow	33 to 38
Acetic acid	45
Spermaceti	49
Stearine	49 to 43
Margaric acid	55 to 60
Unbleached wax	61
White wax	68
Stearic acid	70
Phosphorus	43
Potassium	58
Sodium	90
Iodine	107
Sulphur	114
Tin	230

Names	Centigrade.
Bismuth	202
Lead	320
Zinc	360
Antimony	432
Bronze	900
Silver, very pure	1000
Standard gold	1180
Very fine gold	1250
White cast iron, very fusible	1050
White cast iron, second fusion	1200
Grey cast iron, very fusible	1100
Grey cast iron, second fusion	1200
Manganesed cast iron	1250
The more fusible steels	1300
The less fusible steels	1400
Soft iron (French)	1500
English hammered iron	1600

FUSIBLE METAL. This alloy owes its peculiar property of melting at a comparatively low temperature to the presence of bismuth.

8	parts of bismuth,	5	of lead,	3	of tin	melt at 212° F.
2	do.	1	do.	1	do.	do. 201° F.
5	do.	3	do.	2	do.	do. 199° F.

8 do. 5 do. 4 of tin, and one of type metal is an alloy much used on the Continent for producing casts of metals by the *clichée* process. A mixture of bismuth, lead, tin, and antimony is used in this country for obtaining copies from wood-blocks. Mr. Cowper used 1 of bismuth and 2 of tin to make the alloy most suitable for rose engine and excentric turned pattern, to be printed from after the manner of letter-press. A good fusible alloy consists of—cadmium 2 parts, bismuth 8 parts, tin 2 parts, lead 4 parts; melts at 160° F.

The soft solders used by pewterers consist of tin, lead, and bismuth in various proportions; indeed, bismuth enters to a greater or a less extent into all the soft solders.

Fusible metal has also been employed as a sort of safety valve for steam-boilers. By adjusting the proportions of the above-named metals, an alloy can be made which will melt at any required temperature; therefore, when the boiler rose to this temperature, the metal plug gave way and the steam escaped. See Alloy.

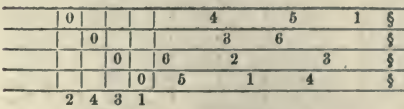
FUSTIAN is a species of coarse thick tweeled cotton, and is generally dyed of an olive, leaden, or other dark colour. Besides the common fustian, which is known by the name of pillow (probably pilaw), the cotton stuffs called corduroy, velveret, velveteen, and thickset, used for men's wearing apparel, belong to the same fabric. The commonest kind is merely a tweel of four, or sometimes five leaves, of a very close stout texture,, and very narrow, seldom exceeding 17 or 18 inches in breadth. It is cut from the loom in half pieces, or ends as they are usually termed, about 35 yards long, and after undergoing the subsequent operations of dyeing, dressing, and folding, is ready for the market.

The draught and cording of common fustian is very simple, being generally a regular or unbroken tweel of four or five leaves. Below are examples of a few different kinds, selected from those most general in Lancashire.

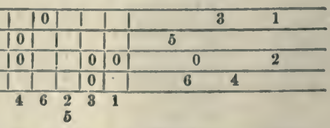
The number of leaves of heddles are represented by the lines across the paper, and the *cording* by the cyphers in the little squares, those which raise every leaf being distinguished by these marks, and those which sink them left blank, as more particularly explained in the article Textile Fabric.

When the material is silk, it is called velvet; when cotton, velveteen. A common tweeled cloth, when composed of silk is called satin; when of cotton, fustian or jean; of woollen, plaiding, serge, or kerseymere.

No. 1.—Pillow Fustian.



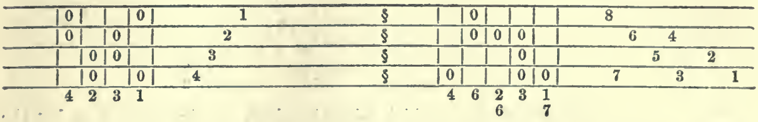
No. 2.—Plain Velveret.



Of the above, each contains four leaves of heddles or healds: that represented by No. 1 is wrought by four treddles, and that which is distinguished by No. 2, by five;

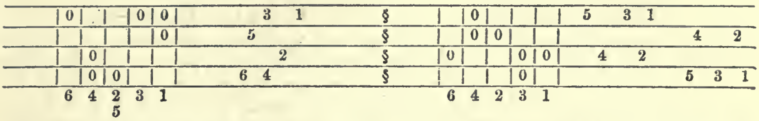
the succession of inserting the threads of warp into the heddles will be discovered by the figures between the lines, and the order in which the treddles are to be successively pressed down by the figures below.

No. 3.—Double Jean. No. 4.—Plain Thickset.



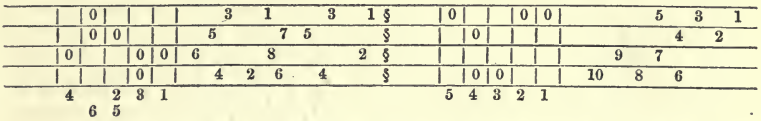
These, like the former, are wrought with leaves. No. 3 requires four, and No. 4 five treddles. The succession of inserting the threads of warp, and of working the treddles, are marked by the respective numbers between and under the lines, as in the former example. Both are fabrics of cloth in very general use and estimation as low-priced articles.

No. 5.—Best Thickset. No. 6.—Velvet Tuft.



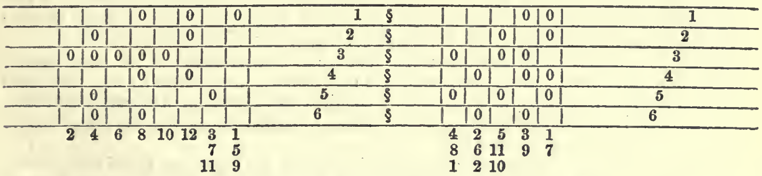
These are further specimens of what may be, and is, executed with four leaves, and in both examples five treddles are used. With two other specimens we shall conclude our examples of this description of work, and shall then add a very few specimens of the more extensive kinds.

No. 7.—Cord and Velveret. No. 8.—Thickset Cord.



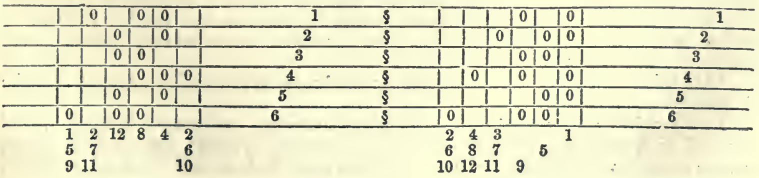
In these the succession of drawing and working are marked like the former. The next are examples of patterns wrought with six leaves. No. 9 has eight, and No. 10 five heddles.

No. 9.—Double Corduroy. No. 10.—Genoa Thickset.



In both these the warp is inserted into the heddles the same way. The difference is entirely in the application of the cords, and in the succession of pressing down the treddles. We now give four specimens of the flushed and cut work, known by the name of velveteen. They are also upon six leaves, and the difference is solely in the cording and in the treading.

No. 11. Queen's Velveteens. No. 12.



No. 13.—Plain Velveteen. No. 14.—Genoa Velveteen.

The additional varieties of figure which might be given are almost endless, but the limits of this article will not admit a further detail. Those already given are the articles in most general use. The varieties of fancy may be indulged to great extent, but it is universally found, that the most simple patterns in every department of ornamental weaving, are those which attract attention and command purchasers. We shall therefore only add an example of king's cord or corduroy, and of Dutch cord, with one of Genoa and one of common velvet, to show the peculiarities.

No. 15.—King's Cord. No. 16.—Dutch Cord.

After the fustian cloth is taken from the loom-beam, it is carried to the cutter, who, rips up the surface-threads of weft, and produces thereby a hairy-looking stuff.

Preparatory to its being cut, the cloth is spread evenly upon a table about six feet long, upon each end of which a roller mounted with a ratchet-wheel is fixed: the one to give off, and the other to wind up the piece, in the above six-feet lengths.

The knife is a steel rod about two feet long, and three-eighths of an inch square, having a square handle at the one end; the other end is tapered away to a blade, as thin as paper. To prevent this point from turning downwards and injuring the cloth, its under side is covered by a guide which serves to stiffen it, as well as to prevent its lower edge from cutting the fustian.

The operative (male or female) grasps the handle in the right hand, and insinuating the projecting point of the guide under the weft, pushes the knife smartly forward though the whole length of six feet, with a certain dexterous movement of the shoulder and right side, balancing the body meanwhile, like a fencer, upon the left foot. This process is repeated upon every adhesive line of the weft.

The next process to which fustians are exposed is steeping in hot water, to take out the dressing paste. They are then dried, reeled, and brushed by a machine, &c. From twenty to thirty pieces, each eighty yards long, may be brushed in an hour. The breadth of the cloth is twenty inches. The maceration is performed by immersing the bundled pieces in tanks of water, heated by waste steam; and the washing by means of a reel or winch, kept revolving rapidly under the action of a stream of cold water, for an hour or longer.

After being thus ripped up, it is taken to the brushing or teazling machine, to make it shaggy.

This consists of a series of wooden rollers, turning freely upon iron axles, and covered with tin-plate, rough with the burs of punched holes; and blocks of wood, whose concave under surfaces are covered with card-cloth or card-brushes, and which are made to traverse backwards and forwards in the direction of the axes of the revolving rollers, during the passage of the cloth over them.

After they are brushed in the machine, the goods are singed by passing their cut surface over a cylinder of iron, laid in a horizontal direction, and kept red hot by a flue. They are now brushed again by the machine, and once more passed over the singeing surface. The brushing and singeing are repeated a third or even occasionally a fourth time, till the cord acquires a smooth polished appearance.

The goods are next steeped, washed, and bleached by immersion in solution of chloride of lime. They are then dyed by appropriate chemical means. After which they are padded (imbued by the padding machine of the calico-printers) with a solusition of glue, and passed over steam cylinders to stiffen them.

Smooth fustians, when cropped or shorn before dyeing, are called moleskins; but when shorn after being dyed, are called beverteen; they are both tweeled fabrics. Cantoon is a fustian with a fine cord visible upon the one side, and a satiny surface of yarns running at right angles to the cords upon the other side. The satiny side is sometimes smoothed by singeing. The stuff is strong, and has a very fine aspect.

FUSTIC, or *Yellow Wood.* (*Bois jaune*, Fr.; *Gelbholz*, Ger.) The *old fustic* of the English dyer. It is the wood of the *Morus tinctoria.* It is light, not hard, and pale yellow with orange veins; it contains two colouring matters, one resinous, and another soluble in water. Chevreul has given the name of *morin* to the colouring matter obtained from fustic. It is procured by boiling ground fustic in distilled water, passing the decoction rapidly through a filter, and allowing the liquid to stand for several days, when the colouring matter (*morin*) is precipitated.

The decoctions of fustic in water are brightened by the addition of a little glue, and still more so by curdled milk. This wood is rich in colour, and imparts permanent dyes to woollen stuffs, when aided by proper mordants. It unites well with the blue of the indigo vat, and Saxon blue, in producing green of various shades. Alum, tartar, and solution of tin, render its colour more vivid; sea-salt and sulphate of iron deepen its hue. From 5 to 6 parts of old fustic are sufficient to give a lemon colour to 16 parts of cloth. This wood is often employed with sulphate of iron in producing olive and brownish tints, which agree well with its dull yellow. For the same reason it is much used for dark greens.

The bichromates of potash and of lead have nearly superseded the use of fustic, but still it is employed for producing some green in cotton yarn, and in light cotton fabrics, as gauzes and muslins.

FUSTIC, YOUNG. (*Fustet*, Fr.) The wood of the *Rhus cotinus*, a shrub which grows principally in the south of France and in Italy, called also *Venetian sumach.* This wood contains a large quantity of yellow colouring matter, named *fusteric.* This colouring matter has a strong attraction for oxygen, which affects its use as a dye, rendering it very fugitive. It is rarely used alone, but as an assistant to strike some particular tint.

FUSTIN. A name given to the colouring matter of the *Rhus cotinus* or young fustic.

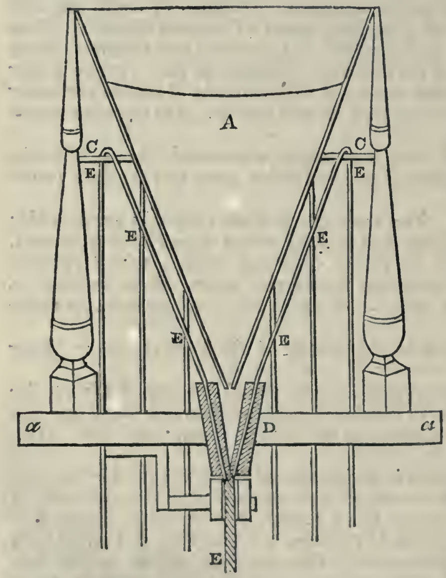
FUZE. Gunpowder, or some other explosive agent placed in a case or tube, to fire the powder placed in the cannon, or in the hole bored in rocks for blasting. See ELECTRICITY, BLASTING BY, for a description of Abel's fuzes. See also FUZE, SAFETY.

FUZE, SAFETY. The safety fuze is an instrument manufactured for the purpose of conveying fire to the charge in blasting. It is made of flax with a column of fine gunpowder in its centre, and appears like a hard, varnished cord. To use it—one end of the required length is placed in the charge, and the hole is tamped with any soft substance which will not cut the fuze. Fire must be applied to the fuze itself, which slowly and surely burns to the charge, if care has been taken to select that kind of fuze which the operation requires. It then affords the very best means of blasting ever devised, combining certainty, economy, and safety. The safety fuze was the invention of Mr. Bickford, who thus describes it in the specification of his process:—

'I embrace in the centre of my fuze, in a continuous line throughout its whole length, a small portion, or compressed cylinder, or rod of gunpowder, or other proper combustible matter prepared in the usual pyrotechnical manner of firework for the discharging of ordnance; and which fuze so prepared, I afterwards more effectually secure and defend by a covering of strong twine made of similar material, and wound thereon, at nearly right angles to the former twist, by the operation which I call countering, hereinafter described; and I then immerse them in a bath of heated varnish, and add to them afterwards a coat of whiting, bran, or other suitable powdery substance, to prevent them from sticking together, or to the fingers of those who handle them; and I thereby also defend them from wet or moisture, or other deterioration, and I cut off the same fuze in such lengths as occasion may require for use; each of these lengths constituting, when so cut off, a fuze for blasting of rocks and mining, and I use them either under water or on land, in quarries of stone and mines for detaching portions of rocks, or stone, or mine, as occasions require, in the manner long practised by, and well known to, miners and blasters of rocks.

‘At the left-hand end of an apartment which is 65 ft. long, is made an enclosed recess or closet of about 2 ft. square, and 6 ft. high, with a door or doors in front; in which closet, at about the height of 4 ft. 10 in., is placed a wooden shelf, about 1 in. thick at least, extending the whole length and breadth of such closet. In the centre of this shelf is made a hole, into which hole is inserted a collar. This collar is of metal, in form the frustum of a cone inverted. It is 3 in. long, 2 in. diameter at the upper end, and $1\frac{1}{4}$ in. at the bottom; through the centre of this is a hole of $\frac{3}{4}$ an inch diameter at the top, and $\frac{3}{16}$ths of an inch diameter at the bottom. Around this in a circle are twelve holes of about $\frac{1}{8}$th of an inch diameter, which converge towards a centre hole at the bottom, so as to be separated from it only by a fine edge of metal. *Fig.* 1011, D is a vertical section of the collar; this collar when placed in the hole in the shelf *a a*, projects both above and below the wooden shelf. In the upper projecting part of the cone or collar is then to be placed a common funnel, A, 12 in. high, and 10 in. in diameter at the top; around this funnel, at about 10 in. high from the before-mentioned shelf, is placed a ring made of cane, marked C C, and supported by a small frame of two or more pillars, resting on the before-mentioned shelf. At about 2 ft. 6 in. high from the floor of this room, and passing through the said closet, and extending the whole length of the said room, 65 ft. long, is a stage or shelf, or bench; the outside of this stage, or shelf, or bench, has a ledge or raised edge rising 1 in. above its surface, and on a similar raised edge on the inside, rising $1\frac{1}{2}$ in., is a line rack with teeth or cogs, twenty teeth to a foot. This stage, or shelf, or bench, is intended to support thereon a machine, being part of the apparatus thus used by me in my invention, called the monkey; which monkey consists, first, of a plane piece of board 20 in. long and 6 in. wide, supported by, and running on, three wheels of $1\frac{1}{2}$ in. diameter: on this board, supported by, and turning in, two centres, is a transverse axle placed quite across the plane bed of the monkey, supported by brackets, and turning round in holes made in the brackets, on the inside end of which is fixed a wheel of 10 in. diameter. Close to this wheel, and directly over the line rack, is placed on the said axle a pinion, which works on the cogs of the line-rack, on the side of which wheel at its outer edge are twenty-four teeth or cogs; these teeth or cogs work into corresponding teeth on the inner circle of another wheel, which has two circles of teeth or cogs, the inner and smaller circle working as already described, in those of the former wheel, and the outer circle of cogs working into a second pinion: connected with this pinion is a crook, and to the crook the threads of twine or other material are attached for twisting. A string or cord is fastened to the board of the monkey, and stretching along the stage, or shelf, or bench, passes over a pulley, and returning through holes made in the supports of the stage, or shelf, or bench, is attached to a winding roller; in this situation of the apparatus twelve balls of twine or other material intended to form the fuze are placed in the recess or closet on a floor raised there for that purpose 6 in. higher than the floor of the room, and the running threads from these balls are each led perpendicularly up through holes of 1 in. diameter, made for that purpose in a circle of 12 in. diameter in the shelf in which the before-mentioned collar is placed, and also perpendicular to and passed from the out-

1011



side to the inside over the said cane ring next to the funnel hereinbefore mentioned, and from thence the said threads are again led down by the side of the funnel to and through the holes in the upper and under sides of the aforesaid collar, which threads will then converge towards the lower point of the inner cone or collar, and there hang parallel and near to each other, and from thence they are to be led together to the pulley. Thence passing under the said pulley at a right angle they go to the monkey on the stage, or shelf, or bench, and are there made fast to the crook. The winding roller being now put in motion, communicates that motion to the monkey, which travels on the stage, or shelf, or bench, and at the same time by the pinion working on the line-rack; the cog-wheels before mentioned work the second pinion, and turning thereby the crook, completely twist the twelve threads (*Fig.* 1011) so made fast together, and continue that very twist up to the very point of the cone projecting downwards from under the funnel; at the very same time of putting the monkey in motion the funnel is charged with the gunpowder or other combustible matter for making the fuze, and then it is important to carefully watch the progress of the threads, and prevent or rectify any entanglement thereof; and also regulate the exit of the powder and prevent the dispersion of any surplus that falls to waste through the point of the cone or collar under the funnel during the operation of twisting. In this operation of twisting the powder passing the funnel lodges in the centre of the twelve threads, and is simultaneously embraced by all the threads, and the twisted part thus containing the powder is by the monkey drawn down and passes under the pulley, and continues its course with the monkey twisting the fuze along the stage, or shelf, or bench, to the end of the room. Here the monkey stops, and this part of the fuze so charged and twisted is then cut off, over a box placed on the said stage, or shelf, or bench, to receive any gunpowder or other combustible matter used therein that may fall from the ends when so cut asunder, the two ends thus separated are secured by a knot or tie made on each; the part so twisted and separated is put aside for the subsequent operation of "countering." By the monkey just described only one fuze could be spun at the same time, whereas it is desirable that several fuzes should be spun at once.

'Our second improvement in manufacturing fuzes relates to the mode of introducing the gunpowder. According to the method described in the said specification the gunpowder is not supplied from the funnel with the rapidity, regularity, and certainty which may be attained by our improvement. We introduce into the centre of the fuze a small strong thread or yarn, smaller and less fibrous than the yarns employed for the fuze. The thread or yarn which we employ is that known as No. 135 white-brown thread. This we supply from a reel or other source conveniently placed above the funnel containing the gunpowder. This thread or yarn is passed down through the gunpowder, and spun into the centre of the fuze by being attached to the monkey and drawn on with it as the fuze is spun. By means of this thread, so drawn on as the fuze is spun, the gunpowder in the lower part of the funnel is constantly kept in motion, and travels on with the threads so as to flow regularly down into the fuze. By this means the continuity and regularity of the cylinder of gunpowder is ensured.

'Our third improvement relates to the coating or varnishing applied to those fuzes which are to be used for blasting in dry ground, and in close or confined situations, or which are subject to considerable variation in temperature. The coating or varnishing heretofore applied, consisting of tar or resin, burns with a great deal of smoke and heat, and is affected by changes of temperature. Instead of a coating or varnish of either of those materials, we take 4 lbs. of best glue, and 2 lbs. of yellow soap, and having dissolved them in 12 gallons of water by a gentle heat, we add 56 lbs. of whiting, to give it a body. The varnish so made is applied to the fuzes by any suitable arrangement. The new varnish not being waterproof must not be employed for fuzes which are to be immersed in water; but, being less affected by temperature than the old varnish, and being non-inflammable, or burning with little smoke, is much preferable for general purposes. After the fuze has been coated or varnished with tar or resin varnish, and before the coating is hard or quite set, the fuze is fastened to crooks and made to revolve as if for countering, and a strip of brown paper is wound around the fuze in a spiral form, so as to completely envelope and cover the whole surface of the fuze. A thread is then wound round over the paper, which fixes the paper and prevents it shifting; another coat of tar or resin varnish is then applied to the paper, and by this means the fuze may be completely waterproofed, and protected against the action of the water.'

The following are the principal varieties of the safety fuzes in general use for special purposes:—

Common Safety Fuze.—This is the smallest kind of fuze which is made, and is only adapted for immediate use in dry ground, where the utmost care is taken in its application, and where the tamping is of a soft and homogeneous character, and is cautiously packed into the hole. In such circumstances it may be usefully employed.

Patent Safety Fuze.—This fuze is adapted for all blasting in dry ground, being made with an ample quantity of the best materials. When kept at a moderate temperature and carefully used, its operation is certain.

Ditto (2).—This is the same fuze as the preceding, and is only adapted to the same kind of blasting, but is specially varnished for any given climate. That varnish which is suitable for a cold country becomes soft and sticky if exposed to much heat; while that which is suitable for a hot country becomes hard and brittle if exposed to great cold. This inconvenience is remedied, as far as possible, by the special preparation of the varnish to suit any given temperature.

Patent Taped Sump Fuze.—This fuze is adapted for use in wet ground, and is specially protected so as to operate effectively even when the tamping is saturated with water. In such cases the charge of gunpowder should be placed in a cartridge, the end of the fuze should be inserted into the centre of the charge, and the junction of the fuze with the cartridge should be properly protected with a waterproof varnish. If employed in this manner, its certain operation is warranted.

Patent Double-Taped Sump Fuze.—This fuze is covered with a second coating of tape and varnish, and is intended for blasting in very wet ground.

Patent Gutta-Percha Fuze.—This fuze is adapted to sub-aqueous blasting.

Patent Taped Gutta-Percha Fuze.—This is the same fuze as the last, and is adapted to the same use and duty; but, having an exterior coating of tape and varnish which delays the oxidation of the gutta-percha, it retains its efficiency for a much longer time. It is therefore well adapted for service in distant countries.

In all sub-aqueous operations great care must be taken that the union of the fuze and cartridge be by a perfectly water-tight joint, and the fuze must be strengthened as much as possible both at and near the place of junction, else its swaying to and fro is very likely to break the joint, which would allow the water to soak into the charge.

G

GABBRO. An Italian name originally applied to a serpentine containing diallage, but now extended to a class of rocks consisting essentially of a triclinic felspar and an augite. The felspathic mineral is generally either labradorite or anorthite, but is in some cases represented by Saussurite; whilst the augitic constituent is either diallage or smaragdite. Hypersthene-rocks are also included by some writers under the term of gabbro.

GABIAN OIL. A mineral naphtha exuding from a bituminous shale at Gabian in Languedoc.

GABRONITE, is a yellowish stony substance of a greasy lustre. This mineral is distinguished by the large quantity of soda which it contains; its constituents being, silica, 54; alumina, 24; soda, 17·25; magnesia, 1·5; oxide of iron, 1·25; water, 2. It is most probably a variety of Scapolite.

GAD. A miner's tool; a pointed wedge having its sides of a parabolic figure.

GADIDÆ. The cod-fish family. This family of fishes is one of great importance to man. The value of the fisheries established in various parts of the northern seas is very great. The common cod, *Morrhua vulgaris*, is one of the most important species of this family. The catching and curing of this fish give employment to thousands. The haddock (*Morrhua æglefinus*) is nearly allied to, although smaller than, the cod. The coal-fish (*Merlangus carbonarius*) is much less valuable than either the cod or haddock. It is a coarse fish, and derives its name from the dusky pigment which tinges the skin, and soils the fingers like moist coal. The whiting (*Merlangus vulgaris*) is a well-known fish, forming a delicate article of food. The hake or stock fish (*Merlucius vulgaris*) is caught very abundantly on our southern coasts, and forms a valuable article of food; prejudice alone keeps it from taking its place at the tables of the wealthier classes. The ling (*Lota molva*) is caught in abundance around the Scilly Isles and the coast of Scotland, forming a considerable article of commerce. The torsk (*Brosmius brosme*) is found in great quantity around the Shetland Isles, where it is much prized. The best cod-liver oil is obtained from the livers of this fish. See COD.

GADOLINITE, called also *Yttrite* and *Ytterbyite*, is a mineral of a black, brownish, or yellowish colour, granular, or compact, with vitreous and conchoidal fracture; of sp. gr. 4·0 to 4·5, readily scratching glass; at the blowpipe it forms an opaque glass, sometimes with intumescence, but does not fuse into a bead. It is remarkable for containing from 45 to 55 per cent. of the earth yttria; its remaining constituents being silica, 25·8; oxide of cerium, 17·92; oxide of iron, 11·43. This mineral, which is very rare, is found in Sweden; also at Disko in Greenland; in the south of Norway; and near Galway. Its peculiar constituent was discovered by Professor Gadolin, after whom it is named.

GAGATES. The name by which jet was known to the ancients, derived probably from Gagis, a town in Lycia, where it was said to have been found. See JET.

GALACTITE, so called from its giving the colour of milk to water, when triturated with that fluid; analyses have shown it to be a variety of natrolite. See NATROLITE.

GALACTOMETER, or **LACTOMETER**, is an instrument to ascertain the quality of milk; an article often sophisticated in various ways. Fresh milk, rich in cream, has a less specific gravity than the same milk after it has been skimmed; and milk diluted with water becomes proportionally lighter. Hence, when our purpose is to determine the quantity of cream, the galactometer may consist merely of a long graduated glass tube standing upright upon a sole. Having filled 100 measures with the recent milk, we shall see, by the measures of cream thrown up, its value in this respect. A delicate long-ranged glass hydrometer, graduated from 1·000 up to 1·060, affords the most convenient means of detecting the degree of watery dilution, provided the absence of thickening materials has been previously ascertained by filtration. Good fresh milk indicates from 1·030 to 1·032; when the cream is removed, 1·035 to 1·037. When its density is less than 1·028, we may infer it has been thinned with water.

GALACTOSE. A saccharine substance obtained by boiling sugar of milk with dilute acids.

GALBANUM is a gum-resin, which exudes either spontaneously or from incisions made in the stem of a plant of the family of *Umbelliferæ*, which grows in Africa, particularly in Ethiopia. The source of this gum-resin is not distinctly known, but is believed to be the *Ferula galbaniflua*. Galbanum contains 67 of resin; 19·3 of gum; 6·4 of volatile oil and water; 7·5 of woody fibres and other impurities; with traces of acid malate of lime.

GALENA (*Plomb sulfuré*, Fr.; *Bleiglanz*, Ger.) is a sulphide (sulphuret) of lead. It is of a lead-grey colour, crystallises in the cubical system, and is susceptible of cleavages parallel to the faces of the cube; sp. gr. 7·7592; fusible at the blowpipe with exhalation of sulphureous vapours; is easily reduced to metallic lead. Nitric acid first dissolves it, and then throws down sulphate of lead as a white precipitate; the solution affording with plates of zinc brilliant laminæ of lead (*arbor Saturni*). It consists of sulphur, 13; lead, 85; with a little iron, and generally a small quantity of silver. This is the richest ore of lead, and it occurs in almost every geological formation, in veins, in masses, or in beds. Galena in powder, called *Alquifoux*, is employed as a glaze for coarse earthenware. See LEAD.

GALIPOT is a name of a white semi-solid viscid resin, found on fir-trees; or an inferior sort of turpentine, poor in oil.

GALL OF ANIMALS. A peculiar fluid, called also *bile*, secreted by the cells of the liver; it is taken up by the biliary ducts, which unite to form the hepatic duct, by which the secretion is either discharged directly into the duodenum, or is conveyed through the cystic duct into the gall bladder, wherein it becomes accumulated, and to some extent inspissated. Gall or bile from different animals finds several uses in the arts. It is used for cleansing woollen goods, and by artists it is employed to ensure the uniform spreading of water colours upon paper. For the constitution of the gall of different animals, see Watts's 'Dictionary of Chemistry.' See BILE.

GALL OF GLASS, called also *Sandiver*, is the neutral salt skimmed off the surface of melted crown glass; which, if allowed to remain too long, is apt to be reabsorbed in part, and to injure the quality of the *metal*, as the workmen call it. See GLASS.

GALLATES. Salts consisting of gallic acid combined with bases; the most important being that with oxide of iron, constituting a principal part of the black dye.

GALLERY, *in mining*, an underground horizontal excavation.

GALLIARD, a North of England term for a hard, smooth, flinty grit.

GALLIC ACID is the peculiar acid extracted from gall-nuts. See GALL-NUTS.

GALLIPOLI OIL is a coarse olive oil, containing more or less mucilage, imported from a seaport so named, of the province of Otranto, in the kingdom of Naples. See OLIVE OIL.

GALL-NUTS or **GALLS** (*Noix de Galle*, Fr.; *Galläpfel*, Ger.) are excrescences found upon the leaves and leaf-stalks of a species of oak, called *Quercus* *infectoria*, which grows in the Levant. They are produced in consequence of the puncture of the female of the gall-wasp (*Cynips folii quercus*), made in order to deposit her eggs; round which the juice of the tree exudes, and dries in concentric portions. When the insect gets fully formed, it eats through the nut and flies off.

The Levant galls are of two different appearances and qualities; the first are heavy, compact, imperforated, the insect not having been sufficiently advanced to eat its way through the shell; prickly on the surface; of a blackish or bluish green hue; about the size of a musket-ball. These are called *black*, blue, or Aleppo galls. The second are light, spongy, pierced with one or more holes; smooth upon the surface, of a pale greyish or reddish yellow colour, generally larger than the first, and are called *white* galls; but they are inferior to the former, and great care should be taken in the purchase of the best quality, for these are often dyed by dishonest traders to imitate the best blue Aleppo galls, but the fraud may be detected by the small hole made by the insect in the white galls, so that if the blue galls have holes, we may be sure they are not genuine.

Besides the galls of the Levant, others come from Dalmatia, Illyria, Calabria, &c.; but they are of inferior quality, being found upon the *Quercus cerris*; they are smaller, of a brownish colour, and of inferior value. The farther south the galls are grown, the better they are reckoned.

The galls of the *Quercus cerris* and common oak (*Galles à l'épine*, Fr.; *Knoppern*, Ger.) are of a dark-brown colour, prickly on the surface, and irregular in shape and size. They are used chiefly for tanning in Hungary, Dalmatia, and the southern provinces of the Austrian States, where they abound.

Galls consist principally of three substances: tannin, or tannic acid; yellow extractive; and gallic acid. Their decoction has a very astringent and unpleasant bitter taste. The following are their habitudes with various reagents:—

Litmus paper is powerfully reddened. Stannous chloride (protomuriate of tin) produces an Isabel-yellow precipitate. Alum: a yellowish grey precipitate. Acetate of lead: a thick yellowish white precipitate. Acetate of copper: a chocolate-brown precipitate. Ferric sulphate (red sulphate of iron): a blue precipitate. Sulphuric acid: a dirty yellowish precipitate. Acetic acid brightens the muddy decoction.

Tannin or tannic acid is prepared as follows: Into a long narrow glass adopter tube, shut at its lower orifice with a cotton wick, a quantity of pounded galls is put, and slightly pressed down. The tapering end of the tube being inserted into a matrass or bottle, the vacant upper half of the tube is filled with sulphuric ether, and then closed with a ground-glass stopper. Next day there will be found in the bottle a liquid in two distinct strata; of which the more limpid occupies the upper part, and the other, of a syrupy consistence and amber colour, the lower. More ether must be filtered through the galls, till the thicker liquor ceases to augment. Both are now poured into a funnel, closed with the finger, and after the dense liquor is settled at the bottom, it is steadily run off into a capsule. This, after being washed repeatedly with ether, is to be transferred into a stove chamber, or placed under the receiver of an air-pump to be evaporated. The residuary matter swells up in a spongy crystalline form of considerable brilliancy, sometimes colourless, but more frequently of a faintly-yellowish hue.

This is pure tannin, which exists in galls to the amount of from 40 to 45 per cent. It is indispensable that the ether employed in the preceding process be previously agitated with water, or that it contain some water, because by using anhydrous ether, not a particle of tannin will be obtained.

Tannic acid is a white or yellowish solid, inodorous, extremely astringent, very soluble in water and alcohol, much less so in sulphuric ether, and uncrystallisable. Its watery solution, out of contact of air, undergoes no change; but if, in a very dilute state, it be left exposed to the atmosphere, it loses gradually its transparency, and lets fall a slightly-greyish crystalline matter, consisting almost entirely of gallic acid. For procuring this acid in a perfectly pure state, it is merely necessary to treat that solution thus changed with animal charcoal, and to filter it in a boiling state, through paper previously washed with dilute muriatic acid. The gallic acid will fall down in crystals as the liquid cools.

If the preceding experiment be made in a graduated glass tube containing oxygen over mercury, this gas will be absorbed, and a corresponding volume of carbonic acid gas will be disengaged. In this case the liquor will appear in the course of a few weeks as if traversed with numerous crystalline colourless needles of gallic acid.

Tannin or tannic acid consists of carbon, 51·56; hydrogen, 4·20; oxygen, 44·24.

From the above facts it is obvious that gallic acid does not exist ready formed in gall-nuts, but that it is produced by the reaction of atmospheric oxygen upon the tannin of these concretions.

Gallic acid is a solid, feebly acidulous and styptic to the taste, inodorous, crystallising in silky needles of the greatest whiteness; soluble in about 100 times its weight of cold, and in a much smaller quantity of boiling water; more soluble in alcohol than in water, but little so in sulphuric ether.

Gallic acid does not dissolve the salts of protoxide of iron, but it forms, with the sulphate of the peroxide, a dark blue precipitate, much less insoluble than the tannate of iron.

GALMEI. German mineralogists usually recognise the silicate of zinc (Smithsonite) under this name. See Zinc.

GALVANISED IRON. This is the name, improperly given, first in France and subsequently adopted in this country, to iron coated with zinc by a peculiar patent process.

In 1837 Mr. H. W. Crawfurd patented a process for zincing iron. In the 'Repertory of Patent Inventions' his process is thus described:—Sheet iron, iron castings, and various other objects in iron are cleaned and scoured by immersion in a bath of water, acidulated with sulphuric acid, heated in a leaden vessel, or used cold in one of wood, just to remove the oxide. They are then thrown into cold water, and taken out one at a time to be scoured with sand and water with a piece of cork, or more usually with a piece of the husk of the cocoa-nut, the ends of the fibres of which serve as a brush, and the plates are afterwards thrown into cold water.

Pure zinc covered with a thick layer of sal-ammoniac is then melted in a bath, and the iron, if in sheets, is dipped several sheets at a time in a cradle or grating. The sheets are slowly raised to allow the superfluous zinc to drain off, and are thrown whilst hot into cold water, on removal from which they only require to be wiped dry.

Thick pieces are heated, before immersion, in a reverberatory furnace, to avoid cooling the zinc. Chains are similarly treated, and on removal from the zinc require to be shaken until cold to avoid the links being soldered together. Nails and small articles are dipped in muriatic acid, and dried in a reverberatory furnace, and then thrown altogether in the zinc, covered with the sal-ammoniac, left for one minute, and taken out slowly with an iron skimmer; they come out in a mass soldered together, and for their separation are afterwards placed in a crucible and surrounded with charcoal-powder, then heated to redness and shaken about until cold for their separation. Wire is reeled through the zinc, into which it is compelled to dip by a fork or other contrivance. It will be understood that the zinc is melted with a thick coat of sal-ammoniac to prevent the loss of zinc by oxidation.

Mr. Mallet coated iron with zinc by the following process:—

The plates are immersed in a cleansing bath of equal parts of sulphuric or muriatic acid and water, used warm; the works are then hammered and scrubbed with emery and sand to detach the scales, and to thoroughly clean them; they are then immersed in a 'preparing bath' of equal parts of saturated solutions of muriate of zinc and sal-ammoniac, from which the works are transferred to a fluid metallic bath, consisting of 202 parts of mercury and 1292 parts of zinc, both by weight, to every ton weight of which alloy is added above one pound of either potassium or sodium, the latter being preferred. As soon as the cleaned iron-works have attained the melting heat of the triple alloy, they are removed, having become thoroughly coated with zinc. At the proper fusing temperature of this alloy, which is about 680° Fahr., it will dissolve a plate of wrought iron of an eighth of an inch thick in a few seconds.

Morewood and Rogers's galvanised tinned iron is prepared under several patents. Their process is as follows:—

The sheets are pickled, scoured, and cleaned, just the same as for ordinary tinning. A large wooden bath is then half filled with a dilute solution of muriate of tin, prepared by dissolving metallic tin in concentrated muriatic acid, which requires a period of two or three days. Two quarts of the saturated solution are added to 300 or 400 gallons of the water contained in the bath. Over the bottom of the bath is first spread a thin layer of finely-granulated zinc, then a cleaned iron plate, and so on, a layer of granulated zinc and a cleaned iron plate alternately, until the bath is full; the zinc and iron, together with the fluid, constitute a weak galvanic battery, and the tin is deposited from the solution so as to coat the iron with a dull uniform layer of metallic tin in about two hours.

The tinned iron is then passed through a bath containing fluid zinc, covered with sal-ammoniac mixed with earthy matter, to lessen the volatilisation of the sal-ammoniac, which becomes as fluid as treacle. Two iron rollers immersed below the surface of the zinc are fixed to the bath and are driven by machinery to carry the plates through the fluid metal at any velocity previously determined. The plates are received one by one from the tinning bath, drained for a short time, and passed at once, whilst still wet, by means of the rollers, through the bath as described. The plates take up a very regular and smooth layer of zinc, which, owing to the presence of the tin beneath, assumes its natural crystalline character, giving the plates an appearance resembling that known as the *moirée metallique.*—See *Hunt's Handbook to the Great Exhibition.*

It is stated that galvanised iron plates cut with shears so as to expose the central iron become zinced round the edges, and at the holes where the nails were driven. We are also informed that *ungalvanised iron* will, if moist when near galvanised plate, become zinced, and that telegraph wires, where cut through, become coated by the action of the rain-water on the galvanised portion of the surfaces.

It has been stated that the galvanised iron is not more durable than unprotected iron; that, indeed, where the zinc is by any accident removed the destruction is more rapid than ordinary. We have made especial enquiries, and find that in forges where there is any escape of sulphur-vapour the galvanised iron does not stand well; but that under all ordinary circumstances it has the merit of great durability in addition to its other good qualities.

GALVANO-PLASTIC. The German name of Electro-metallurgy. See ELECTRO-METALLURGY.

GAMBIR, or **GAMBIER.** The Malayan name of an extract obtained from the *Uncaria Gambier.* It is the *Terra Japonica* of tanners.

Two methods of obtaining gambir are described: one consists in boiling the leaves in water, and inspissating the decoction; the other, which yields the best gambir, consists in infusing the leaves in warm water, by which a fecula is obtained, which is inspissated by the heat of the sun, and formed into cakes. The best gambir is made at Rhio, in the Isle of Brittany, in the Eastern Archipelago; and the next best is that of Lingin. It is principally imported from Singapore, and is used principally for tanning, under the name of *Terra Japonica.* The *Mimosa catechu* yields a different extract from the gambir, but catechu and gambir are often confounded.

GAMBIR CATECHU. See CATECHU.

GAMBOGE. (*Gomme gutte,* Fr.; *Gutti,* Ger.) Gamboge appears to have been first brought from China in 1603, and its oriental name was said to be *Ghittaiemon.*

It is generally supposed to be produced from the *Hebradendron cambogioides* of Graham and the *Xanthochymus ovalifolius* of Roxburgh; but different kinds of gamboge appear to have different botanical sources, several species of *Garcinia* and *Cambogia* yielding this substance. In Ceylon the gamboge is obtained by wounding the bark of the tree in various places with a sharp stone, when the flowers begin to appear. Gamboge is imported from Siam, by way of Singapore and Penang. It is known in three forms: in rolls or solid cylinders; in pipes or hollow cylinders; in cakes or amorphous masses. Gamboge in small quantities is also obtained in Ceylon. Gamboge consists of resin, 74·2; soluble gum, 21·8; moisture, 4·8.

Gamboge is employed as an artist's colour; it is used to colour varnishes and lacquers, and it is administered medicinally.

Our imports of gamboge were in 1863, 388 cwts., value 3,268*l.*; in 1864, 42 cwts., value 520*l.*; they have not been reported of late years.

GAMMAM. A dye-stuff, so called, from Tunis. Examples were sent to this country in 1851, but it does not appear to have been introduced since that time.

GANGUE. A word derived from the German *Gang*, a vein or channel. It signifies the mineral substance which either encloses or usually accompanies any metallic ore in the vein. Quartz, carbonate of lime, sulphate of baryta, sulphate of lime, and fluoride of calcium, generally form the gangues; but a great many other substances become such when they predominate in a vein. In mineral works the first thing is to break the mixed ore into small pieces, in order to separate the valuable from the useless parts, by processes called stamping, picking, sorting. Literally, *Gang* is a course or passage. See MINING.

GANNISTER. The name of a bed of highly siliceous fire-clay. It is usually extremely hard, and contains many Stigmaria roots. It is found beneath some of the seams of coal in Lancashire and other places. The gannister when crushed and, if necessary, mixed with a little more plastic clay, produces a brick of the most refractory description. It is also used for lining the Bessemer converters, and similar purposes.

GARANCEUX. See MADDER.

GARANCIN. See MADDER.

GARLIC. *Allium sativum.* This plant is well known, and is much used in flavouring sauces.

It is found by analysis to contain an acrid volatile oil, gum, woody fibre, albumen, water, with sulphur, starch, and saccharine matter. The *oil of garlic* is a sulphide of allyle, $AllS = C^6H^5S$. [$(\mathbf{C}^3\mathbf{H}^5)^2\mathbf{S}$.]

GARNET. (*Grenat*, Fr.; *Granat*, Ger.) Garnet is a double silicate of certain bases, such as alumina, lime, magnesia, oxide of iron, &c.

There are six sub-species of garnet, viz.:—

I. *Alumina-lime garnet*, consisting of the silicates of alumina and lime.

II. *Alumina-magnesia garnet*, consisting of the silicates of alumina and magnesia.

III. *Alumina-iron garnet*, consisting of the silicates of alumina and iron.

IV. *Alumina-manganese garnet*, consisting of the silicates of alumina and manganese.

V. *Iron-lime garnet*, consisting of the silicates of iron and lime.

VI. *Lime-chrome garnet*, consisting of the silicates of lime and oxide of chromium.

I. Lime-garnet, or grossular, is composed of silica, 40·1; alumina, 22·7; lime, 37·2 = 100·0. Colour, pale greenish, clear red, and reddish orange, cinnamon colour. Before the blowpipe, fuses to a slightly greenish glass or enamel; soluble, when powdered, in concentrated muriatic acid.

This section comprises cinnamon-stone or Essonite, grossular or Wiluite, Romanzovite, topazolite, and succinite.

II. Magnesia-garnet is of a deep coal-black colour, with a resinous lustre. The variety from Arendal is composed of silica, 42·45; alumina, 22·47; protoxide of iron, 9·29; protoxide of manganese, 6·27; magnesia, 13·43; lime, 6·53; = 100·44.—(*Wächtmeister.*) Before the blowpipe, easily fusible, forming with intumescence a dark greyish-green globule, which is non-magnetic.

III. Iron-garnet comprises the almandine or precious garnet, allochroite, and common garnet. It is composed of silica, 36·3; alumina, 20·5; protoxide of iron, 43·2 = 100·0. Before the blowpipe, fuses rather easily with an iron reaction.

IV. Manganese-garnet, or spessartine, is of a brownish-red colour, and is composed of silica, 35·83; alumina, 18·06; protoxide of iron, 14·93; protoxide of manganese, 30·96 = 99·78. (Analysis of M. garnet from Haddam, U.S., by *Seybert.*) Before the blowpipe, gives a manganese reaction.

V. Iron-lime garnet includes aplome, colophonite, melanite, and pyreneite. These vary in colour from dark red, brownish-black, to black, and possess a shining lustre, which is sometimes resinous, as in colophonite.

Analysis of the aplome of Altenau:—Silica, 35·64; lime, 29·22; protoxide of iron, 30·00; protoxide of manganese, 3·01; potash, 2·35 = 100·22.—*Wächtmeister.*

VI. Lime-chrome garnet, or ouvarovite, is of an emerald-green colour. Sp. gr., 3·418. Before the blowpipe it is infusible alone, but with borax affords a chrome-green glass. It occurs at Bissersk, in Russia.

Analysis by *Erdmann*:—Silica, 36·93; alumina, 5·68; peroxide of iron, 1·96; oxide of chrome, 21·84; magnesia, 1·54; carbonate of lime, 31·66; oxide of copper, a trace, = 99·58.

The garnet varies greatly in transparency, fracture, and colour; but when the colours are rich, and the stone is free from flaws, it constitutes a valuable gem, which may be distinguished by the following properties:—

The colour should be blood or cherry-red; on the one hand often mixed more or less with blue, so as to present various shades of crimson, purple, and reddish violet, and on the other hand, with yellow, so as to form orange-red and hyacinth-brown.

The stones vary in size from the smallest pieces that can be worked to the size of a nut. When above that size they are scarcely ever free from flaws, or sufficiently transparent for the purposes of the jeweller.

The garnets of commerce are procured from Bohemia, Ceylon, Pegu, and the Brazils. By jewellers they are classed as Syrian, Bohemian, or Cingalese, rather from their relative value and fineness, than with any reference to the country from which they are supposed to have been brought.

Those most esteemed are called Syrian garnets, not because they come from Syria, but after Syrian, the capital of Pegu, which city was formerly the chief mart for the finest garnets. The colour of the Syrian garnet is violet-purple, which, in some rare instances, vies with that of the finest oriental amethyst; but it may be distinguished from the latter by acquiring an orange tint by candle-light. The Syrian garnet may be also distinguished from all the other varieties of garnet in preserving its colour (even when of considerable thickness and unassisted by foil), unmixed with the black tint which usually obscures this gem. The Bohemian garnet is generally of a dull poppy-red colour, with a very perceptible hyacinth-orange tint when held between the eye and the light. When the colour is a full crimson it is called pyrope, or fire garnet, a stone of considerable value when perfect and of large size.

The best manner of cutting the pyrope, is *en cabochon*, with one or two rows of small facets round the girdle of the stone. The colour appears more or less black when the stone is cut in steps, but when cut *en cabochon*, the points on which the light falls display a brilliant fire-red.

Garnet is easily worked, and when facet-cut is nearly always (on account of the depth of its colour) formed into thin tables, which are sometimes concave or hollowed out on the under side. Cut stones of this latter description, when skilfully set, with a bright silver foil, have often been sold as rubies.

The garnet may be distinguished from corundum or spinel by its duller colour. Coarse garnets reduced to a fine powder are sometimes used as a substitute for emery in polishing metals.

Bohemian garnet. See Pyrope.—H. W. B.

GARNET, SOLUBLE (*Grenat soluble*). See Carbolic Acid.

GAS. (*Gas*, Fr.; *Gaz*, Ger.) The generic name of all such elastic fluids as are aeriform under a considerable pressure, at the zero of Fahrenheit. Oxygen, hydrogen, and nitrogen, are permanent gases; many of the other vaporiform bodies have been condensed by the joint power of cold and mechanical force. See Watts's 'Dictionary of Chemistry.'

GAS, AIR. The idea of carburetting air, or a gas of low illuminating power, is not by any means new, having been started almost at the same period that lighting by coal-gas in the ordinary way was introduced; but it was not until the opening up and working of the American oil-wells, by which a supply of very light petroleum oil or spirit was obtainable, that any scheme in this direction had any chance of success. In 1862 a patent was taken out in France by a M. Mongruel, which proposed to pass air through an exceedingly light and inflammable spirit, the air thus becoming charged with a certain amount of a highly luminous hydrocarbon-vapour, in such a quantity as to render the mixture inflammable, and to allow of its being burned as an ordinary combustible gas. This idea was introduced into England by a company known as the Photogenic Gas Company, which received some amount of support at the time, but from some cause or other did not prove a success.

The various inventions brought into notice since that time for the purpose of carburetting air and other gases have been based upon precisely the same principle, but have differed considerably in the apparatus employed.

Many erroneous statements have been made on this matter for the want of scientific knowledge; for instance, in most cases the patentees themselves have declared that a union takes place, other than mechanical, between the gases of the air and the vapours of certain hydrocarbons, which result in the production of such gases as olefiant gas, or acetylene; an utter absurdity which would be evident to anyone who would consider under what circumstances such gaseous mixtures are produced. A vapour of any hydrocarbon will, whether it exist by itself or whether it be diffused through another gas or gases, always be such a vapour, and will invariably exhibit the properties characteristic of it; and, if diffused through a gas, will be found condensible to the liquid from which it was formed, if proper means be applied. It is a matter of simple calculation from known data to ascertain the exact amount of hydrocarbon-vapour taken up by a given volume of air at certain temperatures. The following tables show this:—

Boiling points of light petroleum spirit of different specific gravity.

Specific Gravity	Boiling Point
0·600	4 deg. C.
0·628	30 ,,
0·669	68 ,,

20 ,,	(68 ,,)	27·0
40 ,,	(104 ,,)	39·0

Now for an 'air-gas' scheme to be successful, the air must hold in solution a sufficient quantity of vapour to confer upon it inflammability and luminosity.

The liquid hydrocarbons, which at present are almost exclusively proposed to be employed for the purposes of carburation, are the light oils which form the first distillate in the preparation of paraffin oil from the crude American mineral oil. As this light oil is too volatile and inflammable to be burned in any sort of lamp at present in use, and no other commercial application has been discovered, very large quantities of it are disposed of as an entirely waste product, obtainable at a small cost.

The illuminating power of 'air-gas' when first obtained is very high, as high indeed as 30 candles, although this statement requires a slight qualification, as the illuminating power of the flame is not expressed by it, but only the fact that if it were possible (which it is not) to burn the gas at the rate required by the photometric test—viz. five cubic feet per hour, this illuminating power would be obtained, it being a fact that a very much smaller amount of air-gas can be burned from the ordinary argand burner, or from a batswing, to obtain the same rise of flame than in the case of coal-gas; this effect is no doubt due to the greater density of 'air-gas.' It may be mentioned that these air-gases do not burn well under pressure, and hence are only suited to burners which afford exceedingly free passage to the issuing gas, such as argands, there being a tendency with burners of the batswing and fishtail class for the air and vapour to separate, possibly explainable by the more rapid transpiration of the lighter substance through a narrow opening.

Mr. J. F. G. Kromschröder has spent nearly fourteen years in the endeavour to effect the mixture of common air with the hydrocarbonous vapours, so as to produce an 'air-gas' suitable for the illumination of small towns or dwelling-houses. He claims to have succeeded in his design, and he is probably the first man who has lighted a whole town upon a system of gas illumination which excludes the use of coal—Great Marlow in Buckinghamshire having been lighted by him with his air-gas. Mr. Kromschröder first applied his method to lighting the Battersea Water-works, and for five months he kept 104 burners supplied at a cost below that of ordinary gas. Farther, a quantity of his hydrocarbonised air was there stored over water for nearly four months, and at the end of that time it was said to be a far better illuminator than when first prepared, but this can scarcely be correct.

The experiments made at Great Marlow have been thus described:—

The generator is a kind of box, of sheet iron, in bulk not exceeding two cubic yards, standing upon a shallower box, holding a liquid hydrocarbon. A small dome on the upper surface covers an ingenious air- or force-pump, moved by clockwork, and capable of easy regulation. The liberation of a weight starts the operation, and a steady current of air is driven over the surface of the liquid in the receiver, which is kept at a constant level. An absorbent substance is employed to increase the evaporative surface, and to oppose a slight obstacle to the passage of the current, since it is found that, within certain limits, the slowest stream of air takes up the largest amount of combustible vapour. The hydrocarbon employed is a petroleum or shale-oil of specific gravity ·660, somewhat similar, we believe, to the cheap spirit burned in common sponge lamps. Seventy cubic feet of air, after complete saturation with the vapour, become a hundred cubic feet of 'gas,' of a density of 1·2, air itself being unity. The Kromschröder gas is thus about double the density of coal-gas, and contains nearly one-third its bulk of hydrocarbon-vapour. As to illuminating power, the trial by Bunsen's photometer proved satisfactory. Burning at the rate of 3½ cubic feet per hour, Sugg's improved argand being employed, a light equal to 18·1 candles was indicated, which, reduced to the standard of 5 feet per hour, is equal to about 26 candles, or nearly double the value of gas as usually burned.

Granting an equality in lighting power, there are three points in which any proposed substitute for coal-gas must satisfy consumers before it can come into use. First, its cost must not be greater; secondly, it must bear storage; thirdly, it must 'travel.' With regard to the first condition, Mr. Kromschröder makes no definite promises, but is confident that his gas can be generated more cheaply than coal-gas. Certainly the process is much less troublesome, and as the machine is self-acting, there can be but little expense for wages. One gallon of petroleum, worth about eighteenpence, will make about 700 cubic feet of gas, and this is alleged to burn as long as 1,200 feet of ordinary gas, giving a better light. As to storage and travelling power, Mr. Hastings, engineer at the Marlow Gasworks, having had full opportunity for three months of testing the gas in every possible way, and having, to begin with, a prejudice against it, reports favourably. In fact, he says that storage for a week or ten days improves the gas, his theory being that a chemical union takes place between its constituents. We could not, however, learn that the results of chemical examination confirmed this supposition. Mr. Hastings, we understood, mixes the new gas with the coal-gas supplied to the town in order to raise its light-giving power. The mains in the streets are nearly five miles in length, and the gas is said to bear travelling through this length of pipe very well. A considerable amount of cold is of course produced in the generator by the evaporation of spirit, but it does not follow that the farther cooling of the gas will not condense some of the hydrocarbonous vapour. Farther experience, therefore, is desirable to fully settle this point, though the home manufacture of gas in factories and large houses is a part of the inventor's scheme which does not entirely depend for success upon the power of the gas to travel. The inn, a mile and a quarter from the works, was lighted up on the occasion of a special trial during dinner, by coal-gas and Kromschröder gas in turns, and the greater brilliancy of the latter was thus rendered strikingly evident, even after at least two miles' conveyance, and in spite of a defect of pressure, arising from the hotel being at a 'dead end.'

The inventor does not claim to be able to supersede coal-gas in large towns and cities. He reckons that it may usefully and cheaply be applied to small towns consuming about a million cubic feet per annum, a consumption which would hardly justify the expense of erecting coal-gas works. The Great Marlow experiments have confirmed the confidence of himself and his co-workers in his system.—*Report made to 'Iron.'*

Messrs. Harrison are also the patentees of an 'Air-Gas.' This process is very simple, and consists merely in drawing air through light petroleum spirit, the air thereby becoming so charged with the inflammable vapour of the spirit, as to burn with a brilliant light. It is stated by the inventors that the mixture of air and vaporised spirit is perfectly permanent, and can be stored in holders, or passed through indefinite lengths of pipe, at varying temperatures, without suffering any condensation or diminution of lighting power. This statement is somewhat difficult of belief, as the gas produced by this process is a purely mechanical mixture, not the least combination (in a chemical sense) taking place, and there is every reason to think that variations of temperature, such as must necessarily occur in the ordinary distribution of such a gas, would cause a partial deposition of the petroleum spirit, and consequently much loss of illuminating power.

The air-gas invented by Mr. Wright, a plumber of Sheffield, must also be noticed here. His process is protected and involved by several patents: considerable mystery is made of the process by which his 'oil' is obtained, but it is, of course, essentially one of the liquid hydrocarbons. Mr. Thomas Wills, in his paper read before the Society of Arts, thus describes this patent:—

From the specification which is taken out in the name of Mr. William Wright, of Sheffield, we gather the following details. A light petroleum, or other spirit, is to be used, as in other cases; but the apparatus differs from any that has as yet been introduced. A number of cylinders of iron or other metal are placed side by side, each being supported in a perpendicular position by means of trunnions, or swivel-joints, which allow of the cylinder being reversed with ease; in the interior of these cylinders there are fitted a number of fixed pistons formed of cotton or other spongy material. The number of these pistons varies with the size of the apparatus; a hollow chamber at the top and bottom of each cylinder acts as a reservoir for the spirit, which, in the first instance, is poured in excess through the top, and gradually percolates through the cotton pistons, at the same time saturating them; the excess of spirit accumulates in the bottom reservoir, air is then driven through the cylinder, and consequently through the saturated cotton. This air enters through the swivel-joint, and passes to the bottom of the cylinder, where it enters just above the bottom chamber, and has to find its way up through the pistons, out at the top just below the upper chamber, and thence down to the opposite swivel-joint—much, in fact, in the same way as the steam passes into and out of the cylinder of an ordinary oscillating condensing engine. After so much air has passed as to carry away in suspension the greater quantity of the spirit in the cotton, the cylinder is reversed, when the liquid that had accumulated in the lower vessel percolates once more through the pistons from the top to the bottom. In this manner it is found possible to place into the cylinder a known quantity of spirit that shall be sufficient to charge a certain volume of air, and to work it completely out by successive reversals of the apparatus. The swivel-joints are made also to act as stopcocks, cutting off all communication between the inlet or outlet during the period occupied in reversing the cylinder. If a number of such cylinders are used, they are made to communicate with each other, so as to equalise the amount of spirit in each. The air used is supplied from two ordinary gas-holders, but so coupled together by pulleys that one rises as the other descends, a valve opening inwards being placed at the top of each for this purpose. Weights being added to the holder that is full, or, what comes to the same thing, some of the balance-weights being removed so as to allow the full weight of the holder to compress the air, this air is driven through the charging cylinders and can afterwards be used as an ordinary illuminating gas; at the same time the second holder is rising, and on the exhaustion of one the second is ready by a transference of the weights to supply a continuous stream of air. The work required to keep such apparatus in use does not seem to be great, an occasional reversing of the cylinders, and the removal or addition of weights to the holder, being all that is necessary. Doubtless even this would be found impracticable on the large scale, but it is only intended to use this process for isolated buildings and small districts.

With regard to the character of the gas produced, it is much the same as other air-gases, and subject to just the same laws; and, of course, this process can claim nothing more than an improvement in the apparatus used for carburetting the air. If air-gases are to come into use at all, and there seems to be no real obstacle to prevent their adoption to a limited extent, the direction for improvement must be looked for in the apparatus employed, and this new patent certainly deserves a fair trial, which no doubt in good time it will have. Probably some means will have to be taken to prevent the reduction of temperature which invariably occurs when evaporation goes on at all rapidly; but as it is generally accepted that almost the shortest possible contact of the air and spirit is sufficient to allow of the former taking up as much of the latter as it is possible for it to do, this cooling may be confined to a very small extent, and may be neutralised altogether, if proper means be applied. It appears to be rather a difficult matter for inventors to obtain the best spirit for the purposes of carburetting air, for we have seen several samples of spirit supposed to be effective for such purposes, which would have been found, if used, of very little if any good, consisting, as they did, almost entirely of a light paraffin oil. The truth is, that very little of the real *spirit* from the petroleum comes into this country, its exceeding volatility rendering it a very dangerous freight for a ship; it might, however, possibly pay to have the petroleum sent over in its rough state, and to distil the spirit here. The oil, which is valued as burning material, could be distilled afterwards, and it, and the pitch remaining, would have little difficulty in finding a ready market. If the promoters of any one of the recent schemes could command a continuous supply of the light spirit at a reasonable figure, a great advance towards success would be made. That very great interest is still taken in these new schemes by the public is undoubted, and this last one is not likely to form an exception. Meanwhile there is nothing that should be relied upon but a fair trial on such a scale as shall be satisfactory to all.

GAS, COAL. Although the employment of gas for illuminating purposes can be traced back to remote periods of antiquity, yet the substantial history of this application may be related in few words. In various places and at different times issues of inflammable gas from the earth have been observed; the holy fires at Baku on the shores of the Caspian Sea, and those of Pietra Mala in Italy are instances; but such issues have usually been only regarded with superstitious dread by the ignorant people who have observed them. The Chinese alone, if we are to believe the accounts of that boastful people, have many centuries ago turned these natural sources of inflammable gas to useful account, and have rendered them available both for heating and illuminating purposes. Abundant sources of inflammable gas exist in the coal districts of this country; and in some localities, as at Chat Moss in Lancashire for instance, so easy is this gas procurable, that it is only necessary to plunge an iron rod a few yards deep into the soft peat, and then on its withdrawal to insert a tin tube, in order to secure a copious discharge of gas, which is evolved in a continuous stream at a high pressure, and apparently for an unlimited period of time. But as this gas consists of nearly pure light carburetted hydrogen, and contains no luminiferous constituent, it yields scarcely any light when burnt in the ordinary manner, and cannot therefore be rendered available for illuminating purposes. It has, however, been successfully employed as a source of heat, and a jet of it was long made use of as the sole fuel to heat a four-horse boiler used for agricultural purposes. As early as the year 1659 Mr. Thomas Shirley communicated to the Royal Society a paper describing some experiments upon an inflammable gas issuing from a well near Wigan in Lancashire, and nearly a century later the Rev. John Clayton, having noticed the same phenomenon in the same locality, and finding on digging a few feet into the soil, that the gas issued from a bed of coal, he was led to try whether a similar gas could not be obtained artificially, by exposing coal to heat in close vessels. He succeeded in obtaining an illuminating gas, and amused his friends by collecting it in bladders and burning it from a hole pricked in the bladder. The particulars of these experiments Mr. Clayton communicated to the Royal Society in the year 1739. But he does not appear to have thought of applying his discovery to any practical purpose; and it was not until 1792 that the gas thus artificially obtained was used for illumination by Mr. Murdock, who first lighted his house and office at Redruth in Cornwall, and afterwards, having made several improvements in the apparatus, he lighted the factory of Messrs. Boulton and Watt at Soho about the year 1804, and in 1805 the large cotton mills of Messrs. Philips and Lee at Manchester; those of Mr. Lodge at Halifax having been lighted about the same time by Mr. Clegg, a gentleman to whose energy and scientific skill gas-lighting, in its earlier stages especially, is much indebted. In the year 1810 the Act of Parliament incorporating the London and Westminster Chartered Gas-light and Coke Company was passed, and, on the 31st of December 1813, Westminster Bridge was lighted with gas. This step was soon followed by the introduction of gas in the place of oil in several of the chief thoroughfares of the metropolis. From that period the progress of this branch of the chemical arts has been extremely rapid and satisfactory, so far at least as the extension of the manufacture and the improvement of the mechanical part of the processes are concerned. Nevertheless, although the methods employed for the generation and purification of gas have been rendered more economical, it can hardly be said that the average of the gas, supplied to consumers in London and the provincial towns, is either purer or better in quality than that furnished in the earlier years of the manufacture.

Before proceeding to describe the actual processes now employed for the generation of illuminating gas, it will be advisable to consider briefly the general scientific principles involved in those processes, and especially the chemical relations of the materials employed for the generation and purification of illuminating gas, together with the bearings of chemistry upon the operations of generating, purifying, and burning such gas.

The chemistry of gas manufacture.—The chief materials employed in the manufacture of gas for illuminating purposes are—coal, oil, resin, peat, and wood. These materials, though very dissimilar in appearance, do not essentially differ from each other in their chemical constituents; they may all be regarded as consisting chiefly of the elements, carbon, hydrogen, and oxygen, and their value for the production of illuminating gas increases with the increase of the proportion of hydrogen, and with the diminution of the relative amount of oxygen. Accordingly we find that oil and resin generally produce gas larger in volume and better in quality than coal, whilst peat and wood, owing to the large proportion of oxygen which they contain, are greatly inferior to coal for the purposes of the gas-manufacturer. The relative proportions of carbon, hydrogen, and oxygen, in the organic part of these substances, is seen from the following comparisons:—

	Percentage of Carbon	Percentage of Hydrogen	Percentage of Oxygen
Cannel (Boghead)	80·35	11·21	6·71
Cannel (Wigan)	85·95	5·75	8·14
Coal	88·15	5·26	5·41
Oil	78·90	10·97	10·13
Resin	79·47	9·93	10·59
Peat	60·41	5·57	34·02
Wood	50·00	5·55	44·45

In addition to the three essential constituents above mentioned most of these materials contain small and variable proportions of sulphur, nitrogen, and inorganic matter, the latter constituting, when the substance is burnt, what we term *ash*. When these substances are heated to redness, they undergo decomposition, a considerable quantity of inflammable gases and vapours being evolved, whilst a residue, consisting of carbon, or of carbon and ash, remains behind in the solid form. When atmospheric air has free access during this heating operation, the inflammable gases and vapours burn with a more or less bright flame, as in a common fire; whilst the carbonaceous residue continues afterwards to glow, until nearly the whole of the carbon is consumed. If, however, the application of heat be made without access of air, by inclosing the materials for instance in an iron retort provided only with an outlet for the escape of gases, the decomposition goes on in much the same manner as before, but the various products formed, being no longer exposed to the simultaneous action of atmospheric oxygen, do not undergo combustion; the inflammable gases and vapours are evolved through the outlet pipe in an unburnt condition, and the carbonaceous residue also remains unconsumed in the retort. Upon cooling the gases and vapours thus evolved, the latter condense more or less into liquids which separate into two layers, the lower one forming a dense black oily fluid, commonly known as tar, and containing several solid hydrocarbons partly in solution and partly in suspension; whilst the other one consists chiefly of an aqueous solution of salts of ammonia, if the organic matters operated upon contained nitrogen. Thus the volatile products of this process of *destructive distillation* consist of solids, liquids, and gases. These constituents may be thus tabulated:—

I. Gaseous.

Name	Chemical formulæ	
Hydrogen	H	$\mathbf{H}$
Light carburetted hydrogen	C^2H^4	$\mathbf{CH^4}$
Acetylene	C^4H^2	$\mathbf{C^2H^2}$
Carbonic oxide	CO	$\mathbf{CO}$
Olefiant gas	C^4H^4	$\mathbf{C^2H^4}$
Propylene	C^6H^6	$\mathbf{C^3H^6}$
Butylene	C^8H^8	$\mathbf{C^4H^8}$
Carbonic acid	CO^2	$\mathbf{CO^2}$
Sulphuretted hydrogen	SH	$\mathbf{SH^2}$
Nitrogen	N	$\mathbf{N}$

II. Liquid.

	Name	Chemical formulæ	
Aqueous layer:—	Water	HO	$\mathbf{H^2O}$
Oily layer:—	Bisulphide of carbon	CS^2	$\mathbf{CS^2}$
,,	Benzol	$C^{12}H^6$	$\mathbf{C^6H^6}$
,,	Toluol	$C^{14}H^8$	$\mathbf{C^7H^8}$
,,	Cumol	$C^{18}H^{12}$	$\mathbf{C^9H^{12}}$
,,	Cymol	$C^{20}H^{14}$	$\mathbf{C^{10}H^{14}}$
,,	Aniline	$C^{12}H^7N$	$\mathbf{C^6H^7N}$
,,	Picoline	$C^{12}H^7N$	$\mathbf{C^6H^7N}$
,,	Leucoline	$C^{18}H^8N$	$\mathbf{C^9H^8N}$
,,	Carbolic acid (Phenol)	$C^{12}H^6O^2$	$\mathbf{C^6H^6O}$
,,	Other hydrocarbons	$C_n\,H_n$ *	
,,	,, ,,	$C_n\,H_{n+2}$	
,,	,, ,,	$C_n\,H_{n-6}$	

* Here *n* means an even number, as 2, 4, 6, &c.

III. Solid.

	Name	Chemical formulæ	
In aqueous layer :—	Carbonate of ammonia	NH^4OCO^2	$\mathbf{2(NH^4)CO^3}$
,,	Hydrosulphate of sulphide of ammonium	NH^4S+HS	$\mathbf{2(NH^4)S+H^2S}$
,,	Sulphite of ammonia	NH^4OSO^2	$\mathbf{2(NH^4)SO^3}$
,,	Chloride of ammonium	NH^4Cl	$\mathbf{NH^4Cl}$
In oily layer :—	Paraffine	$C^{40}H^{42}$	$\mathbf{C^{20}H^{42}}$
,,	Naphthaline	$C^{20}H^8$	$\mathbf{C^{10}H^8}$
,,	Paranaphthaline (Anthracene)	$C^{28}H^{10}$	$\mathbf{C^{14}H^{10}}$
,,	Pyrene	$C^{30}H^4$	$\mathbf{C^{15}H^4}$
,,	Chrysene	$C^{32}H^{12}$	$\mathbf{C^{16}H^{12}}$

In practice, there is not such a perfect separation of the products as is represented in the above table: thus a small proportion of the gases dissolves in the liquid products, whilst most of the liquids, and even some of the solids, diffuse themselves in the form of vapour, to a certain extent, into the gases; and the solids are in most cases almost completely dissolved in the liquids. The relative proportions also in which these products occur greatly depend upon the temperature employed in the destructive distillation, and the length of time during which the volatile products are exposed to it; a low temperature and short exposure favouring the formation of solids and liquids, whilst a higher heat and longer exposure determine the production of a larger proportion of gases at the expense of the solids and liquids.

The usual process of gas-making consists in exposing coal or cannel to a bright-red heat, in close vessels of convenient size and shape, until all, or the greater part, of the volatile matter is expelled. Coke is the material left in the retort, and the matters volatilised consist of condensible vapours, and of permanent gases more or less saturated with these vapours. By a simple process of refrigeration nearly the whole of the vapours may be readily condensed, thus separating the gases more or less perfectly from the liquid and solid products of the distillation. But this preliminary process of purification leaves the gases still in a state totally unfitted for use in the production of artificial light. They still retain constituents, which are either noxious in themselves, or generate noxious compounds when they are burnt, such as sulphuretted hydrogen, sulphide of ammonium, carbonate of ammonia, and bisulphide of carbon. They also contain carbonic acid, which greatly diminishes the amount of light yielded by the illuminating gases with which it is mixed.

Besides these injurious ingredients, which may be conveniently included in the term *impurities*, there are others which do not contribute anything to the illuminating power of the mixture, and which may be denominated *diluents*. We can thus classify the constituents of gas-coal as follows:—

Illuminants	Diluents	Impurities
Olefiant gas. Acetylene. Propylene. Butylene. Hydrocarbon vapours of the formulæ $C_n H_n$ and $C_n H_{(n-6)}$. Vapours of hydrocarbons of the formula $C_n H_{(n-12)}$.	Hydrogen. Light carburetted hydrogen. Carbonic oxide.	Sulphuretted hydrogen. Hydrosulphate of sulphide of ammonium. Carbonate of ammonia. Carbonic acid. Vapour of bisulphide of carbon. Nitrogen. Oxygen. Aqueous vapour.

As the intelligent manufacture of gas for illuminating purposes requires a knowledge of the leading properties of the compounds included under the three heads just mentioned, we will now proceed briefly to describe them.

I. Illuminants.

Olefiant gas.—This gas has been proved by Berthelot to exist in coal-gas, and it is probably always a constituent of the illuminating gases from resin, oil, peat, and wood. It is occasionally, though rarely, met with in nature, as a product of the action of volcanic heat upon coal-bearing strata; it never occurs, however, in coal strata under ordinary circumstances, and no trace of it has ever been met with amongst the gases issuing from the coal strata of this country, and which have been investigated by Graham, Playfair, and others. Olefiant gas can be prepared nearly pure by heating in a glass retort a mixture of 1 part by weight of alcohol, and 6 parts oil of vitriol. The gas must be passed through solution of caustic soda, to remove sulphurous and carbonic acids with which it is generally contaminated.

Olefiant gas is colourless, and possesses a peculiar and slightly unpleasant odour. Its specific gravity is rather less than that of atmospheric air, being ·9784: 100 cubic inches, at 60° F. and 30 inches barometrical pressure, weigh 30·3418 grains. It consists of two volumes of carbon-vapour and four volumes of hydrogen, the six volumes being condensed to two. It contains, in a given bulk, exactly twice as much carbon as is contained in light carburetted hydrogen. Olefiant gas is inflammable, but does not support combustion: when inflamed as it issues from a jet into the atmosphere, it burns with a white flame, emitting a very brilliant light without smoke. In burning, it consumes three times its volume of oxygen, and produces twice its volume of carbonic acid. Exposed to a full red heat, as in passing through a red-hot tube, it is rapidly decomposed, carbon being deposited, whilst hydrogen and light carburetted hydrogen are produced; exposure to a full red heat consequently soon entirely destroys its illuminating power.

Acetylene.—This hydrocarbon may be formed synthetically by the direct union of its elements. Berthelot has shown that when the electric light is produced between carbon poles in an atmosphere of hydrogen, the high temperature thus produced determines the formation of acetylene. Among other modes of generating acetylene may be mentioned the incomplete combustion of gases and vapours containing carbon and hydrogen; the decomposition of olefiant gas, alcohol-vapour, or ether-vapour, by the action of heat, and the decomposition of marsh-gas by the passage of electric sparks from an induction-coil.

Acetylene is a colourless transparent gas, of peculiar odour. Its specific gravity is 0·92. The gas burns with an intensely luminous flame, much brighter than that of olefiant gas; for a given volume of acetylene contains the same bulk of carbon with only half as much hydrogen as in an equal volume of olefiant gas. Mixed with chlorine, acetylene explodes, even in diffused daylight, with separation of carbon as a dense black smoke. Acetylene passed through a solution of subchloride of copper (cuprous chloride) yields a red precipitate, which, when dried, forms an amorphous solid substance that readily explodes on being struck with a hammer, or on being suddenly heated to a temperature a little higher than that of boiling water. See ACETYLENE.

Propylene and Butylene.—The first of these highly-illuminating constituents of coal-gas may be obtained by passing the vapour of *fusel oil* through a red-hot tube, and the second by the electric decomposition of valerate of potash. Both these gases are colourless, possess a light ethereal odour, and burn with a brilliant white flame. Like olefiant gas, they are rapidly decomposed at a bright red heat, depositing much carbon, and being converted into the non-illuminating gases—hydrogen and light carburetted hydrogen. Propylene consists of three volumes of carbon-vapour, and six volumes of hydrogen condensed to two volumes. It therefore contains, in a given volume, one-half more carbon than olefiant gas. Its specific gravity is 1·4511.

Butylene consists of four volumes of carbon-vapour and eight volumes of hydrogen, the twelve volumes being condensed to two; it consequently contains, in a given volume, twice as much carbon as olefiant gas. Its specific gravity is 1·9348.

Vapours of hydrocarbons of the formula $C_n H_n$.—A considerable number of compounds having this formula are known to exist in coal-tar, and, as many of them are very volatile, they must be diffused as vapours in coal-gas; but as they have not yet been successfully disentangled from each other, no account of their individual properties can be given; they all, however, contain more carbon, in a given volume, than butylene, and must therefore contribute, proportionally to their volume, a greater illuminating power than any of the gaseous hydrocarbons. They are all readily decomposed at a bright red heat, chiefly into carbon and non-illuminating gases.

Vapours of hydrocarbons of the formula $C_n H_{(n-6)}$.—These consist chiefly of benzol, toluol, cumol, and cymol; compounds which, being components of the more volatile portions of the tar, diffuse themselves into the gaseous products of distillation, contributing in no inconsiderable degree to the total illuminating effect of the gas. The composition of these substances has been already given in the Table; and it is therefore only necessary here to remark that benzol-vapour contains, in a given volume, three times as much carbon as olefiant gas, whilst the vapours of toluol, cumol, and cymol contain respectively 3½, 4½, and 5 times the amount of carbon contained in olefiant gas. For a further account of these and other hydrocarbons, see NAPHTHA; COAL; DESTRUCTIVE DISTILLATION.

Vapours of hydrocarbons of the formula $C_n H_{(n-12)}$.—The only vapour of this composition known to be present in coal-gas is naphthaline, $C^{20}H^{8}$ ($\mathbf{C^{10}H^{8}}$), which, although a solid at ordinary temperatures, yet emits a considerable quantity of vapour; in fact, its presence occasions to a great extent the peculiar odour of coal-gas.

Naphthaline is a frequent source of serious annoyance to the gas-manufacturer, by condensing in the street mains and gradually blocking them up, or so narrowing their bore as to prevent the passage of the needful supply of gas. This effect can only be produced when the gas charged with naphthaline-vapour is allowed to leave the holder at a temperature higher than that of the mains through which it subsequently flows; but as this cannot always be avoided, the prevention of such deposits might perhaps be best effected by passing the gas over a large surface of coal-oil before it is led into the mains. The oil would absorb so much of the naphthaline as to prevent any subsequent deposition. The vapour of naphthaline contains, in an equal volume, five times as much carbon as olefiant gas. The amount of light yielded by these illuminating constituents is directly proportionate to the amount of carbon contained in an equal volume of each; taking, therefore, the illuminating power of olefiant gas as unity, the following numbers exhibit the relative illuminating values of equal volumes of the several luminiferous constituents of gas:—

Propylene	1·5	Benzol	3·0
Butylene	2·0	Toluol	3·5
Amylene	2·5	Heptylene	3·5
Hydride of amyl	2·5	Cumol	4·0
Hydride of hexyl	3·0	Cymol	5·0
Hexylene	3·0	Naphthaline	5·0

II. Diluents.

Hydrogen.—This element constitutes one ninth of the total weight of the waters of our globe, and with one or two unimportant exceptions, enters into the composition of all animal and vegetable substances and of the products derived from them, as peat, coal, oils, bitumen, &c. It is, however, very rarely met with in nature in a free or uncombined state; having hitherto only been thus found in the gases emitted from volcanoes.

Hydrogen gas may be obtained in abundance and nearly pure by passing steam over iron, zinc, and several other metals, in a fine state of division, at a full red heat. Mixed with carbonic oxide and carbonic acid gases, it is also generated in large quantity when steam is passed over charcoal, coke, or other carbonaceous substances at a red heat. In all these cases the watery vapour is decomposed, its hydrogen being liberated, whilst its oxygen unites with the metal or carbon, forming in the first case a solid non-volatile oxide, which encrusts the pure metal, and soon stops further action; in the second case a gaseous oxide of carbon is generated, and passes off along with the hydrogen, thus leaving the carbon freely exposed to the further action of the watery vapour. When carbon is used, that portion of the steam which is converted into hydrogen and carbonic oxide yields its own volume of each of these gases; and that portion which forms hydrogen and carbonic acid affords its own volume of hydrogen and half its own volume of carbonic acid. The amount of watery vapour which undergoes the latter decomposition decreases as the temperature at which the operation is conducted increases. At a white heat scarcely a trace of carbonic acid is produced.

Hydrogen is the lightest of all known bodies, its specific gravity being only ·0691: 100 cubic inches, at 60° Fahr. and 30 inches barometric pressure, weigh only 2·1371 grains. It has a powerful affinity for oxygen, but develops scarcely any light during combustion; when, however, solid substances, such as lime, magnesia, or platinum, are held in the flame of hydrogen, considerable light is emitted. Burnt in air or oxygen gas, it is entirely converted into watery vapour, which condenses upon cold surfaces held above the flame.

Light carburetted Hydrogen.—This gas consists of carbon and hydrogen in the proportion of 6 parts by weight of the former element combined with 2 parts of the latter. Owing to its being copiously generated in marshy swampy places, it is frequently termed *marsh gas*, and from certain considerations relative to its chemical constitution, it has more recently received the name of *hydride of methyl*. It enters largely into the composition of coal-gas, and is also a natural product of the slow decomposition of coal, and of putrefaction in general. Thus it occurs in enormous quantities in the coal strata, and bubbles up from stagnant pools and ditches which contain putrefying organic remains. As thus generated, it is mixed with small quantities of carbonic acid and nitrogen; it can, however, be artificially prepared perfectly pure, but the processes need not be described here.

Light carburetted hydrogen when pure is colourless, tasteless, and inodorous; it is neutral to test papers, and nearly insoluble in water; its specific gravity is ·5594, and 100 cubic inches, at 60° Fahr. and 30 inches barometric pressure, weigh 17·4166 grains. It does not support combustion or respiration, but is inflammable, burning with a blue, or slightly yellow flame, yielding scarcely any light. Mixed with a due proportion of atmospheric air or oxygen, and ignited, it explodes with great violence: the products of its combustion are water and carbonic acid.

When light carburetted hydrogen is exposed to a white heat, it is slowly decomposed, depositing carbon, and yielding twice its volume of hydrogen.

Carbonic Oxide.—This gas consists of 6 parts by weight of carbon, and 8 parts of oxygen. It is formed when carbon is consumed in a limited quantity of air or oxygen, and is also generated, as stated above, when steam is passed over ignited coke or charcoal, or when coal-tar and steam meet in a red-hot vessel. It is always a constituent of coal-gas.

Carbonic oxide is a colourless and inodorous gas, rather lighter than atmospheric air, and having exactly the specific gravity of olefiant gas, ·9727; it is very sparingly soluble in water, but is very soluble in ammoniacal solution of chloride of copper. Carbonic oxide is inflammable, burning with a beautiful blue flame almost devoid of light; the product of its combustion is carbonic acid. It is said to be very poisonous.

III. Impurities.

Sulphuretted Hydrogen.—This gas consists of sixteen parts of sulphur and one part of hydrogen; it may be produced by passing hydrogen along with the vapour of sulphur through a red-hot tube, but it is best prepared pure by decomposing protosulphuret of iron with dilute sulphuric acid, and collecting the evolved gas at the pneumatic trough or over mercury. It is always an ingredient in crude coal-, peat-, or wood-gas.

Sulphuretted hydrogen is a colourless gas, of a very nauseous odour, resembling that of putrid eggs: its specific gravity is 1·1747. It is highly inflammable, burning with a blue flame, destitute of light, and generating a large amount of sulphurous acid; it is chiefly this latter circumstance which renders its presence in coal-gas objectionable. It is readily absorbed by metallic solutions, by hydrated oxide of iron, and by lime both in the wet and dry states, and is easily recognised in coal-gas by exposing a strip of paper impregnated with acetate of lead to a stream of the gas; if the paper becomes discoloured, sulphuretted hydrogen is present.

Hydrosulphate of sulphide of Ammonium.—This compound is formed by the combination of equal volumes of ammonia and sulphuretted hydrogen. It consists of 14 parts by weight of nitrogen, 15 of hydrogen, and 32 of sulphur. It is always largely produced in the manufacture of coal-gas, but is almost completely condensed and retained in the aqueous layer of liquid products, contributing principally to the unbearable odour of *gas liquor*; a mere trace of this body is therefore present in crude coal-gas. When quite pure it is a colourless crystalline solid, very soluble in water, and volatile at ordinary temperatures. Its vapour, when present in coal-gas, is absorbed and decomposed by hydrate of lime both in the wet and dry states, ammonia being liberated. It is also decomposed by acids, but in this case the ammonia is retained by the acid, whilst sulphuretted hydrogen is evolved.

Carbonic Acid.—This gas is met with in nature as a constituent of atmospheric air, and is produced in large quantities during the earlier stages of the formation of coal in the earth's strata. Thus, in the lignite districts of Germany, it is copiously evolved, and meeting with water in its passage to the surface, it is absorbed, and forms those sparkling mineral springs commonly known as seltzer-water.

Carbonic acid is also formed during fermentation, by the combustion of carbon in air, and in the decomposition of water by carbon at a red heat.

At ordinary temperatures carbonic acid is a colourless and invisible gas, but it may be liquefied by very intense cold or pressure. It consists of 6 parts, by weight of carbon united with 16 parts of oxygen, and thus differs from carbonic oxide by containing twice as much oxygen as the latter gas. By passing carbonic acid over ignited coke, charcoal, or other carbonaceous matters, it takes up as much carbon as it already contains, and becomes converted into carbonic oxide; but it is impossible in this way to convert the whole of the carbonic acid into carbonic oxide unless the process be very frequently repeated. Carbonic acid is pungent, acidulous, and soluble in an equal bulk of water, to which it communicates that briskness which we so much admire in soda-water; it is considerably heavier than atmospheric air, its specific gravity being 1·524. This gas is uninflammable, and cannot support combustion or animal life. Its acid properties are not strongly developed, but it unites readily with alkaline bases, forming carbonates: it is upon this property that the removal of carbonic acid from coal-gas depends. On passing coal-gas containing this acid through slaked lime in fine powder, or through milk of lime, the whole of the carbonic acid disappears, having united with the lime. Quick-lime, slaked in such a manner as to be neither dust-dry nor very perceptibly moist, is most effective for the absorption of high percentages of carbonic acid, a layer three inches in thickness not allowing a trace of the acid gas to pass through it.

The presence even of a small percentage of carbonic acid in coal-gas is much to be deprecated, on account of the great loss of light which it occasions, 1 per cent. of carbonic acid diminishing the illuminating power of coal-gas to the extent of about 6 per cent.; the addition which it makes to the carbonic acid produced during combustion is, however, too minute to be of any importance.

Carbonate of ammonia.—During the destructive distillation of coal, a considerable proportion of the nitrogen contained in the coal is converted into carbonate of ammonia, the greater part of which condenses in the aqueous layer of liquid products; but as carbonate of ammonia is very volatile, even at ordinary temperatures, crude coal-gas always contains a small quantity of this compound. It is a volatile, white, crystalline solid, very soluble in water, and possessing a pungent smell like ammonia. Its vapour is decomposed by lime, which unites with carbonic acid, liberating ammonia. The presence of this salt, or of ammonia, in coal-gas is very undesirable, as it corrodes brass fittings, and is also partially converted into nitrous acid during the combustion of the gas.

Bisulphide of Carbon.—This compound consists of 6 parts, by weight, of carbon, and 32 parts of sulphur; it is formed whenever sulphur and carbonaceous matter are brought together at a bright red heat, and therefore, owing to the presence of sulphur in all varieties of coal, its vapour is generally, and probably always, present in coal-gas. Bisulphide of carbon is a colourless liquid, of a most insupportable odour resembling garlic; it is very volatile, boiling at 108°. It does not mix with water, but dissolves in alcohol and ether; it is also very soluble in solution of caustic soda or potash in methylic, ethylic, or amylic alcohol. It is very inflammable, and generates during combustion much sulphurous acid; on this account its presence in coal-gas is very injurious, and as there has hitherto been no known means of removing it on a large scale by any mode of purification, its non-generation in the process of gas-making becomes a problem of great importance. Few attempts have yet been made to solve this difficulty, but Mr. Wright, the eminent engineer of the Western Gas Company, has observed that its formation is greatly hindered, if not entirely prevented, by the employment of a somewhat moderate temperature. In corroboration of this observation it has frequently been noticed that the gas furnished by companies who use a high heat contains a very large quantity of this noxious material, whilst gas generated at lower temperatures, as for instance, that produced by White's hydrocarbon process, contains mere traces of this compound. Although no process for the absorption of bisulphide-of-carbon vapour from coal-gas is sufficiently cheap for employment on a large scale, yet advantage might be taken of its solubility in a solution of caustic potash in fusel oil (a by-product in spirit distilleries), or in methylated spirit of wine, for its removal from the gas supplied to private houses, where the damage done by the sulphurous acid is most annoying. By passing the gas over a considerable surface of this solution, contained in a small private purifier, the bisulphide-of-carbon vapour is completely removed.

A method of removing bisulphide of carbon from coal-gas has, however, been recently suggested by Mr. Vernon Harcourt, F.R.S. This chemist found that when impure gas was passed through an iron tube, 3 inches in diameter, filled with iron turnings and heated to low redness for a length of about two feet, the amount of bisulphide of carbon could be so far reduced that the gas, after purification from sulphuretted hydrogen, contained only 5 or 6, instead of about 30 cubic inches, in 100 cubic feet. A yet greater reduction in the amount of sulphur may be effected by heating the gas after, instead of before, purification, and then purifying the product a second time. In these experiments the sulphur of the bisulphide of carbon combines with hydrogen, perhaps with the aid of watery vapour, and forms sulphuretted hydrogen, which can be readily removed by the ordinary methods. Under certain circumstances, it appears that the illuminating power of the gas is actually increased by this process of heating to remove the bisulphide of carbon.

Bisulphide-of-carbon vapour can be readily detected in coal-gas by a very simple apparatus devised by Mr. Wright[1]; in this instrument the products of the combustion of a jet of gas are made to pass through a small Liebig's condenser; if the liquid dropping from this condenser strongly redden blue litmus paper, it is highly probable

---

[1] This instrument can be had on application to Mr. Wright, 55 and 55A Millbank Street, Westminster, S.W.

that bisulphide of carbon is present. As a decisive test, 50 or 60 drops of the condensed fluid should be collected in a small test-tube, and a few drops of pure nitric acid added: on heating this mixture to boiling-point over a spirit lamp, and then adding a drop or two of a solution of chloride of barium, the liquid will become more or less milky if bisulphide of carbon has been present in the gas. It is necessary here to remark, that the absence of sulphuretted hydrogen must be first ascertained by the non-colouration of paper imbued with acetate of lead, and held for some minutes in a stream of the gas.

Nitrogen.—This gas is the chief constituent of atmospheric air, 100 cubic feet of air containing rather more than 79 cubic feet of this gas. It also enters into the composition of a large number of animal and vegetable substances. All descriptions of coal contain small quantities of this element. When nitrogen is eliminated from combination in contact with oxygen, it usually takes the form of nitrous or nitric acid; whilst in contact with an excess of hydrogen it generates ammonia. It is in this latter form that it is eliminated from coal in the process of gas-generation.

Nitrogen is a colourless, inodorous, and tasteless gas, of specific gravity 0·976. It is incombustible under ordinary circumstances, and instantaneously extinguishes burning bodies. Under certain conditions, however, nitrogen does undergo combustion, as when it is exposed to a very intense heat in the presence of oxygen. This occurs, for instance, when a small quantity of nitrogen is added to a mixture of hydrogen, with a somewhat larger proportion of oxygen than is requisite to form water, and the mixture then ignited: a loud explosion takes place, and a considerable quantity of nitric acid is formed, owing to combustion of the nitrogen, or in other words, its union with oxygen gas. This formation of nitric acid possibly occurs also to a limited extent during the burning of coal-gas; and as the temperature required to form nitric acid is very high, the greater the volume of gas consumed from one burner in a given time, the greater will be the relative quantity of nitric acid produced. The formation of such a corrosive material as nitric acid under these circumstances shows the importance of preventing the admixture of the products of the combustion of coal-gas with the atmosphere of the apartments in which it is consumed. The nitrogen contained in coal-gas is due entirely to the admission of atmospheric air, and not to the elimination of the nitrogen contained in the coal; for this latter nitrogen appears to be evolved only in combination with hydrogen as ammonia. As nitrogen is incombustible, it is not only a useless ingredient in coal-gas, but, owing to its abstracting heat from the flame of such gas, it causes a diminution of light, and is thus decidedly injurious. The admixture of this element ought therefore to be avoided as much as possible.

Oxygen.—This element is always present in coal-gas, although in very small quantity if the manufacture be properly conducted. It is never evolved from the coal itself, but it makes its way into the gas through leaky joints, and also to a certain extent through the water in which the holders are immersed. Its presence is highly injurious to the illuminating power of the gas; and since, when once introduced, it cannot be abstracted by any practicable means, its admixture ought to be carefully guarded against.

Oxygen is a colourless, invisible, and inodorous gas, very sparingly soluble in water, and which has hitherto resisted all attempts to liquefy it by cold or pressure. It is evolved from the leaves of plants under the influence of light, and constitutes about one fifth of the bulk of our atmosphere. By far the largest amount of oxygen, however, exists in combination with other elements; thus eight out of every nine tons of water are pure oxygen, and it forms at least one third of the total weight of the mineral crust of our globe. It is therefore the most abundant of all elements. Oxygen gas is heavier than atmospheric air; 100 cubic inches, at 63° Fahr. and 30 inches barometric pressure, weighing 34·193 grains, whilst 100 cubic inches of the latter weigh only 31·0117 grains. The specific gravity of oxygen is 1·1026. It eminently supports combustion, all combustible bodies when introduced into it burning much more vividly than in common air; indeed it is owing to the presence of this gas in our atmosphere, that common air possesses the property of supporting combustion.

Aqueous Vapour.—Water is volatile at all natural temperatures, and therefore its vapour always exists to a greater or less extent diffused in coal-gas, even as delivered to the consumer. The percentage amount of aqueous vapour thus present in coal-gas is always small, even when the gas is saturated; nevertheless the presence of even this small proportion of aqueous vapour diminishes to a certain extent the light produced by the combustion of gas. This effect is no doubt owing to the action of aqueous vapour upon carbon at a high temperature, by which action hydrogen, carbonic oxide, and carbonic acid gases are produced. The presence of aqueous vapour therefore tends to reduce the number of particles of carbon floating in the gas flame, and consequently the light is diminished. The following table shows the maximum percentages of aqueous vapour which can be present in gas at different temperatures. As a general rule the gas will contain the maximum amount at the lowest temperature to which it has been exposed in its passage from the retorts to the burners:—

Temperature	Percentage of aqueous vapour	Temperature	Percentage of aqueous vapour	Temperature	Percentage of aqueous vapour
32° F.	0·6	42° F.	0·9	52° F.	1·3
33	0·6	43	0·9	53	1·3
34	0·7	44	1·0	54	1·4
35	0·7	45	1·0	55	1·4
36	0·7	46	1·0	56	1·5
37	0·7	47	1·1	57	1·5
38	0·8	48	1·1	58	1·6
39	0·8	49	1·1	59	1·7
40	0·8	50	1·2	60	1·8
41	0·9	51	1·2		

Aqueous vapour has a specific gravity of ·6201, and one cubic foot of it contains one cubic foot of hydrogen and half a cubic foot of oxygen. In contact with ignited carbon, or carbonaceous substances, it is decomposed; producing a mixture of hydrogen, carbonic oxide, and carbonic acid gases. When passed over ignited iron, it yields its own volume of nearly pure hydrogen.

Having thus described the more important properties of the constituents of coal-gas, we are now prepared to discuss the conditions involved in the generation, purification, and combustion of gas.

On the generation of illuminating gas.—The production of gas for illuminating purposes whether derived from coal, peat, wood, or oil, depends, as we have seen, upon a re-arrangement of the elements composing the material employed. The nature of this re-arrangement is dependent upon the temperature employed. The lower the heat at which it can be effected, the less the weight of coke or carboniferous residue left in the retort, and, consequently, the greater the amount of carbon remaining combined with the hydrogen; the hydrocarbons thus formed being chiefly solids and liquids. On the other hand, the higher the temperature employed, the greater is the weight of carbonaceous residue, and, therefore, the smaller is the amount of carbon contained in the volatilised matters, whilst the proportion of gases in these latter becomes larger as the temperature increases. By employing a very low temperature for the destructive distillation, the production of gas may be almost entirely prevented, whilst by the employment of a very high temperature the three chief constituents of coal might without doubt be completely converted into coke, carbonic oxide, and hydrogen. Now the results produced by both these extremes of temperature are valueless to the gas manufacturer, and it is therefore necessary to employ a heat sufficiently high to prevent as much as possible the volatile substances from escaping in the form of condensible vapours, but not high enough to decompose the luminiferous constituents of the evolved gas. If coal were a definite and single chemical compound, and could be so exposed to heat as to suddenly raise the temperature of every particle to a uniform and definite degree, it is highly probable that the results of the distillation would be far less complex than they are in the present mode of gas manufacture; and it might even be possible to find such a degree of temperature as would convert the whole of the hydrogen into one or more of the higher gaseous compounds of carbon, thus giving results of maximum value to the gas manufacturer. In the ordinary processes of gas-making, where a charge of several cwts. of coal, often in large lumps, is thrown into an ignited retort, it is impossible to attain any such uniform temperature. The heat is conducted very gradually to the interior of the mass of coal, and therefore various portions of the charge are exposed to very unequal temperatures, especially in the earlier stages of the distillation. The natural consequence of these conditions is the production, on the one hand, of products resulting from excessive temperature, viz. hydrogen and light carburetted hydrogen, and, on the other, of tar, which may be regarded as the consequence of deficient heat. Notwithstanding several attempts, these disadvantages have not yet been successfully overcome; but the importance of a practical process which would secure a tolerably uniform temperature during the whole course of distillation, is seen from the remarkable results obtained with Clegg's revolving web retort: a form of apparatus undoubtedly the most ingenious yet invented for the production of gas, and which, although in its present form too complicated for successful practical use, yet embodies, when we consider the early date of its invention, in a remarkable manner, the true scientific principles of gas-making. This retort, of which a description will be found at p. 578, obviated to a great extent the inequality and uncertainty of temperature in the ordinary gas-retorts, and the result was an increase of from 30 to 40 per cent. in the quantity of gas produced, the quality being also improved, whilst scarcely any tar was formed.

But besides the great influence exercised by the temperature to which coal is exposed in the process of gas-making, *the length of time,* during which the volatile products of decomposition are exposed to that temperature, is a most important circumstance as regards the successful manufacture of gas. If we take into consideration the behaviour of the luminiferous constituents of gas when exposed to a bright red heat, and which has been described above, it will be evident that a second most important condition in the manufacture of gas is the rapid removal of these luminiferous constituents from the destructive influence of the red-hot retort as soon as they are generated: every second during which these gases are allowed to remain in their birthplace diminishes their value as illuminating agents. The only method hitherto employed for the rapid removal of the gases from the retorts is White's process, the mechanical details of which are fully described below. This process consists essentially in transmitting a current of *water-gas* through the retorts in which coal or cannel gas is being generated. The water-gas is produced by transmitting steam through retorts filled with coke or charcoal, and consists of a mixture of hydrogen, carbonic oxide, and carbonic acid gases. These gases, which are not in themselves luminiferous on combustion, necessarily become mixed with the coal or cannel gas, and thus diminish the illuminating power of the latter whilst they increase its volume. Nevertheless, if the admission of water-gas be properly managed, the luminiferous constituents saved from destruction by their rapid removal from the retorts, compensate for the dilution of the gas, so as to render the diluted gas equal in illuminating power to the gas produced from the same coal or cannel in the ordinary process of manufacture. When cannels yielding very highly luminiferous gas are employed, it is desirable to dilute them to a much greater extent, and this can be easily effected by admitting into the coal-retort a larger proportion of water-gas. In some cases the total amount of light yielded by the gas from a given weight of coal when treated according to White's process is more than double that obtained by the ordinary process, and in all cases the gain in total amount of light is very large, thus showing the importance of removing the gases from the red-hot retorts as rapidly as possible. This remark applies especially to gases very rich in luminiferous hydrocarbons, because such gases suffer relatively much more deterioration than those containing a larger proportion of diluents. In addition to these advantages, such a dilution of rich cannel-gases with any of the non-luminous constituents, hydrogen, carbonic oxide, or light carburetted hydrogen, increases the illuminating power of the gas in another way: this is effected by their forming a medium for the solution of the vapours of such hydrocarbons as exist in the liquid or even solid state at the ordinary temperature of the atmosphere, and they thus enable us to convert an additional quantity of illuminating materials into the gaseous form, which they retain permanently, unless the temperature fall below the point of saturation. The gain in illuminating power which is thus obtained will be perhaps better seen from the following example:—Suppose 100 cubic inches of olefiant gas were allowed to saturate itself with the vapour of a volatile hydrocarbon, containing three times as much carbon in a given volume of its vapour as that contained in an equal volume of olefiant gas, and that it took up or dissolved 3 cubic inches of this vapour; then, if we express the value of 1 cubic inch of olefiant gas by unity, the illuminating power of the 103 cubic inches of the mixture of olefiant gas and hydrocarbon-vapour will be 109. Now if we mix these 103 cubic inches with 100 cubic inches of hydrogen, the mixture will be able to take up an additional 3 cubic inches of hydrocarbon-vapour, and the illuminating power of the 206 cubic inches will then become 118; thus the hydrogen produces a gain in illuminating power equal to 9 cubic inches of olefiant gas, or nearly 4·5 per cent. upon the volume of mixed gases. When we consider that coal-naphtha contains hydrocarbons of great volatility, and that these are the surplus remaining after the saturation of the gas from which they are condensed, the importance of this function of the non-illuminating class of combustible gases will be sufficiently evident. It may here be remarked that incombustible gases could not be employed for this purpose, since their cooling influence upon the flame during the subsequent burning of the gas would diminish the light to a greater extent than the hydrocarbon-vapour could increase it.

It is evident that all the three non-illuminating gases, forming the class of diluents, would perform both the offices here assigned to them perfectly well, and therefore we have as yet seen no reason for giving our preference in favour of any one of these diluents; if, however, we study their behaviour during combustion, we shall find that where the gas is to be used for illuminating purposes, hydrogen has qualities which give it a very decided preference over the other two. When gas is used for lighting the interior of public buildings and private houses, it is very desirable that it should deteriorate the air as little as possible, or, in other words, it should consume as small a quantity of oxygen and generate as little carbonic acid as possible. The oppressive heat which is so frequently felt in apartments lighted with gas also shows the advantage of the gas generating a minimum amount of heat.

The following is a comparison of the properties of the three non-illuminating gases in reference to the points just mentioned:—

One cubic foot of light carburetted hydrogen, at 60° Fahr. and 30 inches barometrical pressure, consumes 2 cubic feet of oxygen during its combustion, and generates 1 cubic foot of carbonic acid, yielding a quantity of heat capable of heating 5 lbs. 14 oz. of water from 32° to 212°, or causing a rise of temperature from 60° to 80°·8 in a room containing 2,500 cubic feet of air.

One cubic foot of carbonic oxide, at the same temperature and pressure, consumes, during combustion, ½ a cubic foot of oxygen, generates 1 cubic foot of carbonic acid, and affords heat capable of raising the temperature of 1 lb. 14 oz. of water from 32° to 212°, or that of 2,500 cubic feet of air from 60° to 66°·6.

One cubic foot of hydrogen, at the same temperature and pressure, consumes ½ a cubic foot of oxygen, generates no carbonic acid, and yields heat capable of raising the temperature of 1 lb. 13 oz. of water from 32° to 212°, or that of 2,500 cubic feet of air from 60° to 66°·4.

This comparison shows that light carburetted hydrogen is very objectionable as a diluent, not only on account of the carbonic acid which it generates, but also by reason of the very large quantity of oxygen which it consumes, and the very great amount of heat which, in relation to its volume, it evolves on combustion; the consumption of oxygen being four times, and the absolute thermal effect more than three times as great as that of either of the other gases.

The quantity of heat evolved by the combustion of equal volumes of carbonic oxide and hydrogen is nearly, and the amount of oxygen consumed quite, the same; but the carbonic acid evolved from the first gives a decided preference to hydrogen as the best diluent.

The same comparison also shows that when the gas is to be used for heating purposes, and the products of combustion are carried away, light carburetted hydrogen is by far the best diluent.

The experiments of Dulong on the absolute thermal effects of hydrogen, light carburetted hydrogen, and carbonic oxide are taken as the basis of the foregoing calculations. Dulong found that—

1 lb. of hydrogen	raised the temperature of	1 lb. of water	through	62,471° F.
1 lb. of carbonic oxide	„	„	„	4,505° F.
1 lb. of light carburetted hydrogen		„	„	24,244° F.

These considerations indicate the objects that should chiefly be regarded in the generating department of the manufacture of gas for illuminating purposes. They are—

1st. The extraction of the largest possible amount of illuminating compounds from a given weight of material.

2nd. The formation of a due proportion of illuminating and non-illuminating constituents, so that on the one hand the combustion of the gas shall be perfect, and without the production of smoke or unpleasant odour, and on the other, the volume of gas required to obtain a certain amount of light shall not be too large.

3rd. The presence of the largest possible proportion of hydrogen amongst the non-illuminating constituents, to the exclusion of light carburetted hydrogen, and carbonic oxide; so as to produce the least amount of heat and atmospheric deterioration in the apartments in which the gas is consumed.

For some time previous to the strike of the gas-stokers, and to the temporarily-diminished illumination which it produced, a number of ingenious persons were busy with endeavours to improve and cheapen the manufacture of gas; and the strike had the good effect of attracting to their labours more attention than these would otherwise have commanded. About that time two new methods were brought prominently before the public—one of them being the process of Messrs. Porter and Lane, the property of the Gas Generator Company, and the other being the process of Mr. Ruck, which is now vested in the New Gas Company. See Gas, Water.

The method of Messrs. Porter and Lane consists essentially in an improved arrangement of the retorts, by which the distillation of coal is greatly facilitated. It has now been experimentally in use, upon a working scale, in the manufactory of the Chartered Gas Company in the Horseferry-road, and is established on a larger scale at their principal works at Beckton. Instead of the usual horizontal retorts, which are charged and emptied with great difficulty by severe labour, Messrs. Porter and Lane use vertical retorts, within which a screw, with an oblique blade, slowly revolves on a vertical axis. The coal is placed in a chamber or hopper above, and trickles down into the retort as room is made for it by the subsidence of that which is below. The apparatus is, therefore, self-feeding, and only requires that the hopper should be supplied at proper intervals by easy labour, such as can be done by anyone who can handle a spade and a barrow. The revolution of the screw keeps a spiral line of coal in constant contact with the inner side of the retort; and the intervals between the turns of the blade allow room for the disengagement of the gas. By the time the coal reaches the bottom of the screw it is exhausted, and it falls as coke into a vertical chamber below, which is continuous with the retort, but beneath the furnace, and in which it is instantly quenched. The coke-chamber can be emptied by one man, as often as necessary, in one minute; and the whole process requires scarcely any interference from those in charge of it. By establishing a proper relation between the length of the screw, the speed of its rotation, and the heat of the furnace, the distillation of the coal can be carried exactly to the most desirable point, so as to obtain from it all the gas it can yield, and to stop short of the evolution of a variety of noxious products. In the horizontal retorts the outer crust of the mass of enclosed coal becomes over-burnt long before the inner portion is exhausted, and in this way many sulphur compounds are produced, even although the charge, as a whole, is withdrawn flaming and manifestly unexhausted. In Porter and Lane's process, on the contrary, the charge falls out bit by bit in a glowing condition, and yields a coke which is said to be much better adapted for household purposes than that ordinarily made. It is said to be lighter and more spongy in texture, and to kindle readily when placed on a common fire; but it burns out with great rapidity.

The results hitherto obtained by this method at the works of the Chartered Gas Company seem to show a constantly-increased production of gas to the extent of 2,000 cubic feet for each ton of coal, and also an increased production of coke. Moreover, the division and distribution of coal by the screw exposes it so completely to the action of heat that the retorts may be kept at a lower temperature than in the ordinary method, and thus the life of each retort will be proportionately prolonged. The saving of labour, of course, speaks for itself; and the quality of the gas, especially with reference to the presence of sulphur-compounds, is very superior to that made in the usual way. The retorts remain free from carbonaceous deposit, and their vertical arrangement has admitted of improvement in the furnace, by which a considerable saving in repairs, fuel, and labour is effected.

The following remarks on the manufacture of gas for illuminating purposes are mainly derived from a paper read by Mr. Thomas Wills before the Society of Arts. After a few remarks on the constitution of wood, lignite, and coal, and the products of their gradual resolution into simpler compounds, their more rapid decomposition by heat was illustrated by the following table, showing the proportion of hydrogen and carbon in coal-gas as distilled at different temperatures, the hydrogen being maintained constant:—

Temperature	Hydrogen	Carbon	Name of gas
Dull red heat . .	100	614	Principally olefiant gas (C_2H_4).
Red heat . . .	100	580	
Bright red heat .	100	472	Olefiant gas (C_2H_4) mixed with marsh gas (CH_4).
White heat . .	100	325	Marsh gas (CH_4).
Continued white heat	100	7	Nearly pure hydrogen, carbon deposited.

The number of well-known intermediate products obtained during the destructive distillation of coal is very large, and coal-gas itself not only contains certain permanent gases, but also a large quantity of the vapours of volatile hydrocarbons, which contribute in no small degree to its luminosity. Still, the greater bulk of the gas is composed of hydrogen, the flame of which is without any light-giving properties whatever, and marsh gas, a gas possessing the least light-giving power of any hydrocarbon, as it contains the smallest proportion of carbon to the largest of hydrogen.

Average Composition of Coal-Gas supplied by the following Companies:—

	Great Central	Imperial	Chartered
Illuminating hydrocarbons	3·56	3·67	3·53
Marsh gas	35·28	40·66	35·26
Hydrogen	51·24	41·15	51·80
Carbonic oxide	7·40	8·02	8·05
Carbonic acid	0·28	0·29	
Nitrogen	1·80	5·01	0·38
Oxygen	0·44	1·20	0·08
	100·00	100·00	100·00

There can be no question that a great advance in the manufacture of coal-gas would be made if, by any means, applied either with primary distillation of the coal or to the gas after its production, whereby the amount of acetylene (C^2H^2) or of olefiant gas (C^2H^4) could be increased; for olefiant gas contains, in a given bulk, just twice as much carbon as marsh gas, and acetylene a still larger quantity. The value of this increase is not to be measured only by the increased quantity of carbon contained in a given bulk of gas, for a small portion of either of the above compounds, diffused through a non-illuminating gas, is much more than equivalent to a similar quantity of carbon combined in some less condensed compound. An illustration of this occurs in the case of marsh gas. If marsh gas, possessing, it will be remembered, only a small amount of luminosity, be decomposed, either by its passage through a heated tube, or by the electric spark, the carbon it contains will be deposited, while the amount of hydrogen set free will occupy double the volume of the original gas. Yet the flame of this nearly pure hydrogen will be found to possess a greater luminosity than the flame of the original marsh gas, although it has lost nearly the whole of its light-giving material, accounted for by the presence of a very small quantity of acetylene, produced during the decomposition.

In 1871 a patent was taken out for 'Improvements in the manufacture and purification of gas, and in certain parts of the apparatus employed therein.' This process is carried out by distilling the coal at a much lower temperature than usual—in the original scheme from 600° to 1,000° Fah. is mentioned, but in practice from 1,300° to 1,400° Fahr. will probably be employed; at this temperature, from a ton of gas-coal about 8,500 cubic feet of gas are obtained, together with a greater than ordinary yield of tar and oil: this tar is condensed, by special means employed for securing a greater rapidity in the process, and collected as free from water as possible, with a view to its being re-distilled in a separate and peculiar retort.

The following are some of the more important points brought out by examination of this process by Messrs. Keates and Odling. The highest yield of gas obtained directly from the coal was 9,775 cubic feet, the temperature of distillation being between 1,300° and 1,400° Fahr. The quantity of oil and tar obtained from one ton of coal varied considerably with the nature of the coal used; thus, Silkstone coal-gas 16·4 gallons of tar and oil per ton, Clay Cross main 11·9 gallons, and Pelaw main 13·9 gallons, or a mean of 14 gallons. The highest yield of gas which was obtained by the continued distillation and redistillation of the oily tar was 29 cubic feet per gallon. The mean lighting power of the gas produced from coal was 23·0 candles, and of that obtained from the tar 25·0 candles. The quantity of coke used to maintain the heat in the various parts of the apparatus was about 33 per cent. of that produced, and in the event of the distillation being repeated until complete separation into pitch and vaporisable matters takes place, this amount would be much exceeded. It is a generally-accepted fact that the quicker coal be carbonised in gas-making, provided it be done effectually, the more successful will be the operation. A plan for effecting this has recently been brought forward, the principle of which is as follows:—The retort in this case is set in a vertical position, and through its centre revolves a broad and somewhat deep screw, placed together in sections, the thread of which is placed at an angle of 45°, and which comes nearly into contact with the sides of the retort. Through a nipple at the top, coal is supplied, in pieces of small but regular size; the inclination of the thread of the screw impels the pieces against the heated sides, where comparatively rapid carbonisation takes place, and the rate of revolution of the screw is so regulated, that by the time the fuel has arrived at the bottom of the retort the process is complete, and coke of a somewhat inferior quality is discharged into a suitable receptacle. The yield of gas is greater by this means, and of higher illuminating power, the amount of tar being correspondingly less; the difficulties in this case appear to be chiefly mechanical. That the process is successful, will be seen from the following results:—

Coal carbonised	Quantity of Gas obtained	Illuminating power of Gas	Amount of Tar
ton		candles	gallons
1	11,040	16	85
1	10,160	17	
1	12,000	16	

The fact of the existence of a large number of hydrocarbons of great volatility, the vapours of which, when ignited, burn with exceedingly luminous flame, has been a very great incentive with inventors to produce some scheme whereby these vapours might be used to confer luminosity upon a combustible non-luminous gas, or further inflammability, coupled with luminosity, upon a non-combustible and negative gas.

Another process which has claimed some attention is that of Dr. Eveleigh, which has been used by the Patent Gas Company, and investigated, and reported on, by Dr. Odling and Mr. Keates.

The process consists in the distillation of coal in iron retorts of double the ordinary capacity, at a lower temperature than that usually employed. A smaller yield of gas is thus procured of comparatively high lighting power, together with a certain quantity of oily tar, which is subsequently submitted to destructive distillation in a peculiarly-constructed apparatus, in which the oil suffers a partial conversion into permanent gas. These two processes are, in practice, carried on simultaneously, the resulting gases mixing during their passage to the holder. The combined result of the distillation of the coal and oil by this method gives a larger yield of gas per ton of coal, it is of considerably higher lighting power, and is comparatively free from sulphur-compounds.

The apparatus used for the distillation of the oil consists of three vessels placed at increasing distances from the source of heat. The oil flows into that having the lowest temperature (about 900° F.), where the fixed portion of the oil remains as pitch, while the more volatile vapour, after becoming further heated by passing through the second chamber, enters the last or hottest vessel. This is an iron pan filled with charcoal, and heated to about 1,300° F. The highly-heated vapour of the oil, during its passage through the incandescent charcoal, is partially converted into permanent gas. This gas, after leaving the oil-still, enters a tank containing a little water, through which it passes, in order to condense any undecomposed oil: it is then conducted along a pipe, where it meets with the gas from the coal, the mixture going through the purifiers to the holder in the usual way.

The highest yield of gas obtained by this method from ordinary Norfolk Silkstone coal, during the experiments of Mr. Keates and Dr. Odling, was 10,500 cubic feet of 25-candle gas to the ton, the sulphur being as low as 6 grains per 100 cubic feet. This is certainly a striking result, as compared with the ordinary yield of the same coal, which is about 9,300 feet of 14-candle gas, frequently containing over 30 grains of sulphur per 100 feet.

Although it has been proved possible to obtain the above favourable result by Dr. Eveleigh's process, it is to be feared that the extra amount of plant, labour, and fuel required, necessitates such increased expenditure as to more than compensate for the increased yield.

On the purification of illuminating gas.—If we except the insignificant quantities of nitrogen and oxygen, which become mixed with illuminating gas through imperfections in the joints of the apparatus employed, and by the transferring power of the water of the gasholder, all impurities arise from the presence of the three elements sulphur, oxygen, and nitrogen in the generating material used.

The sulphur, uniting with portions of the hydrogen and carbon of the coal, generates, with the first-named element, sulphuretted hydrogen, and with the second, bisulphide of carbon. It is also probable that volatile organic compounds of sulphur are produced by the union of this element with carbon and hydrogen simultaneously, although we have as yet no positive evidence of their presence in illuminating gas. The oxygen, uniting with another portion of carbon, forms carbonic acid, whilst the nitrogen unites with hydrogen to form ammonia, which, by combination with sulphuretted hydrogen, produces hydrosulphate of sulphide of ammonium, and, with carbonic acid and water, carbonate of ammonia. With the exception of bisulphide of carbon and the organic sulphur-compounds just mentioned, the removal of all these impurities is not difficult. Slaked lime, either in the form of moist powder, or suspended in water as milk of lime, absorbs the whole of them; whilst it has no perceptible effect upon the other constituents of the gas. By this process of purification the sulphuretted hydrogen and caustic lime are converted into sulphide of calcium and water; the former being non-volatile, does not mix with the gas. Hydrosulphate of sulphide of ammonium is in like manner converted into sulphide of calcium, water, and ammonia: part of the latter is retained by the moisture present in the purifying material, but the remainder mixes with the gas, from which, however, it can be removed by contact with a large surface of water. Carbonic acid unites with caustic lime with great energy, forming carbonate of lime, a perfectly non-volatile material; and thus the acid gas is effectually retained. Carbonate of ammonia is under similar circumstances decomposed, carbonate of lime being formed and ammonia liberated; the last, as before, being only partially retained by the moisture present, and requiring, when 'dry lime' is used, a subsequent application of water for its complete removal. Although in the wet-lime purifying process a given weight of lime can remove a much larger volume of impurities, yet the dry-lime process possesses so many manipulatory advantages that it is now all but universally employed where lime is used as the purifying agent. The maximum amount of sulphuretted hydrogen or of carbonic acid which can be absorbed by 1 lb. of quick-lime, in the so-called dry and wet states respectively, is seen from the following table:—

	Cubic feet of Sulphuretted hydrogen	Cubic feet of Carbonic acid
1 lb. of quick-lime used as dry lime absorbs	6·78	3·39
1 lb. of quick-lime used as wet lime absorbs	6·78	6·78

In practice, however, the absorption actually effected is, even under the most favourable circumstances, considerably less than here indicated. As a substitute for lime in the purification of gas a mixture of hydrated peroxide of iron and sulphate of lime has lately come into extensive use. This material is prepared in the first place by mixing slaked lime with hydrated peroxide of iron, the composition being rendered more porous by the addition of a certain proportion of sawdust. This mixture is now in a condition to remove those impurities from coal-gas which are abstracted by lime. The peroxide of iron absorbs sulphuretted hydrogen and sulphide of ammonium, and becomes converted into sulphide of iron. The slaked lime absorbs carbonic acid and carbonate of ammonia until it is converted into subcarbonate of lime. When the absorbing powers of the mixture are nearly exhausted, the covers of the purifiers are removed and the mixture is exposed to the air. The following change is then said to take place. The sulphide of iron rapidly absorbs oxygen and becomes converted first into sulphate of protoxide of iron and finally into sulphate of peroxide, which latter is decomposed by the carbonate of lime, carbonic acid being evolved as gas, whilst sulphate of lime and peroxide of iron are produced; the mixture is thus again rendered available for the process of purification; the peroxide of iron acts as before, but in the place of quick-lime we have now sulphate of lime, which is quite effectual for the removal of carbonate of ammonia, with which it forms carbonate of lime and sulphate of ammonia; but the mixture is incapable of removing free carbonic acid, and it is therefore necessary to provide a separate dry-lime purifier for the removal of this gas. When the purifying material is again saturated with the noxious gases, another exposure to atmospheric oxygen restores it again to its active condition, the only permanent effect upon it being the accumulation of sulphate of ammonia within its pores. If this latter salt be occasionally dissolved out with water, the mixture may be used over and over again to an almost unlimited extent. It has been found that this process can be much simplified; and Mr. Hills, who has brought gas-purification to great perfection, recommends that hydrated peroxide of iron should be merely mixed with a considerable bulk of sawdust and placed in the purifiers. After the gas has passed through this mixture for 18 hours, it is shut off and replaced by a current of air forced through by a fanner for 3 hours. The sulphide of iron is thus oxidised, sulphur being separated and hydrated peroxide of iron regenerated; and the purifying material being now revivified, the gas may be passed through it again as before. In this way it is only found necessary to remove the material once a month in order to separate the lowest stratum of about an inch in thickness, which has become clogged up with tar. A proportional quantity of fresh mixture of hydrated peroxide of iron and sawdust having been added, the whole is again returned to the purifier. It is difficult to conceive a more simple and inexpensive process of purification than this. It does not, however, remove carbonic acid. Several other materials have been proposed for the separation of sulphuretted hydrogen from coal-gas, such as sulphate of lead, and chloride of manganese, but they possess no peculiar advantages, and have never been extensively adopted.

It has been already mentioned that, in addition to sulphuretted hydrogen and carbonic acid, which are readily removed by the processes just described, there also exist in coal-gas, as impurities, various quantities of bisulphide of carbon and probably sulphuretted hydrocarbons. Now all these sulphur-compounds produce sulphurous acid during the combustion of the gas, and where the quantities of these impurities is considerable, as is the case with much of the gas now manufactured, the atmosphere of the apartments in which such gas is used becomes so strongly impregnated with sulphurous acid, as to be highly offensive to the senses and very destructive to art decorations, bindings of books, &c. It becomes, therefore, a matter of considerable importance to prevent, as far as possible, the occurrence of these injurious constituents; in fact, until this is effected, gas will never be more than very partially adopted as a means of illumination in dwelling-houses. When once generated with coal-gas all attempts to remove these constituents have hitherto proved ineffectual; and there seems little ground for hope that any practicable process will be devised for their abstraction. Attention may, therefore, more profitably be directed to the conditions which tend to diminish the amount generated in the retorts, or altogether to prevent their formation. Mr. Wright, who has paid considerable attention to this problem, finds that the employment of a moderate heat for the generation of the gas has the effect of greatly reducing the relative quantity of these noxious ingredients, and thus by simply avoiding excessive heat in the retorts, and rejecting the last portions of gas, he has, to a great extent, prevented their formation. Unfortunately, however, this remedy is not likely to find favour amongst gas-manufacturers in general, inasmuch as it considerably reduces the yield of gas. A few well-directed chemical experiments could scarcely fail to discover the conditions necessary for the non-production of these sulphuretted compounds. Probably the proper admixture of salt or lime with the coals before carbonisation would have the desired effect. The subject is one of so much importance to the future of gas illumination, that it ought not to be suffered to rest in its present unsatisfactory condition.

On the consumption of gas.—The proper consumption or burning of illuminating gas depends upon certain physical and chemical conditions, the due observance of which is of great importance in the development of a maximum amount of light. The production of artificial light depends upon the fact that, at certain high temperatures, all matter becomes luminous. The higher the temperature the greater is the intensity of the light emitted. The heat required to render matter luminous in its three states of aggregation differs greatly. Thus solids are sometimes luminous at comparatively low temperatures, as phosphorus and phosphoric acid. Usually, however, solids require a temperature of 600° or 700° Fahr. to render them luminous in the dark, and must be heated to 1000° Fahr. before their luminosity becomes visible in daylight. Liquids require about the same temperature. But to render gas luminous, they must be exposed to an immensely higher temperature; even the intense heat generated by the oxyhydrogen blowpipe scarcely suffices to render the aqueous vapour produced visibly luminous, although solids, such as lime, emit light of the most dazzling splendour when they are heated in this flame. Hence it has generally been maintained that those gases and vapours only can illuminate which produce, or deposit, solid or liquid matter during their combustion. This dependence of light upon the production of solid matter is strikingly seen in the case of phosphorus, which when burnt in chlorine produces a light scarcely visible, but when consumed in air or oxygen emits light of intense brilliancy. In the former case the *vapour* of chloride of phosphorus is produced, in the latter, *solid* phosphoric acid.

Several gases and vapours possess this property of depositing solid matter during combustion, but a few of the combinations of carbon and hydrogen are the only ones capable of practical application; these latter compounds evolve during combustion only the same products as those generated in the respiratory process of animals, viz. carbonic acid and water. The solid particles of carbon which they deposit in the interior of the flame, and which are the source of light, are entirely consumed on arriving at its outer boundary; their use as sources of artificial light, under proper regulations, is therefore quite compatible with the most stringent sanitary rules.

The constituents of purified coal-gas have already been divided into illuminating and non-illuminating gases; amongst the latter will be found light carburetted hydrogen, which, although usually regarded as an illuminating gas, has been proved by the experiments of Frankland to produce, under ordinary circumstances, no more light than hydrogen or carbonic oxide, and therefore for all practical purposes it must be regarded as entirely destitute of illuminating power. This is owing chiefly to the temperature required for the deposition of its carbon being higher than that attained in an ordinary gas burner; for Frankland has proved that, if the temperature of the light carburetted hydrogen flame be increased by previously heating the gas and air nearly to redness, then the flame becomes luminous to a considerable degree. It is not improbable that when gas is consumed in very large burners this necessary temperature is attained, and the light carburetted hydrogen contributes considerably to the aggregate illuminating effect; a view which is, to a certain extent, confirmed by the fact, that a relatively much larger amount of light is obtained from coal-gas when the latter is consumed in a large flame than when it is allowed to burn in a small flame.

Omitting light carburetted hydrogen and carbonic oxide, the remaining carboniferous constituents of coal-gas yield, during combustion from suitable burners, an amount of light directly proportionate to the quantity of carbon which they contain in a given volume.

In order to understand the nature of the combustion of a gas flame, it is necessary to remember that the flame is freely permeable to the air, and that according to the well-known laws of gaseous mixture, the amount of air which mixes with the ignited gases will be increased, first, by an increase of the velocity with which the gas issues from the orifice of the burner; and secondly, by the velocity of the current of air immediately surrounding the flame. It is well known that a highly luminiferous gas may be deprived of all illuminating power either by being made to issue from the burner with great velocity, or by being burnt in a very rapid current of air produced by a very tall glass chimney.

The foregoing considerations indicate the conditions best adapted for obtaining the maximum illuminating effect from coal-gas. The chief condition is the supply of just such a volume of air to the gas flame as shall prevent any particles of carbon from escaping unconsumed. Any excess of air over this quantity must diminish the number of particles of carbon deposited within the flame, and consequently impair the illuminating effect.

Dr. Frankland has shown that the luminosity of a flame is materially modified by the pressure of the atmosphere in which it burns; the denser the air the more brilliant the light, the carbon combining more rapidly with the increased quantity of oxygen. Hence the illuminating effect of the same gas will vary in different localities; thus, a quantity of gas which gives in London the light of 100 candles would give in Munich (1,700 feet above the sea-level) only the light of 91 candles, and if the same gas were burned in the city of Mexico (about 7,400 feet above the level of the sea) it would yield the light of only 61½ candles.

The following remarks on increasing the illuminating power of coal-gas by carburetting or naphthalising, are derived from the Rev. W. R. Bowditch's work on 'The Analysis, Technical Valuation, Purification, and Use of Coal-gas':—

'Carburetting gas signifies adding to it vapours of hydrocarbons, which contain a large proportion of carbon in comparison of their other constituent, hydrogen; and as coal-naphtha was first used for this purpose, and is yet the chief substance employed, the process was named naphthalising, from the fluid employed. Coal-naphtha is a mixture of hydrocarbons, and is made up of a solid (carbon) and a gas (hydrogen), which, when united, form a fluid that contains a far higher percentage of carbon than gas does. It is to this high percentage of carbon it owes its use in improving the light of gas, to which its vapour is added. In fact, the light-giving power of gas supplied to us for combustion is largely due to the pressure in it of vapours which, when they are condensed into a fluid we call naphtha. We need not be chemists to ascertain that naphtha is much richer in carbon than coal-gas is; for if we light gas it burns with a luminous, but not with a smoky flame, whereas if we apply a light to a little naphtha in a saucer, it burns with a red flame, which affords but little heat, and deposits large quantities of carbon in the well-known form of soot. The proportion of carbon is so large that there is not heat enough to burn it, and hence the smoke. The cause of this is obvious. When the naphtha-vapour is fired, both of its constituents burn, but the heat-producing constituent, hydrogen, is relatively so small in quantity that its heat cannot raise the carbon to the temperature required for its union with oxygen or, as it is popularly called, burning, and therefore the unburnt carbon is deposited in visible black particles, instead of being converted into an invisible gas (carbonic acid), as it would have been had the hydrogen been in sufficient quantity to heat up the carbon to the temperature requisite for its combustion. Had this been the case the flame would have been smokeless instead of smoky, and white instead of red. The case of gas is very different. When that is lighted much more than enough heat is produced to burn its carbon perfectly. The richness of naphtha in carbon may also be inferred from the fact that while a cubic foot of common gas weighs but about 224 grains, a cubic foot of naphtha weighs more than 370,000 grains. Now, this naphtha is composed of carbon and hydrogen only. Hydrogen is the lightest substance known in nature, and a cubic foot of it weighs but 37·1 grains, from which it is easy to see that the other constituent (carbon) gives the weight to the naphtha. Why is it necessary to add to gas these highly carburetted bodies? Because the solid carbon which they contain is required to give light. A gas which does not contain a solid gives but a mere trace of light, however great the heat produced by its combustion. This is well seen in the case of the gas hydrogen. When it burns, the heat produced is very intense. Solid substances held in the flame become strongly ignited and afford light; but without the solid the burning gas gives so little light that we cannot imagine a flame sufficiently large to afford us useful illuminations; and, if we could produce such a flame, the heat of it would be unbearable. Hydrogen does not contain a solid, and the sole product of its combustion is water. If we pass hydrogen over naphtha we find by the smell that it has carried with it a quantity of the vapour; and if we then burn the hydrogen so mixed with vapour, we obtain light, and the light increases as the quantity of vapour mixed with the hydrogen increases. In this case the hydrogen burns as soon as it comes into contact with the air, and produces intense heat. This heat decomposes the naphtha-vapour and sets free its carbon in the solid form, and then heats it to whiteness, at which temperature it affords light; the quantity of light being regulated, first, by the quantity of carbon present in the flame; and, secondly, by the temperature to which the solid carbon is raised. The greater the quantity of carbon and the higher its temperature, the greater the light. Another change is observed to take place when the hydrogen is mixed with the vapour. The flame of hydrogen alone is small in comparison of the flame produced by the same quantity of coal-gas, but if the hydrogen be passed over naphtha and burnt at the same rate as before, the flame is considerably expanded by the white-hot carbon contained in it. That which occurs in this case occurs universally. An increase of luminosity is always attended by an increased size of flame when the gases compared are burnt at the same rate.

'What has now been said applies to the case of coal-gas thus: The principal portion of coal-gas consists of heat-producing substances which do not give light, and which, like hydrogen, require to be mixed with bodies rich in carbon before they can be made useful. In gas itself we find some of these richly-carburetted bodies, but their quantity is small even in the best gas, and of course much smaller in gas of inferior quality. Professor Bunsen of Heidelberg has published an analysis of Manchester gas, in which he shows the percentage of illuminants and non-illuminants; and although the Manchester gas is made principally from cannel coal, and has an illuminating power of from 20 to 22 sperm candles for a consumption of five feet per hour, the quantity of non-illuminating gas is far larger than is suspected by persons not familiar with the subject. The following is Professor Bunsen's statement, ("Gasometry," p. 113):—

Analysis of Manchester gas. In 100 *parts.*

Non-illuminating heat-producers	Hydrogen	45·58	87·12 per cent.
	Marsh gas	34·90	
	Carbonic oxide	6·64	
Illuminants.	Elayl	4·08	6·46 per cent.
	Ditetryl	2·38	
Impurities.	Sulphuretted hydrogen	0·29	
	Nitrogen	2·46	
	Carbonic acid	3·67	
		100·00	

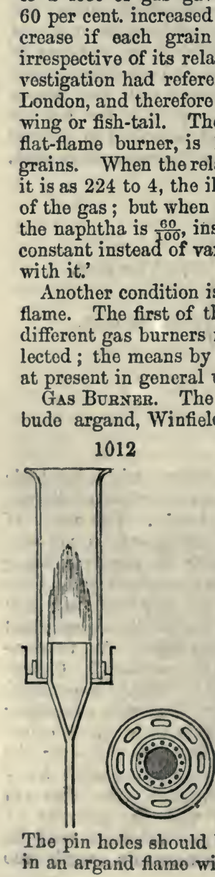
'This is cannel-gas. In common gas, such as that of London—which has little more than half the illuminating power of Manchester gas—the proportion of illuminants is smaller, and of non-illuminating heat-producers is larger. The mean of results obtained by many chemists shows that common 12-candle gas does not contain more than 4 per cent. of illuminating constituents, the other 96 per cent. being non-illuminating heat-producing compounds; that is, 4 feet in a hundred yield light and 96 feet yield heat. It seems extraordinary, that when we buy and burn 100 cubic feet of cannel gas we obtain and use only 6½ feet of useful illuminants, and are obliged to take 87 feet of gases which do not furnish any light. An unscientific person is apt to exclaim "Can this be? and if it be, is it necessary? Cannot the illuminants be made and sold without the heat-producers?" This is impossible. Gas cannot be made without its bulk being non-illuminating. But still something can be done to *increase the proportion* of illuminants, and this is what is called naphthalising or carburetting. We find by experiment if we pass gas over the highly-carburetted substance called naphtha, that every foot of gas carries away with it as vapour a part of the naphtha; that the naphtha-vapour burns with the gas; and that the light-giving power of the gas increases with the quantity of naphtha-vapour so removed and burnt. We can measure the gas, weigh the naphtha removed, determine the increase of light obtained, and thus ascertain exactly the illuminating value of each grain of naphtha burnt with the gas. The naphtha thus added to gas does not burn with a red flame, which gives off much smoke, as it does when burnt alone, but it gives a bright, white, smokeless flame. This result is due to the non-illuminating but heat-producing compounds of the gas. The naphtha contains so much carbon and so little heat-producing hydrogen, that when it is set on fire alone the carbon is not heated sufficiently to burn and still less to render it highly luminous; wherefore its light is feeble, and much of the carbon is deposited as soot. But when it is burnt with gas the heat-producers in the gas raise the carbon of the naphtha to a sufficient temperature to enable it to give off a brilliant light, and to burn without smoke. Thus, the heat-producers are rendered directly useful. They raise the carbon to the temperature required for illumination and combustion. The naphtha, on the other hand, remedies the want of luminosity in the gas by adding to it much carbon, in which it is deficient, and but little hydrogen, in which the gas itself abounds.

'But for the teaching of experiment we should expect that if a given quantity of naphtha added to a given quantity of gas raised it in illuminating value (a) candles, then double the quantity of naphtha added to the same quantity of gas would raise it ($2\,a$) candles, three times the quantity ($3\,a$) candles, and so on. In other words, we should expect the illuminating value of a grain of naphtha to be the same however it was burnt with gas. Experience shows this to be a mistake, and proves that the illuminating value of a grain of naphtha depends upon *the relation which it bears to the bulk of gas with which it is burnt*, and that within certain limits its illuminating value varies greatly. Dr. Letheby investigated the increase of illuminating power obtained by naphthalising, and his results are published in the "Chemical News," vol. vi. pp. 283–292. It is there stated that four grains of naphtha added to a foot of gas gave 25 per cent. increased light, whereas 8 grains per foot gave 60 per cent. increased light, instead of 50 per cent., which would have been the increase if each grain of carburetting material had a constant illuminating value irrespective of its relation to the bulk of gas with which it is consumed. The investigation had reference to the use of naphtha in the public lamps of the city of London, and therefore the results must have been obtained in flat-flame burners, bat's-wing or fish-tail. The average illuminating value of a foot of common gas burnt in a flat-flame burner, is 1·6 candle, and the weight of a foot of such gas is about 224 grains. When the relation between the weight of the gas and the naphtha burned with it is as 224 to 4, the illuminating value of the naphtha is $\frac{25}{100}$ of the illuminating value of the gas; but when the relation is altered to 224 to 8, then the illuminating value of the naphtha is $\frac{60}{100}$, instead of 50, as it would have been if its illuminating value were constant instead of variable, and depending much upon the quantity of gas consumed with it.' . . .

Another condition is the attainment of the highest possible temperature within the flame. The first of these conditions has been more or less perfectly obtained in the different gas burners now in use. The second has been hitherto almost entirely neglected; the means by which it may be attained will be discussed after the burners at present in general use have been described.

Gas Burner. The chief burners now in use are the bat's-wing, fish-tail, argand, bude argand, Winfield's argand, Guise's argand, Leslie's argand.

1012



The *bat's-wing* consists of a fine slit cut in an iron nipple, giving a flat fan-like flame.

The *fish-tail* consists of a similar nipple perforated by two holes, drilled so that the jets of gas are inclined towards each other at an angle of about 60°. A flat film of flame is thus produced, somewhat resembling the tail of a fish. This form of burner is especially adapted for the consumption of cannel and other highly illuminating gases.

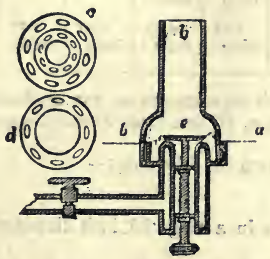
The *argand* consists of a hollow annulus (see *fig.* 1012), from the upper surface of which the gas issues through a number of small apertures, which are made to vary in diameter from $\frac{1}{32}$nd of an inch to $\frac{1}{50}$th of an inch, according to the richness of the gas; the most highly illuminating gases requiring the smallest apertures. The distances of the orifices for coal-gas should be ·16 to ·18 inch, and for rich cannel-gas ·13 inch. If the argand ring has 10 orifices, the diameter of the central opening should be $=\frac{4}{10}$ths of an inch; if 25 orifices, it should be one inch for coal-gas; but for oil-gas, with 10 orifices, the central opening should have a diameter of $\frac{1}{2}$ an inch, and for 20 orifices, 1 inch. The pin holes should be of equal size, otherwise the larger ones will cause smoke, as in an argand flame with an uneven wick.

The *Bude burner* consists of 2 or 3 concentric argand rings perforated in the manner just described. It is well adapted for producing a large body of very intense light with a comparatively moderate consumption of gas.

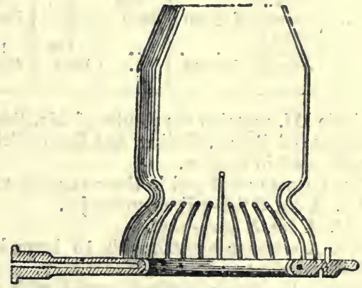
Winfield's argand.—The chief distinction between this and the ordinary argand burner consists in the introduction of a metallic button above the annulus, so as to cause the internal current of air to impinge against the flame. A peculiarity in the shape of the glass chimney, as seen in the figure, produces the same effect upon the outer current of air. See *fig.* 1013.

Guise's argand contains 26 holes in a ring, the inner diameter of which is ·6 inch, and the outer diameter 1·9 inch. Like the Winfield burner, it has a metal button ½ an inch in diameter, and 1 inch above the annulus. The glass chimney, which is cylindrical, is 2 inches in diameter and 6 inches long.

1013



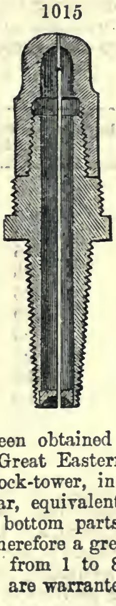
1014



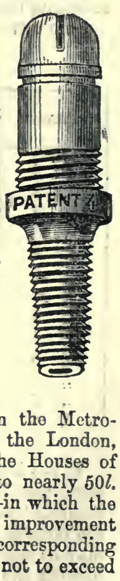
Leslie's argand consists, as seen in the figure (*fig.* 1014), of a series of fine tubes arranged, in a circle by which a more uniform admixture of air with the gas is effected. A sufficient current of air for all these argand burners can only be obtained by the use of a glass chimney, the rapidity of the current depending upon the height of the chimney. In the Leslie's argand the height of the chimney is especially adapted to the amount of light required, and in order to consume gas economically, this point must be attended to in all argand burners.

Brönner's burners, introduced by Messrs. Greene and Son, have lately attracted attention. The accompanying illustrations show the principle of this patent burner. *Fig.* 1015 is a section, and *Fig.* 1016 a full-sized drawing, from which it may be seen that, instead of the gas being admitted through a large opening and emitted through two small ones, as in the ordinary fish-tail burner, it is made to pass through a small aperture at the bottom into a circular chamber, and thence through a larger opening at the top, thus obviating all undue and variable pressure, the gas being fully consumed as it is emitted from the burner, instead of being forced through into the atmosphere partly unconsumed, to the injury of both health and furniture, &c. &c. By this method the disagreeable hissing noise, which is often noticed in the ordinary burner, is done away with, and the light given is pure, brilliant, and steady, of a whitish yellow instead of a bluish yellow flame, a very great improvement. That these burners, through improved combustion, produce a saving in the consumption of gas of from 20 to 40 per cent., is proved by the following facts :—

1015



1016



At the King's Cross station, Great Northern Railway, the saving in gas for six months was 1,072,000 cubic feet. A proportionately satisfactory result has also been obtained on the Metropolitan, the Great Western, the North London, the Great Eastern, the London, Chatham, and Dover, and other railways. At the Clock-tower, in the Houses of Parliament, 182,800 cubic feet were saved in one year, equivalent to nearly 50*l.* These burners are made of brass, having the top and bottom parts—in which the orifices are—of steatite, an incorrodible substance, and therefore a great improvement on the ordinary burners, and in eleven different sizes, from 1 to 8, corresponding to the number of cubic feet of gas per hour, while they are warranted not to exceed in consumption in any ordinary working pressure.

The following experiments made with different burners, by three eminent experimenters, upon the gas from three different kinds of coal, show the relative values of these burners for the gases produced from the chief varieties of coal used for the manufacture of gas in this country. (For Table I. see opposite page.)

Table III. contains the results of Mr. Barlow's experiments on gas produced from a mixture of Pelton, Felling, and Dean's Primrose, all first-class Newcastle gas-coals, largely used in London.

The burners employed in these experiments were the following:—

1st. A No. 3 fish-tail, or union jet.

2nd. A No. 5 bat's-wing.

3rd. A common argand, with 15 large holes in a ring ·85 inch diameter, and a cylindrical chimney-glass 7 inches high.

4th. A Platow's registered argand, with large holes in a ring, ·9 inch, with inside and outside cone, and cylindrical chimney-glass 8·5 inches high.

5th. A Bizzner patent No. 3 argand, with 28 medium-sized holes in a ring ·75 inch diameter, and cylindrical chimney-glass 8·65 inches high.

6th. A Winfield's registered argand, with 58 medium-sized holes in 2 rings of 29 holes in each, the mean diameter being 1 inch, with deflecting button inside and gauge below, bellied chimney-glass 8 inches high.

7th. A Leslie's patent argand, with 28 jets in a ring ·95 inch diameter, and chimney-glass 3·5 inches high.

8th. A Guise's registered shadowless argand, with 26 large holes in a ring ·85 inch diameter, and deflecting button, cylindrical chimney-glass 6·1 inches high, and glass reflecting cone to outside gallery.

On an average of numerous trials the annexed results were obtained:—

It has been stated that one of the conditions necessary for the production of the maximum illuminating power from a gas flame, is the attainment of the highest possible temperature, and that this condition has been almost entirely neglected in the burners hitherto in use. Dr. Frankland has, however, proved that this condition may be easily secured by employing the waste heat radiating from the gas flame, for heating the air previous to its employment for the combustion of the gas; and that the increased temperature thus obtained has the effect of greatly increasing the illu-

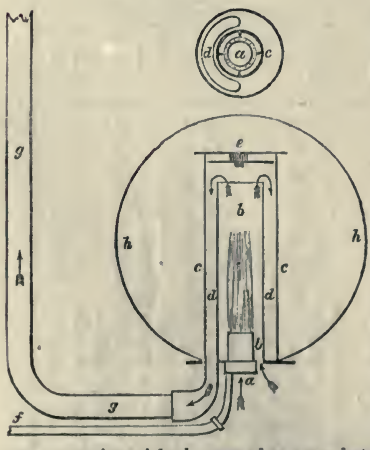
minating power of a given volume of the gas. *Fig.* 1017 shows the burner contrived by Dr. Frankland for this purpose. *a* is a common argand burner, or better, a Leslie's argand, furnished with the usual gallery and glass chimney *b*, *c*; the latter must be 4 to 6 inches longer than usual. *d d* is a circular disc of plate glass, perforated in the centre, and fixed upon the stem of the burner, about 1½ inch below the gallery, by the collar and screw *e*. *f f* is a second glass chimney, somewhat conical, ground at its lower edge so as to rest air-tight, or nearly so, upon the plate *d d*; and of such a diameter as to leave an annular space ¼ inch broad between the two cylinders at *g g*. The cylinder *f* should be of such a length as to reach the level of the apex of the flame. The action of this burner will now be sufficiently evident. When lighted, atmospheric air can only reach the flame by passing downwards through the space between the cylinders *f* and *c*; it thus comes into contact with the intensely-heated walls of *c*, and has its temperature raised to about 500° or 600° before it reaches the gas flame. The passage of this heated air over the upper portion of the argand burner also raises the temperature of the gas considerably before it issues from the burner. Thus the gases taking part in the combustion are highly heated before inflammation, and the temperature of the flame is consequently elevated in a corresponding degree. Experiments with this burner prove a great increase in light, due chiefly to the higher temperature of the radiating particles of carbon; but, no doubt, partly also to the heat being sufficiently high to cause a deposition of carbon from the light carburetted hydrogen; thus rendering this latter gas a contributor to the total illuminating effect, whilst, when burnt in the ordinary manner, it merely performs the functions of a diluent. The following are the results of Dr. Frankland's experiments with this burner:—

1017

	Rate of Consumption per Hour.	Light in Sperm Candles, each burning 120 grs. per Hour.
I. Argand burner without external cylinder.	3·3 cubic feet	13·0 candles.
	3·7 "	15·5 "
	4·2 "	17·0 "
II. Same burner with external cylinder.	2·2 "	13·0 "
	2·6 "	15·5 "
	2·7 "	16·7 "
	3·0 "	19·7 "
	3·3 "	21·7 "

1018



These results show that the new burner, when compared with the ordinary argand, saves on an average 49 per cent. of gas, when yielding an equal amount of light; and also that it produces a gain of 67 per cent. in light for equal consumptions.

Faraday's ventilating Burner.—This admirable contrivance, the invention of the late Prof. Faraday, completely removes all the products of combustion, and prevents their admixture with the atmosphere of the apartments in which the gas is consumed. The burner consists of an ordinary argand, *fig.* 1018, *a*, fitted with the usual gallery and chimney, *b b*. A second wider and taller cylinder, *c c*, rests upon the outer edge of the gallery which closes at bottom the annular space, *d d*, between the two glass cylinders. *c c*, is closed at top with a double mica cap, *e*. *f* is the tube conveying the gas to the argand; *g g* is a wider tube 1½ inch in diameter, communicating at one extremity with the annular space between the two glass cylinders, and at the other, either with a flue or the open air. The products of combustion from the gas flame are thus compelled to take the direction indicated by the arrows, and are therefore prevented from contaminating the air of the apartment in which the gas is consumed, *h* is a ground glass globe enclosing the whole arrangement, and having only an opening below for the admission of air to the flame. In order to dispense with the descending tube, to which there are some objections, Mr. Rutter has constructed a ventilating burner in which the ordinary glass chimney is made to terminate in a metal tube, through which the products of combustion are conveyed away. Mr. Dixon has also constructed a modification of Faraday's burner, the peculiarity of which consists in the use of a separate tube bringing air to the flame from the same place, outside the building, to which the products of the burner are conveyed; this contrivance is said to prevent downward draughts through the escape-pipe, and a consequently unsteady flame.

ON THE ESTIMATION OF THE VALUE OF ILLUMINATING GAS.

There are two methods in use for estimating the illuminating value of gas, viz.—

1st. The photometric method.

2nd. Chemical analysis.

The photometric method consists in comparing the intensity of the light emitted by a gas flame, consuming a known volume of gas, with that yielded by some other source of light taken as a standard. The standard employed is usually a spermaceti candle, burning at the rate of 120 grains of sperm per hour. A spermaceti candle of six to the pound usually burns at a somewhat quicker rate than this; but in all cases the consumption of sperm by the candle during the course of each experiment ought to be carefully ascertained by weighing, and the results obtained corrected to the 120-grain standard. Thus, suppose that during an experiment the consumption of sperm was at the rate of 130 grains per hour, and that the gas flame being tested gave a light equal to 20 such candles, and it is required to know the light of this flame in standard 120 grain candles, then—

$$120 : 130 :: 20 :: 21{\cdot}7,$$

or, 20 candles burning at the rate of 130 grains per hour, are equal to 21·7 candles burning at the rate of 120 grains per hour.

There are two methods of estimating the comparative intensity of the light of the gas and candle flames, both founded upon the optical law that the intensity of light diminishes in the inverse ratio of the square of the distance from its source. Thus, if a sheet of writing paper be held at the distance of one foot from a candle, so that its surface is perpendicular to a line joining the centre of the sheet and the flame, it will be illuminated with a light four times as intense as that which would fall upon a sheet of paper held in the same position at a distance of 2 feet; whilst at a distance of 3 feet the light would have but $\frac{1}{9}$th of the intensity which it possessed at 1 foot. One method of estimating the comparative intensity of the gas and candle flames, consists in placing the two lights and an opaque rod nearly in a straight line, and in such a way as to cause each light to project a shadow of the rod upon a white screen placed at a distance of about 1 foot behind the rod. The two shadows must now be rendered of equal intensity by moving the candle either nearer to the rod or further from it. The shadows will be of equal intensity when the light falling upon the white screen from both sources is equal; and if now the respective distances of the candle and gas flame from the screen be measured, then the square of the distance of the gas flame divided by the square of the distance of the candle will give the illuminating power of the gas in candles. Thus, if equally intense shadows fall upon the screen when the candle is 3 feet distant and the gas flame 12 feet, the illuminating power of the gas flame will be—

$$\frac{12^2}{3^2} = \frac{144}{9} = 16 \text{ candles.}$$

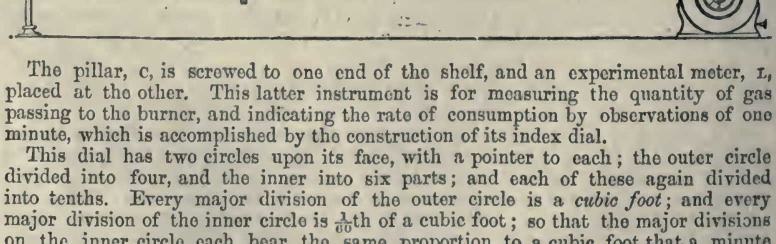
This method of estimating the illuminating power of a gas flame, known as the *shadow test*, is very easy of execution, and would appear from the description to be capable of yielding results of considerable accuracy; nevertheless, an unexpected difficulty arises from the great difference in colour of the two shadows; that of the gas being of a bluish brown, whilst that of the candle is of a yellow-brown tinge. This difference of tint renders it exceedingly difficult for the observer to ascertain when the two shadows possess equal intensity; and, consequently, the limits of error attending determinations by this test are probably, even in the hands of an experienced operator, never less than 5 per cent., and frequently even as much as 10 per cent. The shadow test has, therefore, been all but superseded by the *Bunsen's Photometer*, which consists of a graduated metal or wooden rod about 8 or 10 feet long, and sufficiently strong to be inflexible. At one extremity of this rod is placed the gas flame, and at the opposite end the standard candle. A stand which slides easily along the rod supports a small circular paper screen, at the same height as the two flames, and at right angles to the rod. This screen consists of colourless, moderately thin writing paper, saturated with a solution of spermaceti in spirit of turpentine, except a spot in the centre, about the size of a shilling, which is to be left untouched by the solution. The spirit of turpentine soon evaporates, and the paper is now ready for use. Being more transparent in the portion which has been saturated with the spermaceti solution, it becomes a delicate test of equality of light when placed between two luminous bodies; for if the light of one of the bodies impinge with greater intensity upon one side of the screen than the other light does upon the opposite side, the difference of the transparency of the two portions of the screen will become distinctly visible; the spot in the centre appearing comparatively opaque on the less illuminated side. When the screen is brought into such a position between the two sources of light as to render the central point nearly or quite invisible on both sides, the illuminating effect of both lights at that point may be regarded as equal; and all that now remains to be done is to measure the respective distances of the candle and gas from the screen, and divide the square of the distance of the gas by the square of that of the candle; the quotient expresses the illuminating power of the gas in candles. One of the most convenient forms of this instrument has been contrived by Mr. Wright, and may be had at 55 Millbank Street, Westminster. It consists of the following parts:—

1. A wooden rod, exactly 100 inches long (*fig.* 1019) from the centres of sockets at its ends, A B.
2. An upright pillar, C.
3. A candle holder, D.
4. A mahogany slide, E, having a metal socket, F, on its top, to hold the circular frame G, and a small pointer in its front.
5. A circular metal frame, G, made to hold a prepared paper.
6. A blackened conical screen, H, diminishing in size from its centre, where it opens with a hinge towards its ends, with two holes in front.

The long rod is graduated in accordance with the laws of distribution of light, from its centre each way into squares of distances in divisions numbered respectively 1, 2, 3, &c., to 36; to measure smaller differences than those amounting to 1 candle in value, each major division to 9 is subdivided into 10 parts, each, of course, representing $\frac{1}{10}$th of an increment. From thence to 20, the subdivisions indicate $\frac{1}{2}$. Beyond that point no subdivisions are made, because the major divisions become so small that, practically, such divisions would be useless.

The manner of fitting the apparatus together will be understood by reference to the annexed sketch.

1019



The pillar, C, is screwed to one end of the shelf, and an experimental meter, L, placed at the other. This latter instrument is for measuring the quantity of gas passing to the burner, and indicating the rate of consumption by observations of one minute, which is accomplished by the construction of its index dial.

This dial has two circles upon its face, with a pointer to each; the outer circle divided into four, and the inner into six parts; and each of these again divided into tenths. Every major division of the outer circle is a *cubic foot*; and every major division of the inner circle is $\frac{1}{60}$th of a cubic foot; so that the major divisions on the inner circle each bear the same proportion to a cubic foot that a minute does to an hour. If, therefore, the number of these divisions and tenths of divisions, which the hand passes over in a minute, is observed, it will evidently only be necessary to read them off as feet and tenths of a foot to obtain the hourly rate of consumption.

Thus, suppose the pointer passes from the upper figure 6 to the fifth minor division beyond the figure 4, it would read off as $4\frac{5}{10}$ths and $\frac{5}{600}$ths of a cubic foot in $\frac{1}{60}$th of an hour. Multiplying these quantities by 60, and we obtain the quantity of gas consumed in the hour.

A pillar, J, having a pressure gauge, and two cocks at K, one with a micrometer movement, screws on to the top of the meter, and is intended for receiving burners when experimenting. The graduated rod is supported in an exactly horizontal position by the pillars C and J, and screwed together by its binding screws.

The candle socket D is screwed on to the top of C, and the mahogany slide C placed on the rod, with its pointer to the scale, carrying the frame G, containing a prepared paper, and covered by the cone H.

The prepared paper is made by coating white blotting-paper with sperm, so as to render it semi-transparent, leaving a small spot in the centre plain, and therefore opaque. See G in the figure.

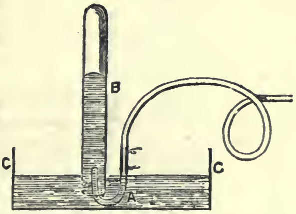
All that now remains to render the apparatus ready for experimenting, is to put a piece of candle into the socket, and consume the gas through a proper burner over the meter, taking care that the *centres* of the *candle-flame, paper, and gas flame*, are in one *horizontal line*, and adopting the precautions previously laid down.

Unfortunately the determination of the exact point of equality of the two lights, is by no means easy, even after considerable practice; and the maximum amount of error to which even the practised operator is liable in such estimations of illuminating power, cannot be set down at less than 5 per cent. It is scarcely necessary to add, that all photometric experiments must be conducted in an apartment from which all light from other sources is excluded, and the walls of which are rendered as absorbent as possible, by being coated with a mixture of lampblack and size, or by being hung with black lustreless calico.

Analytical method of estimating the value of illuminating gas.—Frankland has shown that the resources of chemical analysis place in our hands a method for the determination of the illuminating value of gas considerably more accurate than the photometric process just described, although the execution of the necessary operations requires more skill, and is usually much more troublesome. As the determination of the illuminating power of a sample of gas by the analytical method necessitates most of the operations required for the performance of a complete analysis of coal-gas, we shall here include in our description of the former process the additional details necessary for the latter.

1. *Collection of the sample of gas.*—In all analytical operations upon gases, it is of the utmost importance, that the latter should be preserved from all admixture with atmospheric air. This can only be done, either by collecting the samples of gas over mercury, or by enclosing them in hermetically sealed tubes. When the sample of gas is collected at the place where the analysis is to be made, the former plan is usually most convenient, but when the sample has to be obtained from a locality at some distance from the operator's laboratory, the latter plan is usually adopted. To collect a sample of gas over mercury, attach one end of a piece of vulcanised India-rubber tube to the gas pipe, and insert into the other extremity a piece of glass tube bent, as shown at A, *fig.* 1020, allow the gas to stream through these tubes for two or three minutes, and then suddenly plunge the open extremity of the glass tube beneath the surface of the mercury in the trough C. Then fill the small gas jar B completely with mercury, taking care to remove all air-bubbles from its sides by means of a piece of iron wire, and closing its mouth firmly with the thumb, invert it in the trough C, introducing the end of the bent tube A into its open extremity, in such a way as to bring the mouth of A above the level of the surface of the mercury in C. The gas will then flow into B, until the level of the mercury in B is somewhat lower than that of the metal in the trough. If now, the tube A being removed, a small cup be filled with mercury and brought beneath B, the latter may be removed from the trough, and will be thus preserved from any appreciable atmospheric intermixture for several months.

1020

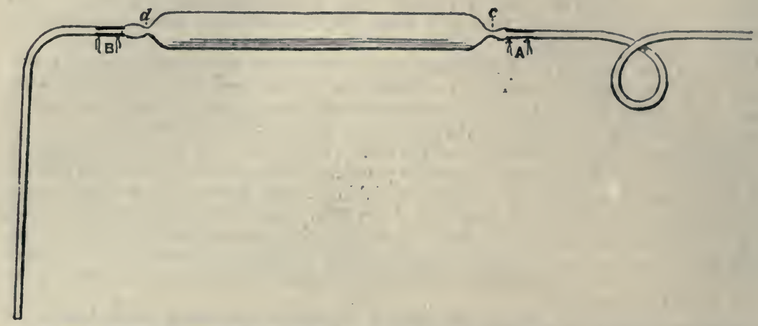


To collect samples of gas in hermetically-sealed tubes, proceed as follows: take a piece of glass tube about $\frac{7}{8}$ths of an inch internal diameter, and 1 foot long; draw it out at both ends before the blowpipe, as shown in *fig.* 1021; attach one extremity, A *fig.* 1022, to a vulcanised India-rubber tube, communicating with a source of the gas, and the opposite extremity B, to a similar flexible tube about three feet long, and which is allowed to hang down perpendicularly from B. After the gas has streamed through this system of tubes for about three minutes, so as to ensure the complete expulsion of atmospheric air, the flame of a mouth blowpipe is directed against the narrow portion of the glass tube, at *c*, so as to fuse it off. With as much expedition as possible, the same operation is performed at the opposite extremity of the tube *d*, which is thus hermetically sealed, and assumes the appearance shown in *fig.* 1023.

1021

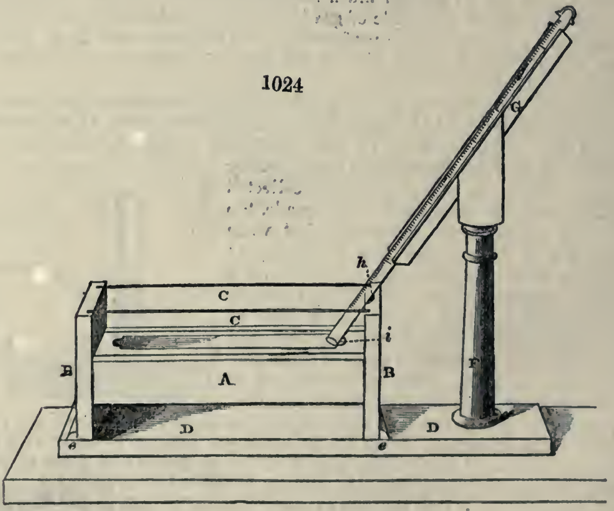
1023

1022



The gas having been thus carefully collected, the necessary analytical operations must be conducted over mercury in a small wooden pneumatic trough, with plate-glass sides, the construction of which is shown in *fig.* 1024. A is a piece of hard well-seasoned wood, 12 inches long and 3 inches broad, hollowed out, as shown in the figure; the cavity is 8¾ inches long, 1¾ inch broad, and 1¾ inch deep. The bottom of this cavity is rounded, with the exception of a portion at one end, where a surface, 1 inch broad, and 1½ inch long, is made perfectly flat, a piece of vulcanised India-rubber, $\frac{1}{10}$th of an inch thick, being firmly cemented upon it. Two end pieces, B B, ¾ths of an inch thick, 3¼ inches broad, and 5 inches high, are fixed to the block A; these serve below as supports for A, and above as the ends of a wider trough, which is formed by the pieces of plate glass C C, cemented into A and B B. The glass plates C C, are 10½ inches long, and 1⅞ inch high; they are slightly inclined, so that their lower edges are about 2⅜ inches, and their upper edges 2⅞ inches apart. This trough stands upon a wooden slab D D, upon which it is held in its place by two strips of wood *e e*. An upright column F, which is screwed into D, carries the inclined stand G, which serves to support the eudiometer during the transference of gas. *h* is a circular inclined slot in B, which allows of the convenient inclination of the eudio-

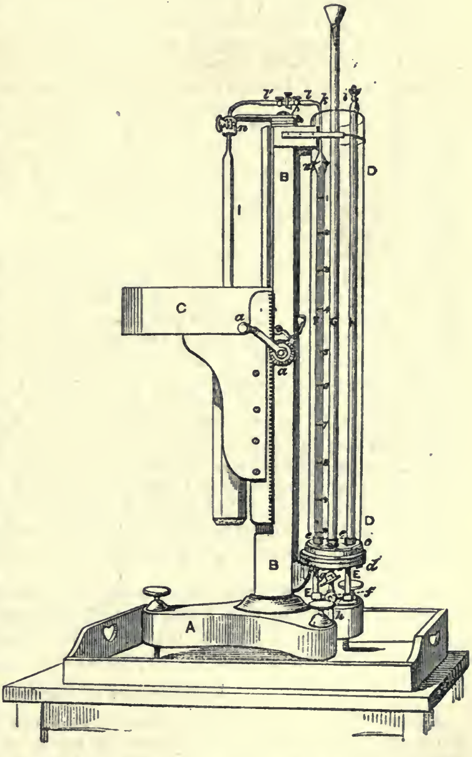
1024



meter in the stand G. *i* is an indentation in which the lower end of the eudiometer rests, so as to prevent its falling into the deeper portion of the trough A. When in use the trough is filled with quicksilver to within an inch of the upper edge of the glass plates C C, about 30 to 35 lbs. of the metal being necessary for this purpose.

The eudiometers or measuring-tubes, should be accurately calibrated and graduated into cubic inches and tenths of a cubic inch, the tenths being subdivided by the eye into hundredths, when the volume of gas is read off; this latter division is readily attained by a little practice. At each determination of volume, it is necessary that the gas should either be perfectly dry, or quite saturated with moisture. The first condition is attained by placing in the gas, for half an hour, a small ball of fused chloride of calcium, attached to a platinum wire[1]; the second condition, by introducing a minute drop of water, into the head of the eudiometer, before filling it with quicksilver. The determinations of volume must either be made when the mercury is at the same level inside and outside the eudiometer, or, as is more frequently done, the difference of level must be accurately measured and allowed for in the subsequent reduction to a standard pressure. The height of the barometer and the temperature of the surrounding atmosphere must also be observed each time the volume of gas is measured, and proper corrections made for pressure, temperature, and also the tension of aqueous vapour, if the gas be moist. As tables and rules for these corrections are given in most treatises on chemistry, they need not be repeated here.

1025



These troublesome corrections and calculations can be avoided by employing an instrument invented some years ago by Dr. Frankland and Mr. W. J. Ward, and which not only does away with the necessity for a room devoted exclusively to gaseous manipulations, but greatly shortens and simplifies the whole operation. This instrument, which is represented by *fig.* 1025, consists of the tripod A, furnished with the usual leveling screws, and carrying the vertical pillar B B, to which is attached, on the one side, the moveable mercury trough C, with its rack and pinion *a a*, and on the other, the glass cylinder D D, with its contents. This cylinder is 36 inches long, and 4 inches internal diameter; its lower extremity is firmly cemented into an iron collar *c*, the under surface of which can be screwed perfectly watertight upon the bracket plate *d* by the interposition of a vulcanised caoutchouc ring. The circular iron plate *d* is perforated with three apertures, into which the caps *e*, *e*, *e*, are screwed, and which communicate below the plate with the T-piece E E. This latter is furnished with a double-way cock *f*, and a single-way cock *g*, by means of which the tubes cemented into the sockets *e*, *e*, *e*, can be made to communicate with each other, or with the exit pipe *h* at pleasure.

---

[1] These balls, which should be of the size of a large pea, are required constantly in operations upon gases; they are readily prepared, when the substances of which they are formed is fusible by heat, as chloride of calcium or caustic potash, by melting these materials in a crucible and then pouring them into a small bullet-mould, in which the curved end of a platinum wire has been placed; when quite cold the ball attached to the wire is readily removed from the mould. Coke bullets are made by filling the mould containing the platinum wire with a mixture of two parts of coke and one of coal, both finely powdered, and then exposing the mould and its contents to a heat gradually increased to redness, for a quarter of an hour.

F, G, H, are three glass tubes, which are firmly cemented into the caps *e*, *e*, *e*. F and H, are each from 15 to 20 millimeters internal diameter, and are selected of as nearly the same bore as possible, to avoid a difference of capillary action. The tube G is somewhat wider, and may be continued to any convenient height above the cylinder. H is accurately graduated with a millimeter scale, and is furnished at top with a small funnel *i*, into the neck of which a glass stopper, about 2 millimeters in diameter, is carefully ground. The tube F terminates at its upper extremity in the capillary tube *k*, which is carefully cemented into the small steel stopcock *l*. F has also fused into it at *m*, two platinum wires, for the passage of the electric spark. After this tube has been firmly cemented into the cap *e*, its internal volume is accurately divided into 10 perfectly equal parts, which is effected without difficulty by first filling it with mercury from the supply-tube G, up to its junction with the capillary attachment, and then allowing the mercury to run off through the nozzle *h* until the highest point of its convex surface stands at the division 10, previously made so as exactly to coincide with the zero of the millimeter scale on H; the weight of the mercury thus run off is carefully determined, and the tube is again filled as before, and divided into 10 equal parts, by allowing the mercury to run off in successive tenths of the entire weight, and marking the height of the convexity after each abstraction of metal. By using the proper precautions with regard to temperature, &c., an exceedingly accurate calibration can, in this way, be accomplished.

The absorption tube I is supported by the clamp *n*, and connected with the capillary tube *k*, by the stopcock and junction-piece *l l′ p*, as shown in the figure. When the instrument is thus far complete, it is requisite to ascertain the height of each of the nine upper divisions on the tube, above the lowest or tenth division. This is very accurately effected in a few minutes by carefully levelling the instrument, filling the tube G with mercury, opening the cock *l*, and the stoppered funnel *i*, and placing the cock *f* in such a position as to cause the tubes F H to communicate with the supply-tube G. On now slightly turning the cock *g*, the mercury will slowly rise in each of the tubes F and H; when its convex surface exactly coincides with the ninth division on F, the influx of metal is stopped, and its height in H accurately observed; as the tenth division on F corresponds with the zero of the scale upon H, it is obvious that the number thus read off is the height of the ninth division above the zero point. A similar observation for each of the other divisions upon F completes the instrument.[1]

Before using the apparatus, the large cylinder D D is filled with water, and the internal walls of the tubes F and H are, once for all, moistened with distilled water, by the introduction of a few drops into each, through the stopcock *l*, and the stoppered funnel *i*. The three tubes being then placed in communication with each other, mercury is poured into G until it rises into the cup *i*, the stopper of which is then firmly closed. When the mercury begins to flow from *l*, that cock is also closed. The tubes F and H are now apparently filled with mercury, but a minute and imperceptible film of air still exists between the metal and glass; this is effectually got rid of by connecting F and H with the exit tube *h*, and allowing the mercury to flow out until a vacuum of several inches in length has been produced in both tubes; on allowing the instrument to remain thus for an hour, the whole of the film of air above mentioned will diffuse itself into the vacuum, to be filled up from the supply-tube G. These bubbles are of course easily expelled on momentarily opening the cock *l* and the stopper *i*, whilst G is full of mercury. The absorption-tube I being then filled with quicksilver, and attached to *l* by the screw-clamp, the instrument is ready for use.

In illustration of the manner of using the apparatus, a complete description of an analysis of coal-gas by this instrument will be given below.

For the analysis of purified coal-gas by means of the mercury trough and eudiometer, the following operations are necessary:—

I. *Estimation of Carbonic Acid.*

A few cubic inches of the gas are introduced into a short eudiometer, moistened as above described; the volume is accurately noted, with the proper corrections, and a bullet of caustic potash is then passed up through the mercury into the gas; it is allowed to remain for at least one hour; the volume of the gas being again ascertained and subtracted from the first volume gives the amount of carbonic acid which has been absorbed by the potash.

II. *Estimation of Oxygen.*

This gas can be very accurately estimated by Liebig's method, which depends upon the rapid absorption of oxygen by an alkaline solution of pyrogallic acid. To apply

---

[1] This instrument may be obtained from Mr. Oertling, philosophical instrument maker.

this solution, a small test tube is filled with quicksilver, and inverted in the mercury trough; a few drops of a saturated solution of pyrogallic acid in water are thrown up into this tube by means of a pipette, and then a similar quantity of a strong solution of potash; a coke bullet attached to a platinum wire is introduced into this liquid, and allowed to saturate itself; it is then withdrawn, and conveyed carefully below the surface of the mercury into the eudiometer containing the residual gas of experiment No. 1; every trace of oxygen will be absorbed in a few minutes, when the bullet must be removed, and the volume being again measured, the diminution from the last reading will represent the amount of oxygen originally present in the gas. It is essential that the coke bullet, after saturation with the alkaline solution of pyrogallic acid, should not come in contact with the air before its introduction into the gas.

III. *Estimation of the Luminiferous Constituents.*

Various methods have been employed for the estimation of the so-called olefiant gas (luminiferous constituents) contained in coal-gas. The one which has been most generally employed, depends upon the property which is possessed by olefiant gas, and most hydrocarbons, of combining with chlorine, and condensing to an oily liquid: hydrogen and light carburetted hydrogen are both acted upon in a similar manner when a ray even of diffused light is allowed to have access to the mixture; but the condensation of the olefiant gas and hydrocarbons takes place in perfect darkness, and advantage is therefore taken of this circumstance to observe the amount of condensation which takes place when the mixture is excluded from light. The volume, which disappears during this action of the chlorine, is regarded as indicating the quantity of olefiant gas present in the mixture. There are many sources of error inseparably connected with this method of operating, which render the results unworthy of the slightest confidence; the same remark applies also to the employment of bromine in the place of chlorine; in addition to the circumstance that these determinations must be made over water, which allows a constant diffusion of atmospheric air into the gas, and *vice versâ*, there is also formed in each case a volatile liquid, the tension of the vapour of which increases the volume of the residual gas; and this increase admits of neither calculation nor determination. The only material by which the estimation of the luminiferous constituents can be accurately effected is anhydrous sulphuric acid, which immediately condenses the luminiferous constituents of coal-gas, but has no action upon the other ingredients, even when exposed to sunlight. The estimation is conducted as follows:—A coke bullet, prepared as described above, and attached to a platinum wire, being rendered thoroughly dry by slightly heating it for a few minutes, is quickly immersed in a saturated solution of anhydrous sulphuric acid, in Nordhausen sulphuric acid, and allowed to remain in the liquid for one minute; it is then withdrawn, leaving as little superfluous acid adhering to it as possible, quickly plunged beneath the quicksilver in the trough, and introduced into the same portion of dry gas, from which the carbonic acid and oxygen have been withdrawn by experiments I. and II.; here it is allowed to remain for about two hours, in order to ensure the complete absorption of every trace of hydrocarbons. The residual volume of gas cannot, however, yet be determined, owing to the presence of some sulphurous acid derived from the decomposition of a portion of the sulphuric acid: this is absorbed in a few minutes by the introduction of a moist bullet of peroxide of manganese, which is readily made by converting powdered peroxide of manganese into a stiff paste with water, rolling it into the shape of a small bullet, and then inserting a bent platinum wire, in such a manner as to prevent its being readily drawn out; the ball should then be put in a warm place, and allowed slowly to dry, it will then become hard, and possess considerable cohesion, even after being moistened with a drop of water, previous to its introduction into the gas. After half an hour, the bullet of peroxide of manganese may be withdrawn, and replaced by one of caustic potash, to remove the watery vapour introduced with the previous one; at the end of another half-hour, this bullet may be removed, and the volume of gas at once read off. The difference between this and the previous reading, gives the volume of the luminiferous constituents contained in the gas. This method is very accurate; in two analyses of the same gas, the percentage of luminiferous constituents seldom varies more than 0·1 or 0·2 per cent.

IV. *Estimation of the Non-Luminiferous Constituents.*

These are light carburetted hydrogen, hydrogen, carbonic oxide, and nitrogen. The percentages of these gases are ascertained in a graduated eudiometer, about 2 feet in length, and $\frac{3}{4}$ths of an inch internal diameter; the thickness of the glass being not more than $\frac{1}{10}$th of an inch. This eudiometer is furnished as its closed end with two platinum wires, fused into the glass, for the transmission of the electric spark. A drop of water, about the size of a pin's head, is introduced into the upper part of the eudiometer before it is filled with mercury and inverted into the mercurial trough: this small quantity of water serves to saturate with aqueous vapour the gases subsequently introduced. About a cubic inch of the residual gas from the last determination is passed into the eudiometer, and its volume accurately read off; about 4 cubic inches of pure oxygen are now introduced, and the volume (moist) again determined. The oxygen is best prepared at the moment when it is wanted, by heating over a spirit or gas flame a little chlorate of potash, in a very small glass retort, allowing, of course, sufficient time for every trace of atmospheric air to be expelled from the retort before passing the gas into the eudiometer. The open end of the eudiometer must now be pressed firmly upon the thick piece of India-rubber placed at the bottom of the trough, and an electric spark passed through the mixture; if the above proportions have been observed, the explosion will be but slight, which is essential if nitrogen be present in the gas, as this element will otherwise be partially converted into nitric acid, and thus vitiate the results. By using a large excess of oxygen, all danger of the bursting of the eudiometer by the force of the explosion is also avoided. The volume after explosion being again determined, a bullet of caustic potash is introduced into the gas, and allowed to remain so long as any diminution of volume takes place; this bullet absorbs the carbonic acid that has been produced by the combustion of the light carburetted hydrogen and carbonic oxide, and also renders the residual gas perfectly dry: the volume read off after this absorption, when deducted from the previous reading, gives the volume of carbonic acid generated by the combustion of the gas.

The residual gas now contains only nitrogen and the excess of oxygen employed. The former is determined by first ascertaining the amount of oxygen present, and then deducting that number from the volume of both gases; for this purpose a quantity of dry hydrogen, at least three times as great as the residual gas, is introduced, and the volume of the mixture determined; the explosion is then made as before, and the volume (moist) again recorded: one-third of the contraction caused by this explosion represents the volume of oxygen, and this deducted from the volume of residual gas, after absorption of carbonic acid, gives the amount of nitrogen.

The behaviour of the other three non-luminous gases on explosion with oxygen enables us readily to find their respective amounts by three simple equations, founded upon the quantity of oxygen consumed, and the amount of carbonic acid generated by the three gases in question. Hydrogen consumes half its own volume of oxygen, and generates no carbonic acid; light carburetted hydrogen consumes twice its volume of oxygen, and generates its own volume of carbonic acid; whilst carbonic oxide consumes half its volume of oxygen, and generates its own volume of carbonic acid. If, therefore, we represent the volume of the mixed gases by A, the amount of oxygen consumed by B, and the quantity of carbonic acid generated by C, and further, the volumes of hydrogen, light carburetted hydrogen, and carbonic oxide respectively by x, y, and z, we have the following equations:—

$$x+y+z=A$$
$$\tfrac{1}{2}x+2y+\tfrac{1}{2}z=B$$
$$y+z=C.$$

From which the following values for x, y, and z, are derived:—

$$x=A-C$$
$$y=\frac{2B-A}{3}$$
$$z=C-\frac{2B-A}{3}.$$

V.—*Estimation of the Value of the Luminiferous Constituents.*

We have now given methods for ascertaining the respective quantities of all the ingredients contained in any specimen of coal-gas, but the results of the above analytical operations afford us no clue to its illuminating power. They give us, it is true, the amount of illuminating hydrocarbons contained in a given volume of the gas, but it will be evident, from what has already been said respecting the luminiferous powers of these hydrocarbons, that the greater the amount of carbon contained in a given volume, the greater will be the quantity of light produced on their combustion; and therefore, as the number of volumes of carbon-vapour contained in one volume of the mixed constituents, condensible by anhydrous sulphuric acid, has been found to vary from 2·54 to 4·36 volumes, it is clear that this amount of carbon-vapour must be accurately determined for each specimen of gas, if we wish to ascertain the value of that gas as an illuminating agent. Fortunately this is easily effected; for if we ascertain the amount of carbonic acid generated by 100 volumes of the gas in its original condition, knowing from the preceding analytical processes the percentage of illuminating hydrocarbons, and also the amount of carbonic acid generated by the non-luminiferous gases, we have all the data for calculating the illuminating value of the gas. For this purpose a known volume of the original gas (about one cubic inch) is introduced into the explosion eudiometer, and mixed with about five times its volume of oxygen; the electric spark is passed, and the volume of carbonic acid generated by the explosion ascertained as above directed. If we now designate the percentage of hydrocarbons absorbed by anhydrous sulphuric acid by A, the volume of carbonic acid generated by 100 volumes of the original gas by B, the carbonic acid formed by the combustion of the non-luminous constituents remaining after the absorption of hydrocarbons from the above quantity of original gas by C, and the volume of carbonic acid generated by the combustion of the luminiferous compounds (hydrocarbons) by x, we have the following equation:—

$$x = B - C,$$

and therefore, the amount of carbonic acid generated by one volume of the hydrocarbons is represented by

$$\frac{B-C}{A}.$$

But as one volume of carbon-vapour generates one volume of carbonic acid, this formula also expresses the quantity of carbon-vapour in one volume of the illuminating constituents. For the purpose of comparison, however, it is more convenient to represent the value of these hydrocarbons in their equivalent volume of olefiant gas, one volume of which contains two volumes of carbon-vapour; for this purpose the last expression need only be changed to

$$\frac{B-C}{2A}.$$

Thus, if a sample of gas contain 10 per cent. of hydrocarbons, of which one volume contains three volumes of carbon-vapour, the quantity of olefiant gas to which this 10 per cent. is equivalent, will be 15.

By the application of this method we obtain an exact chemical standard of comparison for the illuminating value of all descriptions of gas; and by a comparison of the arbitrary numbers thus obtained, with the practical results yielded by the same gases when tested by the photometer, much valuable and useful information is gained.

Analysis of Coal-gas with Frankland and Ward's apparatus.—Introduce a few cubic inches of the gas into the tube I, *fig.* 1025, and transfer it for measurement into F, by opening the cocks *l l′* and placing the tube F in communication with the exit pipe *h*, the transference being assisted, if needful, by elevating the trough C. When the gas, followed by a few drops of mercury, has passed completely into F, the cock *l* is shut, and *f* turned, so as to connect F and H with *h*. Mercury is allowed to flow out until a vacuum of two or three inches in length is formed in H, and the metal in F is just below one of the divisions; the cock *f* is then reversed, and mercury very gradually admitted from G, until the highest point in F exactly corresponds with one of the divisions upon that tube; we will assume it to be the sixth division. This adjustment of mercury and the subsequent readings can be very accurately made by means of a small horizontal telescope placed at a distance of about six feet from the cylinder, and sliding upon a vertical rod. The height of the mercury in H must now be accurately determined, and if from the number thus read off, the height of the sixth division above the zero of the scale on H be deducted, the remainder will express the true volume of the gas. As the temperature is maintained constant during the entire analysis, no correction on that score has to be made; the atmospheric pressure being altogether excluded from exerting any influence upon the volumes or pressures, no barometrical observations are requisite; and as the tension of aqueous vapour in F is exactly balanced by that in H, the instrument is in this respect also self-correcting. Two or three drops of a strong solution of caustic potash are now introduced into I by means of a bent pipette, and mercury being allowed to flow into F and H by opening the cock *g*, the gas returns into I through *l l′*, and there coming into contact with an extensive surface of caustic-potash solution, any carbonic acid that may be present will be absorbed in two or three minutes, and the gas being passed back again into H for re-measurement, taking care to shut *l* before the caustic-potash solution reaches *l'*, the observed diminution in volume gives the amount of carbonic acid present.

The amount of oxygen is determined in like manner by passing up into I a few drops of a saturated solution of pyrogallic acid, which forms with the potash already present pyrogallate of potash. The gas being then brought back into I, oxygen, if present, will be absorbed in a few minutes. Its amount is of course ascertained by re-measuring the gas in F.

The next step in the operation consists in estimating the amount of olefiant gas and illuminating hydrocarbons. For this purpose, whilst the gas, thus deprived of oxygen and carbonic acid, is contained in F, the tube I must be removed, thoroughly cleansed and dried, and being filled with mercury, must be again attached to *l*. The gas must now be transferred from F to I, and a coke bullet, prepared as above described, being passed up into I, must be allowed to remain in the gas for one hour. After its removal, a few drops of a strong solution of bichromate of potash must be admitted into I in order to absorb the sulphurous acid and vapours of anhydrous sulphuric acid resulting from the previous operation. The gas is now ready for measurement; it is therefore passed into F, and its volume determined; the diminution which has occurred since the last reading represents the volume of olefiant gas and illuminating hydrocarbons that were present in the gas.

It now only remains to determine the respective amounts of light carburetted hydrogen, carbonic oxide, hydrogen, and nitrogen present in the residual gas. This is effected as follows:—As much of the residual gas as will occupy about 1½ inch of its length at atmospheric pressure is retained in F, and its volume accurately determined; the remainder is passed into J, and the latter tube removed, cleansed, filled with mercury, and re-attached. A quantity of oxygen equal to about three and a half times that of the combustible gas is now added to the latter, and the volume again determined; then the mixture having been expanded to about the sixth division, an electric spark is passed through it by means of the wires at *m*. The contraction resulting from the explosion having been noted, two or three drops of caustic-potash solution are passed into J, and the gas is then transferred into the same tube. In two minutes the carbonic acid generated by the explosion is perfectly absorbed, and its volume is determined by a fresh measurement of the residual gas. The latter must now be exploded with three times its volume of hydrogen, and the contraction on explosion noted. These operations furnish all the data necessary for ascertaining the relative amounts of light carburetted hydrogen, carbonic oxide, hydrogen, and nitrogen, according to the mode of calculation given here.

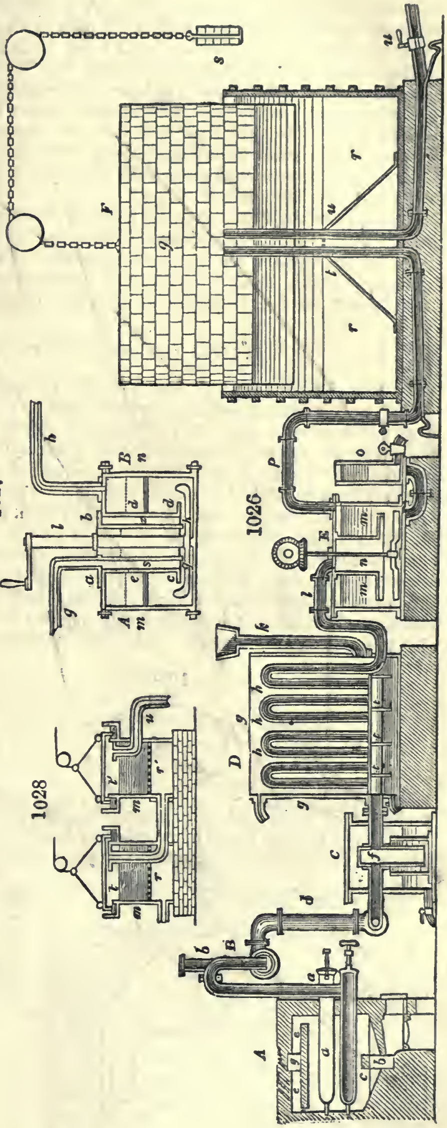
Finally, the value of the luminiferous constituents is obtained as before, by exploding about a cubic inch of the original specimen of gas with from four to five times its volume of oxygen, and noting the amount of carbonic acid produced.

On the Manufacture of Coal-Gas.

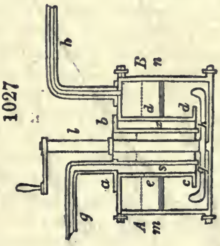
Coal-gas, as usually manufactured, is produced by exposing coal to a bright red heat in retorts. The gas as it issues from the retort cannot be directly employed for illumination, for it contains vapours of tar and naphtha, as also steam impregnated with carbonate of ammonia and hydrosulphate of sulphide of ammonium. These vapours would easily condense in the pipes through which the gas must be distributed, and would produce obstructions; they must therefore be so far removed by previous cooling, as to be liable to occasion no troublesome condensation at ordinary temperatures. The crude coal-gas contains moreover sulphuretted hydrogen, whose combustion would exhale an offensive sulphureous odour, that ought to be avoided as much as possible. Carbonic acid enfeebles the illuminating power of the gas, and should be removed. The disengagement of gas in the retorts is never uniform, but varies at the different stages of the process; for which reason the gas must be received in a gas-holder, where it may experience uniform pressure, and be discharged uniformly into the pipes of distribution, in order to ensure a steady discharge of gas, and uniform intensity of light in burners. A coal-gas apparatus ought therefore to be so constructed as not only to generate the gas itself, but to fulfil the above conditions.

In *fig.* 1026 such an apparatus is represented, where the various parts are shown connected with each other in section.

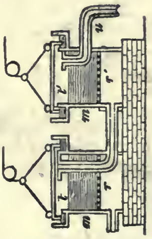
A is the furnace, with its set of cylindrical or elliptical retorts, five in number. From each of these retorts, a tube *b* proceeds perpendicularly upwards, and then by a curve or saddle-tube, it turns downwards, where it enters a long horizontal cylinder under B, shut at each end with a screw cap, and descends to beneath its middle, so as to dip about an inch into the water contained in it. From one end of this cylinder, the tube *d* passes downwards, to connect itself with a horizontal tube which enters into the *tar pit* or *cistern* C, by means of the vertical branch *f*. This branch reaches to near the bottom of the cylindrical vessel, which sits on the sole of the tar-cistern. From the other side of the vertical branch *f*, the main pipe proceeds to the condenser D, and thence by the pipe *l*, into the purifier E; from which the gas is immediately transmitted by the pipe *p* into the gasometer F.



1026



1027



1028

The operation proceeds in the following way:—As soon as gas begins to be disengaged from the ignited retort, tar and ammoniacal liquor are deposited in the cylindrical receiver B, and fill it up till the superfluity runs over by the pipe *d*, the level being constantly preserved at the line shown in the figure. By the same tarry liquid, the orifices of the several pipes *b*, issuing from the retorts are closed; whereby the gas in the pipe *d* has its communication cut off from the gas in the retorts. Hence, if one of the retorts be opened and emptied, it remains shut off from the rest of the apparatus. This insulation of the several retorts is the function of the pipe under B, and therefore the recurved tube *b*, must be dipped as far under the surface of the tarry liquid as to be in equilibrio with the pressure of the gas upon the water in the purifier. The tube *b* is closed at top with a screw cap, which can be taken off at pleasure, to permit the interior to be cleansed.

Both by the overflow from the receiver B, and by subsequent condensation in the tube *d*, tar and ammoniacal liquor collect progressively in the cistern or pit under C, by which mingled liquids the lower orifice of the vertical tube *f* is closed, so that the gas cannot escape into the empty space of this cistern. These liquids flow over the edges of the inner vessel when it is full, and may, from time to time, be drawn off by the stopcock at the bottom of the cistern.

Though the gas has, in its progress hitherto, deposited a good deal of its tarry and ammoniacal vapours, yet, in consequence of its high temperature, it still retains a considerable portion of them, which must be immediately abstracted, as otherwise the tar would pollute the lime in the vessel E, and interfere with its purification. On this account the gas should, at this period of the process, be cooled as much as possible, in order to condense these vapours, and to favour the action of the lime in the purifier E, upon the sulphuretted hydrogen, which is more energetic the lower the temperature of the gas. The coal-gas passes, therefore, from the tube *f* into the tube *h* of the condenser D, which is placed in an iron chest *g*, filled with water, and it deposits more tar and ammoniacal liquor in the under part of the cistern at *t*, *t*. When these liquids have risen to a certain level, they overflow into the tar-pit, as shown in the figure, to be drawn off by the stopcock, as occasion may require.

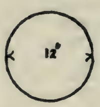
The refrigerated gas is now conducted into the purifier E, which we will suppose to be filled with milk of lime, made by mixing 1 part of slaked lime with 25 parts of water. The gas, as it enters by the pipe *l*, depresses the water in the wide cylinder *n*, thence passes under the perforated disc in the under part of that cylinder, and rising up through innumerable small holes is distributed throughout the lime-liquid in the vessel *m*. By contact with the lime on this extended surface, the gas is stripped of its sulphuretted hydrogen and carbonic acid, which are condensed into the sulphide of calcium and carbonate of lime; it now enters the gas-holder F in a purified state, through the pipe *p t*, and occupies the space *q*. The gas-holder pressing with a small unbalanced force over the counter-weight, *s*, expels it through the main *u u*, in communication with the pipes of distribution through the buildings or streets to be illuminated.

Such are the chief and essential parts of the apparatus used in every gas-work for the generation, refrigeration, purification, and storage of coal-gas. The construction and mode of working these separate portions of the apparatus vary much, however, in different works, and it will therefore be necessary here to enter more minutely into the details of the four departments of the manufacture just enumerated.

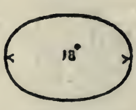
I. Apparatus used in the Generation of Coal-Gas.

Retorts.—The use of this portion of the apparatus is to expose the coal to a high temperature, to exclude atmospheric air, and to deliver the gaseous and vaporous products of distillation into the refrigeratory portion of the apparatus. The materials composing the retorts should therefore possess the following properties:—1st, high conducting power for heat; 2nd, rigidity and indestructibility at a high temperature; and 3rd, impermeability to gaseous matter. The materials hitherto used in the construction of retorts are cast iron, wrought iron, and earthenware; but none of these materials possess the above qualifications in the high degree that could be wished. Thus cast iron, though a good conductor of heat, is not perfectly rigid and indestructible. At high temperatures it becomes slightly viscous, and at the same time undergoes rapid oxidation. Wrought iron is a still better conductor of heat, but its qualities of indestructibility and rigidity are even lower than those of cast iron; whilst earthenware, though rigid, and indestructible by oxidation, is a very bad conductor of heat, and is moreover very liable to crack from changes of temperature. Very various forms of retort have been employed at different times in order to secure as far as possible, the conditions just enumerated.

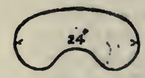
1029



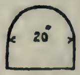
1030



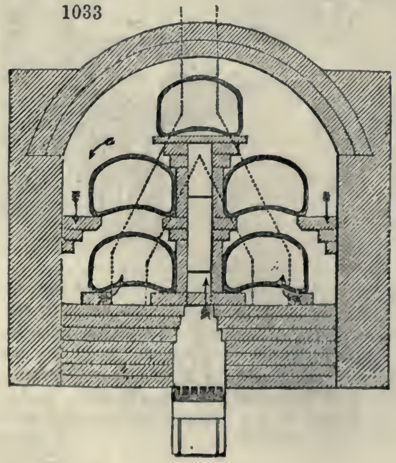
1031



1032

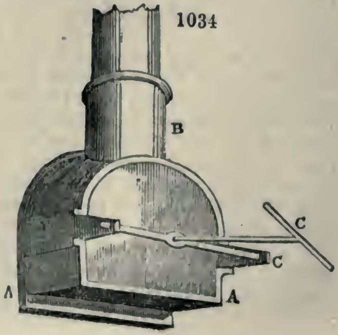


1033



Cast-iron Retorts.—The chief forms of the cast-iron retorts are: First, the cylindrical, *fig.* 1029, used in the Manchester Gas Works, 12 inches diameter, and 6 to 9 feet long; second, the elliptical, 18 inches by 12 inches, by

1034



6 to 9 feet, *fig.* 1030; third, the ear-shape, *fig.* 1031, now little used, 2 feet 9 inches, and of the same length as before; fourth, the D-shaped retort, *fig.* 1032, 20 inches wide and 14 inches high. This form of retort is at present far more extensively used than any of the others.

Fig. 1033 shows a bed of 5 D-shaped iron retorts. The length is 7½ feet, and the transverse area, from one foot to a foot and a half square. The arrows show the direction of the flame and draught.

The charge of coals is most conveniently introduced in a tray of sheet-iron, made somewhat like a grocer's scoop, adapted to the size of the retort, which is pushed home to its further end, inverted so as to turn out the contents, and then immediately withdrawn.

All these retorts are set horizontally in the furnace, and they have a flanch cast upon their open end, to which a mouthpiece, A A, *fig.* 1034, can be securely bolted. The mouthpiece is provided with a socket, B, for the reception of the *standpipe*, and also with an arrangement by which a lid, C C, can be screwed gas-tight upon the front of the mouthpiece as soon as the charge of coal has been introduced. By applying a luting of lime mortar to that part of the lid which comes into contact with the mouthpiece, a perfectly tight joint is obtained.

Sometimes iron retorts are made of double the above length, passing completely through the furnace, and being furnished with a lid and standpipe at each end. Such is the construction of Mr. Croll's and of Lowe's reciprocating retorts. These retorts are charged from each end alternately, and there is an arrangement of valves by means of which the gas evolved from the coal recently introduced is made to pass over the incandescent coke of the previous charge, at the opposite end of the retort. It is highly probable that some advantage is derived from this arrangement during the very early stage of the distillation of the fresh coal; but on the whole, for reasons stated above, the principle is undoubtedly bad, for although it enables the manufacturer to produce a large volume of gas, the quality is so much inferior as to reduce the total illuminating effect obtainable from a given weight of coal.

Wrought-iron Retorts.—Mr. King, the eminent engineer of the Liverpool Gas Works, has for many years successfully used retorts of wrought iron. They are made of thick boiler plates, riveted together, and are of the D shape, 5½ feet wide, 6 feet long, and 18 inches high at the crown of the arch. About 1 ton of coal can be worked off in these retorts in 24 hours. Occasionally the bottoms are of cast iron, which materially prevents the great amount of warping to which wrought iron is subject when exposed to high temperatures.

Earthenware, or Clay Retorts.—These are usually of the D shape, although they are occasionally made circular or elliptical. Their dimensions are about the same as those of the cast-iron retorts commonly used, but their walls are necessarily thicker, varying from 2½ to 4 inches in thickness; this, added to the circumstance that clay is a very bad conductor of heat, undoubtedly causes the expenditure of a larger amount of fuel in heating these retorts; nevertheless, this disadvantage is, perhaps, less than might be supposed, since iron retorts soon become coated outside with a thick layer of oxide of iron, which also greatly hinders the free communication of heat to the iron beneath. Moreover, the lower price and much greater durability of clay retorts are causing their almost universal adoption in gas-works, especially since the removal of pressure by exhausters greatly reduces the amount of leakage to which clay retorts are liable.

The following is an extract relating to clay retorts, from the 'Reports of Juries' of the Great Exhibition of 1851:—

'The use of fire-clay is not of very ancient date, and has greatly increased within the last few years, It is found in England almost exclusively in the coal-measures, and from different districts the quality is found to differ considerably. The so-called 'Stourbridge clay,' is the best known, and will be alluded to presently; but other kinds are almost, if not quite, as well adapted for the higher purposes of manufacture, being equally free from alkaline earths and iron, the presence of which renders the clay fusible when the heat is intense. The proportion of silica and alumina in these clays vary considerably, the former amounting sometimes to little more than 50 per cent., while in others it reaches beyond 70, the miscellaneous ingredients ranging from less than ½ to upwards of 7 per cent.

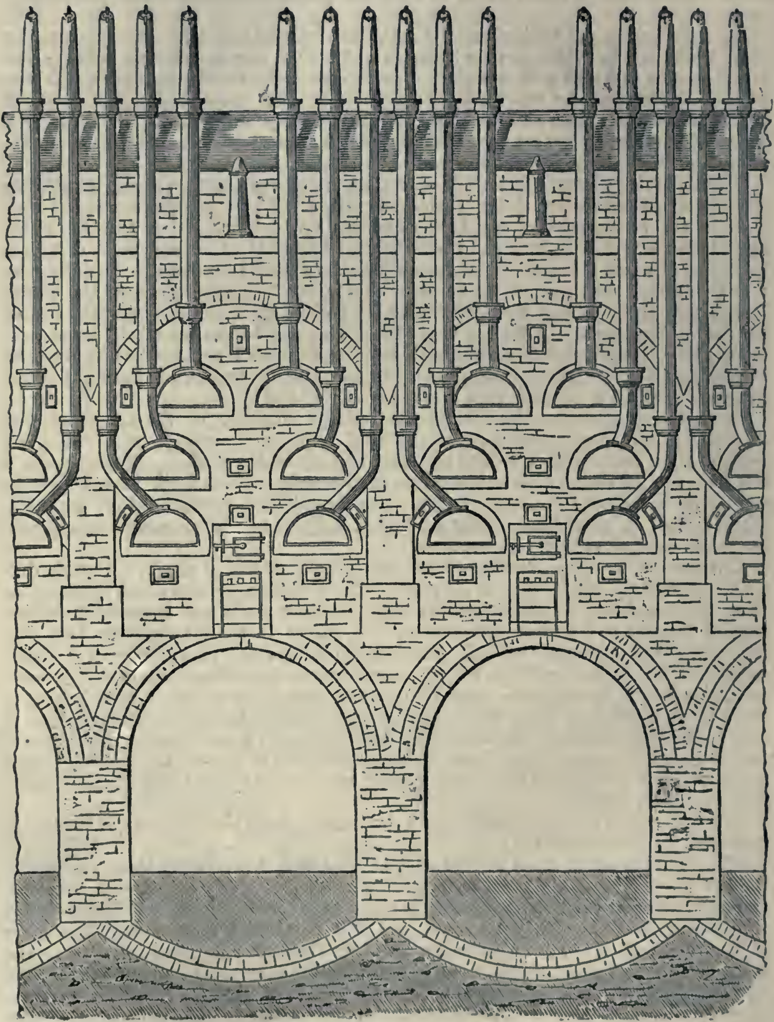
'The works of Messrs. Cowen and Co. are among the most extensive in England, and they obtain their raw material from no less than nine different seams, admitting of great and useful mixture of clay for various purposes.

'After being removed from the mine, the clay is tempered by exposure to the weather, in some cases for years, and is then prepared with extreme care. The objects chiefly made are fire-bricks and gas-retorts; the latter being now much used, and preferred to iron for durability.

'These retorts were first made by the present exhibitors in ten pieces (this being twenty years ago), and since then the number of pieces has been reduced successively to four, three, and two pieces, till in 1844 they were enabled to patent a process for making them in one piece, and at the present time they are thus manufactured of dimensions as much as 10 feet long by 3 feet wide in the inside, which is, however, more than double the size of the largest exhibited by them.

'Gas retorts of very fair quality are shown by Mr. Ramsay of Newcastle, who has also succeeded extremely well in the manufacture of fire-bricks. The retorts show a little more iron than is desirable, but the exhibitor has been considered worthy of honourable mention. Retorts of less creditable appearance are exhibited by Messrs. Hickman and Co. of Stourbridge, and Mr. A. Potter of Newcastle. The surface of both these retorts is cracked and undulating. When we consider the high and long-continued temperature to which these objects are exposed, the absolute necessity of attending to every detail in mixing the clay and moulding the retort will be at once recognised, and the apparently slight defects of some of those sent for exhibition require to be noticed as of real importance.

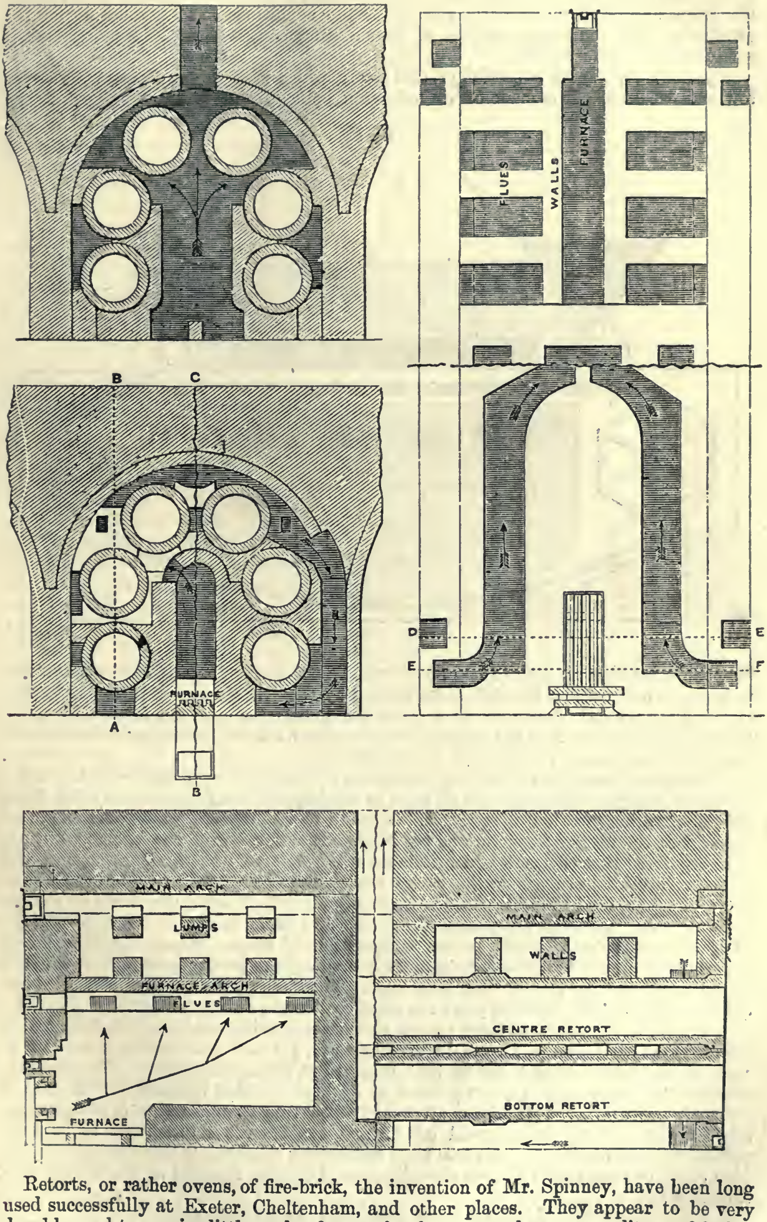
1035



'Next to England, the finest specimens of fire-clay goods on a large scale are from Belgium: the gas-retort sent from France is not remarkable for excellence.'

Fig. 1035 is an elevation of Mr. Wright's plan for a range of long clay retorts.
Fig. 1036 shows the plans and sections of the setting for these retorts.

1036



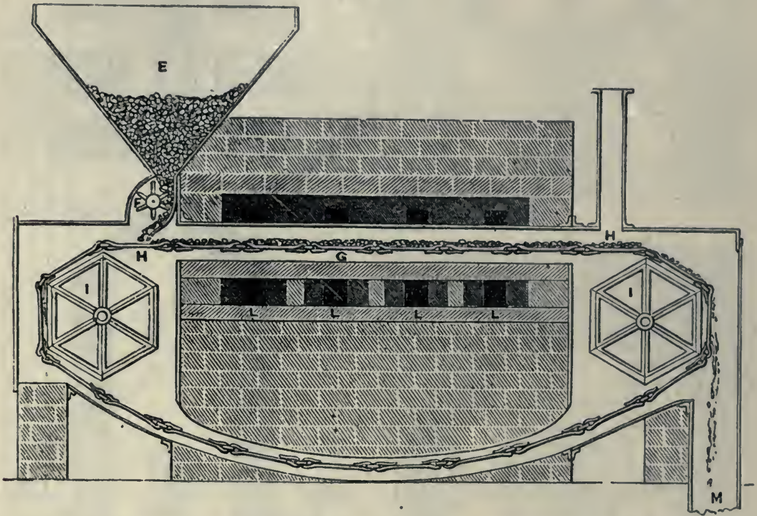
Retorts, or rather ovens, of fire-brick, the invention of Mr. Spinney, have been long used successfully at Exeter, Cheltenham, and other places. They appear to be very durable, and to require little outlay for repairs, but a very large expenditure of fuel is required for heating them. They are of the D shape, 7 feet long, 3 feet 2 inches wide, and 14 inches high at the crown of the arch. Each retort receives a charge of

5 or 6 cwts. of Newcastle or Welsh coal every 12 hours, and produces gas at the rate of 9,000 cubic feet per ton of Welsh, and 10,000 to 12,000 per ton of Newcastle coal.

Clegg's revolving Web Retort.—This retort, the invention of Mr. Clegg, sen., makes the nearest approach to a truly philosophical apparatus for the generation of gas; in it the coal is exposed to a sudden and uniform heat, in a thin stratum, by which means the gases are liberated at once, and under the conditions most favourable for the production of a maximum amount of illuminating constituents. Very little tar is produced from this retort.

Fig. 1037 represents a section of this retort, which is of the D shape, with a very low and flat arch. It is made of wrought-iron boiler plates riveted together. E is a hopper for holding the coal to be carbonised; F is a discharging disc; G is the retort; H is a web on to which the coal is discharged by the disc F; I I are revolving drums, carrying the wrought-iron web H; L L are the flues from a lateral furnace by which the retort is heated; M is the exit-pipe for the coke, its lower extremity is either closed by an air-tight door, or is made to dip into water.

1037



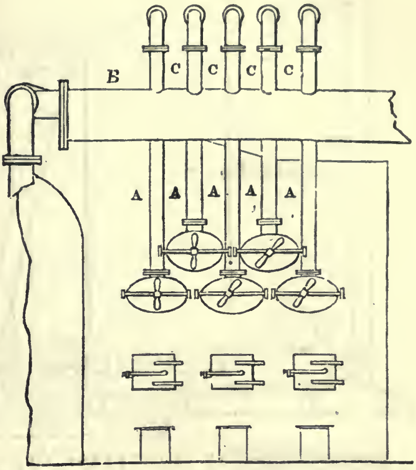
All the coal must be reduced to fragments about the size of coffee-berries, and a 24 hours' charge must be placed at once in the hopper, and secured by a luted cover. The discharging disc has 6 spurs, and is made to revolve uniformly with the drum below it at the rate of 4 revolutions per hour. The diameter of the hexagonal drums is so regulated that the coal, which falls upon the web from the discharging disc, will at one revolution have passed the entire length of the retort. The passage through the retort occupies 15 minutes, which is quite sufficient to expel the whole of the gas from the coal. In each revolution of the disc and drum 745 cubic inches of coal (or 21 lbs.) are distributed over a heated surface of 2,016 square inches. 18 cwts. of coal is carbonised in one of these retorts in 24 hours, and the production of gas is equal to 12,000 cubic feet per ton of Newcastle coal. The quality of the gas is also considerably superior to that obtained from the same coal in the ordinary retorts.

Although the first cost of these retorts and accompanying machinery is considerably greater than that of the retorts in ordinary use, yet the destructible parts can be replaced at about the same cost as that required to replace the latter. The coke produced is greater in quantity, but inferior in quality, owing to its more minute state of division. The minor advantages attendant upon this form are, that it occupies less space, requires much less manual labour, and enables the retort-house to be kept perfectly clean, wholesome, and free from suffocating vapour. If the principle of this plan could be combined with less complication of details, it would no doubt come into extensive use.

II. The Refrigeratory Apparatus.

From the moment that the gas leaves the retorts it is subjected to cooling influences, which gradually reduce its temperature, until, on leaving the so-called condenser, its temperature ought to be only a few degrees higher than that of the atmosphere, except in winter, when it is advisable to maintain a heat, relatively to the external air, greater than in summer. The gas leaves the retort by the *standpipes*, A A A, *fig.* 1038, which are of cast iron, 5 inches in diameter at their lower extremity, and slightly tapering upwards. Some of the least volatile products of decomposition condense in these pipes, but their proximity to the furnaces, and the constant rush of heated gas and vapour through them prevent more than a very slight amount of refrigeration. They conduct to the *hydraulic main*, which is shown at B, *fig.* 1038. It consists of a cylinder running the entire length of the retort-house, and fixed at a sufficient height above the mouths of the retorts to protect it from the flame issuing from the latter during the times of charging and drawing. The diameter varies from 12 to 18 inches, and the recurved extremities of the standpipes (*the dip-pipes*) C C C C, pass through it by gas-tight joints, and dip, to the extent of 3 or 4 inches, into the condensed liquids contained in the hydraulic main. The use of this portion of the apparatus is to cut off the communication in the reverse direction between the gas beyond the standpipes and the retorts, so as to prevent the former rushing back down the standpipe during the time that the lid of the retort is removed. Being maintained half full of tar it effectually seals the lower ends of the dip-pipes, and prevents any return of gas towards the retorts. The condensed products, consisting chiefly of tar, make their exit from the hydraulic main by the pipe D, which leads them to the tar-well. From the hydraulic main the gas passes to the *condenser*, the office of which, as its name implies, is to effect the condensation of all those vapours which could not be retained by the gas at the ordinary atmospheric temperature. The condenser has received a variety of forms, but the one which appears to unite in the highest degree simplicity and efficiency, is the invention of Mr. Wright, of the Western and Great Central Gas Companies. Its construction is shown in *fig.* 1039. A A A A, are 5 double concentric cast-iron cylinders, through which the air is made to circulate in succession by means of the tiepipes B B B B, whilst the inner cylinders being open above and below, a current of air, set in motion by their heated walls, rushes through them, thus securing both an internal and external refrigeratory action. It will be also seen by a reference to the figure that the heated gas enters these cylinders at the top, taking an opposite direction to that pursued by the external and internal currents of air, and thus securing the most perfect refrigeration, by bringing the gas constantly in proximity to air of increasing coldness. Each cylinder is furnished at bottom with a tar receptacle, C, for the collection of the condensed products, which are carried to the tar-well by a pipe not shown in the figure. The details of construction are sufficiently seen from the drawing, and require no further description.

1038

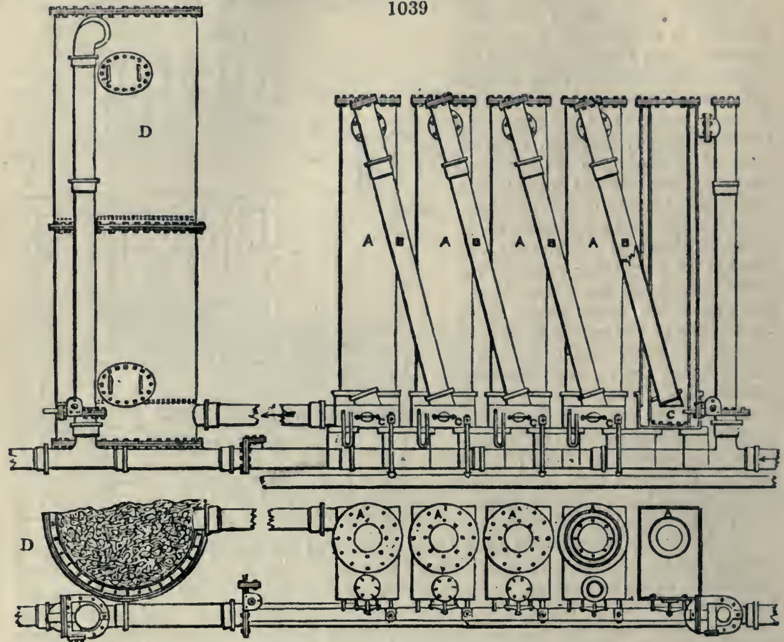


In some country works the condenser represented at D, *fig.* 1026 (p. 573) is used. It consists of a square chest, *g*, made of wrought-iron plates open at top, but having its bottom pierced with a row of holes, to receive a series of tubes. To these holes the upright four-inch tubes *h h* are secured by flanges and screws, and they are connected in pairs at top by the curved or saddle tubes. The said bottom forms the cover of the chest *t t*, which is divided by vertical iron partitions, into half as many compartments as there are tubes.

These partition plates are left open at bottom, so as to place the liquids of each compartment in communication. Thereby the gas passes up and down the series of tubes, in proceeding from one compartment to another. The condensed liquids descend into the box *t t*, and flow over into the tar cistern, when they rise above the level *t t*. The tar may be drawn off from time to time by the stopcock. Through the tube *k* cold water flows into the condenser chest, and the warm water passes away by a pipe at its upper edge.

The extent of surface which the gas requires for its refrigeration before it is admitted into the washing-lime apparatus, depends upon the temperature of the milk of lime, and the quantity of gas generated in a certain time.

1039



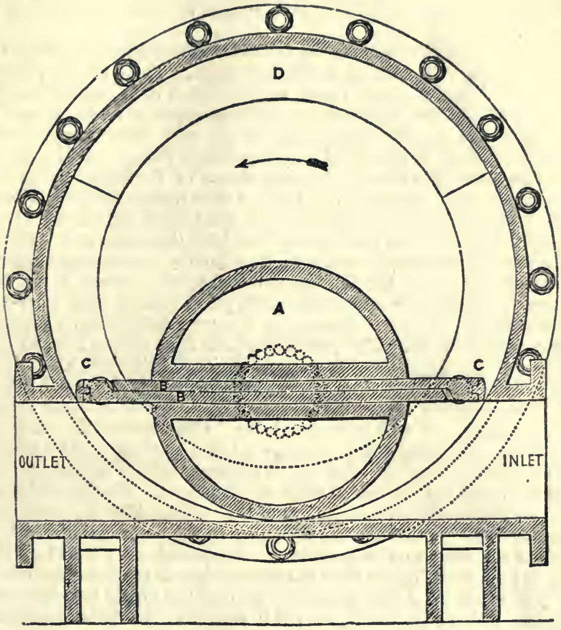
It may be assumed as a determination sufficiently exact, that 10 square feet of surface of the condenser can cool a cubic foot of gas per minute to the temperature of the cooling water. For example, suppose a furnace or arch, with 5 retorts of 150 lbs. of coal each, to produce in 5 hours 3,000 cubic feet of gas, or 10 cubic feet per minute, there would be required, for the cooling surface of the condenser, 100 square feet = 10 × 10. Suppose 100,000 cubic feet of gas to be produced in 24 hours, for which 8 or 9 such arches must be employed, the condensing surface must contain from 800 to 900 square feet.

After the action of the condenser, the gas still retains, chiefly in mechanical suspension, a certain quantity of tarry matter, besides a slight percentage of ammonia. To free it from these, it is passed through a *scrubber* D (*fig.* 1039), which consists of a tall cylinder filled with bricks, paving stones, or coke, and having an arrangement by which a stream of water can be admitted at top and removed at bottom. The chief use of the water is to remove ammonia from the gas, but as it also dissolves some of the luminiferous hydrocarbons, its use is objected to by Mr. Wright, and dry scrubbers are now used at the Western Gas Works. It is also considered by the same gentleman, that the detention of a certain percentage of ammonia by the gas is rather an advantage than otherwise, as it serves in part to neutralise the sulphurous acid which is inevitably produced by the combustion even of the best gas. It must, however, be borne in mind, that the presence of ammonia in gas gives rise to the formation of nitric acid during its combustion.

The Exhauster.—The passage of the gas through the liquid of the hydraulic main, and the other portions of apparatus between the retorts and gasholder, causes a very considerable amount of pressure to be thrown back upon the retorts, an effect which is productive of mischief in two ways: in the first place, if there be any fissure or flaw in the retorts, or leakage in the joints, the escape and consequent loss of gas is greatly augmented; and in the second place, it has been ascertained by Mr. Grafton, of Cambridge, that pressure in the retorts causes the decomposition of the illuminating hydrocarbons with greatly-increased rapidity. It is, therefore, very desirable to remove nearly the whole of this pressure by mechanical means, and this is now done in all well-arranged works, by the use of an apparatus termed an exhauster. Several forms of exhausters are in use, but it will be necessary only to describe that of Mr. J. T. Beale, which has been found by experience to be very effective and economical.

It is shown in section in *fig.* 1040. The axle A is reduced at each end, and passes into two cylindrical boxes bored to a larger diameter than the axle at those parts; and in the annular space between the axle and the box antifriction rollers are introduced, their diameter being equal to the width of the annular space; the box at one end is fitted with a stuffing box, through which the axle passes for the application of the driving power. Upon motion being given to the axle, the sliding pistons B B are carried with it. These sliding pistons are furnished at their ends with cylindrical pins, which project and fit into cylindrical holes bored in the guide blocks C C, which fit into annular recesses D in the end plates, and keep the slides in contact with the cylinder. The slides are fitted with metallic packing to allow of wear. The axle continuing to revolve, as one slide reaches the outlet and ceases to exhaust, the other comes into action, and the exhaustion is unceasing. Thus the pressure upon the retorts (which is indicated by a gauge) is reduced to about half an inch of water.

1040



III. Apparatus used in the Purification of Coal-Gas.

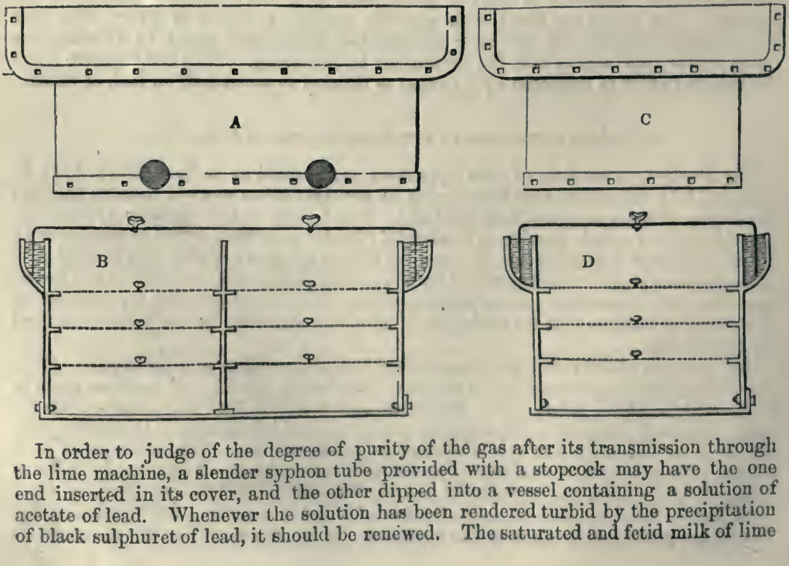
The Purifier.—One form of this apparatus, represented at E, *fig.* 1026 (p. 573), is composed of a cylindrical iron vessel, with an air-tight cover screwed upon it, through which the cylinder *n* is also fixed air-tight. The bottom of this cylinder spreads out like the brim of a hat, forming a horizontal circular partition, which is pierced with holes. Through a stuffing box, in the cover of this interior cylinder, the vertical axis of the agitator passes, which is turned by wheel-and-pinion work, in order to stir up the lime from the bottom of the water in the purifier. The vessel *o*, serves for introducing fresh milk of lime, as also for letting it off by a stopcock when it has become too foul for further use.

The quantity of lime should be proportioned to the quantity of sulphuretted hydrogen and carbonic acid contained in the gas. Supposing that in good coal-gas there is 5 per cent. of these gases, about one pound and a half of lime will be requisite for every hundred cubic feet of coal-gas generated, which amounts to nearly one-sixteenth of the weight of coal subjected to decomposition. This quantity of lime mixed with the proper quantity of water will form about a cubic foot of milk of lime. Consequently, the capacity of the purifier, that is, of the interior space filled with liquid, may be taken at four-sevenths of a cubic foot for every hundred cubic feet of gas passing through it in one operation; or for 175 cubic feet of gas, one cubic foot of liquor. After every operation, that is, after every five or six hours, the purifier must be filled afresh. Suppose that in the course of one operation 20,000 cubic feet of gas passes through the machine, this should be able to contain $\frac{20{,}000}{175} = 114$ cubic feet of milk of lime; whence its diameter should be 7 feet, and the height of the liquid 3 feet. If the capacity of the vessel be less, the lime-milk must be more frequently changed.

In some gas-works the purifier has the following construction, whereby an uninterrupted influx and efflux of milk of lime takes place. Three single purifiers are so connected together that the second vessel stands higher than the first, and the third than the second; so that the discharge-tube of the superior vessel, placed somewhat below its cover, enters into the upper part of the next lower vessel; consequently, should the milk of lime in the third and uppermost vessel rise above its ordinary level, it will flow over into the second, and thence in the same way into the first; from which it is let off by the eduction pipe. A tube introduces the gas from the condenser into the first vessel; another tube does the same thing for the second vessel, &c.; and the tube of the third vessel conducts the gas into the gasometer. Into the third vessel, milk of lime is constantly made to flow from a cistern upon a higher level. By this arrangement, the gas passing through the several vessels in proportion as it is purified, comes progressively into contact with purer milk of lime, whereby its purification becomes more complete. The agitator *c*, provided with two stirring paddles, is kept in continual rotation. The pressure which the gas has here to overcome is naturally three times as great as with a single purifier of like depth.

Fig. 1027 (p. 573) is a simple form of purifier, which has been found to answer well in practice. Through the cover of the vessel A B, the wide cylinder *e d* is inserted, having its lower end pierced with numerous holes. Concentric with that cylinder is the narrower one *s z*, bound above with the flange *a b*, but open at top and bottom. The under edge *g h* of this cylinder descends a few inches below the end *c d* of the outer one. About the middle of the vessel the perforated shelf *m n* is placed. The shaft of the agitator *l*, passes through a stuffing-box upon the top of the vessel. The gas-pipe *g*, proceeding from the condenser, enters through the flange *a b* in the outer cylinder, while the gas-pipe *h* goes from the cover to the gasholder. A stopcock upon the side, whose orifice of discharge is somewhat higher than the under edge of the outer cylinder, serves to draw off the milk of lime. As the gas enters through the pipe *g* into the space between the two cylinders, it displaces the liquor till it arrives at the holes in the under edge of the outer cylinder, through which, as well as under the edge, it flows, and then passes up through the apertures of the shelf *m n* into the milk-of-lime chamber; the level of which is shown by the dotted line. The stirrer, *l*, should be turned by wheel-work, though it is here shown as put in motion by a winch handle.

1041



In order to judge of the degree of purity of the gas after its transmission through the lime machine, a slender syphon tube provided with a stopcock may have the one end inserted in its cover, and the other dipped into a vessel containing a solution of acetate of lead. Whenever the solution has been rendered turbid by the precipitation of black sulphuret of lead, it should be renewed. The saturated and fetid milk of lime is evaporated in oblong cast-iron troughs placed in the ash-pit of the furnaces, and the dried lime is partly employed for luting the apparatus, and partly disposed of for a mortar or manure.

1042

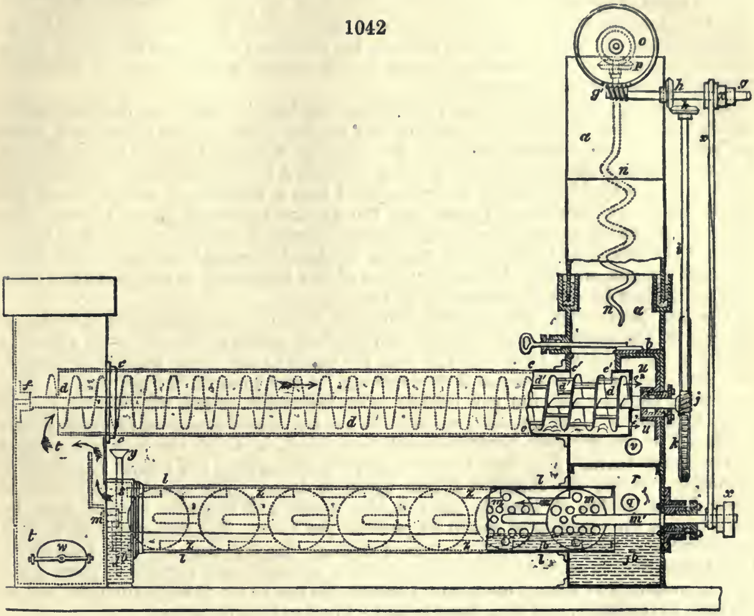


Fig. 1041 shows elevations and sections of dry-lime purifiers, which may also be used for other forms of dry purification. A is the longitudinal elevation; B ditto section; C transverse elevation; D ditto section.

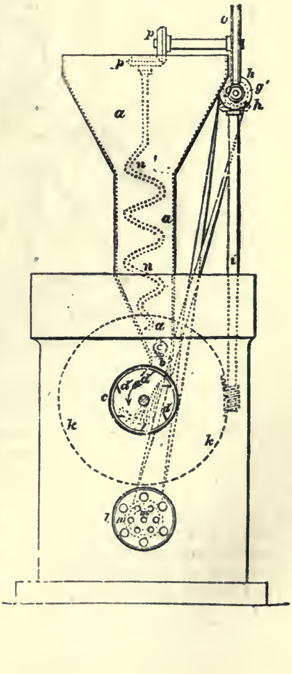
Figs. 1042 and 1043 represent another form of dry purifier, combined with a washer or scrubber, patented by Mr. Lees of Manchester. *Fig.* 1042 is an elevation, partly in section of this apparatus, and *fig.* 1043 is another elevation, also partly in section, of the same. *a* is a hopper, into which the dry lime is fed; *b* is a damper, or sliding door, by which the supply of lime can be regulated; *c* is a sheet-metal tube, containing the worm or screw, *d*, the axis of which is supported at one end by the stuffing-box *e*, and at the other end by the bearing *f*. A slow revolving motion is given to the worm *d* from the driving shaft *g*, by means of the bevel-wheels *h*, upright shaft *i*, worm *j*, and worm-wheel *k*, fixed on the axis of the worm.

1043



The lime in the hopper *a*, is kept in motion by the screw *n*, which is turned slowly round by the worm *g*, the worm-wheel *o* and bevel-wheels *p*, one of which is fixed on the screw *n*. The tube *c* is open at *c'*, to admit the dry lime from the hopper *a*, and the worm or screw *d*, is furnished with cross pieces *d'* to agitate the lime which is gradually moved from the hopper to the other end of the tube *c*, by the revolving of the worm. Below the tube *c* is another tube *l*; *y* is a syphon, by which the washing fluid is supplied and conducted to the chamber *s*, which then flows down the tube *l* to the chamber *r*, keeping the level indicated by *j b*. *z* are two paddles, fixed upon the circular perforated plates, which are set to an angle, and secured to the shaft *m'*, and are revolved speedily by the strap and pulleys *x*. These agitators serve to increase the action of the washing fluid contained in the tube *l*, by which the gas is washed previous to passing through the dry-lime purifier.

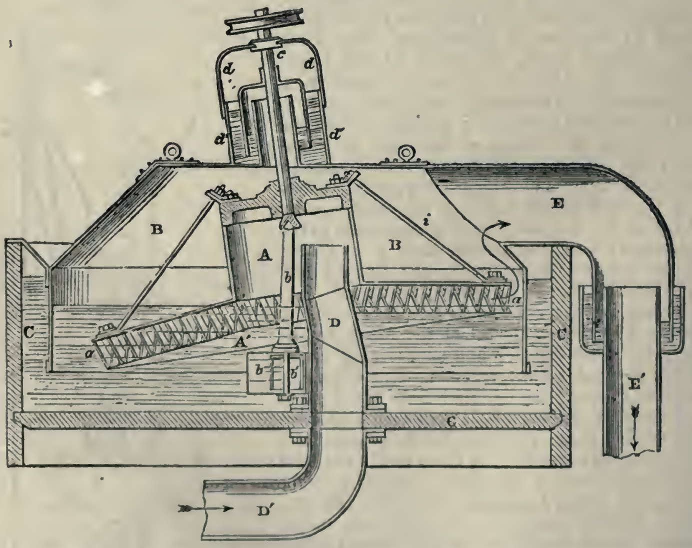
The mode of operation is as follows:—the gas to be purified is admitted through the pipe *q*, to the chamber *r*, from whence it passes along the tube *l*, as shown by the arrows, to the chamber *s*; it then rises into the chamber *t* and enters the tube *c*, along which it passes in the direction shown by the arrows, whence it may be conveyed, through the pipe *v*, to the gasometer.

It will be apparent, as the gas passes along the tube *l*, containing the agitators *m*, which are caused to revolve speedily by the motion given by the straps and speed pulleys *x*, that the washing fluid, which is passing regularly through the syphon *y*, and running into the chamber *s*, and along the tube *l*, into the chamber *r*, keeping the level as shown by *j b*, is caused to be revolved into a centrifugal motion round the tube *l*, by the two paddles *z*, placed upon the circular perforated plates, secured upon the shaft *m*, which are set to an angle, thereby causing a counter-motion from left to right of the tube *l*, and causing the washing fluid to be wrought into a complete spray amongst the gas, whereby the heavier parts of the impurities are carried away more effectually than by any other washers in use.

The gas then enters the chamber *t* through the tube *c*, passes along the coils or threads of the worm or screw *d*, and as the cross pieces *d′* are set to an angle, as shown in *fig.* 1043, the lime is raised from the lower to the upper part of the tube *c*, and then drops down to the gas that is making its way towards the openings c^2; consequently, the lime and the gas become most intimately mixed, whereby the lime is made to absorb a much greater proportion of the impurities contained in the gas than is effected by the dry-lime purifiers usually employed, in which the lime is supported on stationary trays. The lime dropping into the tube *c*, from the hopper *a*, is worked gradually towards the chamber *i*, into which it drops. The speed of the screw or worm *d*, the number of threads upon it, the length and diameter thereof must be made to suit the quantity of gas to be purified per hour. The lime which drops into the chamber *t*, may be removed therefrom through the man-hole *w*. Mr. Lees states that a considerable saving is effected in the lime, owing to each particle or atom being kept in motion, and falling repeatedly through the gas in its passage from one end of the tube to the other, and that there is also a great saving in labour.

Another form of wet purifier, which might also be advantageously used as a scrubber, or as a naphthaliser, has been invented by M. Colladon of Geneva, and is now in use in the gas-manufactory of that city. This apparatus, as shown in vertical section in *fig.* 1044, consists of a section of a very obtuse cone A′ the angle of inclination of which is 164°. Its upper and smaller end is joined to a metal cylinder A, placed on the same axis as A′, and about its own diameter in height. At top it is closed

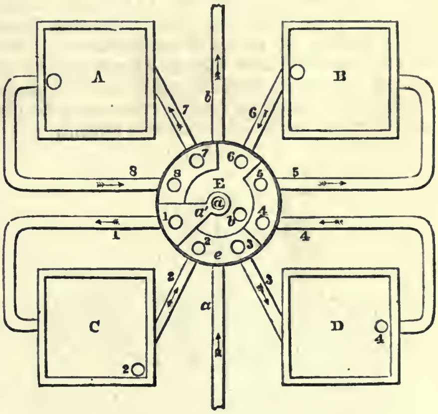
1044



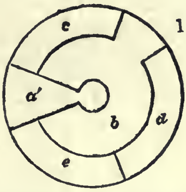
by a cast-iron plate K, through which the axle C passes: the latter communicates a rotary motion to the cylinder and cone A and A′. It is inclined 8° from the perpendicular, and rests upon the steel point of the centre pin *b*′, whilst at top it carries a pulley by which a circular motion is communicated to it. *a a* are a series of metal discs which stand vertically to the inner surface of the cone A′, with spaces of about one inch between them. The discs are arranged concentrically, and have spaces corresponding to the quantity of gas which has to pass through them. They are from 5 to 7 inches long. As the axle *c* and cylinder A are not vertical, but somewhat inclined, one side of the cone A′ will, during the revolution, be in a nearly horizontal position, whilst the opposite side will be immersed in the liquid to the extent of about 16°. The whole of this mechanism is enclosed in a sheet-iron lid B. The centre pin *b* is attached by a cross bar to the lower edge of B, whilst the axle *c* is supported by *d*, which is also attached to B. *d′ d′* is a water-joint permitting of the free motion of *c*. The lid B thus contains the whole of the washing apparatus, and it is held in its proper position in the trough C by lateral attachments. D is the inlet pipe opening into the cylinder A, from which it has to make its way through the discs *a a* to the outlet E. This apparatus gives no sensible pressure, and requires a very small motive power.

Fig. 1045 represents an arrangement of four of the dry purifiers shown in *fig.* 1041, worked by a central valve, as used at the present time in most large gas works; it is the invention of Mr. Malam, and is described in Mr. Peckston's treatise. A, B, C, D, are the four purifiers connected with the central valve E in such a way as to permit of three of them being at work whilst the fourth is emptied and re-charged. The outer case of the central valve E, is a cylinder of cast or wrought iron, 5 to 6 feet in diameter and 3 to 4 feet deep. Its floor receives the open ends of 10 pipes conducting the gas from the condenser or exhauster to the different purifiers, and then to the gas-holders; the ends of these pipes project upwards to the height of 14 inches, and the vessel E is filled with water to the height of 12 inches, thus leaving the orifice of the pipes 2 inches above the water-level. This cylinder has a cover which consists of a smaller cylinder, open below and closed above, fitting into E so as to form a water-lute. Its interior is divided into 5 chambers, as shown in *fig.* 1046; and when the cover is so far lowered into E as to immerse the edges of these chambers into the water, they each connect together a pair of pipes as shown in *fig.* 1045, at E, which exhibits a horizontal section through these chambers. The chambered cover being placed in the position shown in *fig.* 1045, the gas takes the following course: it enters the chamber *a*′ by the pipe *a a*, passes through the pipe marked 1, into the bottom of the purifier C, and after traversing the layers of purifying material in C, it returns to chamber *e* of the central valve by the pipe 2; thence by pipe 3, it enters the purifier D, and returns to chamber *d* of the valve by pipe No. 4. From this chamber it can only make its exit by pipe No. 5, which conducts it into B, whence it returns to chamber *b*, by pipe No. 6, and from this chamber it finally passes to the gasholder through the exit pipe *b b*. Thus the purifier A is left out of the circuit for the purpose of re-charging or revivification; but when the material in C has become exhausted, it can be replaced in the circuit by A, by slightly raising the cover of E, and turning it round so as to bring the chamber *a*′ over pipe 3, and again depressing it to its former position; by this arrangement D, B and A become the working purifiers, whilst C will be thrown out of the circuit. Thus, by the action of the central valve E, each of the four purifiers can in turn be excluded from the circuit, and recharged or revivified.

1045



1046



IV.—Apparatus for the Storage of Coal-Gas.

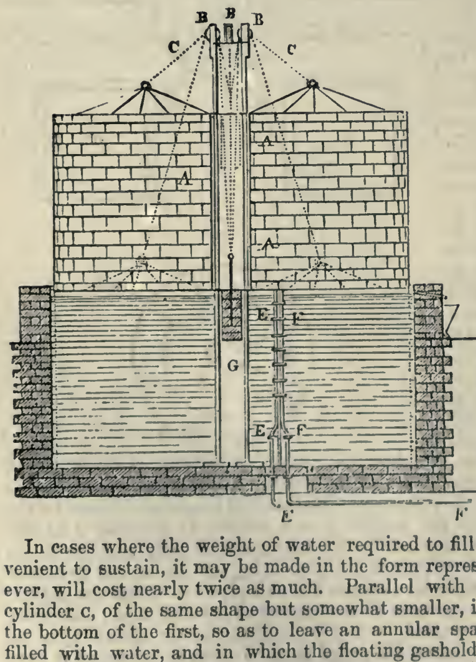
The gasholder serves as a magazine for receiving the gas when it is purified, and keeping it in store for use. It consists of two essential parts: 1, of an under cistern, open at the top and filled with water; and 2, of the upper floating cylinder or chest, which is a similar cistern, inverted, and of somewhat smaller dimensions (see F, *fig.* 1025, p. 573). The best form of this vessel is the round or cylindrical; both because under equal capacity it requires least surface of metal, and it is least liable to be warped by its own weight or accidents. Since a cylindrical body has the greatest capacity with a given surface when its height is equal to its semi-diameter, its dimensions ought to be such that when elevated to the highest point in the water, the height may be equal to the radius of the base. For example, let the capacity of the gasholder in cubic feet be k, the semi-diameter of its base be x, the height out of the water be h;

$h = x = \sqrt[3]{\dfrac{k}{3{\cdot}14}}$. This height may be increased by one or two feet, according to its magnitude, to prevent the chance of any gas escaping beneath its under edge, when it is raised to its highest elevation in the water.

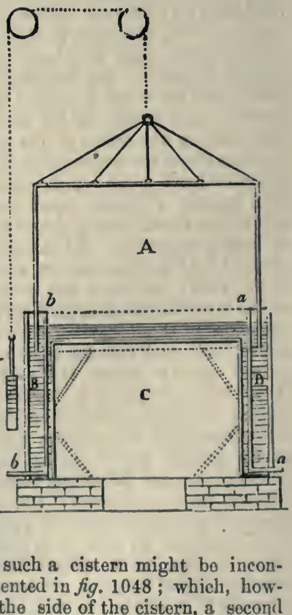
The size of the gasholder should be proportional to the quantity of gas to be consumed in a certain time. If 120,000 cubic feet be required, for instance, in 10 hours for street-illumination, and if the gas-retorts be charged 4 times in 24 hours, 30,000 feet of gas will be generated in 6 hours. Hence the gasholder should have a capacity of at least 70,000 cubic feet, supposing the remaining 50,000 cubic feet to be produced during the period of consumption. If the gasholder has a smaller capacity, it must be supplied from a greater number of retorts during the lighting period, which is not advantageous, as the first heating of the supernumerary retorts is wasteful of fuel.

The water cistern is usually constructed in this country with cast-iron plates bolted together, and made tight with rust cement.

1047



1048



In cases where the weight of water required to fill such a cistern might be inconvenient to sustain, it may be made in the form represented in *fig.* 1048; which, however, will cost nearly twice as much. Parallel with the side of the cistern, a second cylinder C, of the same shape but somewhat smaller, is fixed in an inverted position to the bottom of the first, so as to leave an annular space B B between them, which is filled with water, and in which the floating gasholder A plays up and down. The water must stand above the cover of the inverted cylinder. *a* and *b* are the pipes for leading the gas in and out. Through an opening in the masonry upon which the apparatus rests, the space C may be entered, in order to make any requisite repairs.

The water cistern may also be sunk in the ground, and the sides made tight with hydraulic mortar, as is shown in *fig.* 1047, and to make it answer with less water a concentric cylindrical mass of masonry may be built at a distance of 2 or 3 inches within it.

Every large gasholder must be strengthened interiorly with cross iron rods, to stiffen both its top and bottom. The top is supported by rods stretching obliquely down to the sides, and to the under edge an iron ring is attached, consisting of curved cast-iron bars bolted together; with which the oblique rods are connected by perpendicular ones. Other vertical rods stretch directly from the top to the bottom edge. Upon the periphery of the top, at the end of the rods, several rings are made fast, to which the gasholder is suspended, by means of a common chain which runs over a pulley at the centre. Upon the other end of the chain there is a counterpoise, which takes off the greater part of the weight of the gasholder, leaving only so much as is requisite for the expulsion of the gas. The inner and outer surfaces of the gasholder should be a few times rubbed over with hot tar, at a few days' interval between each application. The pulley must be made fast to a strong frame.

If the water cistern be formed with masonry, the suspension of the gasholder may be made in the following way:—A A, *fig.* 1047, is a hollow cylinder of cast iron, standing up through the middle of the gasholder, and which is provided at either end with another small hollow cylinder G, open at both ends, and passing through the top, with its axis placed in the axis of the gasholder. In the hollow cylinder G, the counterweight moves up and down, with its chain passing over the three pulleys, B, B, B, as shown in *fig.* 1048; E F are the gas-pipes made fast to a vertical iron rod. Should the gasholder be made to work without a counterweight, as we shall presently see, the central cylinder A A serves as a vertical guide.

In proportion as the gasholder sinks in the water of the cistern, it loses so much of its weight as is equal to the weight of the water displaced by the sides of the sinking vessel, so that the gasholder, when entirely immersed, exercises the least pressure upon the gas, and when entirely out of the water, it exercises the greatest pressure. In order to counteract this inequality of pressure, which, where no governor is used, would occasion an unequal velocity in the efflux of the gas, and of course an unequal intensity of light in its flame, the weight of the chain upon which the gasholder hangs is so adjusted as to be equal, throughout the length of its motion, to one-half of the weight which the gasholder loses by immersion. In this case, the weight which it loses by sinking into the water is replaced by the portion of the chain which, passing the pulley and hanging over, balances so much of the chain upon the side of the counterweight; and the weight which it gains by rising out of the water is counterpoised by the links of the chain which, passing over the pulley, add to the amount of the counterweight. The pressure which the gasholder exercises upon the gas, or that with which it forces it through the first main pipe, is usually so regulated as to sustain a column of from one to two inches of water, so that the water will stand in the cistern from one to two inches higher within than without the gasholder. The following computation will place these particulars in a clear light:—

Let the semi-diameter of the gasholder, equal to the vertical extent of its motion into and out of the water, $= x$; let the weight of a foot square of the side of the gasholder, including that of the strengthening bars and ring, which remain plunged under the water, $= p$; then

1. the weight of the gasholder in its highest position $= 3\,p\,\pi\,x^2$;
2. the weight of the sides of the gasholder which play in the water $= 2\,p\,x^2$;
3. the cubical contents of the immersed portion of the gasholder $= \frac{2\,p\,\pi\,x^2}{400}$;
4. its loss of weight in water $= \frac{112}{400}\,p\,\pi\,x^2$;
5. the weight of the gasholder in its lowest position =

$$p\,\pi\,x^2\left(3 - \frac{112}{400}\right) = 2{\cdot}72\,p\,\pi\,x^2;$$

6. the weight of n inches height of water $= \frac{56}{12}\,n\,\pi\,x^2$;
7. the amount of the counterweight $= \pi\,x^2\left(3\,p - \frac{56\,n}{12}\right)$;
8. the weight of the chain for the length $x = \frac{112}{800}\,p\,\pi\,x^2$.

If we reduce the weight of the gasholder, in its highest and lowest positions, to the height of a stratum of water equal to the surface of its top, this height is that of the column of water which would press the gas within the gasometer, were no counterweight employed; it consists as follows:—

9. for the highest position $= \frac{3p}{56}$;

10. for the lowest $= \frac{2{\cdot}72\,p}{50}$;

For the case when the height of the gasholder is different from its semi-diameter, let this height $= mx$; then the height of the water-level is

11. for the highest position $= p\left(\frac{1+2m}{56}\right)$;

12. for the lowest $= p\left(\frac{1+1{\cdot}72\,m}{6}\right)$;

13. the counterweight $= \pi x^2\left(p\,(1+2m)-\frac{56\,n}{12}\right)$;

14. the weight of the equalising chain $= \frac{112}{830}\,p\,\pi\,m\,x^2$.

For example, let the diameter of the gasholder be 30 feet, the height 15 (the contents in cubic feet will be 10,597), $p=4$ lbs.; then the counterweight for a height of 1½ inch of water-pressure = 3,532 lbs.; the weight of the chain for a length of 15 feet = 395 lbs. Were no counterweight employed, so that the gasholder pressed with its whole weight upon the gas, then the height of the equivalent column of water in its highest position = 2·56 inches; and in its lowest, 2·33. The counterweight may hence be lessened at pleasure, if the height of the pressing water column, *n*, be increased. The weight of the equalising or compensating portion of the chain remains the same. When $n=2$ inches, for instance, the counterweight = 1,886 lbs.

The velocity with which the gas passes along the mains for supplying the various jets of light may be further regulated by opening the main cock or slide valve in a greater or less degree.

Gasholders whose height is greater than their semi-diameter are not only more costly in the construction, but require heavier counterweights and equilibration chains.

The above estimate is made on the supposition of the gas in the gasholder being of the same specific gravity as the atmospherical air, which would be nearly true with regard to oil-gas under the ordinary pressure. But coal-gas, whose specific gravity may be taken on an average at about 0·5, exercises a buoyancy upon the top of the gasholder, which of course diminishes its absolute weight. Supposing the cubic foot of gas to be $=0{\cdot}0364$ lbs., the buoyancy will be $=3{\cdot}0364\,\pi x^3$ lbs., a quantity which deserves to be taken into account for large gasometers. Hence,

15. the weight of the gasholder in its highest position $= 3p\pi x^2 - 0{\cdot}1143\,x^3$;

16. the counterweight $= \pi x^2\left(3p-\frac{56\,n}{12}\right)-0{\cdot}1143\,x^2$;

17. the weight of the chain for the length $x, = \frac{112}{800\,p\pi}\,x^2\,\frac{0{\cdot}1143\,x^3}{2}$;

18. the weight of the water-pressure from the highest position, without the counterweight, $= \frac{3p\pi - 0{\cdot}1143\,x}{56\pi}$;

19. the same for the lowest position $= \frac{2{\cdot}72\,p}{56}$ in feet.

The preceding values of p and x, are,

(16) = 3147; (17) = 304; (18) = 2·44 inches; (19) = 2·33 inches.

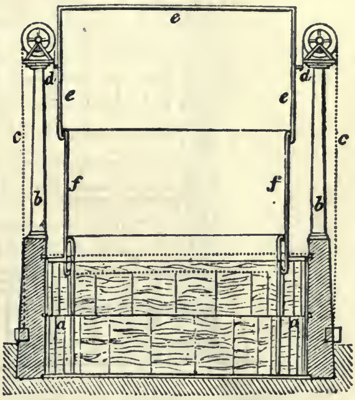
The water-columns in the highest and lowest situations of the gasholder here differ about 0·1 of an inch, and this difference becomes still less when p has a smaller value, for example, 3 lbs., or when the diameter of the gasholder is still greater.

It would thus appear that for coal-gasholders, in which the height of the gasholder does not exceed its semi-diameter, and especially when it has a considerable size, neither a compensation chain nor a counterweight is necessary. The only thing requisite is to preserve the vertical motion of the gasholder by a sufficient number of guide rods or pillars, placed either within the water cistern or round about it. Should the pressure of the gas in the pipe proceeding from the gasholder be less than in the gasholder itself, this may be regulated by the main valve, or by water valves of various kinds. Or, as is now usually done, a *governor* may be introduced between the great gasholder and the main pipe of distribution. With a diameter of 61 feet in the gasholder, the pressure in the highest and lowest positions is the same.

The gasholders employed in storing up gas until required for use, occupy, upon the old plan, much space, and are attended with considerable expense in erecting. The water-tank, whether sunk in the ground or raised, must be of equal dimensions with the gasholder, both in breadth and depth. The improved construction which we are about to describe, affords a means of reducing the depth of the tank, dispensing with the bridge of suspension, and of increasing at pleasure the capacity of the gasholder, upon a given base, thus rendering a small apparatus capable, if required, of holding a large quantity of gas, the first cost of which will be considerably less than even a small gasholder constructed upon the ordinary plan.

Mr. Tait, of Mile-End Road, the inventor, has, we believe, been for some years connected with gas-establishments, and is therefore fully aware of the practical defects or advantages of the different constructions of gasholders now in use. *Fig.* 1049 is a section of Mr. Tait's improved contrivance: *a a* is the tank, occupied with water; *b b* two iron columns with pulley wheels on the top; *c c* chains attached to a ring of iron, *d d*, extending round the gasholder, which chains pass over the pulley wheels, and are loaded at their extremities, for the purpose of balancing the weight of the materials of which the gasholder is composed.

1049.



The gasholder is formed by two or three cylinders, sliding one within the other, like the tubes of a telescope; *e e e* is the first or outer cylinder, closed at the top, and having the ring of iron, *d*, passing round it, by which the whole is suspended; *f f* is the second cylinder, sliding freely within the first, and there may be a third and fourth within these, if necessary.

When there is no gas in the apparatus, all the cylinders are slidden down, and remain, one within the other, immersed in the tank of water; but when the gas rises, through the water pressing against the top of the gasholder, its buoyancy causes the cylinder *e* to ascend. Round the lower edge of this cylinder a groove is formed by the turning-in of the plate of iron, and, as it rises, the edge takes hold of the top rim of the cylinder *f*, which is overlapped for that purpose. The groove at the bottom of the cylinder fills itself with water as it ascends, and, by the rim of the second cylinder falling into it, an air-tight hydraulic joint is produced.

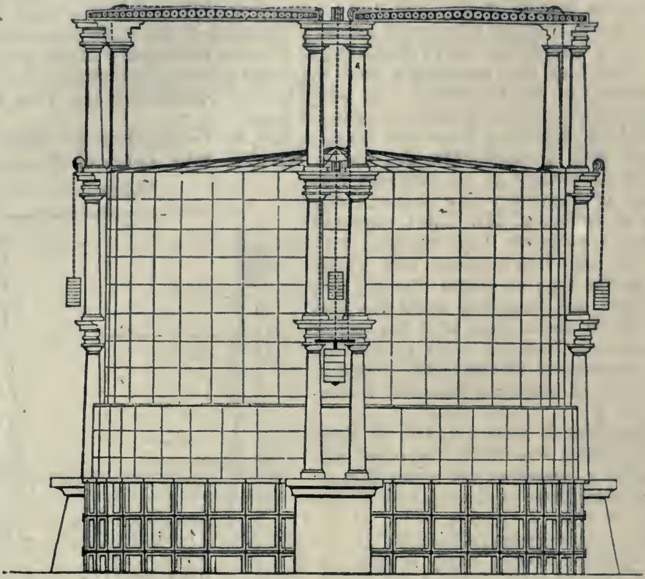
Thus several cylinders may be adapted to act in a small tank of water, by sliding one within the other, with lapped edges forming hydraulic joints, and, by supporting the apparatus in the way shown, the centre of gravity will always be below the points of suspension. A gasholder upon this plan may be made of any diameter, as there will be no need of frame-work or a bridge to support it; and the increasing weight of the apparatus, as the cylinders are raised one after the other, may be counterpoised by loading the ends of the chain *c c*.

Fig. 1050 is an elevation of a double or telescopic gasholder of a modern and approved form, with part of a tank.

The water in the gasholder need not be renewed; but merely so much of it as evaporates or leaks out is to be replaced. Indeed the surface of the water in the cistern gets covered with a stratum of coal-oil, a few inches deep, which prevents its evaporation, and allows the gas to be saturated with this volatile substance, so as to increase its illuminating power.

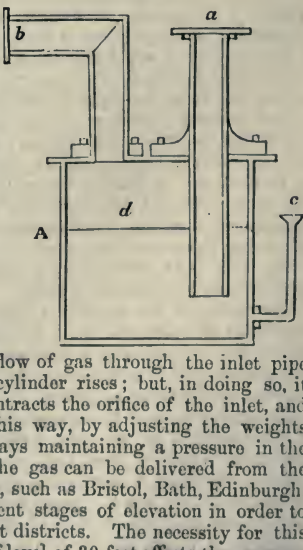
The gasholder may be separated from the purifier by an intermediate vessel, such as is represented by *fig.* 1051, with which the two gas-pipes are connected. A is the cylindrical vessel of cast iron, *a*, the end of the gas-pipe which comes from the purifier, immersed a few inches deep into the liquid with which the vessel is about two-thirds filled; *b* is the gas-pipe which leads into the gasholder, *c* is a perpendicular tube, placed over the bottom of the vessel, and reaching to within one-third of the top, through which the liquid is introduced into the vessel, and through which it escapes when it overflows the level *d*. In this tube the liquid stands towards the inner level higher, in proportion to the pressure of the gas in the gasholder. The fluid which is condensed in the gas-pipe *b*, and in its prolongation from the gasholder, runs off into the vessel A; and therefore the latter must be laid so low that the said tube may have the requisite declivity. A straight stopcock may also be attached to the side over the bottom, to draw off any sediment.

1050



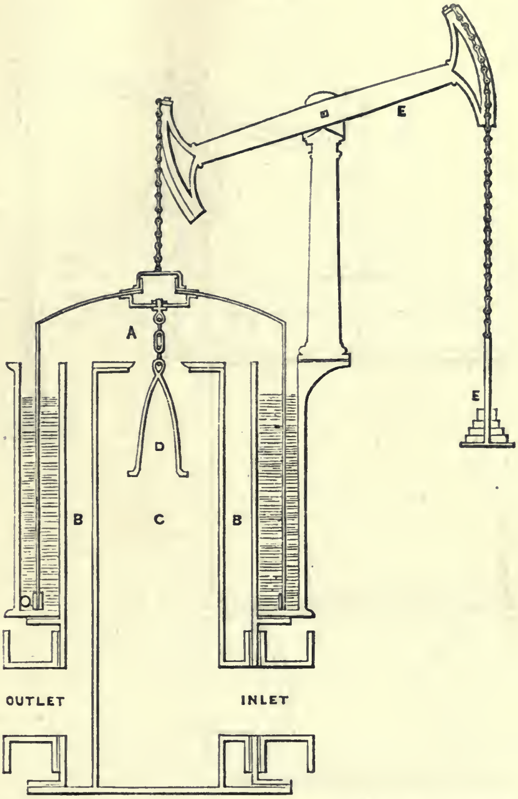
The governor.—Although the gasholder is, to a certain extent, a regulator of pressure, yet it is difficult, by its action alone, to maintain a pressure so steady and uniform as that required for the supply of gas consumers. It would be difficult, if not impossible, to alter the pressure upon the mains frequently during a single night, as is now usually done in towns with a large number of street lamps, without the intervention of an apparatus termed a *governor*. The governor, which occupies a position between the gasholder and supply mains, is a miniature gasholder A (see *figs.* 1052, 1053, and 1054, which represent Mr. Wright's improved governor), the interior of which, however, is nearly filled by the concentric inlet and outlet pipes B and C. Immediately over the mouth of the inlet pipe, and depending from the roof of the inner cylinder, is a parabolic piston D, which hangs within the contracted mouth of the inlet pipe C. The interior cylinder is counterpoised by the lever and weights E E. Now, when the pressure of gas in this small holder increases—that is, when the flow of gas through the inlet pipe exceeds that escaping from the outlet—the inner cylinder rises; but, in doing so, it carries with it the parabolic piston D, and thus contracts the orifice of the inlet, and consequently diminishes the ingress of gas. In this way, by adjusting the weights attached to the lever of the governor, and by always maintaining a pressure in the gasholder greater than is required in the mains, the gas can be delivered from the governor at any required pressure. In hilly towns, such as Bristol, Bath, Edinburgh, &c., it is necessary to employ governors at different stages of elevation in order to produce a tolerably uniform pressure in the different districts. The necessity for this will be obvious when it is stated that a difference of level of 30 feet affects the pressure of the gas in the mains to the extent of $\frac{2}{10}$ths of an inch of water.

1051

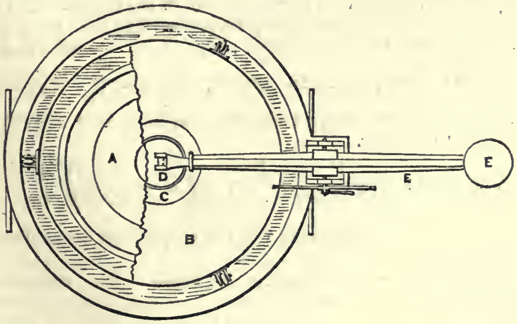


The gas mains.—The pressure by which the motion of the gas is maintained in the pipes is regulated by the governor. From the magnitude of this pressure, and the quantity of gas which in a given time, as an hour, must be transmitted through a certain length of pipes, depends the width or the diameter that the latter should have, in order that the motion may not be retarded by the friction which the gas, like all other fluids, experiences in tubes, whereby the gas might be prevented from issuing with the velocity required for the jets of flame. The velocity of the gas in the main pipe increases in the ratio of the square root of the pressing column of water upon the gasholder, and therefore by increasing this pressure the gas may be

1052

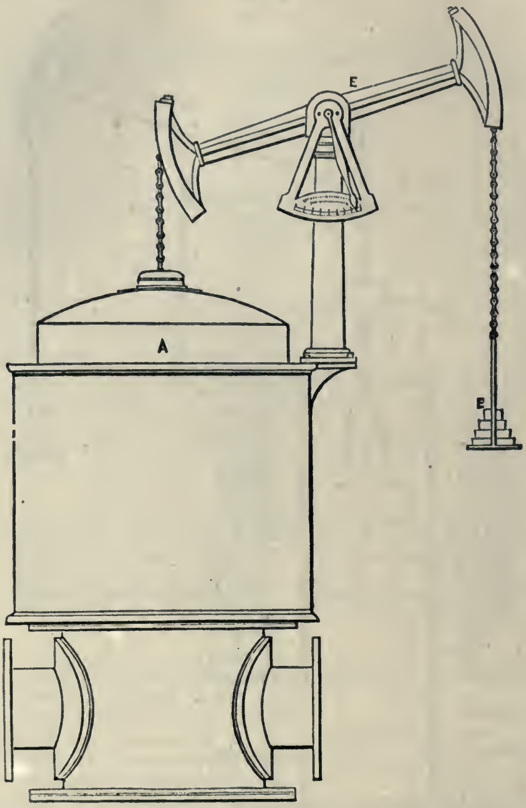


1053



forced more rapidly along the remoter and smaller ramifications of the pipes. Thus it happens, however, that the gas will be discharged from the orifices near the gasholder with superfluous velocity. It is therefore advisable to lay the pipes in such a manner, that in every point of their length, the velocity of discharge may be nearly equal. This may be nearly effected as follows :—

1054



From experiment it appears that the magnitude of the friction, or the resistance which the air suffers in moving along the pipes, under a like primary pressure, that is for equal initial velocity, varies with the square root of the length. The volume of gas discharged from the end of a pipe is directly proportional to the square of its diameter, and inversely as the square root of its length; or, calling the length L, the diameter D, the cubic feet of gas discharged in an hour k; then $k=\frac{D^2}{\sqrt{L}}$. Experience likewise shows, that for a pipe 250 feet long, which transmits in an hour 200 cubic feet of gas, one inch is a sufficient diameter.

$$\text{Consequently, } 200 : k :: \frac{1}{145\sqrt{250}} : \frac{D^2}{\sqrt{L}}; \text{ and } D = \frac{\sqrt{k\sqrt{L}}}{455{,}000}$$

From this formula the following table of proportions is calculated :—

Number of cubic feet per hour	Length of pipe, in feet	Diameter, in inches
50	100	0·40
250	200	1·00
500	600	1·97
700	1000	2·65

Number of cubic feet per hour	Length of pipe, in feet	Diameter, in inches
1000	1000	3·16
1500	1000	3·87
2000	1000	4·47
2000	2000	5·32
2000	4000	6·33
2000	6000	7·00
6000	1000	7·75
6000	2000	9·21
8000	1000	8·95
8000	2000	16·65

These dimensions are applicable to the case where the body of gas is transmitted through pipes without being let off in its way by burners, that is, to the mains which conduct the gas to the places where it is to be used. If the main sends off branches for burners, then for the same length the diameter may be reduced, or for like diameter the length may be greater. For example, if a pipe of 5·32 inches which transmits 2,000 cubic feet through a length of 2,000 feet, gives off, in this space, 1,000 cubic feet of gas; then the remainder of the pipe, having the same diameter, can continue to transmit the gas through a length of 2,450 feet $=\left(\frac{450{,}000}{k}\right)^2$, with undiminished pressure for the purposes of lighting. Inversely, the diameter should be progressively reduced in proportion to the number of jets sent off in the length of the pipe.

Suppose, for instance, the gasholder to discharge 2,000 cubic feet per hour, and the last point of the jets to be at a distance of 4,000 feet. Suppose also that from the gasholder to the first point of lighting, the gas proceeds through 1000 feet of close pipe the diameter of the pipe will be here 4·47 inches; in the second 1,000 feet of length, suppose the pipe to give off, at equal distances, 1,000 cubic feet of gas, the diameter in this length (calculated at 1,500 cubic feet for 1,000 feet long) = 3·87 inches; in the third extent of 1,000 feet, 600 cubic feet of gas will be given off, and the diameter (reckoning 700 cubic feet for 1,000 feet long) will be 2·65 inches; in the fourth and last space (for 200 cubic feet in 1,000 feet long) the pipe has a diameter of only an inch and a half, for which, in practice, a two-inch cast-iron pipe is substituted; this being the smallest used in mains, into which branch pipes can be conveniently inserted.

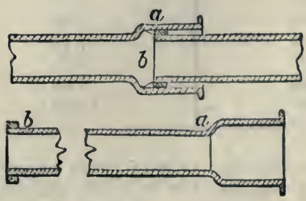
The same relations hold with regard to branch pipes through which the gas is transmitted into buildings and other places to be illuminated. If such pipes make frequent angular turnings, whereby they retard the motion of the gas, they must be a third or a half larger in diameter, The smallest tubes of distribution are never less than one fourth of an inch in the bore.

Where, from one central gas-work, a very great quantity of light is required in particular localities, there ought to be placed near these spots gasholders of distribution, which being filled during the slack hours of the day are ready to supply the burners at night without making any considerable demand upon the original main pipe. Suppose the first main be required to supply 8,000 cubic feet in the hour, for an illumination of 8 hours, at the distance of 2,000 feet, a pipe 10⅜ inches in diameter would be necessary; but if two or three gasholders of distribution, or station gasholders be had recourse to, into which the gas during the course of 24 hours would flow through the same distance continuously from the central gas-works, the quantity required per hour from them would be only one third of 8,000 = 2666·6 cubic feet; consequently, the diameter for such a pipe is only 6·15 inches.

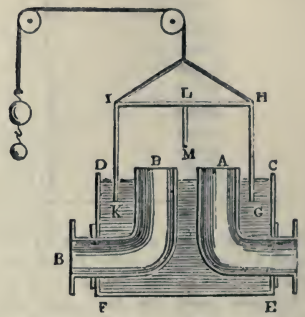
All the principal as well as branch pipes, whose interior diameter exceeds an inch and a half, are made of cast iron, from 6 to 8 feet long, with elbow pipes cast in them where it is necessary. These pipe-lengths are shown in *fig.* 1055, having at one end a wide socket *a*, and at the other a nozzle *b*, which fits the former. After inserting the one in the other in their proper horizontal position, a coil of hemp, soaked with tar is driven home at the junction; then a luting of clay is applied at the mouth, within which a ring of lead is cast into the socket, which is driven tight home with a mallet and blunt chisel.

The pipes should be proved by a force-pump before being received into the gas-works; two or three lengths of them should be joined before laying them down, and they should be placed at least two feet below the surface, to prevent their being affected by changes of temperature, which would loosen the joints. The tubes for internal distribution, when of small size, are made of lead, copper, wrought iron, or tin.

1055



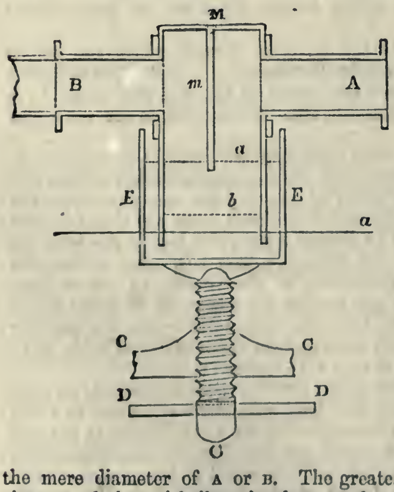
1056



Instead of a stopcock for letting-off the gas in regulated quantities from the gasholder, a peculiarly-formed water or mercurial valve is usually employed. *Fig.* 1056 shows the mode of construction for a water trap or lute, and is, in fact, merely a gasholder in miniature. C D E F is a square cast-iron vessel, in the one side of which a pipe A is placed in communication with the gasholder, and in the other, one with the main B. The moveable cover or lid H G I K has a partition, L M, in its middle. If this cover be raised by its counterweight, the gas can pass without impediment from A to B; but if the counterweight be diminished so as to let the partition plate L M sink into the water, the communication of the two pipes is thereby interrupted. In this case the water-level stands in the compartment A so much lower than outside of it, and in the compartment B, as is equivalent to the pressure in the gasometer; therefore the pipes A and B must project thus far above the water. In order to keep the water always at the same height, and to prevent it from flowing into the mouths of these pipes, the rim C D of the outer vessel stands somewhat lower than the orifices A B; and hence the vessel may be kept always full of water.

If a quicksilver valve be preferred, it may be constructed as shown in *fig.* 1057. A B are the terminations of the two gas-pipes, which are made fast in the rectangular iron vessel M. E is an iron vessel of the same form, which is filled with quicksilver up to the level *a*, and which, by means of the screw G, which presses against its bottom, and works in the fixed female screw C C, may be moved up or down so that the vessel M may be immersed more or less into the quicksilver. The vessel M is furnished with a vertical partition *m*; the passage of the gas from A to B is therefore obstructed when this partition dips into the quicksilver, and from the gradual depression of the vessel E by its screw, the interval between the quicksilver and the lower edge of the partition, through which the gas must enter, may be enlarged at pleasure, whereby the pressure of the gas in B may be regulated to any degree. The transverse section of that interval is equal to the area of the pipe, or rather greater; the breadth of the vessel M, from A to B, amonnts to the double of that space, and its length to the mere diameter of A or B. The greatest height to which the partition *m* can rise out of the quicksilver is also equal to the above diameter, and in this case the line *a* comes to the place of *b*. The vertical movement of the outer vessel E is secured by a rectangular rim or hoop which surrounds it, and is made fast to the upper part of the vessel M, within which guide it moves up and down. Instead of the lever D D, an index with a graduated plate may be employed to turn the screw, and to indicate exactly the magnitude in the opening of the valve.

1057



GAS-ENGINE (*Lenoir's patent*).—From time to time various forms of explosive engines have been introduced. Lenoir's is one of this description which has engaged the public attention; it differs in principle but little from those gas-engines by which it has been preceded.

It resembles a horizontal steam-engine in outward appearance, but the motive power is obtained by exploding a mixture of coal-gas and air on each side of the piston. The explosion is effected by means of a small galvanic battery, which is alternately put in circuit with wires at either end of the cylinder by means of an insulated conductor sliding on the cross head of the piston. Two slide valves are employed, driven by excentrics in the usual manner; one serving for the admission of the mixed gases, whilst the other covers the ports, for the removal of the gases produced by the explosion. The cylinder is kept cool by a current of water, which circulates about its outer surface.

From a report on the mechanical effect produced by this engine, published by M. Tresca, the following data have been obtained:—

The hourly consumption of gas per effective H. P. is 101·7 cubic feet. The ignition of the gases in the interior of the cylinder is effected at a temperature of 536° Fahr. and 175 gallons of water, at 64° Fahr. are employed per hour in cooling the cylinder, the temperature being raised by the contact of the heated metal to 105° Fahr.

It will therefore be seen that there is no economy to be obtained from the use of this engine in the place of steam-power, but it may be conveniently employed for the production of a small power in places where it is considered desirable to dispense with the use of steam boilers. Another, and perhaps more formidable objection, is pointed out by M. Tresca in the fact, that a trace of nitric acid is invariably found in the products of the explosion, which results from the oxidation of a minute quantity of the nitrogen in the air employed, and which is likely to exert a destructive influence on the interior of the cylinder.

The gas-engine known as the *moteur Lenoir*, which was imagined at the commencement of the present century by an engineer named Lebon, was intended to supply motive power in small workshops; the Lenoir engine has answered the end for which it was invented, and has carried motive power into the very residence of the workman. The Lenoir engine has no boiler; it is fed by a current of ordinary gas, mixed with a certain amount of air; an electric spark, produced from a Ruhmkorff coil, excited by the machine itself, sets fire to the mixture, and the heat which results is the true motive power of the engine. The Lenoir engines are of the force of one-half to three-horse and they occupy little space; amongst their advantages are, that they can be started and stopped instantaneously, and present no danger from explosion or fire. They require to be kept, however, in perfect condition, otherwise they are liable to sudden and apparently unaccountable stoppages.

With regard to their economy, according to experiments made with an engine having a cylinder 0·24 meter in diameter, and a stroke of 0·12 meter, the gas used amounted to from 2,699 to 5,352 litres per horse per hour, but the consumption in regular working is about 2,700 litres. The most economical employment corresponded with a little less than the force of one horse, the speed of the flywheel being 107 revolutions per minute. The consumption of water was equal to 120 litres per horse per hour; this water left the cylinder at a temperature inferior to 100° C.

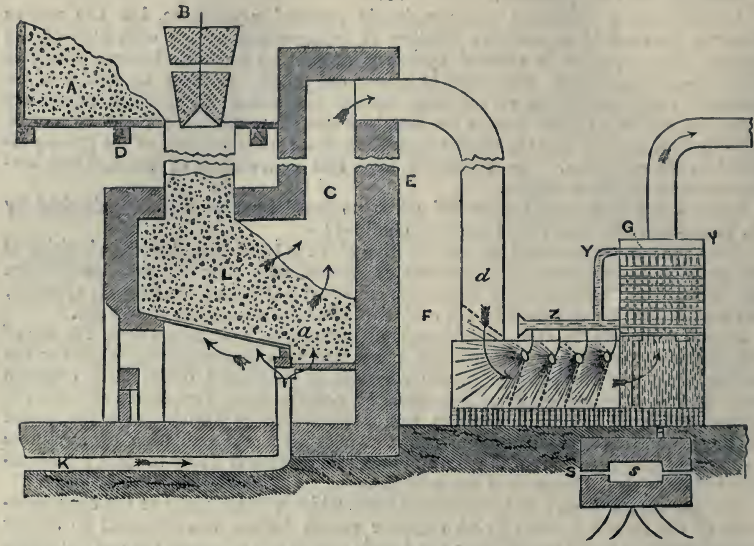
There is another class of machines about which a few words should be said; their applications are not yet numerous, but they doubtless have a great future before them; these are compressed air-engines which allow of work being carried on at the depth of thirty to forty meters below water, and even deeper, for the establishment of the tubular foundations of bridges, and for other purposes. The piercement of Mont Cenis offers an admirable example of the new and important means of employment of compressed air. The works of the grand Alpine tunnel have shown with what facility air compressed under six or seven atmospheres can be conveyed through pipes to great distances, as far as five miles or more, without any sensible loss of pressure to work motive machines similar to ordinary steam-engines. See AIR-ENGINE.

These results are very important, and may contain the germs of the solution of the problem of distributing motive power wherever it is required in towns. We have spoken of the Lenoir engine, but in spite of many improvements introduced into gas motors, they still have their inconveniences; their power, at the same time, is very limited.

GAS-FURNACE. *Lundin's Gas-Furnace.*—Puddling with wood is practised to a considerable extent in Sweden, the best furnace being that of F. Lundin, of Carlstadt Munkfors, *fig.* 1058, designed for the consumption of turf and peat without drying, and of wet sawdust or other moist fuel. A *fig.* 1058, is a pile of green sawdust; B, hopper and cone; D, gas generator for green sawdust; G, condenser; K, air blast; S, chimney, 43 feet high; Y Y, 3,500 lbs. of iron in bars, cooled by the water from pipe

Y Y, to cool the gas and precipitate the water; L sawdust containing 45 per cent. of water; Z water at 2°; at *s* the temperature is 300°, at *d* 350°, at C 400° to 450° C.

1058



The temperature used to burn the gas, calculated from the cold air, is about 2000° C.

At R lead melts slowly; at F lead melts easily; at E zinc sometimes melts.

The gas, before condensation, contains 33 parts by weight of water to 100 of dry gas.

Constituents of Gas.

11·8 vol.	carbonic acid	19·6 weight.
19·8 „	„ oxide	20·8 „
11·3 „	hydrogen	0·87 „
4·0 „	marsh gas	2·4 „
53·1 „	nitrogen	56·3 „

The furnace may be placed at a long distance from the condenser.

In this furnace the fuel is fed by a hopper into a reservoir, resting upon an inclined grate, supplied from below with air from a blower. The products of combustion thus produced pass through a condenser, where all the moisture in the gas is condensed. The gas then passes to the heating furnace, which is furnished with Siemens' regenerators. It is found easy to use fuel containing as much as 45 per cent of water, and the resulting gas contains about 33 lbs. of water to 100 lbs. of dry gas, whilst the water, after condensation, contains about 2 per cent. of its weight in gas, and 3 per cent. of its volume. The condensing apparatus consists of 3,500 lbs. of iron bars piled crosswise on each other, and kept cold by a jet of water from a tuyère. The heat of the gas before condensation of the water always melts lead easily, and sometimes zinc. In the Elkman furnace dry wood containing 8 per cent. of water produces in the generators gas of a temperature of 1394°, while in the Lundin furnace the temperature is 2666°, the combustion in both cases being produced by cold air. The gas produced by seasoned wood contains more water than that which proceeds from the Lundin condenser. The duration of the furnace is very remarkable, and is to be attributed probably to the fact that there is no cinder. In eight weeks the thickness of the roof, 4 in., was only diminished from $\frac{1}{4}$ to $\frac{3}{8}$ in., and the side walls were entirely uninjured. So great is the success of this system of condensation, in connection with the Siemens' regenerators, that in Sweden, and in fact everywhere where moist fuel is employed, the Lundin furnace will supersede every other. Abram S. Hewitt considers that it is available for any kind of fuel whatever.

Siemens' patent Regenerative Gas-Furnaces.—The advantagesof the regenerative gas-furnaces are stated to be—

1.—Saving of fuel, amounting to from 40 to 50 per cent. in the quantity, besides which, the most inferior qualities of fuel, such as slack, coke-dust, lignite, and peat, may be employed, producing a money saving, in many instances, amounting to 75 per cent.

2.—Increase of work done per day in a furnace of given dimensions amounting to 30 per cent. or more, owing to unlimited command of heat with low chimney-draught.

3.—Great purity and gentleness of flame, which greatly diminishes the oxidation, or deterioration, of the material heated in the furnace.

4.—Increased durability of furnace, owing to the absence of ashes, and a perfect uniformity of heat throughout the furnace.

5.—Saving of space within the works, and great cleanliness of operation, the fuel being converted into gas outside the works.

6.—Complete command of the intensity of the heat, and of the chemical nature of the flame, which may be arrested or changed from a reducing to an oxidising flame, or the reverse, at any one moment, tending to facilitate and improve all metallurgical operations.

7.—Complete absence of smoke from the stack, which renders this furnace beneficial to the public in large towns.

The late Professor Faraday, in his last public lecture at the Royal Institution, on the 20th June 1862, described these furnaces in the following terms:—

'The gaseous fuel is obtained by the mutual action of coal, air, and water, at a moderate red heat. A brick chamber, perhaps 6 ft. by 12 ft., and about 10 ft. high, has one of its end walls converted into a fire-grate, *i.e.*, about half-way down it is a solid plate, and for the rest of the distance consists of strong horizontal plate bars where air enters, the whole being at an inclination such as that which the side of a heap of coals would naturally take. Coals are poured, through openings above, upon this combination of wall and grate, and being fired at the under surface, they burn at the place where the air enters; but as the layer of coal is from 2 to 3 feet thick, various operations go on in those parts of the fuel which cannot burn for want of air. Thus the upper and cooler part of the coal produces a large body of hydrocarbons; the cinders or coke which are not volatilised, approach, in descending, towards the grate; that part which is nearest the grate burns with the entering air into carbonic acid, and the heat evolved ignites the mass above it; the carbonic acid, passing slowly through the ignited carbon, becomes converted into carbonic oxide, and mingles in the upper part of the chamber (or gas-producer) with the hydrocarbons. The water, which is purposely introduced at the bottom of the arrangement, is first vaporised by the heat, and then decomposed by the ignited fuel, and re-arranged as hydrogen and carbonic oxide; and only the ashes of the coal are removed as solid matter from the chamber at the bottom of the fire-bars.

'These mixed gases form the gaseous fuel. The nitrogen, which entered with the air at the grate, is mingled with them, constituting about a third of the whole volume. The gas rises up a large vertical tube, for 12 or 15 feet, after which it proceeds horizontally for any required distance, and then descends to the heat regenerator, through which it passes before it enters the furnaces. A regenerator is a chamber packed with fire-bricks, separated so as to allow of the free passage of air or gas between them. There are four placed under a furnace. The gas ascends through one of these chambers, whilst air ascends through the neighbouring chamber, and both are conducted through passage-outlets at one end of the furnace, where mingling, they burn, producing the heat due to their chemical action. Passing onwards to the other end of the furnace, they (*i.e.*, the combined gases) find precisely similar outlets down which they pass; and traversing the two remaining regenerators from above downwards, heat them intensely, especially the upper part, and so travel on in their cooled state to the shaft or chimney. Now the passages between the four regenerators and the gas and air are supplied with valves and deflecting plates, which are like four-way cocks in their action; so that by the use of a lever those regenerators and air-ways, which were carrying off the expended fuel, can in a moment be used for conducting air and gas into the furnace; and those which just before had served to carry air and gas into the furnace, now take the burnt fuel away to the stack. It is to be observed that the intensely-heated flame which leaves the furnace for the stack always proceeds downwards through the regenerators, so that the upper part of them is most intensely ignited, keeping back as it does, the intense heat; and so effectual are they in this action, that the gases which enter the stack to be cast into the air are not usually above 300° Fahr. of heat. On the other hand, the entering gas and air always pass upwards through the regenerators, so that they attain a temperature equal to a white heat before they meet in the furnace, and there add to the carried heat that due to their mutual chemical action. It is considered that when the furnace is in full order, the heat carried forward to be evolved by the chemical action of combustion is about

4000°, whilst that carried back by the regenerator is about 3000°, making an intensity of power which, unless moderated on purpose, would fuse furnace and all exposed to its action.

'Thus the regenerators are alternately heated and cooled by the outgoing and entering gas and air, and the time for alteration is from half an hour to an hour, as observation may indicate. The motive power on the gas is of two kinds: a slight excess of pressure within is kept up from the gas-producer to the bottom of the regenerator to prevent air entering and mingling with the fuel before it is burnt; but from the furnace, downward through the regenerators, the advance of the heated medium is governed mainly by the draught in the tall stack or chimney.

'Great facility is afforded in the management of these furnaces. If, whilst glass is in the course of manufacture, an intense heat is required, an abundant supply of gas and air is given; when the glass is made, and the condition has to be reduced to working temperature, the quantity of fuel and air is reduced. If the combustion in the furnace is required to be gradual from end to end, the inlets of air and gas are placed more or less apart the one from the other. The gas is lighter than the air; and if a rapid evolution of heat is required, as in a short puddling furnace, the mouth of the gas-inlet is placed below that of the air-inlet; if the reverse is required, as in the long tube-welding furnace, the contrary arrangement is used. Sometimes, as in the enameller's furnace, which is a long muffle, it is requisite that the heat be greater at the door-end, because the goods, being put in and taken out at the same end, those which enter last, and are withdrawn first, remain, of course, for a shorter time in the heat at the end; and though the fuel and air enter first at one end and then at the other alternately, still the necessary difference of temperature is preserved by the adjustment of the apertures at the ends.

'Not merely can the supply of gas and air to the furnace be governed by valves in the passages, but the very production of the gas fuel itself can be diminished, or even stopped, by cutting off the supply of air to the grate of the gas-producer; and this is important, inasmuch as there is no gasometer to receive and preserve the aeriform fuel, for it proceeds at once to the furnaces.

'Some of the furnaces have their contents open to the fuel and combustion, as in the puddling and metal-melting arrangements; others are enclosed, as in the muffle furnaces and flint-glass furnaces.

'The economy in the fuel is estimated practically as one-half, even when the same kind of coal is used either directly for the furnace or for the gas-producer; but, as in the latter case, the most worthless kind can be employed—such as slack, &c., which can be converted into a clean gaseous fuel at a distance from the place of the furnace, so, many advantages seem to present themselves in this part of the arrangement.'

Professor Faraday concludes his lecture with the following conclusive figures:—

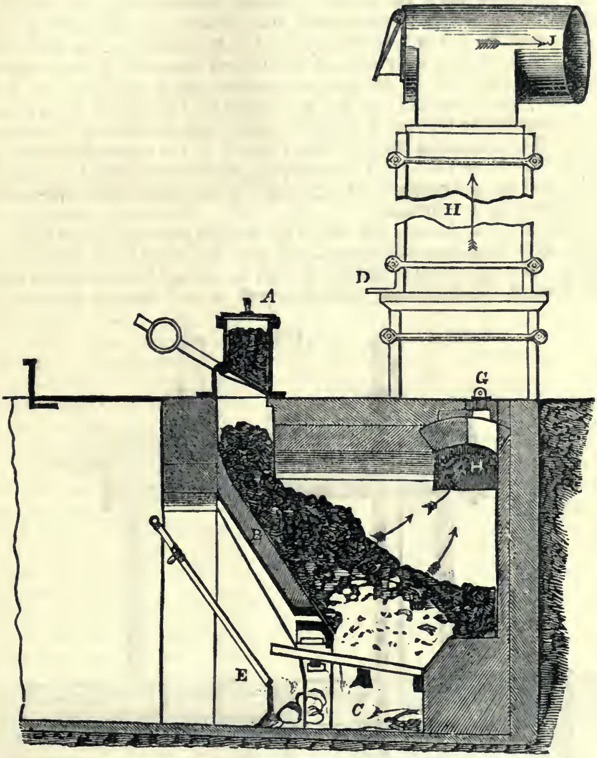
'Carbon burnt perfectly into carbonic acid in a gas-producer would evolve about 4000° of heat; but, if burnt into carbonic oxide, it would only evolve 1200°. The carbonic oxide, in its fuel form, carries on with it the 2800° in chemical force, which evolves when burning in the real furnace with a sufficient supply of air. The remaining 1200° are employed in the gas-producer in distilling hydrocarbons, decomposing water, &c. The whole mixed gaseous fuel can evolve about 4000° in the furnace, to which the regenerator can return about 3000° more.'

The following is a brief description of the regenerative gas-furnaces:—

The gas-producer is shown in *fig.* 1059. The producers are entirely separate from the furnace where the heat is required, and may be made sufficient in number and capacity to supply several furnaces. The fuel is supplied, at intervals of from two to four hours, through the charging boxes A, *fig.* 1059, and descends gradually on the inclined plane B, which is set at an inclination to suit the fuel used. The upper portion of the incline B is made solid, being formed of iron plates covered with firebricks; but the lower portion C is an open grate formed of horizontal flat steps. The large opening under the lowest flat step is convenient for drawing out clinkers, which generally collect at that point. The small stoppered holes F at the front, and G at the top of the producer, are provided to allow of putting in an iron bar occasionally to break up the mass of fuel and detach clinkers from the side walls. Each producer is capable of converting daily about two tons of fuel into a combustible gas, which passes off through the uptake H leading to the furnaces.

The action of the gas-producer in working is as follows:—The fuel descending slowly on the solid portion B of the inclined plane becomes heated, and parts with its volatile constituents, the hydrocarbon gases, water, ammonia, and some carbonic acid, which are the same as would be evolved from it in a gas-retort. There now remains from 60 to 70 per cent. of purely carbonaceous matter to be disposed of, which is accomplished by the current of air slowly entering through the grate C, producing regular combustion immediately upon the grate; but the carbonic acid (a non-combustible gas) thereby produced, in passing slowly on through a layer of incandescent fuel from 2 to 3 feet thick, takes up another equivalent of carbon, and is thus transformed into carbonic oxide (an inflammable gas), which passes off with the other combustible gases to the furnace. For every cubic foot or combustible carbonic oxide thus produced, taking the atmosphere to consist of 1-5th part by volume of oxygen and 4·5ths of nitrogen, two cubic feet of incombustible nitrogen pass also through the grate, tending greatly to diminish the richness or heating power of the gas. Not all the carbonaceous portion of the fuel is, however, volatilised on such disadvantageous terms; for water is brought to the foot of the grate by the pipe E, which, absorbing the spare heat from the fire, is converted into steam; and each cubic foot of steam in traversing the layer of from 2 to 3 feet of incandescent fuel is decomposed into a mixture consisting of one cubic foot of hydrogen and nearly an equal volume of carbonic oxide, with a variable small proportion of carbonic acid. Thus one cubic foot of steam yields as much inflammable gas as five cubic feet of atmospheric air; but the one operation is dependent upon the other, inasmuch as the passage of air through the fire is attended with the generation of heat, whereas the production of the water-gases, as well as the evolution of the hydrocarbons, is carried on at the expense of heat. The generation of steam from the water being dependent on the amount of heat in the fire, regulates itself naturally to the requirements; and the total production of combustible gases varies with the admission of air. And since the admission of air into the grate depends in its turn upon the withdrawal of the gases evolved in the producer, the production of the gases is entirely regulated by the demand for them. The production of gas may even be arrested entirely for twelve hours without deranging the producer, which will begin work again as soon as the gas-valve of the furnace is re-opened; since the mass of fuel and brickwork retain sufficient heat to keep up a dull red heat in the producer during that interval. The gas is, however, of a more uniform quality when there is a continuous demand for it, and for this reason it is best to supply several furnaces from a nest of gas-producers so as to keep them constantly at work. A damper D, shown

1059

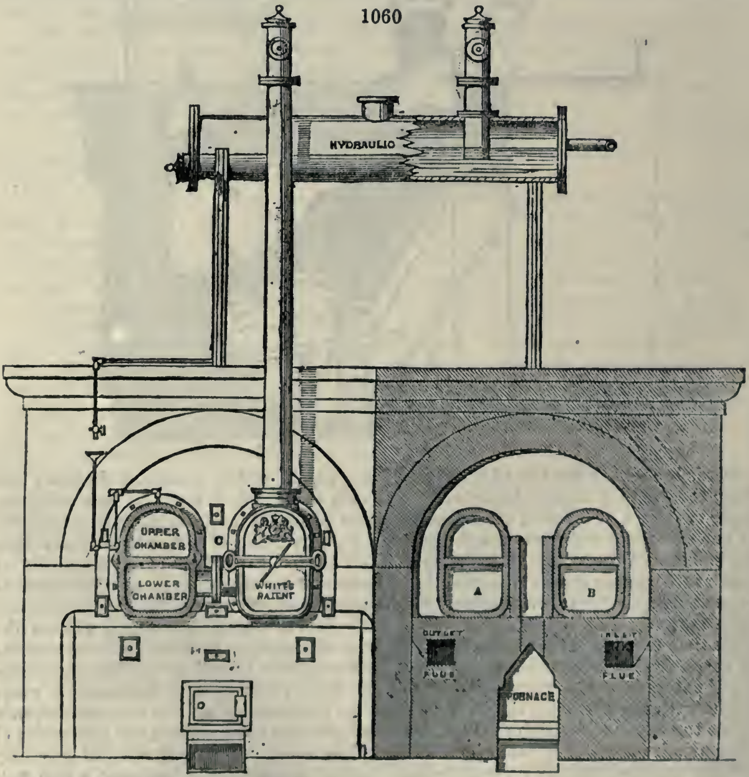


in *fig.* 1059, can be inserted in the uptake so as to shut off any gas-producer at pleasure.

It is important that the main gas-flue leading to the furnaces should contain an excess of pressure, however, slight, above the atmosphere, in order to prevent any inward draught of air through crevices, which would produce a partial combustion of the gas, and diminish its heating power in the furnace, besides causing a deposit of soot in the flues. It is therefore necessary to deliver the gas into the furnace without depending upon the chimney-draught for that purpose. This can be easily accomplished when the gas-producers are placed at a lower level than the furnaces; but as that is not always practicable, the following plan has been adopted. The mixture of gases on leaving the producers has a temperature ranging between 300° and 400° F., which must under all circumstances be sacrificed, since it makes no difference to the result at what temperature the gas to be heated enters the regenerators, the final temperature being in all cases very nearly that of the heated chamber of the furnace, or say 2500° F. The initial heat of the gas is therefore made available for producing a plenum of pressure by making the gas rise about 20 feet above the producers, then carrying it horizontally through a wrought-iron tube J, and letting it again descend to the furnace. The horizontal tube J, being exposed to the atmosphere, causes the gas to lose from 100° F. to 150° F. of temperature, which increases its density from 15 to 20 per cent., and gives a preponderating weight to that extent to the descending column, urging it forward to the furnace.

The regenerative gas-furnace consists of the heating chamber, below which are placed four regenerative chambers, which are filled with firebricks built up with spaces between them. The regenerative chambers work in pairs; the two under the left-hand end of the furnace communicating with that end of the heating chamber, while the other two communicate with the opposite end. The gas enters the heating chamber through one passage, and the air through the other passage whereby they are kept separate up to the moment of entering the heating chamber, but are then able immediately to mingle intimately, producing at once an intense and uniform flame.

1060



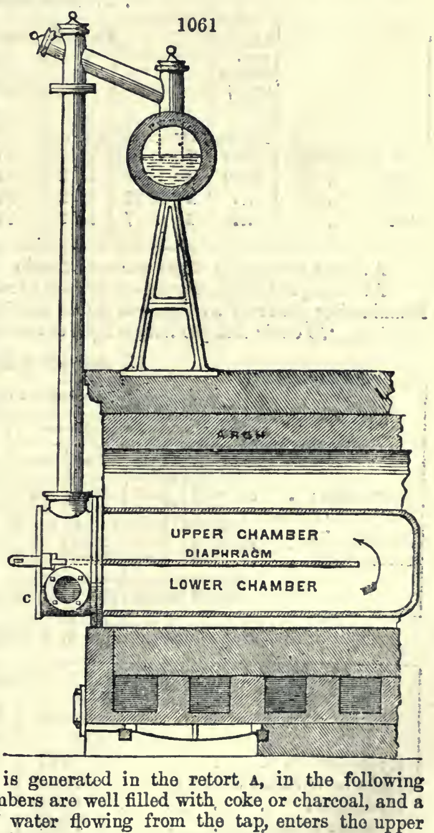
From the air-flue, the entering air is directed by the reversing valve into the air-regenerator, and there becomes heated ready for entering the furnace; at the same time the gas entering from the gas-flue is directed by the reversing valve into the gas-regenerator, where it also becomes heated to the same temperature as the air.

The products of combustion, on leaving the opposite end of the furnace, pass down through the second pair of regenerators (as shown by the arrows), and after being there deprived of their heat, are directed by the reversing valves into the chimney flue. When the second pair of regenerators have become considerably heated by the passage of the hot products of combustion, and the first pair correspondingly cooled by the entering gas and air, the valves are reversed by hand-levers, causing the currents to pass through the regenerators in the contrary direction, whereby the hot pair of regenerators are now made use of for heating the gas and air entering the furnace, while the cool pair abstract the heat from the products of combustion escaping from the furnace. The supply of gas and air to the furnace is regulated by the adjustable stop-valves, whereby the nature and volume of the flame in the furnace may be varied at pleasure, whilst a chimney damper is used to regulate the amount of pressure in the furnace in relation to the atmosphere, so as to allow the opening of the doors or working holes of the furnace.

For a further description of the applications of this gas-furnace and the regenerative system as applied in the Iron manufacture, see Iron and Steel.

GAS, HYDROCARBON. This title has been given to illuminating gas manufactured according to a patent granted some years ago to Mr. White of Manchester. The process of manufacture consists essentially in the generation of non-illuminating combustible gases by the action of steam upon charcoal, coke, or other deoxidising substances, in a separate retort, and the introduction of these gases, technically called water-gas, into the retort in which the illuminating gases are being generated, and in such a manner that these latter gases shall be swept out of the retort as rapidly as possible, so as to remove them from the destructive influence of a high temperature.

1061



The retorts used for the hydrocarbon-gas process may be of various shapes and sizes. The settings are similar to those for the ordinary retorts, and any number which is necessary may be placed in an oven. They differ only from the ordinary retorts by having a horizontal partition, or diaphragm, cast in the centre, dividing the retort into two chambers, and extending to within 12 inches of the back. This diaphragm is found in practice to strengthen the sides of the retorts, and thus to add to their durability. The water-gas retorts may be cast from the same pattern as the cannel retorts, and may be set in exactly the same manner. *Figs.* 1060 and 1061 represent a setting of two retorts in one oven, and show the same in elevation, transverse section, and longitudinal section. The retorts here shown have an internal cubical capacity of about 16 feet, and the bed of two is capable of producing about 10,000 cubic feet per diem of hydrocarbon-gas. The temperature at which the retorts are worked is about the average. The water-gas is generated in the retort A, in the following manner:—The upper and lower chambers are well filled with coke or charcoal, and a a very fine stream, or rapid drops of water flowing from the tap, enters the upper chamber through the siphon pipe, falling into a small steam-generating tube, which is placed inside to receive it, and instantly converts it into steam. The vapour, in passing backwards along the upper chamber, and forwards along the lower one, becomes to a great extent decomposed into hydrogen, carbonic oxide, and carbonic acid gases. The water-gas generated in the retort A, as described above, enters the lower chamber of the retort B, through the connecting pipe C C, cast on the mouthpiece. In the chambers of this retort the illuminating gas is generated, either from coal, cannel, resin, or other suitable material, and being rapidly carried forward by the current of water-gas, its illuminating principles are preserved from the destruction caused by prolonged contact with the incandescent surfaces in the retort, whilst at the same time its volume is increased. When very rich cannels or other materials are used, two, three, or even four water-gas retorts are made to discharge their gas into the cannel retort.

The hydrocarbon process has hitherto been applied only to resin, coals, and cannels. The following is a brief summary of the results of a series of experiments made by Dr. Frankland on the manufacture of hydrocarbon resin-gas. Each hundredweight of resin was dissolved by heat in 7½ gallons of the resin-oil of a former working, and the liquid, whilst still hot, was run into one of the retorts, by means of a siphon tube, in a stream about the thickness of a crowquill, whilst water-gas generated in the second retort, was admitted, as described above. The mixed gases were then made to stream through the usual form of condensing apparatus, and were afterwards compelled to pass successively through wet and dry lime-purifiers before they reached the gasholder. In order to secure a uniform mixture of the gas produced in each experiment, it was allowed to remain at rest in the gasholder for at least twelve hours before a specimen was withdrawn for analysis.

In the following Tables both the practical and analytical results are given.

I. *Practical Results.*

	Average evolution of gas per hour	MATERIALS CONSUMED									PRODUCTS OBTAINED		
		Resin			Coal		Charcoal	Lime	Water		Resin-oil	Gas	Gas per cwt. of resin

This process is especially adapted for the manufacture of gas on a small scale, as in private houses or small manufactories. The necessary operations involve little trouble and unpleasant effluvia.

Dr. Frankland has also investigated the hydrocarbon process as applied to coals and cannels, and the following is a tabulated summary of his experimental results :—

Dr. Frankland thus sums up the advantages which he conceives to result from the application of the hydrocarbon process to coals and cannels :—

1. It greatly increases the produce in gas from a given weight of coal or cannel. the increase being from 46 to 290 per cent., according to the nature of the material operated upon.

2. It greatly increases the total illuminating power afforded by a given weight of coal, the increase amounting to from 12 to 108 per cent., being greatest when coals affording highly illuminating gases are used.

3. It diminishes the quantity of tar, formed by converting a portion of it into gases possessing a considerable illuminating power.

4. It enables us profitably to reduce the illuminating power of the gases produced from such materials as Boghead and Lesmahago cannels, &c., so as to fit them for burning without smoke and loss of light.

Mr. Barlow has also experimented upon this process of gas-making, and finds that a very considerable gain in total illuminating results from its use.

Mr. Clegg's investigation of this process showed, that whilst Wigan cannel produces by the ordinary process of gas-making about 10,000 cubic feet of 20-candle gas per ton; 16,000 cubic feet of 20-candle gas, or 26,000 cubic feet of 12-candle gas, can be made from the same quantity of material by the hydrocarbon process. Also that by the application of the same process to Lesmahago cannel 36,000 cubic feet of 20-candle gas, or 58,000 cubic feet of 12-candle gas per ton can be obtained; whilst Boghead cannel yields 52,000 cubic feet of 20-candle gas, or 75,000 cubic feet of 12-candle gas. The following table presents in a condensed form Mr. Clegg's results as to comparative cost:—

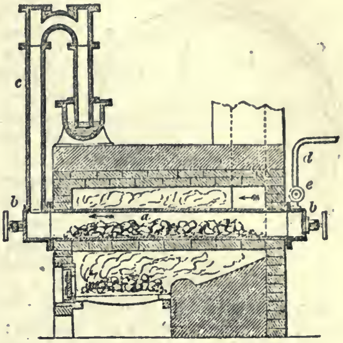
Name of coal	Cost of 1,000 ft. of 20-candle gas by old process	Cost of 1,000 ft. of 20-candle gas by hydrocarbon process	Cost of 1,000 ft. of 12-candle gas by hydrocarbon process
	s. *d.*	*s.* *d.*	*s.* *d.*
Wigan cannel at 14*s.* per ton	1 9¾	1 3½	0 11¼
Lesmahago cannel at 18*s.* per ton . . .	2 5½	0 11¾	0 9¼
Boghead cannel at 20*s.* per ton . . .	2 4½	0 11	0 9¼

The principle of the hydrocarbon process is also adopted by Messrs. Lowe and Evans in their patent process for the manufacture of gas for illuminating purposes.

In carrying out this latter improved manufacture of gas, the patentees pass gas obtained from any of the sources hereinafter specified, through heated retorts containing cannel coal, coal, lignite, resin, pitch, tar, oil, retinite, or other substance or substances capable of yielding carburetted hydrogen gas; by which means such a combination of rich and poor gases may be produced as will be exactly suited to the purposes of illumination. For this purpose, it is proposed to use retorts, open at both ends, as shown in the drawing given in *fig.* 1062, which represents a longitudinal vertical section of the apparatus employed in carrying out this part of the invention. Only one retort is exhibited;

but a similar arrangement of retorts may be adopted to that in general use in gasworks. *a* is the retort, set in a suitable furnace for heating the same; and *b b* are mouthpieces and lids, fitted to both ends of the retort. *c* is the pipe for carrying off the gaseous products generated in the retort; and *d* is a pipe for introducing into the retort the gas which is intended to mix with the gaseous products of the substances under distillation in the retort. As soon as the retort is charged with coal or other carbonaceous matter, a cock *e*, in the pipe *d*, is opened, which allows the gas to flow into the retort; and it then passes in the direction of the arrows, and mingles with the gas that is evolved from the carbonaceous matters contained in the retort: whereby a compound is formed, possessing a much higher illuminating power than could have been obtained had the combination taken place after instead of at the time of the generation of the gas in the retort *a*. The gas, which is brought to the retort by means of the pipe *d*, may be forced into the retort, so as to overcome the internal pressure put on the retort by means of the hydraulic main; or, instead thereof, an exhauster may be applied to draw off the gas from the retort. Should tar, oil, resin (previously melted), or any liquid hydrocarbon be employed for the generation of the gas, it is to be run into the retort in the way generally adopted for making oil- or resin-gas.

1062



The sources from which the patentees propose to obtain inflammable gases, to be applied as above indicated, are wood, sawdust in a damp or dry state, spent tanner's bark, and other like substances capable of yielding an inflammable gas. These substances must be put into a red-hot retort, and distilled like coal. The resulting gases may be either purified at once, or passed directly to the retort containing the coal or other carbonaceous materials. As a general rule, however, these gases are preferred to be stored in gasholders for use; as, in that case, a more uniform and constant supply to the coal-retort may be relied on.

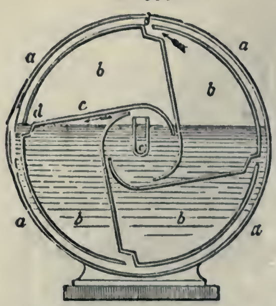
Another source of inflammable gas is from coal of an inferior description, or from peat. These substances having been distilled in a retort, the resulting gas can be then employed as above indicated. It is also proposed to conduct carbonic oxide gas into retorts containing carbonaceous matters under distillation. This gas the patentees obtain from carbonic acid, by passing the latter gas (which may be obtained from any convenient source) through a retort or furnace containing red- or white-hot coke. Or, they utilise a portion of the gases generated in furnaces, by collecting these gases and converting the carbonic acid they contain into carbonic oxide, by passing them through a retort or furnace, as described for treating carbonic acid; or the gases may be conducted directly into retorts, wherein carburetted hydrogen is being generated, for the purpose of effecting the desired combination. See Peat.

From the foregoing description, it will be understood, that the object of this part of the invention is to obtain gas of a uniform quality—that is, possessing a definite amount of illuminating power. Now, it is well known that if the gas be too rich in carbon it will burn with a dull flame, and give off a large amount of smoke; and that, if deficient in carbon, it will burn with a blue flame, and possess very little illuminating power. It is therefore proposed to mix the rich and poor gases, obtained as above described, in such proportions as will be needful to produce a highly-illuminating quality of gas. As the proportions will depend entirely on the quality of the gases to be combined, no rule can be laid down for the amount of the gas required to be passed into the retorts, wherein the distillation is proceeding. The mode, however, in which gas burns on issuing from the retort will be a sufficient test for the workmen in attendance.

GAS-METER. In order to measure the quantity of gas which passes through a pipe for lighting a factory, theatre, &c., the gas-meter is employed, of whose construction a sufficiently precise idea may be formed from the consideration of *fig.* 1063, which shows the instrument in a section perpendicular to its axis.

Within the cylindrical case *a*, there is a shorter cylinder *b b*, shut at both ends, and moveable round an axis, which is divided into four compartments, that communicate by the openings *d*, with the interval between this cylinder and the outer case. The mode in which this cylinder turns round its axis is as follows:—The end of the tube *c*, which is made fast to the side of the case, and by which the gas enters, carries a pivot or gudgeon, upon which the centre of its prop turns; the other end of the axis runs in the cover, which here forms the side of a superior open vessel, in which, upon the same axis, there is a toothed wheel. The vessel is so far filled with water, that the tube *c* rises just above it, which position is secured by the level of the side vessel. When the gas enters through the tube *c*, by its pressure upon the partition *e* it turns the cylinder from right to left upon its axis, till the exterior opening *d* rises above the water, and the gas expands itself in the exterior space, whence it passes off through a tube at top. At every revolution a certain volume of gas thus goes through the cylinder, proportional to its known capacity. The wheel on the axis works in other toothed wheels, whence, by means of an index upon a graduated disc or dial, placed at top or in front of the gas-meter, the number of cubic feet of gas which pass through this apparatus in a given time is registered.

1063



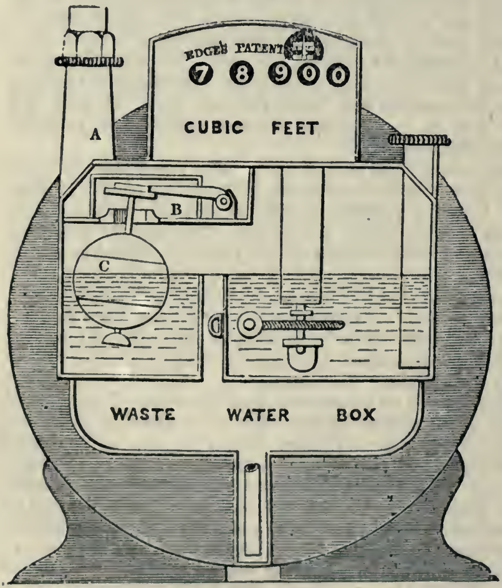
Mr. Thomas Edge, of Great Peter Street, Westminster, has contrived the following meter, of which drawings are annexed:—

Fig. 1064 is a front view of a three-light meter, the front plate being removed, and some of the parts shown in section.

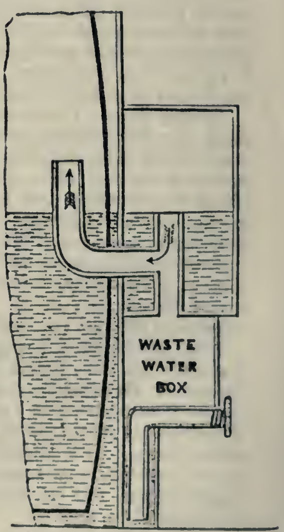
Fig. 1065 is a transverse section of the same.

The gas enters at A into the small chamber B, in the bottom of which is a lever valve (part of Mr. Edge's patent improvement), moving upon its axis and attached by the rod to a metal float C, which in the present drawing is buoyant. The object of this arrangement is to intercept the passage of the gas into the meter, unless a sufficient quantity of water is in it, that being necessary to its proper action; the gas then passes through the inverted siphon or tunnel into the convex cover, whence it passes into the chambers of the drum.

1064



1065

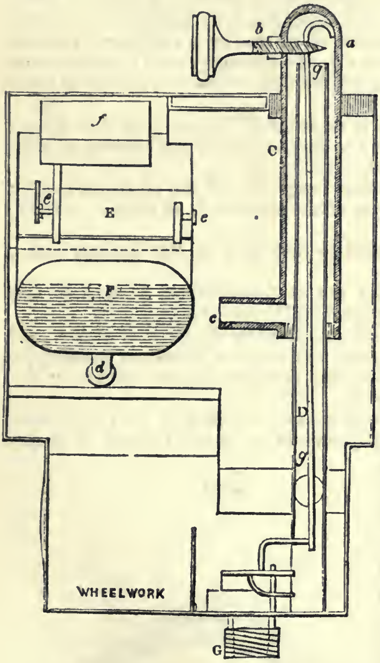


Another of Mr. Edge's improvements consists in the cutting down of this siphon pipe or tunnel to the proper water level, and connecting the bottom of it to a waste water box, into which any surplus water must fall. The importance of this precaution will be seen on investigating the drum, as an excessive height of water will materially interfere with the measurement, the quantity of gas delivered per revolution being considerably less. This, in connection with the lever valve and float, confines the variation of the water levels within such narrow limits, that the measurement may be considered perfectly just on all occasions.

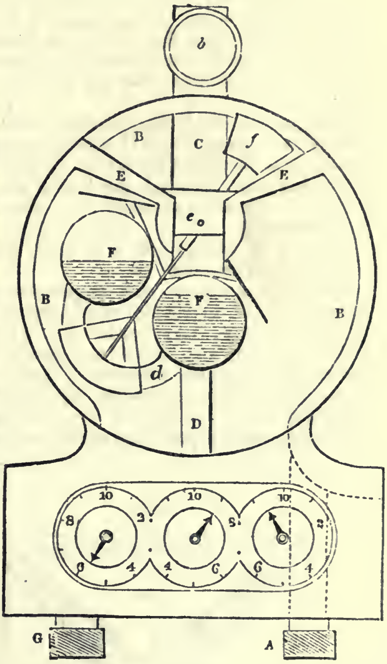
The hydraulic, or wet gas-meter in ordinary use, when properly constructed, measures with great accuracy, and requires only a very slight pressure of gas to work it; but it readily admits of fraudulent means being employed by the consumer, so as to cause the instrument to under-estimate the amount of gas consumed; whilst, on the other hand, the condensation of moisture within the meter may so far elevate the water-level as to cause an over-estimation of the consumption. The water in the hydraulic meter is also liable to freeze in winter, thus completely stopping the supply of gas; at other times, especially when the meter is fixed in a comparatively warm place, the gas, becoming saturated with aqueous vapour, subsequently deposits water during its passage through the cooler portions of the pipes of distribution. The water thus deposited collects in the lower portions of the pipes, breaking the flow of gas into a succession of bubbles, and causing that flickering or dancing of the gas flames which is so frequently a source of annoyance in winter.

These defects and inconveniences are all obviated by the *dry gas-meter*, several forms of which have of late years been invented. The first in point of date is Clegg's patent dry gas-meter, an instrument displaying great ingenuity, although it has never come into very extensive use. *Figs.* 1066 and 1067 show the construction of this meter: the letters of reference are the same in both.

1066



1067



B B, *fig.* 1067, represents a cylindrical vessel, about 3¾ inches in diameter and 4 inches deep, being the dimensions of a meter capable of measuring gas for three burners, called a three-light meter. In this vessel are two glass cylinders F F, connected together by the bent tube *d*. The cylinders being perfectly exhausted of air, and half filled with alcohol, are made to vibrate on centres *e*, *e*, and are balanced by the weight *f*. This instrument accurately indicates the excess of heat to which either cylinder may be exposed upon the principle of Leslie's differential thermometer.

C is a hollow brass box, called the heater, about 4 inches long and ½ an inch broad, projecting out of the meter about 1 inch. At *a* issues a small jet of gas, which, when inflamed, gives motion to the cylinders.

The gas enters the meter by the pipe A, and circulates throughout the double case B. Having passed round the case B, a portion of it enters the top of the box C, by the pipe D, and passes out again at the bottom of the tube *c*, into the meter; the rest of the gas enters the body of the meter through holes in the curved faces of the hoods E E, and, after blowing on the glass cylinders, passes to the burners through the outlet pipe.

To put the meter in action, let the jet *a* be lighted about an hour before the burners are wanted. In most cases this jet will be lighted all day as a useful flame. The hole *a* is so situated on the box C, that whatever be the size of the jet, a fixed temperature is given to the box, that temperature depending on the quantity of flame in contact with the box, and not at all on the length of the jet. The jet being lighted, and the box C thereby heated, the gas which passes through it is raised to the same temperature, and, flowing out at the tube *c*, impinges on the glass cylinder which happens for the time to be the lowest; the heated gas soon raises a vapour in the lower cylinder, the expansion of which drives the liquid into the upper one, until it becomes heavier than the counterpoise *f*, when the cylinders swing on their centre, the higher one descends, and comes in the line of the current of hot gas, and the lower one ascends; the same motion continues as long as the jet *a* burns. The same effect on the cylinder is maintained, however the outward temperature may change, by the cold gas, which, issuing from the curved side of the hood E E, impinges on the upper cylinder, and hastens the condensation of the vapour which it contains.

The cold gas and the heater vary in temperature with the room, and thus counteract each other.

The lighting of the jet *a* is essential to the action of the meters; in order to insure this, the supply of gas to the burners is made to depend on it in the following manner. The pipe G, by which the gas leaves the meter, is covered by a side valve, which is opened and shut by the action of the pyrometer *g*; the pyrometer is in communication with and receives heat from the jet, and opens the valve when hot, closing it again when cold.

The speed at which the cylinders vibrate is an index of the quantity of heat communicated to them, and is in exact proportion to the quantity of gas blowing on them through the pipe *c* and curved side of the hoods E E.

The gas passed through the heater is a fixed proportion of the whole gas passing the meter; therefore the number of vibrations of the cylinder is in proportion to the gas consumed.

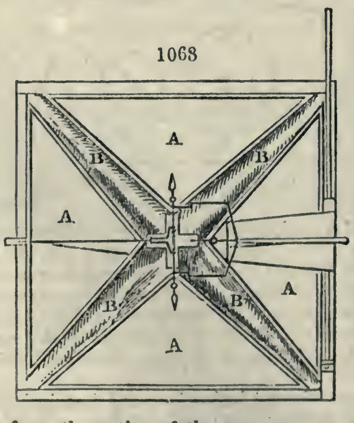
A train of wheel-work with dials, similar to that used in the common meter, registers the vibrations.

Simplicity, accuracy, and compactness are the most remarkable features of this instrument, and the absence of all corrosive agents will ensure its durability.

The most recently-constructed meters on the dry principle are those of Defries, and of Messrs. Croll and Richards. Both of these contrivances consist in causing the gas to fill expansible chambers of definite volume, and the alternate expansion and contraction of these is registered by wheel-work.

Defries' meter has three of these measuring chambers, separated from each other by flexible leather partitions which are partly covered by metallic plates, to protect them from the action of the gas. A A A A, *fig.* 1068, represent these metallic plates, fixed upon the leather diaphragm B B B B. As the gas enters, it causes the flexible partition to expand, which it does by assuming the form of a cone, as seen in *fig.* 1069. Three such chambers are attached to each meter, so as to insure a uniform and steady

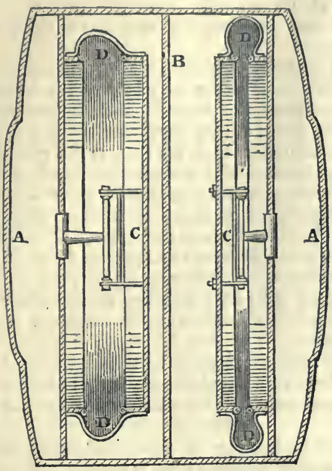
1068



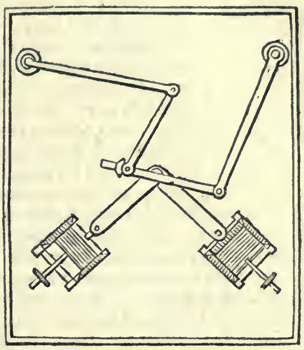
1069

supply of gas, and the motion of the chambers being communicated to clockwork, the consumption of gas is registered upon dials in the usual manner.

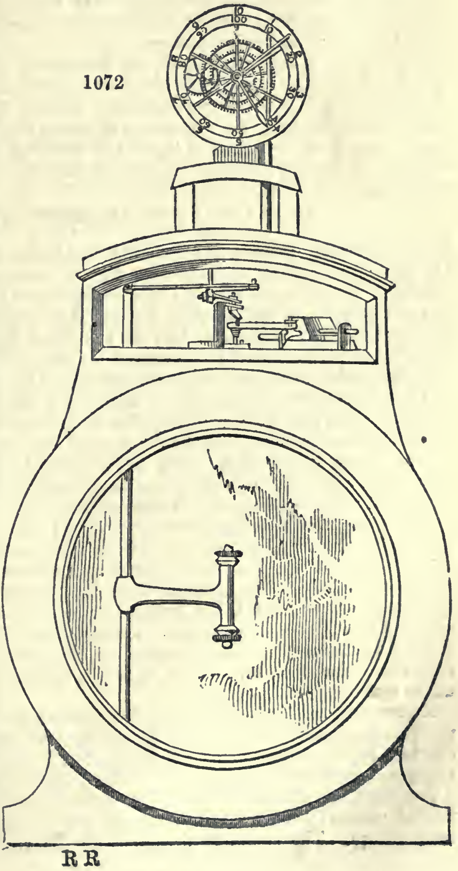
1070



1071



1072



The dry meter invented by Messrs. Croll and Richards is superior in construction and accuracy of measurement to that of Defries. It is shown in *figs.* 1070, 1071, and 1072. A A, *fig.* 1070, is a cylindrical case, divided into two cylindrical compartments by the inflexible metallic diaphragm B. These compartments are closed at opposite ends by the metal discs C C. The latter perform the functions of pistons, and are retained in their proper position by universal joints attached to each. The discs are restrained from moving through more than a fixed space by metallic arms and rods, shown in *fig.* 1072, and when this space has been once adjusted, it cannot afterwards vary. It will be seen that the principle of this meter is that of a piston moving in a cylinder; but, in order to avoid the friction which such an arrangement would cause if literally carried out, bands of leather, D D, are attached, which act as hinges, and allow of the motion of the discs without friction.

The gas enters the cylinder from the upper space containing the levers, valves, &c., *fig.* 1072; its pressure forces the discs forward through the space limited, as above described. The flow of gas is then reversed; that is, a passage to the burners is opened from the internal space, whilst the supply is now directed into the outer chamber, thus forcing the disc back to its original position, and expelling the first portion of gas through the pipes of distribution. Each motion of the disc thus evidently corresponds to a given volume of gas, and being registered by clockwork, indicates the consumption upon the usual dial plates.

Dry gas-meters are generally preferred, and consequently they have come into general use.

To the present system of registering the quantity of gas burnt by the consumer, many honest objections may be raised. Whichever meter may be used, the record of gas passing through it is entirely removed from the inspection of the consumer. The quantity is registered by a servant of the gas company supplying the meter, and whatever may be the number of cubic feet returned by him, for that is the consumer charged and obliged to pay. It seldom happens that the gas companies admit that any error can occur which tells against themselves, but they frequently discover errors in the other direction. Presuming that honesty of purpose actuates equally the supplier and the consumer of gas, it would be perfectly easy to arrange the dials of our domestic gas-meters so that the consumer might note the quantity indicated at any time, and from his knowledge of the number of burners used by him, within any given week or month, be enabled to tell if, as compared with any other period, the indicated result was near to, or far from, the truth, and direct the attention of the servant of the gas company to the circumstance.

GAS, WATER. Various methods have been from time to time introduced for decomposing water, and for employing the hydrogen liberated therefrom for the purposes of heating and lighting. Recently (1874) this 'water-gas' has been introduced to the public under the name of the 'New Gas.'

The possibility, without any great amount of trouble, of obtaining a quantity of hydrogen gas from water has always been a favourite theme with inventors, and many schemes for its practical utilisation have been introduced; and a patent has been obtained for the carbonisation of this gas with some light hydrocarbon liquid, so as to give it a high illuminating power.

The process is dependent upon the decomposition of steam by red-hot coal, coke, or metal. Hydrogen, carbonic oxide, and carbonic acid are produced. An analysis of the gas obtained by passing steam over red-hot charcoal for some hours gave as a mean: carbonic acid, 20 per cent.; carbonic oxide, 20 per cent.; hydrogen, 60 per cent. Any form of carbon is capable of effecting this decomposition if a metal, such as iron, be present; it adds to the quantity of hydrogen obtained according to the following action:—

$$4HO + 3Fe = Fe^3O^4 + 4H \quad (\mathbf{4H^2O + 3Fe = Fe^3O^4 + 4H^2}).$$

This mixture of gases is inflammable, and burns with a non-luminous but hot flame, the heat of which would be increased if the carbonic acid were previously removed, the flame of hydrogen having a temperature of 3,776° Fahr. This heat of the flame is an undoubted advantage when the gas is carburetted, as the particles of carbon are thereby heated to whiteness; but, on the other hand, the presence in the gas of a quantity of carbonic oxide is as great a disadvantage, on account of its injurious and exceedingly harmful character. Carbonic acid is an injurious gas, but its action upon the system is not that of an active poison, but rather that of preventing the necessary amount of oxygen from entering the lungs, and hence death from its effect will be death from suffocation. On the other hand, carbonic oxide is an active poison, and recovery from its effect is much more doubtful; indeed, it is calculated that 2 per cent. in an atmosphere would prove fatal, a result that should cause great caution in the use of a gas containing it in any quantity.

It is thought it will be possible to utilise this gas by itself, as a heating gas; but its chief use is for illumination, and the illuminating power is obtained in the same manner as with air-gas, the hydrogen gas obtained by any of the methods named being caused to bubble through some light spirit, any reduction of temperature by the rapid evaporation being avoided by maintaining the vessel containing it at a constant temperature by means of a steam-pipe. The illuminating power of the gas so obtained is equal to about sixteen or seventeen candles; and its permanent character is declared to be, and no doubt is, sufficient to render it of practical utility under some peculiar conditions.

A company, called the 'New Gas Company,' has been formed for working a patented process, the invention of Mr. Ruck. Instead of manufacturing gas by the distillation of coal, Mr. Ruck first obtains his hydrogen by the decomposition of water, and then charges it with the carbon necessary for illuminating purposes by passing it through a petroleum spirit of specific gravity 0·680. In the first part of the process, superheated steam is conveyed into retorts containing iron and coke raised to a high temperature. The steam is decomposed; the resulting oxygen combines with the iron and the carbon, and the hydrogen is given off, carrying with it a small proportion of carbon compounds. In this state it is valuable for heating purposes, but possesses very little illuminating power, rather resembling, when kindled, the flame of a Bunsen's burner. The various attempts which have been made to combine volatile hydrocarbons with coal-gas, in order to increase its illuminating power, have all failed on account of the speedy precipitation of the former; but Mr. Ruck claims to have discovered that petroleum of the specific gravity stated will remain in combination with the hydrogen. According to the report of Messrs. Quick and Spice, the engineers concerned in the matter, this claim has been subjected to crucial tests, and has withstood them all. The gas has been suddenly reduced in temperature from 60° to 30°, has been kept for a month in a closed vessel, has been passed through miles of iron pipes with many rectangular bends, without any consequent precipitation. The illuminating power appears to be exceedingly good, and it is said that it may be increased almost indefinitely by the removal of a small quantity of carbonic acid by a simple process. The petroleum can be added to the gas at any point between the manufactory and the burner, so that heating gas alone, it is proposed, might be supplied from the mains, say to the kitchens or the conservatories of a large establishment, and the illuminating agent only added to that portion of the supply which was to be used for lighting purposes. The mode of manufacture ensures the complete absence of the noxious sulphur- and ammonia-compounds with which we are familiar, but the gas, although in this sense 'pure,' is not dangerously inodorous. It has a distinct smell, pronounced by those interested in it to be agreeable, but which is certainly sufficient to lead to the discovery of any domestic leakage, and thus to obviate danger from explosions.

At the present price of coal, the discovery of a source of gas which is as plentiful as water, should manifestly have an important bearing on the cost of production. The report of the engineers on this head is to the effect that they can command millions of gallons of the petroleum spirit required, and that the illuminating gas can be made at the cost of 1*s.* 7¾*d.* per thousand cubic feet. They say also, that out of every thirty men required for the manufacture of coal-gas, twenty-nine may be dispensed with in working Mr. Ruck's process. These statements, if borne out by larger experience, cannot fail to attract the attention of the companies.

GAS, WOOD. Attempts were first made in France towards the close of the last century to manufacture an illuminating gas from wood. The Thermo-lamp of Lebon, a wood-gas apparatus, then and for some time afterwards excited considerable attention, especially in the districts of Germany, Sweden, and Russia, where coals are scarce. This mode of illumination, proved however, to be a complete failure, owing to the very feeble illuminating power of the gas produced, and as at this time the production of gas from coal was rapidly becoming better known, anything like a regular manufacture of wood-gas never in any case gained a footing. Subsequent trials only confirmed the failure of Lebon, so that it was universally considered impossible to produce a practically useful gas from wood by the usual process of gas manufacture. In the year 1849 Professor Pettenkofer of Munich had occasion to repeat these experiments, and he found that the gases evolved from wood at the temperature at which it carbonises consist almost entirely of carbonic acid, carbonic oxide, and light carburetted hydrogen; olefiant gas and the illuminating hydrocarbons being entirely absent. Such gas was therefore totally unfit for illuminating purposes.

The temperature of boiling quicksilver, at which coal is not in the slightest degree decomposed, is quite sufficient to carbonise wood completely. If small pieces of wood be placed in a glass retort half filled with mercury and the latter be heated to boiling, a black lustrous charcoal is left in the retort, whilst gas of the following composition is evolved:—

Carbonic acid	57·4
Carbonic oxide	36·6
Light carburetted hydrogen	7·0
	100·0

If however the gases and vapours produced by the above experiment be heated to a considerably higher temperature than that at which the wood is carbonised, Professor Pettenkofer found that a very different result is obtained: the volume of permanent gas is considerably augmented, whilst such an amount of illuminating hydrocarbons is produced as to render the gas actually richer in these constituents than coal-gas. Analysis of various samples of such superheated gas gave the following results:—

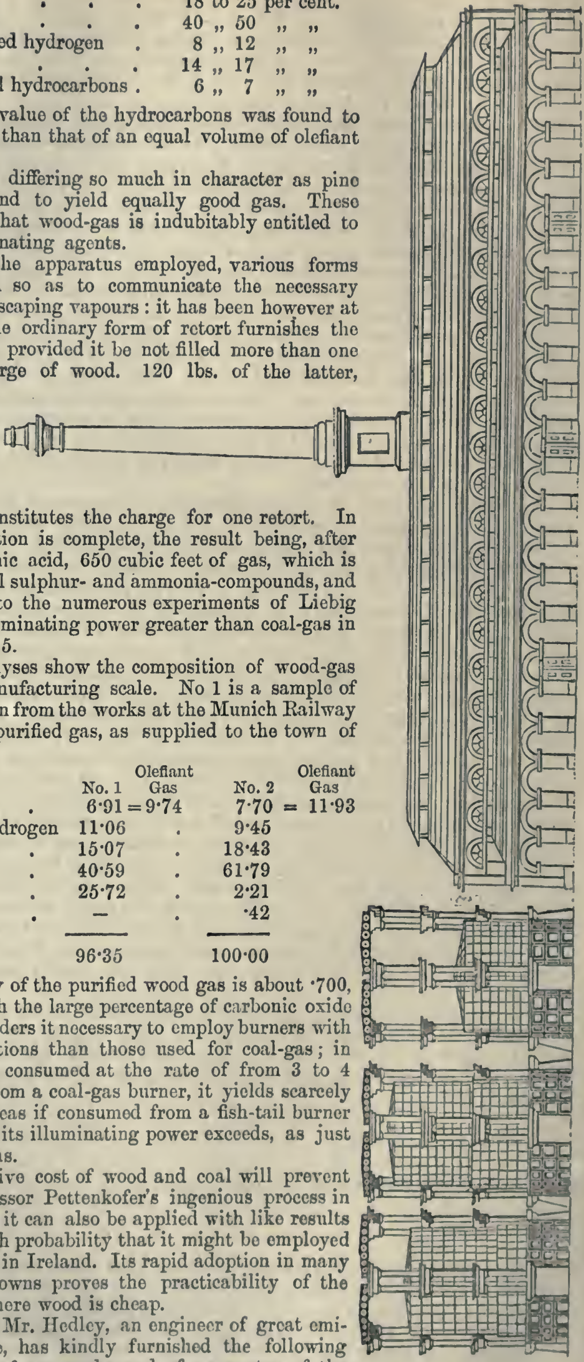
Carbonic acid	18 to 25 per cent.
Carbonic oxide . . .	40 ,, 50 ,, ,,
Light carburetted hydrogen .	8 ,, 12 ,, ,,
Hydrogen	14 ,, 17 ,, ,,
Olefiant gas and hydrocarbons .	6 ,, 7 ,, ,,

The illuminating value of the hydrocarbons was found to be one half greater than that of an equal volume of olefiant gas.

Varieties of wood differing so much in character as pine and beech were found to yield equally good gas. These observations prove that wood-gas is indubitably entitled to rank amongst illuminating agents.

With regard to the apparatus employed, various forms have been contrived so as to communicate the necessary temperature to the escaping vapours: it has been however at length found that the ordinary form of retort furnishes the necessary conditions, provided it be not filled more than one third with the charge of wood. 120 lbs. of the latter, thoroughly dried, constitutes the charge for one retort. In 1½ hour the distillation is complete, the result being, after absorption of carbonic acid, 650 cubic feet of gas, which is perfectly free from all sulphur- and ammonia-compounds, and possesses, according to the numerous experiments of Liebig and Steinheil, an illuminating power greater than coal-gas in the proportion of 6 : 5.

1073



The following analyses show the composition of wood-gas when made on a manufacturing scale. No 1 is a sample of gas before purification from the works at the Munich Railway Station and No 2 is purified gas, as supplied to the town of Bayreuth:—

	No. 1	Olefiant Gas	No. 2	Olefiant Gas
Hydrocarbons . .	6·91	= 9·74	7·70	= 11·93
Light carburetted hydrogen	11·06	.	9·45	
Hydrogen . . .	15·07	.	18·43	
Carbonic oxide . .	40·59	.	61·79	
Carbonic acid . . .	25·72	.	2·21	
Nitrogen . . .	—	.	·42	
	96·35		100·00	

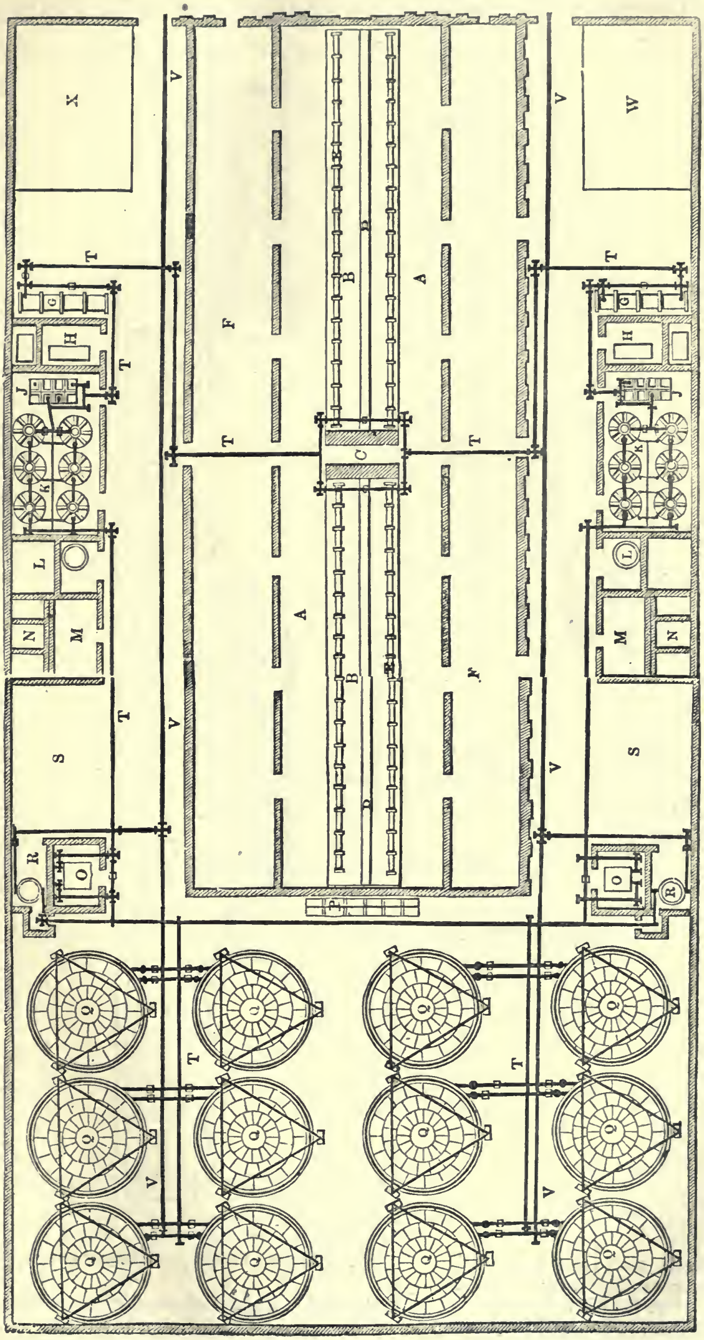
The specific gravity of the purified wood gas is about ·700, and this, coupled with the large percentage of carbonic oxide which it contains, renders it necessary to employ burners with much larger perforations than those used for coal-gas; in fact, if wood-gas be consumed at the rate of from 3 to 4 cubic feet per hour from a coal-gas burner, it yields scarcely any light at all, whereas if consumed from a fish-tail burner with wide apertures, its illuminating power exceeds, as just stated, that of coal-gas.

Although the relative cost of wood and coal will prevent the adoption of Professor Pettenkofer's ingenious process in this country; yet, as it can also be applied with like results to peat, there is a high probability that it might be employed with great advantage in Ireland. Its rapid adoption in many German and Swiss towns proves the practicability of the process in districts where wood is cheap.

GAS WORKS. Mr. Hedley, an engineer of great eminence and experience, has kindly furnished the following plans and drawings of gas-works and of apparatus of the most approved and modern construction, and on the very largest scale as to extent of business or manufacture; also plans and drawings of a gas-work on a smaller scale, with its corresponding apparatus. In the first, or large work, purification by wet lime, before described, is used; in the latter, by dry lime.

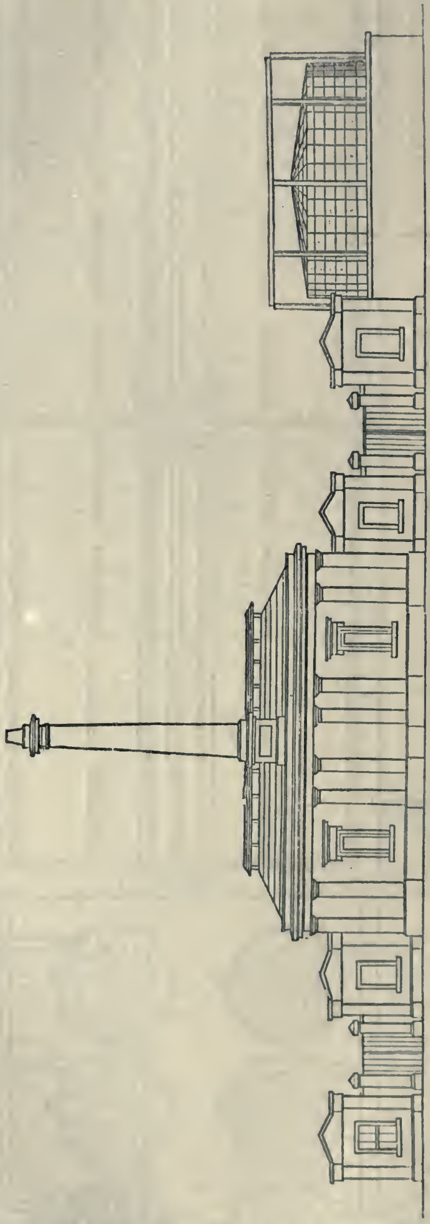
The large work referred to is calculated for, and is arranged to contain, 400 retorts,

1074



12 wet-lime purifiers, and 2 washers; 12 large double or telescopic gasholders, capable of storing 1,000,000 cubic feet of gas; and coal stores capable of holding 10,000 tons of coal.

The smaller work is calculated for, and will contain, 40 retorts, 2 dry-lime purifiers, and a wash vessel; 2 gasholders capable of storing 50,000 cubic feet of gas; and coal stores sufficient for 1,000 tons of coal.



1075

Fig. 1073 is the side elevation (front view) of a gas-work capable of containing 400 retorts, and all their dependencies.

Fig. 1074 is the plan of the retort house, coal, stores, tanks, gasholders, &c., on the largest scale, and most approved form, viz.: A the retort house, 300 feet long, 56 feet wide; B, retort beds; C, chimney stack; D, flues; E, hydraulic mains; F, coal stores, each 300 feet long, 30 feet wide; G, condensers; H, engine-houses; J, wash vessels; K, purifiers and connections; L, lime store and mixing tub; M, smiths' and fitters' shops; N, refuse-lime pits; O, meter houses; P, tar tank; Q, tanks, gasholders, bridges, columns, valves, and connections; R, governors; S, coke stores; T, inlet pipes; V, outlet pipes; W, house and offices; X, stores.

1076

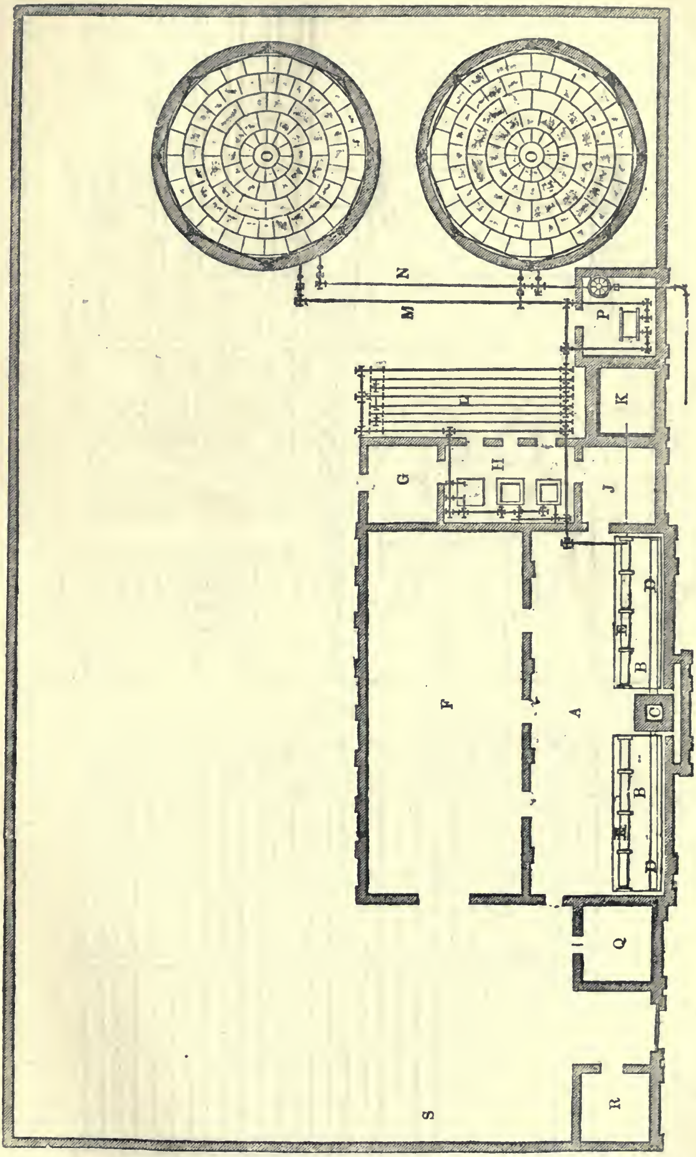


Fig. 1075. Front elevation of gas works on a smaller scale, where dry lime is used.

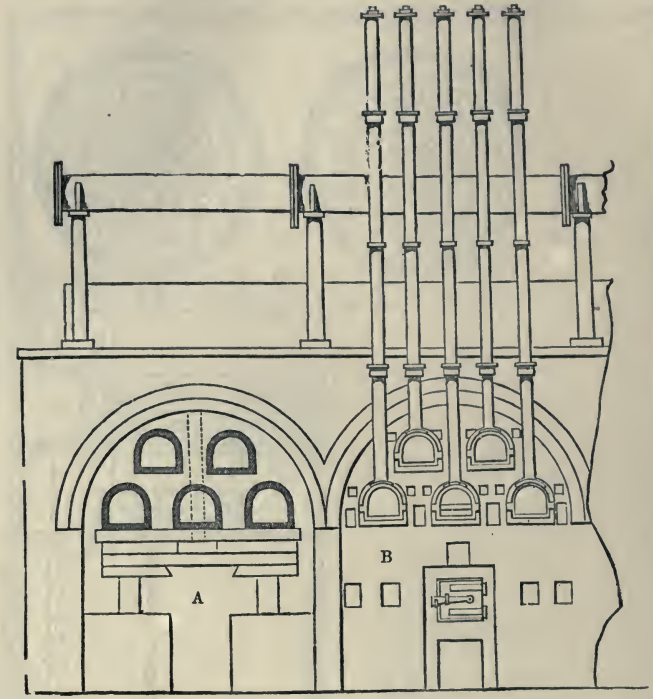
Fig. 1076. Plan of gas works, consisting of A, retort house; B, retort beds; C, chimney stack; D, flue; E, hydraulic main; F, coal store; G, lime store; H, washer and purifiers; J, store; K, tar-tank; L, horizontal condenser laid on the ground; M, inlet pipe, N outlet pipe; O, tanks and gasholders; P, meter and governor; Q, smiths' shop; R, office: S, coke store.

1077



1078

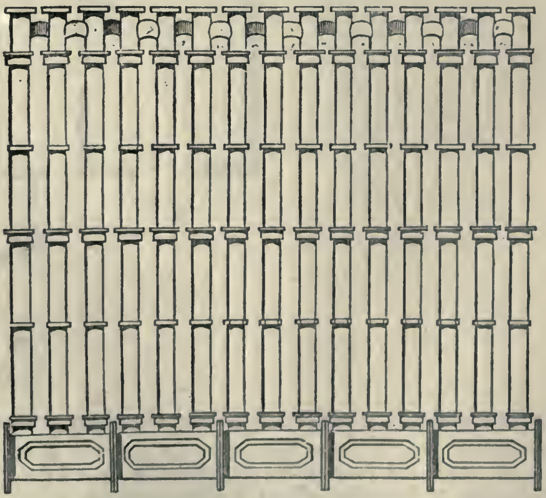


Fig. 1077. Transverse section and elevation of a bed of five retorts. A, transverse section; B, elevation.

Fig. 1078. Elevation of an upright air condenser, consisting of five chambers, with a series of 10-inch pipes.

Fig. 1079. Longitudinal section of a bed of 5 D-retorts.
Fig. 1080. End elevation and plan of air condenser. A, end elevation; B, plan.

ECONOMICAL AND SANITARY RELATIONS OF GAS.

In a lecture delivered at the Royal Institution in 1853, Dr. Frankland thus estimates the comparative cost of an amount of light from various sources equal to that yielded by 20 sperm candles, each burning 120 grains per hour for 10 hours:—

	s.	*d.*
Wax	7	2½
Spermaceti	6	8
Tallow	2	8
Sperm oil (Carcel's lamp)	1	0
London gases: City, Great Central, Imperial, and Chartered.	0	4¼
Western	0	2¼
Manchester gas	0	3

The following table exhibits the amount of carbonic acid and heat produced per hour from the above sources of light, the heat generated by tallow being assumed to be 100 for the purposes of comparison:—

	Carbonic Acid. Cubic Feet	Heat
Tallow	10·1 . .	100
Wax Spermaceti }	8·3 . .	82
Sperm oil (Carcel's lamp)	6·4 . .	63
London gases: City Great Central Imperial Chartered }	5·0 . .	47
Western	3·0 . .	22
Manchester gas	4·0 . .	32

Notwithstanding the great economy and convenience attending the use of gas, and in a sanitary point of view, the high position which, as an illuminating agent, coal-gas of proper composition occupies, its use in dwelling-houses is still extensively objected to. The objections are partly well founded and partly groundless. As is evident from the foregoing table, even the worst gases produce, for a given amount of light, less carbonic acid and heat, than either lamps or candles. But then, where gas is used, the consumer is never satisfied with a light equal in brilliancy only to that of lamps or candles, and consequently, when three or four times the amount of light is produced from a gas of bad composition, the heat and atmospheric deterioration greatly exceed the corresponding effects produced by the other means of illumination. There is, nevertheless, a real objection to the employment of gaslight in apartments, founded upon the production of sulphurous acid during its combustion; this sulphurous acid is derived from bisulphuret of carbon, and the organic sulphur-compounds, which have already been referred to as incapable of removal from the gas by the present methods of purification.

These impurities, which are encountered in almost all coal-gas now used, are the principal if not the only source of the unpleasant symptoms experienced by many sensitive persons in rooms lighted with gas. It is also owing to the sulphurous acid generated during the combustion of these impurities that the use of gas is found to injure the bindings of books, and impair or destroy the delicate colours of tapestry: therefore the production of gas free from these noxious sulphur-compounds is at the present moment a problem of the highest importance to the gas-manufacturer, and one which demands his earnest attention.

The high sanitary position which gas takes, with regard to the production of a minimum amount of carbonic acid and heat for a given amount of light, ought to stimulate the manufacturer to perfect the process, by removing all sulphur-compounds, and attaining the most desirable composition, so that this economical, and if pure, agreeable and sanitary light, may contribute to our domestic comfort to a much greater extent than it has hitherto done.

For the Royal Coal Commission (1869) circulars were issued to all the gas companies in the United Kingdom, public and private, so far as those could be ascertained. Replies, giving very full information, were received from 1,024 works. These used, in 1867, 3,612,954 tons of coal, and in 1868, 3,811,981 tons: the increase being about 200,000 tons for each year. This has been confirmed by subsequent enquiries, so that in 1873 the same number of gas-works would have used about 4,800,000 tons of coal. Those works which are not included in the return from which this quantity is estimated, will have used above 2,500,000 tons; consequently, we may estimate the quantity of coal now (1874) used is 7,300,000 tons.

The number of cubic feet of gas produced from each ton of coal, according to the returns referred to, were 8,300. The total produce of gas would therefore be

60,590,000,000 cubic feet.

The following description of the Brighton and Hove General Gas Company's Works, Portslade, Sussex, by Mr. John Biret Paddon, as it embraces the most recent improvements, (the paper was read on February 3, 1874, at the Institution of Civil Engineers), cannot fail to form a useful appendix to this article:—

'The site of these works was the wildest, most level, and highest part of a tract of shingle lying between the sea and the canal forming the eastern entrance to Shoreham Harbour. This shingle was formerly arrested in its eastward movement by the entrance works to the harbour; but since the construction of the present westerly entrance, it had been greatly wasted by the sea. Between 1865 and 1870, in front of the site of the gas-works, the high-water mark at ordinary spring tides advanced landwards 100 feet; and at high tides, during strong gales of wind, the waves broke over the greater portion of the land referred to. To obtain a deposit of shingle along the sea front as a protection, and to prevent the lighter portions of the waves passing over the bank, two groynes were constructed, one, in accordance with local custom, being at a right angle to the shore. With groynes so built there was an invariable scour and waste on the lee side, so that a repetition of such groynes along the coast to be protected became a necessity. The second groyne was designed to prevent this destructive action, and was projected towards the east at an angle of 45° to the shore. The result has been satisfactory, for soon after its completion a large bank of shingle accumulated on the east side, where it had since remained. A breastwork had also been constructed of creosoted Swedish timber; and although several times exposed to the coincidence of a high tide and a strong gale of wind, it has proved a suitable and efficient protection. At a depth of 14 feet the ends of the piles entered a stratum of sand and gravel of great density and holding-power. A supply of water had been obtained by sinking an iron cylinder to a depth of 50 feet below the ground line. The water from the chalk at this point held in solution 500 grains per gallon of salts (sea-water containing 2,700 grains per gallon), and was available for most of the purposes of the works, except for drinking. The water-tanks over the pump-room furnished storage for 20,000 gallons of water—a quantity sufficient for ordinary operations to an extent represented by the consumption of 100 tons of coal. Excellent material for concrete was found in the excavations, and the foundations of the walls were extended so as to make the proportion of the weight of the superstructure to the bearing surface, 15 cwt. per square foot. The concrete bed under the retort benches was 7 feet 6 inches thick.

'The retort-house was 284 feet 6 inches long and 80 feet wide, inside measurement. The chimneys were constructed with the lower parts of brick and the upper parts of wrought iron, and were sufficiently light to be placed on the benches, so that no floor space was occupied. They were 71 feet 6 inches high, 3 feet square at the bottom, and 3 feet in diameter, at the top, the least sectional area giving one square inch for each lineal foot of retort, a proportion which had been satisfactory. In consequence of the exposure of the roof to storms of great violence, and to rapid corrosion from the proximity of the sea, it was considered desirable that it should be of great strength, and that its parts should be few and accessible. Accordingly the roof was designed to sustain a weight equal to 60 lbs. per square foot of external surface, or 72 lbs. per square foot of plain covered. With that weight no piece of metal was subjected to a tensile strain exceeding five tons per square inch of section, and the strains on the parts in compression varied from two tons to four tons per square inch of section. The roof consisted of ten Warren trusses of 84 feet span and 14 feet deep, placed about 30 feet apart. Across the top beams were laid four lines of latticed purlins, and upon these purlins rested the bars carrying the skin of the upper portion of the roof. The lower portion of the roof was formed with the framed struts of trusses, and some lighter intermediate framed struts were joined to the bars immediately over them. Thrust on the walls was prevented by a series of ties, with screwed couplings, placed between the feet of the intermediate rafters and principal trusses. The laths were of channel-shaped section, and Duchess slates were fastened thereto with screwed clips, two to each slate. Four wrought-iron rudimentary shafts, 10 feet in diameter, enclosing the tops of the chimneys, allowed the smoke to escape; there was also a protected opening, 5½ feet wide, along the ridge for its entire length, for the same purpose. The roof was constructed by Messrs. Newton and Chambers, of the Thorncliffe Ironworks, and its cost, ready for slating, was 8*l.* 16*s.* per square of 100 feet. There was twenty-four benches of these retorts. Each bench had eight long retorts, and there being two mouthpieces to a retort, made 384 mouthpieces in all. The retorts were cylinders 16 inches in diameter and 20 feet long; and each would carbonise one ton of coal per day. Allowing one-sixth the number for reserve, the remainder would produce 1,500,000 cubic feet of gas every twenty-four hours, or 300 millions per annum. The ascension pipes were 6 inches diameter at the bottom, and 5 inches at the top. The hydraulic mains, two to each block of six benches, were of larger section than usual, and were fastened with separate outlets to the collecting main. The buckstaves were of rolled iron, with tie-rods fixed clear of the brickwork. The gas, as it was produced, passed with the tar and liquor from the collecting pipes of the hydraulic mains, at either end of the retort-house, into 12-inch mains carried along the inside, and uniting in the middle of the south wall of the retort-house, from which point they issued by a 16-inch main to the condensers. At the end of the horizontal condensers the tar and liquor were deposited in a tank, whence they were led to the tar-tanks under the coal stores. From this point the gas passed successively through the vertical condensers, exhausters, scrubbers, purifiers, station meters, and driving exhausters, in the main leading to the gasholders at Hove. The mains and connections were 16 inches in diameter throughout.

'The engine-house contained four exhausters, each exhauster being driven directly by an independent engine. Two of these exhausters were for the purpose of removing the gas from the hydraulic mains and driving it through the scrubbers and purifiers. A self-acting by-pass was carried from the inlet of the exhausters to the inlet of the purifiers, and each exhauster was connected with a governor, which also acted as a by-pass. Only one of these exhausters was in use at a time, the other being in reserve. The remaining exhausters were also used one at a time, and were for the sole duty of receiving the gas at the outlet of the station meter, and of delivering it into the mains leading to the gasholders at Hove, so that the works were relieved from all pressure from the weight of gasholders and resistance of the intervening mains. An hydraulic by-pass made to resist back pressure was placed between the meter and the main, and each exhauster being connected with a governor, a slight uniform pressure was maintained at the outlet of the meter.

'The scrubbers used at these works were the first of the kind erected. They consisted of a series of perforated discs or screens, which revolved slowly in a tank half filled with liquor, so that the gas might pass through the portions of the screens above water. The gas was in this way divided into a series of small streams, each stream being brought equally into repeated contact with a thoroughly wetted surface. The screens being fitted at the edge with an elastic fringe, made by preference of bass, there was but little friction against the circular portion of the tank, and as no advantage was gained by a speed of more than fifty revolutions per hour. the power to keep the screens in motion was very small. There was a slight difference in the heights of the bases of the scrubbers, the first being the lowest and the third the highest. In working, the gas passed through each scrubber from the lowest to the highest of the set. Water entered the highest scrubber and ran through the middle and lower scrubbers to the liquor tanks, the desired strength of the liquor being obtained by regulating the volume of water admitted to the highest scrubber. The scrubbers removed 95 per cent. of the ammonia, 50 per cent. of the sulphuretted hydrogen, and from 30 per cent. to 50 per cent. of the carbonic acid existing in the crude gas. They offered no preceptible resistance to the flow of gas and were free from the disadvantages of the vertical scrubbers in ordinary use. There were seven purifiers in a line with each other; each purifier was 36 feet long, 18 feet wide, and 5 feet deep, with water lutes 2 feet 3 inches deep. The covers were lifted at four points, two on each side, by a travelling lift passing on rails through the entire length of the shed. In consequence of the large surface of the covers, and the occasional heavy pressure to which they were subjected, each cover was held down by four Lewis fastenings, instead of by the usual bars and clips. As the purifiers were near high-water mark, they were placed on pile foundations 3 feet above the surface of the ground, and when the pipes and connections had been laid between the piles, the spaces under the purifiers were filled up. Tramways were laid at each side of the line of purifiers, and the purifying material was brought and removed from the oxide and lime sheds at either end in wagons. The shed covering the purifiers was of light construction, and was closed on the side next the sea and open on the other side. The revivifying sheds at either end were each 100 feet long and 50 feet wide, and were fitted with framed moveable louvres. The first three purifiers were for lime, the next three for oxide of iron, and the last was also for oxide of iron, to be used as a check purifier. The collective internal capacity of the purifiers amounted to 22,600 cubic feet. The station meter, one of the largest yet made, was erected by Messrs. Parkinson and Son, to pass 100,000 cubic feet of gas per hour, and was placed next to the engine-house. The gasholders were all at Hove, and their tanks were about 34 feet above the level of the works at Portslade.

'The entire cost of the works was about 72,000*l.*; and when the proposed second retort-house and coal store were erected upon the site allotted for them, the total expenditure would amount to 100,000*l.* The works would then be capable of producing 600 million cubic feet of gas per annum, at a cost of 166*l.* per million on the capital so expended.'

Gas-lighting by Electricity.—The following account is from the pen of Mr. W. L. Wise, A.I.C.E.:—

'Some curiosity has recently been excited relative to experiments made first in Germany and subsequently at Preston, in lighting gas by electricity, on the plan invented by Professor Klinkerfues, director of the Royal Observatory at Göttingen.

'Few persons will question that the art of lighting gas by electricity is as yet in its infancy, and has a great future before it as applied not only to buildings, but also to the lighting-up of large towns. The subtle agent, electricity, by which such marvels as instantaneous communication between points thousands of miles apart have been rendered possible, would seem to be peculiarly adapted as a medium for enabling operations to be simultaneously performed at many distant points, from any given place, and, on this account, has commended itself to many inventive minds as the best means for rapidly lighting gas in towns and large buildings, with what success remains to be seen.

The advantages to be derived from a practical system of igniting gas, without the use of an exposed flame for the purpose, will be fully appreciated by those acquainted with the difficulties and dangers attending the ordinary methods of lighting gas, and the frequent accidents arising from the careless use of matches and negligent ignitions, not only in private houses, but also in warehouses, magazines, cotton-mills, and workrooms, especially where the manufacture of inflammable materials is carried on. There is, also, considerable inconvenience and waste in connection with the lighting-up of turret clocks, and the ignition of gas in other places difficult of access, where, in some cases, to save the great trouble of lighting and extinguishing, the gas is kept constantly burning, instead of being extinguished during the day-time.

'Then, as to street lamps, several important points claim attention. The old-fashioned system of carrying a ladder with a lighted fuse from lamp to lamp, though still used in many towns, has, nevertheless, been somewhat improved upon by the introduction of the lighting staff; notwithstanding the use of which, however, our present mode of street lamp-lighting is a tedious, wasteful, and expensive process. Not only does it involve the employment in every considerable town of a large staff of lamp-lighters, but, in order that all the lamps may be lighted by dusk, the lighting operation has to be commenced some time before any lights are really wanted, so that gas is consumed to no purpose.

'Many plans have been from time to time proposed for igniting gas by electricity.

'Many years ago Admiral Sheringham made experiments in Portsmouth Harbour, with a view to the illuminating of buoys and beacons, &c., by gas ignited by electricity.

'Some years later Mr. Simon Petit proposed lighting several gas-jets simultaneously, or in very rapid succession, by providing each burner with a valve or cock, to be opened and closed by means of an electric current, acting directly upon it by means of an electro-magnet or coil, or indirectly by a releasing detent, an electric spark being passed through the issuing gas at the moment of opening the valve, or immediately afterwards.

'At about the same time Mr. Isham Baggs proposed certain arrangements for instantly igniting gas by the use of frictional or high-tension electricity, as also means for turning on and off the gas when required. The burner of each lamp was to be provided with a strip of glass, or other non-conducting material, placed horizontally, having a couple of wires passed through it, one at each side of the burner, the ends of the two wires being brought close to each other at a short distance above the aperture of the burner. To the lower ends of these wires others were to be attached, suitably insulated from the metallic portion of the lamp, and joined to wires connecting it to the other lamps in a given circuit. Several plans were suggested for turning the gas on and off, one being to provide several burners with a common tap, to be turned on and off by air pressure and vacuum in a small cylinder containing a piston connected to the lever of the gas-tap. For effecting the ignition, Mr. Baggs preferred to use an ordinary plate electrical machine and a Leyden jar, or combination of jars, for sending the requisite currents of electricity through the wires of each circuit.

'Another plan, proposed by Mr. Denny Lane, was the use of a portable battery, to be carried from lamp to lamp, a piece or pieces of platinum wire being suitably placed in proximity to the orifice of each burner.

'More recently Mr. Robert Cornelius has brought out a plan for igniting gas, by an electric spark generated by frictional electricity, at the point of a wire bent over the top of a gas-burner. A chain attached to this wire was carried to some accessible point, and upon being touched by a portable electric apparatus, or acted upon by a stationary battery fixed in any convenient position, a current of electricity was conveyed to the pointed wire over the burner, and the gas issuing from it thereby ignited. He proposed several kinds of small stationary frictional batteries suited to the purpose named, and also a small portable battery, in the form of a tube, with a metal rod, coated with vulcanite working loose in the inside. The tube was to be lined with lambs'-skin or other suitable material adapted for the purposes of frictional electricity, the depression or elevation of one end of the tube causing the metal rod to slide downwards by its own gravity, so as to generate sufficient electricity for lighting the gas issuing from the burner.

'Mr. Barbarin subsequently proposed two plans, one involving the combined use of electricity and clockwork, a very complex arrangement; the other dispensing with the clockwork and electric currents, and employing a quicksilver closing and hydrogen gas, in conjunction with spongy platinum, for igniting the gas.

'The following are the lighting arrangements at the Royal Albert Hall, South Kensington:—The lights are arranged in thirty clusters of five stars each, each star containing twenty-one jets or burners. A bichromate battery is made to work an inductorium, or induction coil, connected to which is a semicircular insulated arrangement. Attached to this are thirty wires, which lead off, one to each of the thirty clusters. The burners are arranged in sets of three, somewhat like a three-pronged fork, and the ends of a couple of platinum wires, connected with the battery, are fixed, within a short distance of each other, near the orifice of the centre burner of one set in each star, there being a special conducting wire from the battery to one of the stars in each cluster, or thirty wires in all. When the galvanic circuit is closed, by lowering the plates of the battery into the acid, a spark is caused to fly from the point of one platinum wire to the other, and thereby ignites the gas issuing from the burner. Since that burner is within lighting range of its neighbours at each side, they in turn with those next to them, and so on, the ignition of the gas proceeds from one to the other all round the star. The platinum wires are held by iron wires, attached by a small block of steatite to the stem of the burner, and are placed slightly below the horizontal line of the small burner orifice, so that when the gas is alight the upward draught draws the flame away, and so prevents deposit of carbon upon them. The gas is turned on and off by stopcocks in the mains in the ordinary way.

'Professor Klinkerfues' arrangements are based upon the use of compact platinum, in connection with a galvanic battery, without the intervention of any coil, the movement of the plates or of the electro-motive liquid by mechanical means, or by gas-pressure completing the galvanic circuit, the gas being at the same time brought into contact with the heated platinum wire, and thereby ignited. His experiments demonstrated that for this purpose less than a red heat was required, as a platinum wire inserted between the poles of a very small pair of zinc and graphite, without showing the slightest emission of light in a dark room, ignited a jet of gas almost immediately. For opening and closing the gas-passage leading to the burner, and lighting and extinguishing the gas as required, by simply altering the pressure in the main, he combines a bell-shaped compartment with the gas-pipe and the vessel containing the electromotive liquid in such a way that when the gas is at its lowest pressure the liquid seals the gas-pipe. By increasing the gas-pressure the passage to the burner is opened, and by a still farther temporary augmentation of the gas-pressure, the galvanic circuit is completed, so that the issuing gas, impinging upon the platinum wire between the poles of the battery, is ignited. In its most simple form his apparatus constitutes a hand-igniter, to be used in lieu of matches, spills, or tapers for lighting gas at any burner. It consists of a thin, hollow, glass vessel, several inches high, closed at the bottom, and provided with a cover which screws into a mounting attached to the neck of the vessel, so as to hermetically close it. The cover has fixed to it, and carries beneath it, the galvanic pair, consisting of a perforated tubular piece of zinc, and a cylindrical piece of graphite or carbon. Above the cover are the electrodes, connected by a piece of platinum wire. The electrodes consist of two brass wires, one of them screwed into the metal cover, which is in direct contact with the zinc; the other passes to the carbon through the cover, from which it is insulated. The electromotive liquid used is the well-known mixture of bichromate of potash with dilute sulphuric acid. In order to light gas with this simple apparatus, it is only necessary to incline it sufficiently to bring the liquid into contact with the zinc-and-carbon pair, and at the same time to hold the platinum wire in contact with the jet of gas issuing from the burner. When the apparatus is placed in an upright position, the zinc and carbon do not touch the liquid, consequently no galvanic action takes place, and no material is consumed.

'The street-lamp arrangement is designed to simultaneously light or extinguish a number of lamps from a single station. But Professor Klinkerfues, considering that galvanic batteries intended for the production of caloric would be of weak resistance, and therefore incompatible with great lengths of conducting wires and long duration of galvanic action, without frequent renovation of the liquid, decided to furnish each lamp-post with its own galvanic apparatus, and to make the galvanic pair touch the liquid only during the short time necessary for lighting up. In his apparatus for this purpose the vessel containing the liquid is provided with an internal tube leading to the burner, and having an enlargement at its lower part, as already mentioned. This tube is attached at its upper end to the cover. The gas-pipe enters the vessel at its lower part, and terminates within the tube. The carbon rests upon the enlargement of the tube leading to the burner; and the zinc, in the form of a ring, which is insulated from the tube, is attached to a screwed wire or rod, surrounded at its lower end by insulating material, and passing up through a suitable insulator in the cover to a connecting bar, upon which rests a nut, whereby the zinc is held and adjusted. One of the electrodes is attached directly to the connecting bar, and the other is insulated from the bar and attached to the cover. The upper end of the gas-pipe, situated within the tube leading to the burner, is perforated, and a cap, adjustable by a screw, which screws into the pipe, fits easily over it, the lower end of the cap passing down below the level at which the liquid stands when the gas is at its lowest pressure. An annular space is thus left between the cap and the gas-pipe, and the interior of the latter communicates by the apertures at its upper end with the annular space.

'The action of the apparatus is as follows:—When the gas is at its lowest pressure, and the surface of the liquid in the annular space between the gas-pipe and its cap is at or about its highest level, the liquid seals the lower part of that annular space, thereby preventing the passage of gas into the tube and thence to the burner. By slightly increasing the pressure of gas, it will force the liquid down in the annular space, thereby raising the level in the main vessel until the gas is permitted to pass by the tube to the burner, and then, by a still further augmentation of the gas-pressure for a few seconds, the liquid is temporarily forced up in the vessel into contact with the zinc, thereby completing the galvanic circle, and igniting the gas issuing from the burner as it comes in contact with the heated platinum wire. After this is effected, a slight remission of the gas-pressure causes the level of the liquid in the vessel to fall below the zinc, thereby breaking the galvanic circuit in order to avoid unnecessary exposure, but without shutting off the supply of gas to the burner. The extinction of the light is effected by reducing the pressure, so that the level of the liquid rises up within the annular space between the pipe and its cap, and thereby shuts off the communication to the burner. The apparatus is accommodated to variations of pressure at different altitudes, by adjusting the position of its cap, and the extent to which it dips in the liquid by means of its screw.

'The practicability of this apparatus was first publicly demonstrated by a three months' test in Göttingen, when it was applied to forty street-lamps in the principal thoroughfares; and the Gas Commission certified that the apparatus had worked continuously to their satisfaction. But the experiments more recently conducted at Preston were as follow:—

'The apparatus was fitted to a lamp near the Lady's Walk, Moor Park, a mile and a quarter distant from the gas works in Glover Street, whence the apparatus was to be operated. The times having been previously agreed upon at which the lamp should be lighted and the light extinguished, watches were carefully compared, so that the feasibility of at will almost instantaneously changing the gas-pressure in the lamp apparatus to a definite extent, by means of a regulator at works far removed from the lamps, might be demonstrated. The regulator in Glover Street being operated upon at the agreed times, the lamp a mile and a quarter distant was lighted with scarcely any perceptible lapse of time, left burning for five minutes, as had been previously arranged, and then was promptly extinguished. This process was repeated several times. Similar experiments were tried on a lamp in Ribblesdale Place, and on another in Fishergate, the two being in sight of each other, about a quarter of a mile apart, and the same distance from the gas-works. They were lighted simultaneously by one operation on the regulator at the agreed time, and both lights were extinguished promptly when the pressure was reduced. The several lamps used for the trial were taken at hap-hazard, none of the service-pipes having been tested for defects; nevertheless, the experiments were considered highly satisfactory.

'For lighting sunlights the foregoing arrangement is modified, only one battery being used for each cluster of lights. The vessel containing the liquid is placed in the middle, and is carried by a hollow centre-piece above it, from which the several arms or branches of the sunlight project radially. The centre-piece is screwed on to the gas-pipe, whose lower end passes down into the vessel containing the liquid, and is enlarged at its lower part, and leads to the centre-piece above. The lower end of the pipe is closed by the liquid when the gas is at its minimum pressure, and opened by increasing the pressure, the galvanic circuit being completed for igniting the gas by a temporary augmentation of pressure, as in the street-lamp apparatus. The electrodes are situated at each side of one burner only, across which the platinum wire passes, and all the burners being within lighting range of each other, the whole of the gas jets are rapidly ignited. The dip of the pipe into the liquid may be varied, as required, by simply turning the centre-piece. The requisite changes in the gas-pressure are effected by means of a suitable regulator, as well understood.

'The office desk, or table apparatus, is an ingenious modification, in which the battery resembles those of the street and sunlight arrangements, except that, there being a hydrostatic tap, and the electromotive fluid being brought into contact with the zinc by the pressure of the gas, the zinc is lowered into the acid by a mechanical arrangement, operated by hand-pressure upon a suitable knob, by which, at the same time, an ordinary gas-tap is opened, the platinum is moved over, and ignites the issuing gas. A spring returns the zinc and platinum wire to their original positions, on the removal of the pressure from the knob.'

GASEOUS. All permanently elastic fluids are usually so called. Oxygen, hydrogen, nitrogen, are gaseous bodies.

GASES, ABSORPTION OF. All bodies, liquid or solid, absorb gases, the amount of gases absorbed depending on some mechanical conditions which are by no means satisfactorily explained. This is not the place to enter into any examination of this most interesting and important question. Yet, as the consideration of the phenomena involved is continually pressing itself upon the manufacturer, some brief notice appears necessary.

Gases are absorbed by liquids under two distinct sets of laws, according as the gas enters into chemical combination with the liquid or not. The amount of gas absorbed by a liquid, on which it exerts no chemical action, depends on the specific nature of the gas and the liquid, on temperature, and on pressure.

Gases are absorbed by solids in virtue of some power residing upon their surfaces. The phenomena of 'catalytic' action, of 'capillary' attraction, and of 'exosmose' and 'endosmose,' appear to be all due to the force which compels the condensation of gases,—*and liquids*—upon the surfaces of all solids. Under CHARCOAL, many examples of this are given. The whole subject demands an investigation which it has not yet received, See Watts's 'Dictionary of Chemistry' for a very full description of all the important experiments which bear upon the subject.

GASES, DIFFUSION OF. All gases and all vapours, have a tendency to diffuse themselves through one another. The spontaneous evaporation of water is an example of vapour-diffusion. The way in which coal-gas mixes itself with the air of an apartment is one of gas-diffusion. The point to be remembered, however, is that this diffusion readily takes place in opposition to the law of gravity; as a light gas, contained in a vessel with an open mouth inverted, gradually descends—is diffused—into the heavier gas in which it may be placed, and eventually a mixture of the two is effected.

This subject was very carefully investigated by the late Professor Graham. See his 'Elements of Chemistry,' and Watts's 'Dictionary of Chemistry.'

GASES, OSMOSE OF. The phenomenon of the passage of a gas through membranaceous diaphragms is so called. See Graham's paper in the 'Philosophical Transactions of the Royal Society.'

GASES, TRANSPIRATION OF. The passage of gases through capillary tubes. All these phenomena are well explained in Watts's 'Dictionary of Chemistry.'

GAS-HOLDER. A vessel for containing and preserving gas, of which various forms are described by chemical writers.

GAS, LAUGHING. *Protoxide of Nitrogen; Nitrous Oxide; or Nitrogen monoxide,* NO (**N^2O**). This gas is always prepared from the nitrate of ammonia. When this salt is heated in the solid state, it is completely resolved into laughing-gas and water. The heat should be applied with caution so as to avoid too sudden a disengagement of gas. Laughing-gas was first described by Priestley in 1776, and carefully studied by Davy. This gas is chiefly remarkable for the peculiar intoxication which it produces when breathed. It is not to be used without much caution. If it is not very pure, serious consequences may ensue; and even when absolutely pure, the editor has seen the nitrous oxide produce very distressing effects. It has of late been extensively used as an anæsthetic by dentists.

GASOMETER, means properly a measurer of gas, though it is employed often to denote a recipient of gas of any kind. See GAS, COAL.

GAS-PIPES. When the illumination by gas was first introduced in the large way by Aaron Manby, Esq., then of the Horsley Iron Works, the old musket-barrels, laid by in quiet retirement from the fatigues of the last war, were employed for the conveyance of gas; and by a curious coincidence, various iron foundries desisted in a great measure from the manufacture of iron ordnance, and took up the peaceful employment of casting pipes for gas and water.

The breech-ends of the musket-barrels were broached and tapped, and the muzzles were screwed externally, to connect the two without detached sockets. From the rapid increase of gas-illumination, the old gun-barrels soon became scarce, and new tubes, with detached sockets, made by the old barrel-forgers, were first resorted to. This led to a series of valuable contrivances for the manufacture of the wrought-iron tubes, commencing with the Russell's patent in 1824, under which the tubes were first bent up by hand hammers and swages, to bring the edges near together; and were then welded between semi-circular swages, fixed respectively in the anvil, and the face of a small tilt hammer worked by machinery, by a series of blows along the tube either with or without a mandrel. The tube was completed on being passed between rollers with half-round grooves, which forced it over a conical or egg-shaped piece at the end of a long bar to perfect the interior surface.

Various steps of improvements have been since made; for instance, the skelps were bent at two squeezes, first to the semi-cylindrical, and then to the tubular form preparatory to welding, between a swage tool five feet long worked by machinery. The whole process was afterwards carried on by rollers, but abandoned on account of the unequal velocity at which the greatest and least diameters of the rollers travelled.

In the present method of manufacturing the patent welded tube, the end of the skelp is bent to the circular form, its entire length is raised to the welding heat in an appropriate furnace, and as it leaves the furnace almost at the point of fusion it is dragged by the chain of a draw-bench, after the manner of wire, through a pair of tongs with two bell-mouthed jaws, these are opened at the moment of introducing the end of the skelp, which is welded without the agency of a mandrel.

By this ingenious arrangement wrought-iron tubes may be made from the diameter of six inches internally, and about one-eighth to three-eighths of an inch thick, to as small as one quarter-inch diameter and one-tenth bore; and so admirably is the joining effected in those of the best description, that they will withstand the greatest pressures of gas, steam, or water to which they have been subjected, and they admit of being bent both in the heated and cold state, almost with impunity. Sometimes the tubes are made one upon the other when greater thickness is required, but these stout pipes and those larger than three inches are comparatively but little used.—(*Holtzapffel.*)

GASSING. In order to remove the hairy filaments from net-lace and other woven fabrics, they are passed over a large number of minute jets of gas, and between rollers.

GAS SINGEING MACHINE. See CALICO-PRINTING.

GAULT sometimes **GOLT,** a local term in some parts of England for clay, has been adopted into geological nomenclature to denote the argillaceous strata which separate the Upper and Lower Greensands. It is a dark blue or grey clay, used for making bricks and tiles; it affords a poor agricultural soil, which is generally converted into pasture.—H. W. B.

GAULTHERIA OIL, or *Wintergreen Oil.* A volatile oil obtained from the *Gaultheria procumbens,* the Wintergreen or Canada tea. It has an agreeable aromatic odour, and is used for scenting soaps.

GAULTHERINE. One of the hydrocarbons isomeric with oil of turpentine which exists in Wintergreen oil, and the oil obtained by distilling the *Betula lenta,* the sweet or cherry birch.

GAUZE. See CRAPE.

GAUZE WIRE CLOTH is a textile fabric, either plain or tweeled, made of brass, iron, or copper wire, of very various degrees of fineness and openness of textures. Its chief uses are for sieves and safety lamps.

GAY-LUSSITE is a white mineral of vitreous fracture, which crystallises in oblique rhomboidal prisms; specific gravity from 1·93 to 1·95; scratches gypsum, but is scratched by calcspar; affords water by calcination; it consists of carbonic acid, 28·66; soda, 20·44; lime, 17·70; water, 32·30; clay, 1·00. It is, in fact, by Dr. Ure's analysis, a hydrated soda-carbonate of lime in atomic proportions. This mineral occurs abundantly in insulated crystals, disseminated through the bed of clay which covers the *urao,* or native sesquicarbonate of soda, at Lagunilla in Columbia. It is known to the natives as *clavos,* or nails. Gay-Lussite is also found in Little Salt Lake, near Ragtown, Nevada.

GAZOLINE. A name given to one of the mineral oils. See NAPHTHA.

GEDGE'S ALLOY. A hard alloy of copper, zinc, and iron, said to be well adapted for sheathing ships. A good alloy contains about—copper 60, zinc 38·2, and iron 1·8 per cent.

GEHLENITE. A silicate of lime, alumina, and sesquioxide of iron; occurring in grey or brown crystals belonging to the pyramidal system. A product agreeing with gehlenite in both chemical composition and crystalline form occurs among blast-furnace slags.

GELATINE (Eng. and Fr.; *Gallerte, Leim,* Ger.), is an animal product which is never found in the humours, but it may be obtained by boiling with water the soft and solid parts, as the muscles, the skin, the cartilages, bones, ligaments, tendons, and membranes. Isinglass consists of from 86 to 93 per cent. of gelatine. This substance is very soluble in boiling water; the solution forming a tremulous mass of jelly when it cools. Cold water has little action upon gelatine. Alcohol and tannin precipitate gelatine from its solution; the former by abstracting the water, the latter by combining with the substance itself into an insoluble compound, of the nature of leather. No other acid, except the tannic, and no alkali, possesses the property of precipitating gelatine. But chlorine and certain salts render its solution more or less turbid; as the nitrate and bi-chloride of mercury, the proto-chloride of tin, and a few others. Sulphuric acid converts a solution of gelatine at a boiling heat into sugar. Gelatine consists of carbon, 47·88; hydrogen, 7·91; oxygen, 27·21.

Gelatine is produced by boiling the skin of animals in water, which in its crude but solid state is called *glue,* and when a tremulous semi-liquid, *size.* See those articles.

A fine gelatine for culinary uses is prepared and sold as Nelson's patent gelatine. It is thus prepared:—After washing the parings, &c., of skin, he scores their surfaces, and then digests them in a dilute caustic soda lye during ten days. They are next placed in an air-tight vat, lined with cement, kept at a temperature of 70° Fahr.; then washed in a revolving cylinder-apparatus with plenty of cold water, and afterwards exposed to the fumes of burning sulphur (sulphurous acid) in a wooden chamber. They are now squeezed to expel the moisture, and finally converted into soluble gelatine, by water in earthen vessels, enclosed in steam-cases. The fluid gelatine, is purified by straining it at a temperature of 100° or 120° Fahr.

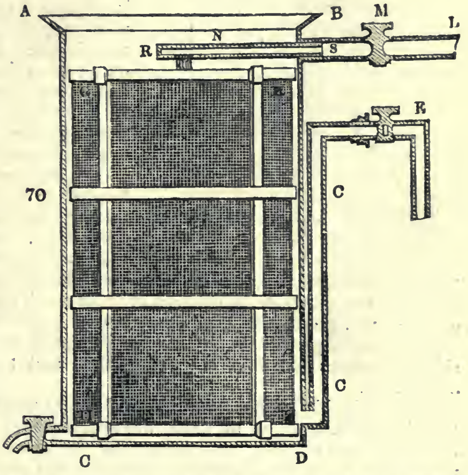
A sparkling gelatine has been prepared under a patent granted to Messrs. J. and G. Cox, of Edinburgh. By their process the substance is rendered perfectly pure, while it possesses a gelatinising force superior even to isinglass. It makes a splendid calves'-feet jelly and a milk-white blanc-mange. The patentees also prepare a semi-solid gelatine, resembling jujubes, which readily dissolves in warm water, as also in the mouth, and may be employed to make an extemporaneous jelly.

The gelatine of bones may be extracted best by the combined action of steam and a current of water trickling over their crushed fragments in a properly-constructed apparatus. When the gelatine is to be used as an alimentary article, the bones ought to be quite fresh, well preserved in brine, or to be dried strongly by a stove. Bones are best crushed by passing them between grooved iron rolls. Tha cast-iron cylinders in which they are to be steamed should be three times greater in length than in diameter. To obtain 1,000 rations of gelatinous soup daily, a charge of four cylinders is required; each being 3½ feet long, by 14 inches wide, capable of holding 70 lbs. of bones. These will yield each hour about 20 gallons of a strong jelly, and will require nearly 1 gallon of water in the form of steam, and 5 gallons of water to be passed through them in the liquid state. The 5 quarts of jelly produced hourly by each cylinder proceeds from the 1 quart of steam-water and 4 quarts of percolating water.

The boiler should furnish steam of about 223° Fahr., at a pressure of about 4 lbs. on the square inch.

In *fig.*1082 A, B, C, D, represent a vertical section of the cylinder; G, H, I, K, a section of the basket or cage, as filled with the bruised bones, inclosed in the cylinder; E, C, C, the pipe which conducts the steam down to the bottom of the cylinder; L, S, a pipe for introducing water into the interior; M, a stopcock for regulating the quantity of water (according to the force of the steam-pressure within the apparatus), which should be 3½ quarts per hour; N is a tube of tin plate fitting tightly into the part S of the pipe L; it is shut at R, and perforated below with a hole; it is inserted in its place, after the cage-full of bones has been introduced. *Fig.* 1083 is an elevation of the apparatus. A, B, C, D, represent the four cylinders, raised about 20 inches above the floor, and fixed in their seats by screws; *h h*, are the lids; *g g*, tubulures or valves in the lids; *i*, ring junction of the lid; *p*, a thermometer; *f f*, stopcocks for drawing off the jelly; *n n*, small gutters of tin-plate; *m*, the general gutter of discharge into the cistern *b*; *o*, a block and tackle for hoisting the cage-full of bones in and out.

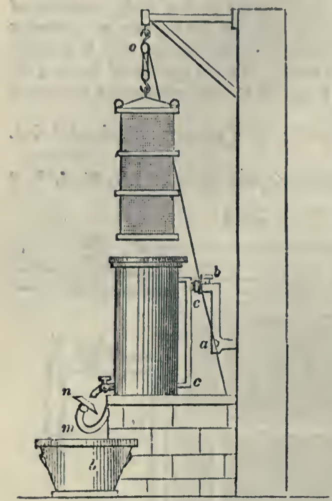
1082



1083

Fig. 1084 is an end view of the apparatus; *a*, the main steam-pipe; *a*, *b*, *c*, *c*, branches that conduct the steam to the bottom of the cylinder; *o*, the tackle for raising the cage; *s*, stopcock; *n*, small gutter; *m*, main conduit; *b*, cistern of reception.

1084



When a strong and pure jelly is wished for, the cylinder charged with the bones is to be wrapped in blanket-stuff; and whenever the grease ceases to drop, the stopcock which admits the cold water is to be shut, as also that at the bottom of the cylinder, which is to be opened only at the end of every hour, and so little as to let the gelatinous solution run out, without allowing any of the steam to escape with it.

Butchers' meat contains, on an average, in 100 pounds, 24 of dry flesh, 56 of water, and 20 of bones. These 20 pounds can furnish 6 pounds of alimentary substance in a dry state; whence it appears that, by the above means, one fourth more nutritious matter can be obtained than is usually got. A keen dispute has been carried on for some time in Paris, between the partisans and adversaries of gelatine as an article of food. It is probable that both parties have pushed their arguments too far. Calf's-foot jelly is still deemed a nutritious article by the medical men of this country, at least; though it is not to be trusted to alone, but should have a due admixture or interchange of fibrine, albumen, caseine, &c. See NUTRITION.

French Gelatine is sold in cakes, marked, like those of common glue, with the nets on which they have been dried. This gelatine is made at Paris, from the cuttings of skins used for making white kid gloves; it is coloured red, green, and blue, as well as sold colourless.

Swinbourne's patent refined Isinglass is a pure form of gelatine, procured from the skins of calves cut into very thin slices and treated simply with water at or about 200°.

D'Arcet, in his *Recherches sur les Substances nutritives que renferment les Os*, states that, in Paris, bones of all kinds are first digested with hydrochloric acid to extract the phosphate of lime, and then boiled in water under pressure. In this way a nutritious soup is prepared for the hospitals and other pauper establishments.

Dr. T. Richardson of Newcastle-on-Tyne treats bones first with muriatic or dilute sulphuric acid to dissolve out a portion of the mineral phosphates which they contain; the residue being then acted upon by sulphurous acid. The gelatine obtained after this process is treated with an alkaline sulphate or hyposulphate, or it may be treated with the phosphates of an alkali, or with the sulphurous-acid solution of the diphosphates of lime and magnesia. By any of these processes, it is said, the hardness and sizing-properties of gelatine from any source may be very considerably improved. See ISINGLASS.

GEMS are precious stones, which, by their colour, limpidity, lustre, brilliant polish, purity, and rarity, are sought after as objects of dress and decoration. Among these beautiful minerals, mankind have agreed in forming a select class to which the title of *gems* or *jewels* has been appropriated; while the term *precious stone* is more particularly given to substances which occur of a larger size and more commonly.

Diamonds, sapphires, emeralds, rubies, topazes, opals, hyacinths, and chrysoberyls, are reckoned the most valuable *gems*.

Crystalline quartz, pellucid, opalescent, or of various hues, amethyst, lapis-lazuli, malachite, jasper, agate, &c., are ranked in the much more numerous and inferior class of *precious stones*. These distinctions are not founded upon any strict philosophical principle, but are regulated by a conventional agreement, not very well defined; for it is impossible to subject these creatures of fashion and taste to the rigid subdivisions of science. We have only to consider the value currently attached to them, and take care not to confound two stones of the same colour, but which may be very differently prized by the *virtuoso*.

Since it usually happens that the true gems are in a cut and polished state, or even set in gold or silver, we are thereby unable to apply to them many of the criteria of mineralogical and chemical science. The cutting of the stone has removed or masked its crystalline character, and the phenomena of double or single refraction are often difficult to be observed; whilst the test by the blowpipe is inadmissible. Hence the only scientific resources that remain are the trial by electricity, which is often inconclusive; the degree of hardness, a criterion requiring great experience in the person who employs it; and lastly, the proof of specific gravity, unquestionably one of the surest means of distinguishing the really fine gems from ornamental stones of similar colour. This proof can be applied only to a stone that is not set.

The specific gravity may be determined by any person of common intelligence, with the aid of a small hydrostatic balance. If, for example, a stone of a fine crimson-red colour be offered for sale as an oriental ruby, the purchaser must ascertain if it be not a Siberian tourmaline, or a spinel ruby. Supposing its weight in air to be 100 grains, if he finds it reduced to 69 grains when weighed in water, he concludes that its bulk is equal to that of 31 grains of water, which is its loss of weight. Now, a real sapphire which weighs 100 grains in air, would have weighed 76·6 in water; a spinel ruby of 100 grains would have weighed 72·2 in water, and a Siberian tourmaline of 100 grains would have weighed only 69 grains in water. The quality of the stone in question is, therefore, determined beyond all dispute, and the purchaser may be thus protected from fraud. See DIAMOND, RUBY, &c. &c.

As the discrimination of one species of gem from another is often a matter of great practical importance, and sometimes of much delicacy, it may be useful to group together such easily-applied tests as will enable even an inexperienced observer to determine the true character of any given stone. In the following comparative tables the specific gravity (S.G.) is placed in the first column, as being in many cases the most valuable characteristic. This may be determined by means either of the hydrostatic balance or of Nicholson's hydrometer. For determining the loss of weight in water, a delicate chemical balance is generally needed; a common pair of grain scales is certainly of no use when operating on specimens weighing less than 10 grains. Distilled water should be employed; but, in its absence, rain-water may be used. With great experience, a rough notion of the specific gravity of a stone may be obtained by poising it in the palm of the hand. In the second column of the table the degree of hardness (H.) is specified. These relative degrees of hardness are expressed on Mohs's mineralogical scale. If the specimen under test be too small to be conveniently held in the fingers, it may be partially embedded in a stick of sealing-wax, and examined in this position. A glazier's diamond is sometimes useful, as it scratches every gem-stone, excepting the diamond; whilst a good steel file is serviceable in distinguishing true stones from pastes. The third column of the tables gives the character of the refraction, whether single (S.R.) or double (D.R.), which each gem exhibits. This character may be ascertained by placing the stone between two crossed plates of tourmaline; if the dark field becomes more or less illuminated, the mineral is doubly-refracting, whilst if it remains dark, it is probably singly-refracting. Other optical characters of cut stones may be examined by the dichroiscope. This instrument is of no service in dealing with singly-refracting minerals, but with doubly-refracting species it gives two images which often differ more or less decidedly in tint. The crystalline form and chemical composition are not noted in the following tables, because they are not available characters in examining cut gem-stones, but they are fully given in the articles which treat specially of each gem. As colour is the most obvious characteristic of a stone, it is used as the basis of arrangement in the following scheme. The colour of a cut stone is seen to greatest advantage when the specimen is held under water, at a depth of about half an inch from the surface.

In order to determine the true colour of a mounted stone, it should be removed from its setting; for the natural colour is often modified either by placing a foil behind the gem, or, occasionally, by painting the back of the stone itself.

Colourless Gems.

The colourless stones most likely to occur in commerce are the diamond, the topaz, and rock-crystal. These may be distinguished by the following characters:—

Diamond	S.G. 3·5	H. 10	S.R.
Topaz	„ 3·5	„ 8	D.R.
Rock-crystal	„ 2·5	„ 7	D.R.

The diamond is distinguished from all other stones by its excessive hardness; a glazier's diamond easily scratches topaz and rock-crystal, but does not touch, or scarcely touches, another diamond. The topaz is distinguished, in addition to the characters given above, by its perfect cleavage in one direction, so that a joint or flaw often runs across the stone; it also becomes electric when heated, or when a smooth face is excited by friction.

In addition to these gems, the following colourless stones, though comparatively rare, may sometimes occur in trade:—

White sapphire	S.G. 4·0	H. 9	D.R.
White spinel	„ 3·5	„ 8	S.R.
White zircon	„ 4·7	„ 7·5	D.R.
White beryl	„ 2·6	„ 7·5	D.R.
Phenakite	„ 3·0	„ 7·5	D.R.
Tourmaline	„ 3·0	„ 7	D.R.
Euclase	„ 3·0	„ 7·5	D.R.

Red Gems.

The following are the chief stones of this colour, to which may be added the red diamond, which occurs, however, but rarely:—

Ruby	S.G. 4	H. 9	D.R.
Spinel	„ 3·5	„ 8	S.R.
Garnet	„ 3·8	„ 7·5	S.R.
Topaz	„ 3·5	„ 8	D.R.
Rubellite	„ 3	„ 7·5	D.R.

Most of these stones present colours which are sufficiently distinct to be discriminated by the experienced eye. The ruby (true or oriental ruby) varies in tint from rose-red to carmine, the most esteemed stones presenting a deep rich red colour, called by jewellers pigeons' blood. The spinel (spinel ruby and balas ruby) is less brilliant in tint than the true ruby, and presents a variety of shades, some of which resemble the colours of certain garnets; the variety known as balas ruby is distinguished by a rose-pink colour, tending to blue. Garnets offer considerable variation in colour; the Bohemian garnet (pyrope) being of a dark fiery red, and the Oriental or Syrian garnet (almandine) varying in colour from deep crimson to violet. The topaz is never decidedly red, but sometimes presents a delicate pink tint, which is produced by the action of heat on stones which are normally of a yellow colour. Rubellite (red tourmaline) is characterized by becoming highly electric when heated or when exposed to friction.

By aid of the dichroiscope the red colour of the oriental ruby may be resolved either into a pale and a dark rose-red, or into a bluish and a yellowish red. The spinel and garnet, being singly-refracting species, do not admit of dichroiscopic examination.

Brown Gems.

Essonite	S.G. 3·6	H. 7·5	S.R.
Hyacinth	„ 4·7	„ 7·5	D.R.
Tourmaline	„ 3·0	„ 7·5	D.R.
Brown quartz	„ 2·6	„ 7	D.R.

Essonite (cinnamon stone or garnet) and hyacinth (zircon) present very similar colours—a fine reddish brown—but are readily distinguished by specific gravity. In the dichroiscope the colour of the zircon is resolved into a mixture of brown with greenish yellow and brown with red.

The brown tourmaline yields images of similar colours, and brown quartz gives a yellowish brown and a violet-brown image.

A few other stones of a brown colour are occasionally met with, namely:—brown diamond, chrysoberyl, axinite, idocrase, andalusite, and epidote.

Yellow Gems.

Topaz	S.G. 3·5	H. 8	D.R.
Chrysoberyl	„ 3·7	„ 8·5	D.R.
Yellow beryl	„ 2·7	„ 8	D.R.
Yellow quartz	„ 2·6	„ 7	D.R.
Zircon	„ 4·7	„ 7·5	D.R.
Oriental topaz	„ 4	„ 9	D.R.

The colour of the topaz is a straw-yellow or wine-yellow; that of the chrysoberyl a greenish yellow; and of the zircon a brownish yellow. The true topaz, false topaz (yellow quartz), and oriental topaz (yellow corundum) may be very similar in colour, but the three species are readily distinguished, as seen in the table, by differences in hardness and specific gravity. The colour of the topaz when examined in the dichroiscope is often different in three different directions, and may thus present a pale straw-yellow, a pale honey-yellow, and a reddish yellow.

Green Gems.

Emerald	S.G. 2·7	H. 8	D.R.
Chrysolite	„ 3·3	„ 6·5	D.R.
Tourmaline	„ 3·0	„ 7·5	D.R.
Oriental emerald	„ 4	„ 9	D.R.

The colour of the true emerald is a very bright green, the pale green and bluish green varieties being distinguished as beryl or aqua-marine: the emerald is rarely without flaws, which are so characteristic as to be imitated in mock stones. The chrysolite or peridot presents a very dull green colour, and is so soft as to be easily abraded when worn, and thus soon loses its brilliancy of surface and sharpness of edge. The dichroiscope resolves the colour of the emerald into a yellowish green and a bluish green; of the tourmaline into a pale green and a dark blackish green; and of the Oriental emerald (green corundum) into green and yellowish green. But the Oriental emerald rarely occurs in trade, and is said indeed to be the rarest of all stones.

Blue Gems.

Sapphire	S.G. 4	H. 9	D.R.
Blue topaz	„ 3·5	„ 8	D.R.
Blue beryl	„ 2·7	„ 8	D.R.
Blue tourmaline	„ 3	„ 7·5	D.R.

By means of the dichroiscope, the colour of sapphire is resolved into a pale and a dark blue; that of topaz into a whitish blue, and a greenish blue; of beryl into similar tints to those of topaz; and of tourmaline into a pale bluish green and a very dark bluish green. Cyanite is occasionally cut as a jeweller's stone.

Purple or Violet Gems.

Amethyst	S.G. 2·6	H. 7·5	D.R.
Oriental amethyst	„ 4	„ 9	D.R.
Iolite	„ 2·6	„ 7	D.R.

The common amethyst (purple quartz) and the Oriental amethyst (purple corundum) are very similar in colour, but are readily distinguished by specific gravity and hardness; it should, however, be remarked that jewellers are in the habit of calling any stone of fine colour 'Oriental amethyst,' though it may have no mineralogical claim to the name. Iolite (dichroite) is characterized by its strongly-marked dichroism, commonly exhibiting a blue colour in one direction and a brownish yellow in another; some varieties are pleochroic, or exhibit several distinct shades in different directions.

Imitation Gems.—In determining a doubtful specimen the observer should always bear in mind the possibility of its being merely a paste, or imitation in fine glass. The inferior hardness of glass, compared with that of any precious stone, renders the determination easy. Although the hardness of glass varies with its composition, it rarely exceeds 5·5; all glass may, therefore, be readily scratched with a steel file. The more brilliant the glass the softer it generally becomes; and, therefore, pastes when worn soon get blunt and jagged at their edges and corners, whilst the surfaces become dull and scratched: such imperfections, if not readily seen by the naked eye, are at once detected by aid of a lens. The specific gravity of paste is not an available test, for it varies from 2·5 to 4·5 according to its composition; the greater the proportion of lead present, the more brilliant, the denser, the softer, and the more fusible is the glass. Like all uncrystallized substances, glass is singly-refracting.

In examining a stone, it is also necessary to guard against *doublets* or *semi-stones*. These are made up of two pieces; the upper half being a real stone, and therefore presenting its proper degree of hardness, whilst the lower half is either an inferior stone or mere glass. When such stones are set, it is difficult to detect the fraud. The deception arising from the use of foil has already been noticed in this article.—F.W.R.

GEMS, ARTIFICIAL. These are glasses, the material of which they are composed being called Strass.

Strass, the paste or glass which generally forms the principal ingredient of imitation gems, is called after the name of a German jeweller by whom it was invented, at the commencement of the last century. It is composed of silica, potash, borax, the various oxides of lead, and sometimes of arsenic: chemically it may be regarded as a double silicate of potash and lead.

The silica may be furnished either by rock crystal, white sand, or flint; but, of these, the first is to be preferred, one of the principal considerations in these preparations being the extreme purity of the materials or ingredients employed. In this manufacture, which is of more importance, and attended with greater difficulty than most persons imagine, perfect success (independently of the choice of materials) depends upon the care taken, and the precautions to be observed. No crucibles should be used but those which have been proved, both as regards their composition, their power of withstanding the strongest heat, and their impenetrability to the action of metallic oxides.

All the substances to be melted should be first pulverised, and even ground with the greatest care. It should be remembered that the most perfect mixture can only be effected by numerous siftings, and that a separate sieve should be used for each ingredient, and never be made to serve for different substances. When mixed, the materials should be melted in a crucible, placed in the middle of a cylindrical furnace, terminated in a dome, the height of which should be 7 feet 6 inches, and its diameter 4 feet 3 inches. The fuel should consist as much as possible of thoroughly dry wood, chopped very small. The melting should be effected by means of a heat raised by degrees, and then steadily maintained, especially at the maximum temperature: then when once the melting has been thoroughly accomplished, which cannot o in less than from twenty to thirty hours, the crucible must be allowed to cool very slowly.

The art of imitating precious stones in paste has amazingly improved since the time of Strass, as was shown by the results of the great Paris Exposition of 1855. The imitations, especially as regards certain colours, leave little to be desired; but there is something still in that respect in which the imitation is far from being perfect.

Now that it is proved that the alkalis and vitrifiable earths are oxides of the metals, all that has to be done to obtain the finest effects is to combine them skilfully with other artificially-prepared metallic oxides, which have undergone the process of vitrification.

Experiments ought to be made with all oxidisable and vitrifiable substances, with the different salts, fluates, phosphates, phosphoric acid, &c.

The following are some of the mixtures generally known, but, it must be observed here that each artist has his own processes, ingredients, and proportions:—

Mixtures for Strass.

	1.	2.	3.	4.
	grains	grains	grains	grains
Rock crystal	3396·2	3007·8	2897·5	3007·8
Minium	5280·8	...	4231·25	
White lead (pure) . . .	...	5641·0	...	5641·0
Potash (pure)	1804·77	1044·0	1625·15	1044·0
Borax	232·1	305·0	181·28	301·5
Arsenic	10·18	10·18	5·09	

Common Strass.

Litharge, 77·16; white sand, 57·73; potash, 7·71.

Strass of Douhaut-Wieland.

Sifted rock crystal . .	2897·5	Deutoxide of arsenic . .	4·92
Boracic acid . . .	181·18	Potash (purest) . . .	1608·53
Minium (purest) . .	4451·37		

English Strass.

Calcined flints . . .	962·5	Calcined borax . . .	361·9
Pure potash . . .	481·25	Fine white lead . . .	120·89

Strass Bastenaire.

	1.	2.	3.	4.	5.
	grains	grains	grains	grains	grains
White sand, treated with hydrochloric acid	1543·23	1543·23	385·8	385·8	385·8
Minium, first quality. . .	6·16	2156·	771·61	925·8	848·65
White potash, well calcined .	370·32	493·76	108·2	61·72	154·32
Calcined borax	308·64	185·16	...	92·58	123·45
Crystallised nitrate of potash (nitre)	185·16	...	123·44	...	77·16
Peroxide of manganese . .	61·72	...	...	154·32	...
Deutoxide of arsenic . . .	...	9·26	...	23·15	...

Topaz: No. 1.

Whitest strass, 842·079; glass of antimony, 36·421; purple of Cassius, 0·738.

Another.

White lead of Clichy, 771·6; flints calcined and pulverised, 771·6.

Another.

White sand, well dressed	1543·23	Oxide of silver	77·16
Borax, calcined	138·88	Calcined potash	493·76
Minium	2237·64		

Sapphire: Whitest strass, 3858·086; pure oxide of cobalt, 57·708.

Ditto: another. Very fine strass, 481·25; purest oxide of cobalt, 1·697.

Emerald, No. 1. Strass, 3858·087; pure green oxide of copper, 35·643; oxide of chrome, 1·697.

Ditto: ordinary. Strass, 7716·174; acetate of copper, 61·11; oxide of iron, 12·731.

Ditto: another. Strass, 481·25; oxide of copper precipitated from the nitrate by potash, 334·45.

Emeralds (*Bastenaire*).

	1.	2.
	grains	grains
Well-washed sand	154·32	154·32
Minium	231·48	231·48
White potash, calcined	46·29	77·16
Borax, calcined	30·86	30·86
Yellow oxide of antimony	7·71	...
Pure oxide of cobalt	1·54	...
Green oxide of chrome	...	3·85

Amethyst (*Bastenaire*).

	Pale	Deep coloured
	grains	grains
Strass	7716·17	3858·08
Oxide of manganese	20·39	36·55
Oxide of cobalt	0·848	20·39
Purple of Cassius	...	0·848

Aquamarine.

Strass, 2913·53; Glass of antimony, 20,370; Oxide of cobalt, 1·265.

Syrian Garnet.

	1.	2.
	grains	grains
Strass	427·931	484·25
Glass of antimony	215·815	...
Purple of Cassius	1·697	2·150
Oxide of manganese	1·697	...

Observations. For topaz, No. 1, the clearest and most transparent glass of antimony should be used. Frequently this mixture only yields an opaque mass, translucent on the edges, and transmitting in thin fragments a red colour when held between the eye and the light: in that case rubies may be made of it.

To make them, a portion of the topaz material is taken, and mixed with eight parts of fine strass: these are melted in a Hessian crucible for thirty hours in a potter's furnace, and the result is a beautiful yellow glass-like strass, which, when cut, produces an imitation of the finest oriental rubies.

These may be made of another tint by using the following proportions:—

Strass, 2411·25; oxide of manganese, 61·310.

In the emerald, No. 1, by increasing the proportion of chrome or oxide of copper, and mixing with it oxide of iron, the green shade may be varied, and the periodot or the deep-tinted emerald may be imitated.

The manufacture of artificial gems has acquired an extreme development; immense factories are established at Septmoncal in the Jura, furnishing employment to more than 100 work people, who produce fabulous quantities.

Many ingenious persons in Paris vie with each other in bringing to perfection the most perfect processes, and produce truly surprising results. M. Savary especially, in his magnificent collections, and his perfect imitation of celebrated diamonds, has arrived at a degree of excellence which, apparently, can scarcely be surpassed.

We have alluded only to those imitations of gems in glass of which a large portion of the cheap jewellery is formed. Some very successful attempts have been made to manufacture true gems by an artificial process. M. Ebelmen has done much in this direction, and M. Henri Sainte-Claire Deville and M. Henri Caron communicated to the Academy of Sciences of Paris, in April 1858, a process which they had discovered for the production of a number of the gems which belong to the corundrum class, as the ruby, sapphire, &c. Essentially, the process consisted in exposing the fluoride of aluminium, mixed with a little charcoal and boracic acid, in a black-lead crucible, protected from the action of the air, to a white heat for about an hour. For details of the process, see *Comptes Rendus*, and *Annales de Chimie*.

GENAPPE. A worsted yarn used in the manufacture of fringes, braids, &c. From its smoothness it combines very readily with silk.

GENEVA. A grain-spirit flavoured with juniper-berries, manufactured extensively in Holland; hence it is frequently called HOLLANDS.

GENISTA. A genus of papilionaceous plants. *G. tinctoria* is the Dyer's Broom, which yields a yellow die, or, when mixed with woad, a green colour. A sprig of genista was the badge of Henry II.'s father, whence the family name Plantagenet (*Planta genista*).

GENTIAN. *Gentiana lutea.* The common or yellow gentian, which is said to owe its name to Gentius, king of Illyria, who introduced it as a medicine about 170 years before Christ.

The roots of the gentian are collected and dried by the peasants of Switzerland, the Tyrol, and in the Auvergne.

The bitter of the gentian is agreeable and aromatic; it is much used in medicine, and has on some occasions been employed instead of hops in beer.

GEOCRONITE. A native sulphantimonide of lead, from the silver mines of Sala, in Sweden. It appears to resemble KILBRICKENITE.

GEODE. A rounded nodule of stone, containing a cavity usually lined with crystals. Geodes frequently consist of agate, chalcedony, &c. See AGATE.

GEOGNOSY (γῆ, the *earth*, and γνῶσις, *knowledge*), means the science of the substances which compose the earth's crust. It originated with the German mineralogists.

GEOLOGY (γῆ, the *earth*, and λόγος, *a discourse*). The science which treats of the structure of the earth, and of the causes which have produced its present physical features.

GERANIUM, OIL OF. A name sometimes applied to the oil of ginger-grass, which is prepared in the East from certain species of *Andropogon.* This has of course, no relation whatever either to our wild geraniums (*crane's bills*) or to our garden geraniums (*Pelargoniums*).

GERHARDT'S ANHYDROUS ACETIC ACID. See ACETIC ACID, and Watts's 'Dictionary of Chemistry.'

GERMAN BLACK. See FRANKFORT BLACK.

GERMAN SILVER. M. Gersdorf, of Vienna, states that the proportion of the metals in this alloy should vary according to the uses for which it is destined. When intended as a substitute for silver, it should be composed of 25 parts of nickel, 25 of zinc, and 50 of copper. An alloy better adapted for rolling consists of 25 of nickel, 20 of zinc, and 60 of copper. Castings, such as candlesticks, bells, &c., may be made of an alloy, consisting of 20 of nickel, 20 of zinc, and 60 of copper; to which 3 of lead are added. The addition of 2 or 2½ of iron (in the shape of tin plate?) renders the alloys much whiter, but, at the same time, harder and more brittle.

Keferstein has given the following analysis of the genuine German silver, as made from the original ore found in Hildburghausen, near Suhl, in Henneberg:—

Copper	40·4
Nickel	31·6
Zinc	25·4
Iron	2·6
	100·0

Chinese *Pakfong*, a white alloy, according to the same authority, consists of 5 parts of copper, alloyed with 7 parts of nickel, and 7 parts of zinc.

The best alloy for making bearings, bushes, and steps for the steel or iron gudgeons, and pivots of machinery to run in, is said to consist of 90 parts of copper, 5 of zinc, and 5 of antimony. See ALLOY and COPPER.

GERMAN STEEL. A metal made of a white iron in forges where charcoal is employed, the ores used being either bog-iron ore or the sparry carbonate.

GERMAN TINDER. See AMADOU.

GERMAN YEAST. See YEAST.

GERMINATION. (Eng. and Fr.; *Das Keimen*, Ger.) The first indication of vital force in the embryo plant. The seed being placed in the soil, a proper temperature existing, and a due quantity of water being supplied, a chemical action is established, and heat is developed. In fact, a slow combustion takes place, during which oxygen is combined with carbon, and carbonic acid is liberated. The starch of the grain, by the process of germination, is converted into sugar by taking into combination one equivalent of the elements of water. While this operation is progressing, the embryo enlarges, sending down its root (radicle) into the soil, and forcing upwards, towards the light, the cotyledons or leaf lobes, and the plumule.

These phenomena of the commencement of vegetable life can be well studied in the process of malting, in which the barley, by the conversion of its starch into sugar, becomes malt. See MALTING.

The direct action of sunlight is injurious to the germinating seed, consequently it is a law of nature that a dark soil should be the bed in which this remarkable operation commences, and is continued, until the first leaves appear above the soil. In the process of malting, care is taken that the floors upon which the germination is established are but dimly illuminated.

It has been proved—the discovery having been first made by the editor of this Dictionary—that *Light* separated by means of absorbent media from the chemical power (*Actinism*) of the sunbeam entirely stops germination, whereas the dark chemical rays have the power of quickening germination, even when the seeds are placed at a considerable depth beneath the soil. As these experiments are rarely repeated, and as even in the most recent chemical publications (Watts's 'Dictionary of Chemistry,' amongst others), they are not alluded to, the old and in every way uncertain experiments of Saussure being adopted, it may be well to state the simple form of experiment by which the fact may be proved.

Take a piece of glass stained yellow with silver; ascertain that it is so, by exposing a little chloride of silver behind it, to sunshine. If the chloride of silver does not darken, the glass is of the right kind; all the chemical rays are cut off. Take another piece of glass of the deepest blue that can be obtained, the blue being the result of cobalt. In the first we have a glass through which the solar light passes freely, but it prevents the permeation of the chemical rays. In the second we have a medium which is traversed freely by the chemical rays (Actinism), but very little light is admitted. Place such pieces of glass over a box of earth, in which are planted an equal number of seeds, at the same depth; all the circumstances, as it regards moisture and temperature, being the same. The seeds under the blue glass will germinate with extraordinary rapidity, while the seeds under the yellow glass will not germinate at all. See 'Researches on Light,' and papers in the *Reports of the British Association* on 'The Influence of Light on the Growth of Plants, &c.,' by Robert Hunt. The following letter from Mr. Charles Lawson, of Edinburgh, September 8, 1853, has practically settled this important discovery:—

'My dear Sir,—I am favoured with yours of the 5th, relative to my practical experience in the effect of the chemical agency of coloured media on the germination of seeds and the growth of plants.

'I must first explain that it is our practice to test the germinating powers of all seeds which come into our warehouses before we send them out for sale; and of course it is an object to discover, with as little delay as possible, the extent that the vital principle is active, as the value comes to be depreciated in the ratio it is found to be dormant. For instance, if we sow 100 seeds of any sort, and the whole germinate, the seed will be of the highest current value; but if only 90 germinate, its value is 10 per cent. less; if 80, its value falls 20 per cent.

'I merely give this detail to show the practical value of this test, and the influence it exerts on the fluctuation of prices.

'Our usual plan formerly was to sow the seeds to be tested in a hotbed, or frame, and then watch the progress and note the results. It was usually from eight to fourteen days before we were in a condition to decide on the commercial value of the seeds under value.

'My attention was, however, directed to your excellent work, "On the Physical

Phenomena of Nature," about five years ago, and I resolved to put your theory to a practical test. I accordingly had a case made, the sides of which were formed of glass coloured blue or indigo, which case I attached to a small gas stove for engendering heat; in the case, shelves were fixed in the inside, on which were placed small pots wherein the seeds to be tested were sown.

'The results were all that could be looked for; the seeds freely germinating in from two to five days only, instead of from eight to fourteen days as before.

'I have not carried our experiments beyond the germination of seeds, so that I cannot afford practical information as to the effect of other rays on the after-culture of plants.

'I have, however, made some trials with the yellow ray in preventing the germination of seeds, which have been successful; and I have always found the violet ray prejudicial to the growth of the plant after germination.

'I remain, my dear Sir, very faithfully yours,

'To Robert Hunt, Esq.' 'Charles Lawson.'

Another application of the principles involved in the discovery—that the luminous rays checked germination and promoted the growth of ligneous fibre—has been made by the cultivators of early potatoes in the West of Cornwall. The seed potatoes are carefully placed on shelves in houses maintained at such a temperature that germination is set up. When they begin to shoot, an abundance of light is admitted to check the germinating process, and render the shoot woody and strong. In March—after the frosts—these potatoes are carefully placed in the soil, and so rapid is their growth and development that they are ready for the market in July. Upwards of 11,000 tons of potatoes, grown under these conditions, were sent from West Cornwall in July 1874.

GEROPIGA, or *Jerupiga.* A factitious liquor, imported, from Portugal, and used in this country for the adulteration of wines. It appears to be a compound of unfermented grape-juice, brandy, sugar, and colouring matter.

GERSDORFFITE. A sulpho-arsenide of nickel, containing, in typical varieties—arsenic, 45·5; sulphur, 19·4; nickel, 35·1. Found at Loos in Sweden, near Hartzgerode in the Hartz, and Craigmuir Mine, Scotland.

GEYSERITE. Siliceous sinter deposited from geysers or hot springs.

GHU-NALA-PAAT. *Corchorus olitorius* or *Hibiscus Manihot.* An Indian fibre much used by the natives. See Fibres.

GIBBSITE. A stalactitic hydrate of alumina, named after Colonel G. Gibbs, whose collection of minerals is now in Yale College.

GIBRALTAR STONE. Stalagmitic carbonate of lime resembling the Algerian onyx-marble, found in limestone-caverns at Gibraltar.

GIG MACHINES, are rotatory drums, mounted with thistles or wire teeth for teazling cloth. See Woollen Manufacture.

GILBERTITE. A micaceous mineral apparently related to kaolin, occurring with the china-stone of St. Austell in Cornwall.

GILDING (*Dorure*, Fr.; *Vergoldung*, Ger.). This art consists in covering bodies with a thin coat of gold, which may be done either by mechanical or chemical means. The mechanical mode is the application of gold-leaf or gold-powder to various surfaces, and their fixation by different means. Thus gold may be appiled to wood, plaster, pasteboard, leather; and to metals, such as silver, copper, iron, tin, and bronze; so that gilding, generally speaking, includes several arts, exercised by very different classes of tradesmen.

I. Mechanical Gilding.—Oil-gilding is the first method under this head, as oil is the fluid most generally used in the operation of this mechanical art. The following process has been much extolled at Paris:—

1. A coat of *impression* is to be given first of all, namely, a coat of white lead paint, made with drying linseed oil, containing very little oil of turpentine.

2. Calcined ceruse is to be ground very well with unboiled linseed oil, and tempered with essence of turpentine, in proportion as it is laid on. Three or four coats of this *hard tint* are to be applied evenly on the ornaments, and the parts which are to be most carefully gilded.

3. *The Gold colour* is then to be smoothly applied. This is merely the dregs of the colours, ground and tempered with oil, which remain in the little dish in which painters clean their brushes. This substance is extremely rich and gluey; after being ground up, and passed through fine linen cloth, it forms the ground for gold-leaf.

4. When the gold colour is dry enough to catch hold of the leaf gold, this is spread on the cushion, cut into pieces and carefully applied with the pallet knife, pressed down with cotton, and on the small ornaments with a fine brush.

5. If the gildings be for outside exposure, as balconies, gratings, statues, &c., they

must not be varnished, as simple oil-gilding stands better; for when it is varnished, a bright sunbeam acting after heavy rain, gives the gilding a jagged appearance. When the objects are inside ones, a coat of spirit-varnish may be passed over the gold-leaf, then a glow from the gilder's chafing dish may be given, and finally a coat of oil-varnish. The workman who causes the chafing dish to glide in front of the varnished surface must avoid stopping for an instant opposite any point, otherwise he would cause the varnish to boil and blister. This heat brings out the whole transparency of the varnish, and lustre of the gold.

Oil-Gilding is employed with varnish polish, upon equipages, mirror-frames, and other furniture. The following method is employed by eminent gilders at Paris :—

1. White lead, with half its weight of yellow ochre, and a little litharge, are separately ground very fine; and the whole is then tempered with linseed oil, thinned with essence of turpentine, and applied in an evenly coat, called *impression*.

2. When this coat is quite dry, several coats of the hard tint are given, even so many as 10 or 12, should the surface require it for smoothing and filling up the pores. These coats are given daily, leaving them to dry in the interval in a warm sunny exposure.

3. When the work is perfectly dry, it is first softened down with pumice stone and water, afterwards with worsted cloth and very finely powdered pumice, till the *hard tint* give no reflexion, and be as smooth as glass.

4. With a camel's-hair brush, there must be given lightly and with a gentle heat, from 4 to 5 coats at least, and even sometimes double that number, of fine lac-varnish.

5. When these are dry, the grounds of the pannels and the sculptures must be first polished with shave-grass (*de la prêle*); and next with putty of tin and tripoli, tempered with water, applied with woollen cloth; by which the varnish is polished till it shines like a mirror.

6. The work thus polished is carried into a hot place, free from dust, where it receives very lightly and smoothly, a thin coat of *gold colour*, much softened down. This coat is passed over it with a clean soft brush, and the thinner it is the better.

7. Whenever the gold colour is dry enough to take the gold, which is known by laying the back of the hand on a corner of the frame work, the gilding is begun and finished as usual.

8. The gold is smoothed off with a very soft brush, one of camel's hair, for example, of three fingers' breadth; after which it is left to dry for several days.

9. It is then varnished with a spirit-of-wine varnish; which is treated with the chafing dish as above described.

10. When this varnish is dry, two or three coats of copal, or oil of varnish, is applied, at intervals of two days.

11. Finally, the pannels are polished with a worsted cloth, imbued with tripoli and water, and lustre is given by friction with the palm of the hand, previously softened with a little olive oil, taking care not to rub off the gold.

In this country, *Burnished gilding* is practised by first giving a ground of size whiting, in several successive coats; next applying gilding size; and then the gold-leaf, which is burnished down with agate, or a dog's tooth.

Gilding in distemper of the French, is the same as our burnished gilding. Their process seems to be very elaborate, and the best consists of 17 operations; each of them is said to be essential.

1. *Encollage*, or the *Glue coat.* To a decoction of wormwood and garlic in water, strained through a cloth, a little common salt, and some vinegar are added. This composition, as being destructive of worms in wood, is mixed with as much good glue; and the mixture is spread in a hot state, with a brush of boar's hair. When plaster or marble is to be gilded, the salt must be left out of the above composition, as it is apt to attract humidity in damp places, and to come out as a white powder on the gilding. But the salt is indispensable for wood. The first glue coating is made thinner than the second.

2. *White preparation.* This consists in covering the above surface with 8, 10, or 12 coats of Spanish white, mixed up with strong size, each well worked on with the brush, and in some measure incorporated with the preceding coat, to prevent their peeling off in scales.

3. *Stopping up* the pores, with thick whiting and glue, and smoothing the surface with dog-skin.

4. Polishing the surface with pumice-stone and very cold water.

5. *Reparation*; in which a skilful artist retouches the whole.

6. *Cleansing*; with a damp linen rag, and then a soft sponge.

7. *Prêler.* This is rubbing with horse's tail (*shave-grass*) the parts to be yellowed, in order to make them softer.

8. *Yellowing.* With this view *yellow ochre* is carefully ground in water, and mixed with transparent colourless size. The thinner part of this mixture is applied hot over the white surface with a thin brush, which gives it a fine yellow hue.

9. *Ungraining*; consists in rubbing the whole work with shave-grass, to remove any granular appearance.

10. *Coat of assiette; trencher coat.* This is the composition on which the gold is to be laid. It is composed of Armenian bole, 1 pound; hematite, 2 ounces; and as much galena; each separately ground in water. The whole are then mixed together, and ground up with about a spoonful of olive oil. The *assiette* well made and applied gives beauty to the gilding. The *assiette* is tempered with a white sheepskin glue, very clear and well strained. This mixture is heated, and applied in three successive coats with a very fine long-haired brush.

11. *Rubbing*, with a piece of dry, linen cloth; except the parts which are be burnished, which are to receive other two coats of *assiette* tempered with glue.

12. *Gilding.* The surface being damped with cold water (iced in summer) has then the gold-leaf applied to it. The hollow grounds must always be gilded before the prominent parts. Water is dexterously applied by a soft brush, immediately behind the gold-leaf, before laying it down, which makes it lie smoother. Any excess of water is then removed with a dry brush.

13. *Burnishing*, with bloodstone.

14. *Deadening.* This consists in passing a thin coat of glue, slightly warmed, over the parts that are not to be burnished.

15. *Mending*; that is, moistening any broken points with a brush, and applying bits of gold-leaf to them.

16. The *vermeil coat.* Vermeil is a liquid which gives lustre and fire to the gold: and makes it resemble *or-moulu.* It is composed as follows: 2 ounces of annotto, 1 ounce of gamboge, 1 ounce of vermilion, half an ounce of dragon's blood, 2 ounces of salt of tartar, and 18 grains of saffron, are boiled in a litre (2 pints English) of water, over a slow fire, till the liquid be reduced to a fourth. The whole is then passed through a silk or muslin sieve. A little of this is made to glide lightly over the gold, with a very soft brush.

17. *Repassage*; is passing over the dead surfaces a second coat of deadening glue, which must be hotter than the first. This finishes the work, and gives it strength.

Leaf gilding, on paper or vellum, is done by giving them a coat of gum-water or fine size, applying the gold-leaf ere the surfaces be hard dry, and burnishing with agate.

Gold lettering, on bound books, is given without size, by laying the gold-leaf on the leather, and imprinting it with hot brass types.

The *edges of the leaves of books are gilded*, while they are in the press where they have been cut smooth, by applying a solution of isinglass in spirits, and laying on the gold when the edges are in a proper state of dryness. The French workmen employ a ground of Armenian bole, mixed with powdered sugar-candy, by means of white-of-egg. This ground is laid very thin upon the edges, after fine size or gum-water has been applied; and when the ground is dry it is rubbed smooth with a wet rag, which moistens it sufficiently to take the gold.

Japanners' gilding is done by sprinkling or daubing with wash-leather, some gold-powder over an oil sized surface, mixed with oil of turpentine. This gives the appearance of frosted gold. The gold-powder may be obtained, either by precipitating gold from its solution in *aqua regia* by a solution of pure sulphate of iron, or by evaporating away the mercury from some gold-amalgam.

II. Chemical Gilding, or the application of gold by chemical affinity to metallic surfaces.

A compound of copper with one-seventh of brass is the best metal for gilding on; copper by itself being too soft and dark coloured. Ordinary brass, however, answers very well. We shall describe the process of wash gilding, with M. D'Arcet's improvements, now generally adopted in Paris.

Wash gilding consists in applying evenly an amalgam of gold to the surface of a copper alloy, and dissipating the mercury with heat, so as to leave the gold film fixed. The surface is afterwards burnished or deadened at pleasure. The gold ought to be quite pure, and laminated to facilitate its combination with the mercury; which should also be pure.

Preparation of the amalgam.—After weighing the fine gold, the workman puts it in a crucible, and as soon as this becomes faintly red, he pours in the requisite quantity of mercury; which is about 8 to 1 of gold. He stirs up the mixture with an iron rod, bent hookwise at the end, leaving the crucible on the fire till he perceives that all the gold is dissolved. He then pours the amalgam into a small earthen dish containing water, washes it with care, and squeezes out of it with his fingers all the running mercury that he can. The amalgam that now remains on the sloping sides of the vessel is so pasty as to preserve the impression of the fingers. When this is squeezed in a chamois-leather bag, it gives up much mercury; and remains an amalgam, consisting of about 33 of mercury, and 57 of gold, in 100 parts. The mercury which passes through the bag, under the pressure of the fingers, holds a good deal of gold in solution; and is employed in making fresh amalgam.

Preparation of the mercurial solution.—The amalgam of gold is applied to brass, through the intervention of pure nitric acid, holding in solution a little mercury.

100 parts of mercury, and 110 parts by weight of pure nitric acid, specific gravity 1·33, are to be put into a glass matrass. On the application of a gentle heat the mercury dissolves with the disengagement of fumes of nitrous gas, which must be allowed to escape into the chimney. This solution is to be diluted with about 25 times its weight of pure water, and bottled up for use.

1. *Annealing.*—The workman anneals the piece of bronze after it has come out of the hands of the turner and engraver. He sets it among burning charcoal, or rather peats, which have a more equal and lively flame; covering it quite up, so that it may be oxidised as little as possible, and taking care that the thin parts of the piece do not become hotter than the thicker. This operation is done in a dark room, and when he sees the piece of a cherry-red colour, he removes the fuel from about it, lifts it out with long tongs, and sets it to cool slowly in the air.

2. The *decapage.*—The object of this process is to clear the surface from the coat of oxide which may have formed upon it. The piece is plunged into a bucket filled with extremely dilute sulphuric acid; it is left there long enough to allow the coat of oxide to be dissolved, or at least loosened; and it is then rubbed with a hard brush. When the piece becomes perfectly bright, it is washed and dried. Its surface may, however, be still a little variegated; and the piece is therefore dipped in nitric acid, specific gravity 1·33, and afterwards rubbed with a long-haired brush. The addition of a little common salt to the dilute sulphuric acid would probably save the use of nitric acid, which is so apt to produce a new coat of oxide. It is finally made quite dry (after washing in pure water), by being rubbed well with tanners' dry bark, sawdust, or bran. The surface should now appear somewhat depolished; for when it is very smooth, the gold does not adhere so well.

3. *Application of the amalgam.*—The gilder's *scratch-brush* or pencil, made with fine brass wire, is to be dipped into the solution of nitrate of mercury, and is then to be drawn over a lump of gold-amalgam, laid on the sloping side of an earthen vessel, after which it is to be applied to the surface of the brass. This process is to be repeated, dipping the brush into the solution, and drawing it over the amalgam, till the whole surface to be gilded is coated with its just proportion of gold. The piece is then washed in a body of water, dried, and put to the fire to volatilise the mercury. If one coat of gilding be insufficient, the piece is washed over anew with amalgam, and the operation recommenced till the work prove satisfactory.

4. *Volatilisation of the mercury.*—Whenever the piece is well coated with amalgam, the gilder exposes it to glowing charcoal, turning it about, and heating it by degrees to the proper point; he then withdraws it from the fire, lifts it with long pincers, and, seizing it in his left hand, protected by a stuffed glove, he turns it over in every direction, rubbing and striking it all the while with a long-haired brush, in order to equalise the amalgam. He now restores the piece to the fire, and treats it in the same way till the mercury be entirely volatilised, which he recognises by the hissing sound of a drop of water let fall on it. During this time he repairs the defective spots, taking care to volatilise the mercury very slowly. The piece, when thoroughly coated with gold, is washed, and scrubbed well with a brush in water acidulated with vinegar.

If the piece is to have some parts burnished, and others dead, the parts to be burnished are covered with a mixture of Spanish white, bruised sugar-candy, and gum dissolved in water. This operation is called in French *épargner* (*protecting*). When the gilder has *protected* the burnished points, he dries the piece, and carries the heat high enough to expel the little mercury which might still remain on it. He then plunges, it, while still a little hot, in water acidulated with sulphuric acid, washes it, dries it, and gives it the burnish.

5. The *burnish* is given by rubbing the piece with burnishers of hematite (bloodstone). The workman dips his burnisher in water sharpened with vinegar, and rubs the piece always in the same direction backwards and forwards, till it exhibits a fine polish, and a complete metallic lustre. He then washes it in cold water, dries it with fine linen cloth, and concludes the operation by drying it slowly on a grating placed above a chafing-dish of burning charcoal.

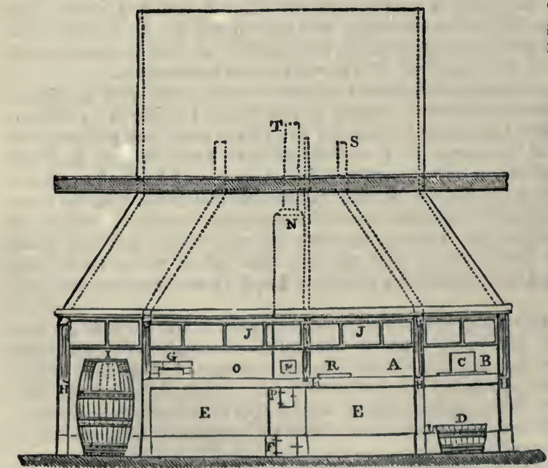
6. The *deadening* is given as follows:—The piece, covered with the *protection* on those parts that are to be burnished, is attached with an iron wire to the end of an iron rod, and is heated strongly so as to give a brown hue to the *épargne* by its partial carbonisation. The gilded piece assumes thus a fine tint of gold; and is next coated over with a mixture of sea salt, nitre, and alum fused in the water of crystallisation of the latter salt. The piece is now restored to the fire, and heated

till the saline crust which covers it becomes homogeneous, nearly transparent, and enters into true fusion. It is then taken from the fire and suddenly plunged into cold water, which separates the saline crust, carrying away even the coat of *épargne.* The piece is lastly passed through very weak nitric acid, washed in a great body of water, and dried by exposure either to the air, over a drying stove, or with clean linen cloths.

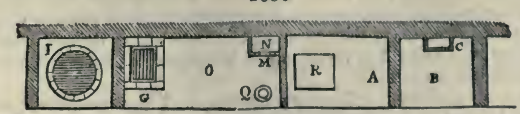
7. *Of or-moulu colour.*—When it is desired to put a piece of gilded bronze into *or-moulu* colour, it must be less scrubbed with the scratch-brush than usual, and made to *come back again* by heating it more strongly than if it were to be deadened, and allowing it then to cool a little. The *or-moulu* covering is a mixture of hematite, alum, and sea salt. This mixture is to be thinned with vinegar, and applied with a brush so as to cover the gilded brass, with reserve of the burnished parts. The piece is then put on glowing coals, urged a little by the bellows, and allowed to heat till the colour begins to blacken. The piece ought to be so hot that water sprinkled on it may cause a hissing noise. It is then taken from the fire, plunged into cold water, washed, and next rubbed with a brush dipped in vinegar, if the piece be smooth; but if it be chased, weak nitric acid must be used. In either case, it must be finally washed in a body of pure water, and dried over a gentle fire.

8. *Of red gold colour.*—To give this hue, the piece, after being coated with amalgam, and heated, is in this hot state to be suspended by an iron wire, and tempered with the composition known under the name of gilder's wax; made with yellow wax, red ochre, verdigris, and alum. In this state it is presented to the flame of a wood fire, is heated strongly, and the combustion of its coating is favoured by throwing some drops of the wax-mixture into the burning fuel. It is now turned round and round over the fire, so that the flame may act equally. When all the wax of the colouring is burned away, and when the flame is extinguished, the piece is to be plunged in water, washed, and scrubbed with the scratch-brush and pure vinegar. If the colour is not beautiful, and quite equal in shade, the piece is coated with verdigris dissolved in vinegar, dried over a gentle fire, plunged in water, and scrubbed with pure vinegar, or even with a little weak nitric acid if the piece exhibit too dark a hue. It is now washed, burnished, washed anew, wiped with linen cloths, and finally dried over a gentle fire.

1085



1086



The following is the outline of a complete gilding factory, as now fitted up at Paris:—

Figs. 1085, 1086, front elevation and plan of a complete gilding workshop.

P. Furnace of *appel*, or draught, serving at the same time to heat the deadening pan (*poêlon au mat*).

F. Ash-pit of this furnace.

N. Chimney of this furnace constructed of bricks, as far as the contraction of the great chimney, S, of the forge, and which is terminated by a summit pipe rising 2 or 3 yards above this contraction.

B. Forge for annealing the pieces of bronze; for drying the gilded pieces, &c.

C. Chimney of communication between the annealing forge B, and the space D below the forge. This chimney serves to carry the noxious fumes into the great vent of the factory.

U. Bucket for the brightening operation.

A. Forge for passing the amalgam over the piece.

R. Shelf for the brushing operations.

E E. Coal cellarets.

O. Forge for the deadening process.

G. Furnace for the same.

M. An opening into the furnace of *appel*, by which vapours may be let off from any operation by taking out the plug at M.

I. Cask in which the pieces of gilded brass are plunged for the deadening process. The vapours rising thence are carried up the general chimney.

J J. Casement with glass panes, which serves to contract the opening of the hearths, without obstructing the view. The casement may be rendered moveable to admit larger objects.

H H. Curtains of coarse cotton cloth, for closing at pleasure, in whole or part, one or several of the forges or hearths, and for quickening the current of air in the places where the curtains are not drawn.

Q. Opening above the draught furnace, which serves for the heating of the *poêlon au mat* (deadening pan).

Gilding on polished iron and steel.—If a nearly neutral solution of gold in muriatic acid be mixed with sulphuric ether, and agitated, the ether will take up the gold, and float above the denser acid. When this auriferous ether is applied by a hair-pencil to brightly-polished iron or steel, the ether flies off, and the gold adheres. It must be fixed by polishing with the burnisher. This gilding is not very rich or durable. In fact the affinity between gold and iron is feeble, compared with that between gold and copper and silver. But polished iron, steel, and copper, may be gilded with heat, by gold-leaf. They are first heated till the iron takes a bluish tint, and till the copper has attained to a like temperature; a first coat of gold-leaf is now applied, which is pressed gently down with a burnisher, and then exposed to a gentle heat. Several leaves either single or double are thus applied in succession, and the last is burnished down cold.

Mr. Elkington obtained a patent, in June 1836, for gilding copper, brass, &c., by means of potash or soda combined with carbonic acid, and with a solution of gold. Dissolve, says he, 5 oz. troy of fine gold in 52 oz. avoirdupois of nitro-muriatic acid of the following proportions: viz. 21 oz. of pure nitric acid, of spec. grav. 1·45, 17 oz. of pure muriatic acid, of spec. grav. 1·15, with 14 oz. of distilled water.

The gold being put into the mixture of acids and water, they are to be heated in a glass or other convenient vessel till the gold is dissolved; and it is usual to continue the application of heat after this is effected, until a reddish or yellowish vapour ceases to rise.

The clear liquid is to be carefully poured off from any sediment which generally appears, and results from a small portion of silver, which is generally found in alloy with gold. The clear liquid is to be placed in a suitable vessel of stone; pottery ware is preferred, Add to the solution of gold 4 gallons of distilled water, and 20 pounds of bicarbonate of potash of the best quality; let the whole boil moderately for 2 hours, the mixture will then be ready for use.

The articles to be gilded having been first perfectly cleaned from scale or grease, they are to be suspended on wires, conveniently for a workman to dip them in the liquid, which is kept boiling. The time required for gilding any particular article will depend on circumstances, partly on the quantity of gold remaining in the liquid, and partly on the size and weight of the article; but a little practice will readily give sufficient guidance to the workman.

Supposing the articles desired to be gilded be brass or copper buttons, or small articles for gilt toys, or ornaments of dress, such as earrings or bracelets, a considerable number of which may be strung on a hoop, or bended piece of copper or brass wire, and dipped into the vessel containing the boiling liquid above described, and moved therein, the requisite gilding will be generally obtained in from a few seconds to a minute; this is when the liquid is in the condition above described, and depending on the quality of the gilding desired; but if the liquid has been used some time, the quantity of gold will be lessened, which will vary the time of operating to produce a given effect, or the colour required, all of which will quickly be observed by the workman; and by noting the appearance of the articles from time to time, he will know when the desired object is obtained, though it is desirable to avoid as much as possible taking the articles out of the liquid.

When the operation is completed, the workman perfectly washes the articles so gilded with clean water; they may then be submitted to the usual process of colouring.

If the articles be cast figures of animals, or otherwise of considerable weight, compared with the articles above mentioned, the time required to perform the process will be greater.

In case it is desired to produce what is called a dead appearance, it may be performed by several processes: the one usually employed is to dead the articles in the process of cleaning, as practised by brass founders and other trades; it is produced by an acid, prepared for that purpose, sold by the makers under the term 'deading aquafortis,' which is well understood.

It may also be produced by a weak solution of nitrate of mercury, applied to the articles previous to the gilding process, as is practised in the process of gilding with mercury, previous to spreading the amalgam, but generally a much weaker solution; or the articles having been gilded may be dipped in a solution of nitrate of mercury, and submitted to heat to expel the same, as is practised in the usual process of gilding.

Cold gilding.—Sixty grains of fine gold and 12 of rose copper are to be dissolved in two ounces of aqua regia. When the solution is completed, it is to be dropped on clean linen rags, of such bulk as to absorb all the liquid. They are then dried, and burned into ashes. Those ashes contain the gold in powder.

When a piece is to be gilded, after subjecting it to the preliminary operations of softening or annealing and brightening, it is rubbed with a moistened cork, dipped in the above powder, till the surface seems to be sufficiently gilded. Large works are thereafter burnished with pieces of hematite, and small ones with steel burnishers, along with soap water.

In gilding small articles, as buttons, with amalgam, a portion of this is taken equivalent to the work to be done, and some nitrate-of-mercury solution is added to it in a wooden trough; the whole articles are now put in, and well worked about with a hard brush, till their surfaces are equably coated. They are then washed, dried, and put together into an iron frying-pan, and heated till the mercury begins to fly off, when they are turned out into a cap, in which they are tossed and well stirred about with a painter's brush. The operation must be repeated several times for a strong gilding. The surfaces are finally brightened by brushing them along with small beer or ale grounds.

For the processes of gilding by electro-chemical means, see ELECTRO-METALLURGY.

GIMP, or **GYMP**, a silk, woollen, or cotton twist, with often a metallic wire, but sometimes a coarse thread running through it; it is much used in coat-lace making.

GIN, or *Geneva*, from *Genièvre* (juniper), is an ardent spirit manufactured in London, and other places, in great quantities, and flavoured generally with juniper-berries. It is also made in Holland, and hence called Hollands gin in this country, to distinguish it from British gin. The materials employed in the distilleries of Schiedam are, two parts of unmalted rye from Riga, weighing about 54 lbs. per bushel, and one part of malted bigg, weighing about 37 lbs. per bushel. The mash-tun, which serves also as the fermenting tun, has a capacity of nearly 700 gallons, being about 5 feet in diameter at the mouth, rather narrower at the bottom, and 4½ feet deep; the stirring apparatus is an oblong rectangular iron grid made fast to the end of a wooden pole. About a barrel, = 36 gallons of water, at a temperature of from 162° to 168° (the former heat being best for the highly-dried rye), are put into the mash tun for every 1½ cwt. of meal, after which the malt is introduced and stirred, and lastly the rye is added. Powerful agitation is given to the magma till it becomes quite uniform; a process which a vigorous workman piques himself upon executing in the course of a few minutes. The mouth of the tun is immediately covered over with canvas, and further secured with a close wooden lid, to confine the heat; it is left in this state for two hours. The contents being then stirred up once more, the *transparent* spent wash of a preceding mashing is first added, and next as much cold water as will reduce the temperature of the whole to about 85° F. The best Flanders yeast, which had been brought, for the sake of carriage, to a doughy consistence by pressure, is now introduced to the amount of one pound to every 100 gallons of the mashed materials.

The gravity of the fresh wort is usually from 33 to 38 lbs. per Dicas' hydrometer; and the fermentation is carried on from 48 to 60 hours, at the end of which time the attenuation is from 7 to 4 lbs., that is, the specific gravity of the supernatant wash is from 1·007 to 1·004.

The distillers are induced, by the scarcity of beer-barm in Holland, to skim off a quantity of the yeast from the fermenting tuns, and to sell it to the bakers, whereby they obstruct materially the production of spirit, though they probably improve its quality, by preventing its impregnation with yeasty particles; an unpleasant result which seldom fails to take place in the whisky distilleries of the United Kingdom.

On the third day after the fermenting tun is set, the wash containing the grains is transferred to the still, and converted into low wines. To every 100 gallons of this liquor, two pounds of juniper-berries, from 3 to 5 years old, being added, along with about one quarter of a pound of salt, the whole are put into the low wine still, and the fine Hollands spirit is drawn off by a gentle and well-regulated heat, till the magma becomes exhausted; the first and the last products being mixed together; whereby a spirit, 2 to 3 per cent. above our hydrometer proof, is obtained, possessing the peculiar fine aroma of gin. The quantity of spirit varies from 18 to 21 gallons per quarter of grain; this large product being partly due to the employment of the spent wash of the preceding fermentation; an addition which contributes at the same time to improve the flavour.

London gin is, as we have stated, a corn spirit, which is, however, rendered sweet and cordial-like, by the use of several injurious substances. Plymouth gin, as manufactured by Coates and Co. of Plymouth, is a far purer spirit. The rectifiers employ a pure grain spirit, and flavour with the wash of the whisky distilleries. When wash is distilled, the fluid that comes over is called *singlings*, or *low wines*. It is concentrated or *doubled* by a second distillation, and becomes *raw corn spirit;* this is sold to the rectifier at 11 or 25 per cent. over proof.

Mr. Brande has given the following table of the quantities of alcohol (sp. gr. at 60° F.; 0·825) contained in different ardent spirits:—

Proportion of Alcohol in ardent Spirits.

	In 100 parts	
Brandy	55·39	by measure
Rum	53·68	,,
Gin	51·60	,,
Whisky, Scotch	54·32	,,
Do. Irish	53·20	,,

GINGER. *Zingiber officinale.* This species is herbaceous, with a creeping or tuberous rhizome. The flowers are irregular, and disposed in form of a dense spike or raceme. The *Zingiberaceæ* are natives of all parts of the intertropical zone: the common ginger is originally indigenous to the East Indies, but it is now cultivated in almost all warm parts of the globe. The rhizome or rootstock is the ginger of commerce. It is imported in large quantities from the East and West Indies and Africa.

GINGER BEER. A fermented drink containing an infusion of ginger. The following is a good and useful form for its manufacture:—

Barbadoes ginger root	12 ounces.
Tartaric acid	3 ounces.
White sugar	8 pounds.
Gum arabic	8 ounces.
Essence of lemon	2 drachms.
Water	9 gallons.

The ginger root, bruised, is to be boiled for an hour; then, the liquor being strained, the tartaric acid and sugar added, boiled and the same removed. The gum arabic dissolved in a separate portion of water, is added with the essence of lemons. When the whole has cooled to about 100° Fahr., some fresh yeast is to be added, and the beer carefully fermented. Then bottle for use.

Ginger-beer powders are thus prepared:—

White sugar	5 ounces.
Tartaric acid	1½ ounce.
Carbonate of soda	1½ ounce.
Powdered Jamaica ginger	2 drachms.
Essence of lemon	10 drops.

All the materials are to be carefully dried, and mixed while yet warm, in a warm mortar, and immediately bottled.

If the acid and the carbonate of soda are kept separate, these precautions are not necessary.

GINNING is the name of the operation by which the filaments of cotton are separated from the seeds. See COTTON MANUFACTURE.

GINSENG. The root of the *Panax Schinseng*, a plant belonging to the *Araliaceæ*, or ivy-order. This is highly esteemed as a medicine by the Chinese, who are said to value it at its weight in gold. The *American Ginseng* is the root of a closely-related plant *P. quinquefolium.*

GIRASOL. The name given by the French to fire-opal. See OPAL.

GLAIRE. The white-of-egg. This consists, according to Gmelin, of albumen 12·0, mucus 2·7, salts 0·3, water 85·0. Glaire or albumen (*ovalbumen*), is distinguished from the albumen of the serum of the blood (*seralbumen*), by its being coagulated by ether. Glaire is used by bookbinders in finishing the backs of books, and for a few other purposes in the arts. See ALBUMEN.

GLANCE. Any minerals exhibiting a brilliant lustre especially of a metallic character were so called, the term signifying *splendour.* Lead-glance, iron-glance, and the like are examples.

GLANCE-COAL, a name given to anthracite, of which there are two varieties, the *slaty* and the *conchoidal.* See ANTHRACITE and COAL.

GLANCE-COBALT. See COBALT.

GLANCE-COPPER. See COPPER.

GLASERITE. Native sulphate of potash, from Vesuvius.

GLASS (*Verre*, Fr.; *Glas*, Ger.) is a transparent solid formed by the fusion of siliceous and alkaline matter. It was known to the Phœnicians, and constituted for a long time an exclusive manufacture of that people, in consequence of its ingredients—natron, sand, and fuel—abounding upon their coasts. It is certain that the ancient Egyptians were acquainted with glass, for, although we find no mention of it in the writings of Moses, we discover glass ornaments in tombs which are as old as the days of Moses. According to Pliny and Strabo, the glass works of Sidon and Alexandria were famous in their times, and produced beautiful articles, which were cut, engraved, gilt, and stained of the most brilliant colours, in imitation of precious stones. The Romans employed glass for various purposes; and have left specimens in Herculaneum of window-glass, which must have been blown by methods analogous to the modern. The Phœnician processes seemed to have been learned by the Crusaders, and transferred to Venice in the 13th century, where they were long held secret, and formed a lucrative commercial monopoly. Soon after the middle of the seventeenth century Colbert enriched France with the blown mirror-glass manufacture.

Chance may have had a share in the invention of this curious fabrication, but there were circumstances in the most ancient arts likely to lead to it; such as the fusing and vitrifying heats required for the formation of pottery, and for the extraction of metals from their ores. Pliny ascribes the origin of glass to the following accident:—A merchant-ship laden with natron being driven upon the coast at the mouth of the river Belus, in tempestuous weather, the crew were compelled to cook their victuals ashore, and having placed lumps of the natron upon the sand, as supports to the kettles, found to their surprise masses of transparent stone among the cinders. The sand of this small stream of Galilee, which runs from the foot of Mount Carmel, was in consequence supposed to possess a peculiar virtue for making glass, and continued for ages to be sought after and exported to distant countries for this purpose. There exists good evidence that the manufacture of glass and of vitreous glazes is much older than the time ascribed by Pliny.

Agricola, the oldest author who has written technically upon glass, describes furnaces and processes closely resembling those employed at the present day. Neri, Kunckel, Henckel, Pott, Achard, and some other chemists, have since then composed treatises upon the subject; but Neri, Bosc, Antic, Loysel, and Allut, in the *Encyclopédie Méthodique*, are the best of the older authorities.

The Venetians were the first in modern times who attained to any degree of excellence in the art of working glass; but the French became eventually so zealous of rivalling them, particularly in the construction of mirrors, that a decree was issued by the court of France, declaring not only that the manufacture of glass should not derogate from the dignity of a nobleman, but that nobles alone should be masters of glass-works. Within the last fifty years, Great Britain has made rapid advances in this important art, and at the present day her pre-eminence in some departments hardly admits of dispute.

The window-glass manufacture was first begun in England in 1557, in Crutched Friars, London: and fine articles of flint-glass were soon afterwards made in the Savoy House, Strand. In 1635 the art received a great improvement from Sir Robert Mansell, by the use of coal-fuel instead of wood. The first sheets of blown glass for looking-glasses and coach-windows were made in 1673 at Lambeth, by Venetian artisans employed under the patronage of the Duke of Buckingham.

The casting of mirror-plates was commenced in France about the year 1688, by Abraham Thévart: an invention which gave rise soon afterwards to the establishment of the celebrated works of St. Gobain, which continued for nearly a century the sole place where this highly-prized object of luxury was well made. In cheapness, if not in excellence, the French mirror-plate has been for some time rivalled by the English.

The analyses of modern chemists, which will be detailed in the course of this article, and the light thrown upon the manufacture of glass in general by the accurate means now possessed of purifying its several ingredients, would have brought the art long since to the highest state of perfection in this country, but for the long-continued vexatious interference and obstructions of our Excise laws now happily at an end.

The researches of Berzelius having removed all doubts concerning the acid character of silica, the general composition of glass presents now no difficulty of conception. This substance consists of one or more salts, which are silicates with bases of potash, soda, lime, oxide of iron, alumina, or oxide of lead; in any of which compounds we can substitute one of these bases for another, provided that one alkaline base be left. Silica in its turn may be replaced by boracic acid, without causing the glass to lose its principal characters.

Under the title 'glass' are therefore comprehended various substances fusible at a high temperature, solid at ordinary temperatures, brilliant, generally more or less transparent, and always brittle. The following chemical distribution of glasses has been proposed:—

1. Soluble glass; a simple silicate of potash or soda; or of both these alkalis.
2. Crown-glass; silicate of potash and lime.
3. Bottle-glass; silicate of soda, lime, alumina, and iron.
4. Common window-glass; silicate of soda and lime; sometimes also of potash.
5. Plate-glass; silica, soda or potash, lime, and alumina.
6. Ordinary crystal-glass; silicate of potash and lead.
7. Flint-glass; silicate of potash and lead; richer in lead than the preceding.
8. Strass; silicate of potash and lead; still richer in lead.
9. Enamel; silicate and stannate or antimonate of potash or soda, and lead.

The following analyses of these varieties of glass will place their composition more completely before the reader:—

	Silica	Potash or soda	Lime	Oxide of lead	Alumina	Water
1. Soluble glass . .	62	26	0	0	0	12
2. Crown-glass . .	63	22	12	0	3	0

No. 1. Bohemian glass from Neufeld (M. Grus).

No. 2. A fine table glass from Neuwelt (M. Berthier); it is exceedingly beautiful, and is prepared, according to M. Perdonnet, with a mixture of 100 quartz, 50 caustic lime, 75 carbonate of potash, and a very small quantity of nitre, arsenious acid, and oxide of manganese.

No. 3. Old Bohemian glass (M. Dumas).

No. 4. Crown-glass of German manufacture (M. Dumas).

No. 5. Glass for mirrors (M. Dumas).

No. 6. Another glass for mirrors (M. Dumas).

No. 7. White table glass, from Siberberg near Gratzen.

No. 8. Mirror-glass from New-Hurkenthal, for the manufacture of cast mirrors.

Peligot gives the analysis of Venetian aventurine as follows :—

Silica	67·7	Oxide of Tin	2·3
Potash	5·5	Oxide of Lead	1·1
Lime	8·9	Metallic Copper	3·9
Soda	7·1	Oxide of Iron	3·5

See Aventurine.

The following analyses of different varieties of Continental glass are instructive :—

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.	No. 6.
Silica	71·7	69·2	62·8	60·4	53·55	42·5
Potash	12·7	15·8	22·1	3·2	5·48	11·7

,, manganese	0·2					
,, lead	...	...	...	...	...	43·5
Baryta	...	...	...	0·9		

No. 1. is a very beautiful white wine-glass of Neuwelt in Bohemia.

No. 2. Glass tubes, much more fusible than common wine-glasses.

No. 3. Crown-glass of Bohemia.

No. 4. Flask-glass of St. Etienne, for which some heavy spar is used.

No. 5. Glass of Sèvres.

No. 6. Guinand's flint-glass.

Some specimens of ancient glass, analysed by Richard Phillips, have the following composition:—

	Silica	Alumina	Oxide of iron	Manganese	Lime	Magnesia	Soda
Roman vase . .	70·58	1·80	0·53	0·48	8·00	trace	18·86
„ flatted glass .	71·95	trace	3·45	0·57	7·33	0·60	15·30
„ lachrymatory .	71·45	2·15	1·02	·17	8·14	trace	16·62

Thus we see that these ancient glasses were all soda-glasses.

Devitrification.—The glasses which contain several bases are liable to suffer different changes when they are melted or cooled slowly. The silica is divided among these bases, forming new compounds in definite proportions, which, by crystallising, separate from each other, so that the general mixture of the ingredients which constitute the glass is destroyed. It becomes then very hard, fibrous, opaque, much less fusible, a better conductor of electricity and of heat, forming what Réaumur styled *devitrified* glass; and what is called after him 'Réaumur's porcelain.'

This altered glass can always be produced in a more or less perfect state, by melting the glass and allowing it to cool very slowly; or merely by heating it to the softening pitch, and keeping it at that heat for some time. The process succeeds best with the most complex vitreous compounds, such as bottle-glass; next with ordinary window-glass; and, lastly, with glass of potash and lead.

This property ought to be kept constantly in view in manufacturing glass. It shows why in making bottles we should fashion them as quickly as possible with the aid of a mould, and re-heat them as seldom as may be absolutely necessary. If glass is often heated and cooled, it loses its ductility, becomes refractory, and exhibits a multitude of stony granulations throughout its substance. When coarse glass is worked at the enameller's lamp, it is apt to change its nature in the same way, if the workman be not quick and expert at his business.

Fusibility, Cooling, Annealing.—All glass is more or less fusible; when it is softened by the action of heat, it may be worked with the greatest ease, and may be drawn out into threads as fine as those of the cocoon of the silkworm. Glass, when it is submitted to rapid cooling, becomes very fragile, and presents several very remarkable phenomena, among which, as an example, Prince Rupert's drops may be instanced. Glass supports variations of temperature better in proportion as it has been more slowly cooled; thus, when it has been slightly annealed, or not at all, its fragility may be considerably diminished by annealing it in water, or better, in boiling oil.

Action of Atmospheric and Chemical Agents.—The harder and more infusible a glass is, the less it is alterable by the action of atmospheric and chemical agents, with the exception of hydrofluoric acid. Glass which is too alkaline attracts gradually the moisture of the air, and loses its lustre and polish. Many glasses are perceptibly attacked by a prolonged boiling with water, and *à fortiori* by acid and alkaline solutions; thus, the bottle-glass is frequently attacked by the tartar which is found in the wine. According to Guyton-Morveau, all glass which is attacked by prolonged boiling with concentrated solutions of alum, common salt, sulphuric acid, or potassa, is of bad quality.

From these facts we perceive the importance of making a careful choice of the glass intended to be worked in considerable masses, such as the large object-glasses of telescopes; as their annealing requires a very slow process of refrigeration, which is apt to cause devitrified specks and clouds. For such purposes, therefore, no other species of glass is well adapted, except that with bases of potash and lead; or that with bases of potash and lime. These two form the best flint-glass and crown-glass; and they should be exclusively employed for the construction of the object-glasses of achromatic telescopes.

Glass, it will be apparent from the analyses given (pp. 645, 646), may be defined, in technical phraseology, to be a transparent homogeneous compound formed by the fusion of silica with oxides of the alkaline, earthy, or common metals. It is usually colourless, and then resembles rock-crystal, but is occasionally stained by accident or design with coloured metallic oxides. At common temperatures it is hard and brittle, in thick pieces; in thin plates or threads, flexible and elastic; sonorous when struck; fracture conchoidal, and of that peculiar lustre called vitreous: at a red heat, becoming soft, ductile and plastic. Other bodies are capable of entering into vitreous fusion, as phosphoric acid, boracic acid, arsenic acid, as also certain metallic oxides, as of lead and antimony, and several chlorides; some of which are denominated glasses.

Silica, formerly styled the earth of flints, which constitutes the basis of all commercial glass, is infusible by itself in the strongest fire of our furnaces; but its vitreous fusion is easily effected by a competent addition of potash or soda, either alone or mixed with lime or litharge. The silica, which may be regarded as belonging to the class of acids, combines at the heat of fusion with these bases, to form saline compounds; and hence glass may be viewed as a silicate of certain oxides, in which the acid and the bases exist in equivalent proportions. Were these proportions, or the quantities of the bases which silica requires for its saturation at the melting point, exactly ascertained, we might readily determine beforehand the best proportions of materials for the glass-manufacture. But as this is far from being the case, and as it is, moreover, not improbable that the capacity of saturation of the silica varies with the temperature, and that the properties of glass also vary with the bases, we must in the present state of our knowledge, regulate the proportions rather by practice than by theory, though the latter may throw an indirect light upon the subject. For example, a good colourless glass has been found by analysis to consist of 72 parts of silica, 13 parts of potash, and 10 parts of lime, in 95 parts. If we reduce these numbers to the equivalent ratios, we shall have the following results, taking the atomic weights as given by Berzelius:—

1	atom	potash =	590	14·67	
1		lime	356	8·84	
3		silica	1,722	42·79	71·49
2		silica	1,155	28·79	
			3,823	95·00	

This glass would therefore have been properly better compounded with the just atomic proportions, to which it nearly approaches, viz. 71·49 silica, 14·67 potash, and 8·84 lime, instead of those given above as its actual constituents.

The proportions in which silica unites with the alkaline and other oxides are modified by the temperature as above stated; the lower the heat, the less silica will enter into the glass, and the more of the base will in general be required. If a glass which contains an excess of alkali be exposed to a much higher temperature than that of its formation, a portion of the base will be set free to act upon the materials of the earthen pot, or to be dissipated in fumes, until such a silicate remains as to constitute a permanent glass corresponding to that temperature. Hence the same mixture of vitrifiable materials will yield very different results, according to the heats in which it is fused and worked in the glass-house; and therefore the composition should always be referrible to 'the going' of the furnace. When a species of glass, which at a high temperature formed a transparent combination with a considerable quantity of lime, is kept for some time in fusion at a lower temperature, a portion of the lime unites with the silica into another combination of a semi-vitreous or even of a stony aspect, so as to spoil the transparency of the glass altogether. There is probably a supersilicate and a subsilicate formed in such cases; the latter being much the more fusible of the two compounds. The Réaumur's porcelain already mentioned, is an example of this species of vitreous change in which new affinities are exercised at a lower temperature. An excess of silica, caused by the volatilisation of alkaline matter with too strong firing, will bring on similar appearances.

The specific gravity of glass varies from 2·3 to 3·6. That of least specific gravity consists of merely silica and potash fused together; that with lime is somewhat denser, and with oxide of lead denser still. Plate-glass made from silica, soda, and lime, has a specific variety which varies from 2·3 to 3·6; crystal or flint-glass containing lead from 3·0 to 3·6.

The density of several glasses *without lead* is as follows:—

Old Bohemian glass (Dumas)	2·396
Bohemian bottle-glass	3·782
Do. window-glass	2·642
Fine glass, called Bohemian crystal	2·892
Mirror-glass of Cherbourg (Dumas)	2·506
Do. St. Gobain	2·488
Do. Newhaus, 1812 (Scholz)	2·551
Do. do. 1830	2·653

The power of glass to resist the action of water, alkalis, acids, air, and light is in general the greater the higher the temperature employed in its manufacture, the smaller the proportion of its fluxes, and the more exact the equivalent ratios of its constituents. When glass contains too much alkali, it is partially soluble in water. Most crystal-glass is affected by having water boiled in it for a considerable time; but crown-glass being poorer in alkali, and containing no lead, resists that action much longer, and is therefore better adapted to chemical operations. In general, also, potash-glass is more apt to become damp than soda-glass, agreeably to the respective hygrometric properties of these two alkalis, and also to the smaller proportion of soda than of potash requisite to form glass.

Air and light operate upon glass probably by their oxidising property. Bluish or greenish coloured glasses become by exposure colourless, in consequence undoubtedly of the peroxidation of the iron, to whose protoxide they owe their tint; other glasses become purple-red from the peroxidation of the manganese. The glasses which contain lead suffer another kind of change in the air, if sulphuretted hydrogen be present; the oxide of lead is converted into a sulphuret, with the effect of rendering the surface of the glass opaque and iridescent. The more lead is in the glass, the quicker does this iridescence supervene. By boiling concentrated sulphuric acid in a glass vessel, or upon glass, we can ascertain its power of resisting ordinary menstrua. Good glass will remain smooth and transparent; bad glass will become rough and dim. The conditions of decomposition, as it occurs in glass of great age, have not been satisfactorily explained; the glass of the Roman tombs decomposes from the surface, exfoliating in a remarkable manner, film after film, of a pearly and beautifully iridescent character, falling off one after the other. The same kind of change is seen on the windows of our ancient churches.

The brittleness of unannealed glass by change of temperature is sometimes very great. This defect may be corrected by slowly heating the vessel in salt-water or oil to the highest pitch consistent with the nature of these liquids, and letting it cool very slowly. Within the limits of that range of heat it will, in consequence of this treatment, bear alternations of temperature without cracking.

It has been said that glass made from silica and alkalis alone will not resist the action of water, but that the addition of a little lime is necessary for this effect. In general 100 parts of quartzose sand require 33 parts of dry carbonate of soda for their vitrification, and 45 parts of dry carbonate of potash. But to make unchangeable alkaline glass, especially with potash, a smaller quantity of this than the above should be used with a very violent heat. A small proportion of lime increases the density, hardness, and lustre of glass; and it aids in decomposing the alkaline sulphates and muriates always present in the pearlash of commerce. From 7 to 20 parts of dry-slaked lime have been added for 100 of silica, with advantage, it is said, in some German glass-manufactories, where the alkaline matter is soda; for potash does not assimilate well with the calcareous earth.

In many glass works on the Continent, sulphate of soda is the form under which alkaline matter is introduced into glass. This salt requires the addition of 8 per cent. of charcoal to decompose and dissipate its acid: a result which takes place at a high heat, without the addition of any lime. 88 lbs. of quartz-sand, 44 lbs. of dry Glauber salt, and 3 lbs. of charcoal, properly mixed and fused, afford a limpid, fluid, and workable glass; with the addition of 17 lbs. of lime, these materials fuse more readily into a plastic mass. If less carbon be added, the fusion becomes more tedious.

By a proper addition of galena (the native sulphide of lead) to Glauber salt and quartz-sand, without charcoal, it is said a tolerably good crystal-glass may be formed. The sulphuric acid of the salt is probably converted by the reaction of the sulphuret of lead into sulphurous-acid gas, which is disengaged.

One atom of sulphide of lead = 1495·67, is requisite to decompose 3 atoms of sulphate of soda = 2676. It is stated, on good authority, that a good colourless glass may be obtained by using Glauber salt without charcoal, as by the following formula:—

Quartz-sand . . .	100 lbs.	Lime	20 lbs.
Calcined Glauber salt. .	20 ,,	Cullet of soda-glass .	12 ,,

The melting-heat must be continued for 26½ hours. A small quantity of the sand is reserved to be thrown in towards the conclusion of the process, in order to facilitate the expulsion of air-bubbles. The above mixture will bear to be blanched by the addition of manganese and arsenic. The decomposition of the salt is in this case effected by the lime, with which the sulphuric acid first combines, which is then converted into sulphurous acid, and dissipated. Glass made in this way was found by analysis to consist of 79 parts of silica, 12 lime, and 9·6 soda, without any trace of gypsum or sulphuric acid.

Glauber salt is partially volatilised by the heat of the furnace, and acts upon the arch of the oven and the tops of the pots. This is best prevented by introducing at first into the pots the whole of the salt mixed with the charcoal, the lime, and one-fourth part of the sand; fusing this mixture at a moderate heat, and adding gradually afterwards the remainder of the sand, increasing the temperature at the same time. If we put in the whole ingredients together, as is done with potash-glass, the sand and lime soon fall to the bottom, while the salt rises to the surface, and the combination becomes difficult and unequal.

Sulphate of potash acts in the same way as sulphate of soda.

Chloride of sodium also, according to Kirn, may be used as a glass-flux with advantage. The most suitable proportions are 4 parts of potash, 2 of common salt, and 3 of lime, agreeably to the following compositions:—

	1.	2.
Quartz-sand	60·0	57·1
Calcined carbonate of potash . . .	17·8	19·1
Common salt	8·9	9·5
Lime	13·3	14·3

For No. 1, the melting heat must be 10 hours, which turns out a very pure, solid, good glass; for No. 2, 23 hours of the furnace are required. Instead of the potash, Glauber salt may be substituted; the proportions being then 19·1 Glauber salt, 9·5 chloride of sodium, 14·3 lime, 57·1 sand, and 1·3 charcoal.

.The oxide of lead is an essential constituent of the denser glasses, and may be regarded as replacing the lime, so as to form with the quartz-sand a silicate of lead. It assimilates best with purified pearlash, on account of the freedom of this alkali from iron, which is present in most sodas.

Its atomic constitution may be represented as follows:—

				Computation	Analysis
Silica	5 atoms	=	2877·0	59·19	59·20
Oxide of lead	1	=	1394·5	28·68	28·20
Potash	1	=	590·0	12·13	9·00
Oxides of iron and manganese .			...	...	1·40
			4861·5	100·00	97·80

The above analysis by Berthier relates to a specimen of the best English crystal-glass, perfectly colourless and free from air-bubbles. This kind of glass may, however, take several different proportions of potash and silica to the oxide of lead.

The composition of mirror-plate, as made on the Continent, is as follows:—

White quartz-sand	300 lbs.
Dry carbonate of soda	100 ,,
Lime slaked in the air	43 ,,
Cullet, or old glass	300 ,,

The manganese should not exceed one-half per cent. of the weight of soda.

Optical glass requires to be made with very peculiar care. It is of two different kinds: namely, *crown-glass* and *flint-glass*. The latter contains a considerable proportion of lead, in order to give it an increased dispersive power upon the rays of light, in proportion to its mean refractive power.

Optical crown-glass should be perfectly limpid, and have so little colour, that a pretty thick piece of it may give no appreciable tinge to the rays of light. It should be exempt from striæ or veins as well as air-bubbles, and have not the slightest degree of milkiness. It should, moreover, preserve these qualities when worked in considerable quantities. Potash is preferable to soda for making optical crown-glass, because the latter alkali is apt to make a glass which devitrifies and becomes opalescent, by long exposure to heat in the annealing process. A simple potash-silicate would be free from this defect, but it would be too attractive of moisture, and apt to decompose eventually by the humidity of the atmosphere. It should, therefore, contain a small quantity of lime, and as little potash as suffices for making a perfect glass at a pretty high temperature. It is probably owing to the high heats used in the English crown-glass works, and the moderate quantity of alkali (soda) which is employed, that our crown-glass has been found to answer so well for optical purposes.

The following recipe for crown-glass is excellent:—

	Parts
5 atoms of silica (2½ ?)	80
1 carbonate of soda	54
5 silica	80
1 carbonate of lime	50
1 atom of carbonate of baryta	98
5 atoms of silica	80

Silicates of lime and baryta *per se*, or even combined, are very refractory; but they vitrify well along with a third silicate, such as that of soda or potash.

The following are additional recipes for making different kinds of glass:—

1. *Bottle glass.*—11 lbs. of dry Glauber salt; 12 of soaper salts; a half bushel of waste soap ashes; 56 lbs. of sand; 22 of glass skimmings; 1 cwt. of green broken glass; 25 lbs. of basalt. This mixture affords a dark green glass.

2. Yellow or white sand, 100 parts; kelp, 30 to 40; lixiviated wood ashes, from 160 to 170; fresh wood ashes, 30 to 40; potter's clay, 80 to 100; cullet or broken glass, 100. If basalt be used, the proportion of kelp may be diminished.

In two bottle-glass houses in the neighbourhood of Valenciennes, an unknown ingredient, sold by a Belgian, was employed, which he called *spar*. This was discovered by chemical analysis to be sulphate of baryta. The glass-makers observed that the bottles which contained some of this substance were denser, more homogeneous, more fusible, and worked more kindly than those formed of the common materials. When one equivalent of the silicate of baryta = 123, is mixed with three of the silicate of soda = (3 × 77·6) 232·8, and exposed in a proper furnace, vitrification readily ensues, and the glass may be worked a little under a cherry-red heat, with as much ease as a glass of lead, and has nearly the same lustre.

3. *Green window-glass, or broad glass.*—11 lbs. of dry Glauber salt; 10 of soaper salts; half a bushel of lixiviated soap waste; 50 lbs. of sand; 22 of glass-pot skimmings; 1 cwt. of broken green glass.

4. *Crown-glass.*—300 parts of fine sand; 200 of good soda ash; 33 of lime; from 250 to 300 of broken glass; 60 of white sand; 30 of purified potash; 15 of saltpetre (1 of borax); ½ of arsenious acid.

5. *Nearly white table-glass.*—20 lbs. of potashes; 11 of dry Glauber salt; 16 of soaper salt; 55 of sand; 140 of cullet of the same kind.

Another.—100 lbs. of sand; 235 of kelp; 60 of wood ashes; 1⅓ of manganese; 100 of broken glass.

6. *White table-glass.*—40 lbs. of potashes; 11 of chalk; 76 of sand; ½ of manganese; 95 of white cullet.

Another.—50 lbs. of purified potashes; 100 of sand; 20 of chalk; 2 of saltpetre.

Bohemian table- or plate-glass is made with 63 parts of quartz; 26 of purified potashes; 11 of sifted slaked lime; and some cullet.

7. *Crystal glass.*—60 parts of purified potashes; 120 of sand; 24 of chalk; 2 of saltpetre; 2 of arsenious acid; $\frac{1}{16}$ of manganese.

Another.—70 parts of purified pearlashes; 120 of white sand; 10 of saltpetre; ½ of arsenious acid; ⅓ of manganese.

A third.—67 parts of sand; 23 of purified pearlashes; 10 of sifted slaked lime; ¼ of manganese; (5 to 8 of red lead).

A fourth.—120 parts of white sand; 50 of red lead; 40 of purified pearlashes; 20 of saltpetre; ⅓ of manganese.

A fifth.—120 parts of white sand; 40 of purified pearlashes; 35 of red lead; 13 of saltpetre; $\frac{1}{12}$ of manganese.

A sixth.—30 parts of the finest sand; 20 of red lead; 8 of purified pearlashes; 2 of saltpetre; a little arsenious acid and manganese.

A seventh.—100 parts of sand; 45 of red lead; 35 of purified pearlashes; ⅐ of manganese; ⅕ of arsenious acid.

8. *Plate-glass.*—300 parts of very white sand; 100 of dry purified soda; 43 of carbonate of lime; 1 of manganese; 300 of cullet.

Another.—720 parts of finest sand; 450 of purified soda; 80 of quicklime; 25 of saltpetre; 425 of cullet.

A little borax has also been prescribed; much of it communicates an exfoliating property to glass.

Practical Details of the Manufacture of Glass.

There are five different species of glass, each requiring a peculiar mode of fabrication and peculiar materials:—1. The coarsest and simplest form of this manufacture is *bottle-glass*. 2. Next to it in cheapness of material may be ranked *broad* or *spread window-glass*. An improved article of this kind is now made near Birmingham, under the name of British or German plate. 3. *Crown-glass* comes next, or window-glass, formed in large circular plates or discs. This glass is peculiar to Great Britain. 4. *Flint-glass*, *crystal-glass*, or glass of lead. 5. *Plate* or *fine mirror-glass*.

The Pots.—The materials of every kind of glass are vitrified in pots made of a pure refractory clay; the best kind of which is a species of shale or fire-clay dug out of the coal-measures near Stourbridge. It contains hardly any lime or iron, and consists of silica and alumina in nearly equal proportions. The masses are carefully picked, brushed, and ground under edge iron wheels of considerable weight, and sifted through sieves having 20 meshes in the square inch. This powder is moistened with water (best hot), and kneaded by the feet or a loam-mill into an uniform smooth paste. A large body of this dough should be made up at a time, and laid by in a damp cellar to ripen. Previously to working it into shapes, it should be mixed with about a fourth of its weight of cement of old pots, ground to powder. This mixture is sufficiently plastic, and being less contractile by heat, forms more solid and durable vessels. Glass-house pots have the figure of a truncated cone, with the narrow end undermost; those for bottle- and window-glass being open at top, about 30 inches diameter at bottom, 40 inches at the mouth, and 40 inches deep; but the flint-glass pots are covered in at top with a dome-cap, having a mouth at the side, by which the materials are introduced, and the glass is extracted. Bottle and crown-house pots are from 3 to 4 inches thick; those for flint-houses are an inch thinner, and of proportionally smaller capacity. See Clay.

The well-mixed and kneaded dough is first worked upon a board into a cake for the bottom; over this the sides are raised, by laying on its edges rolls of clay above each other with much manual labour, and careful condensation. The clay is made into lumps, is equalised, and slapped much in the same way as for making pottery. The pots thus fashioned must be dried very prudently, first in the atmospheric temperature, and finally in a stove floor, which usually borrows its heat directly from the glass-house. Before *setting the pots* in the furnace, they are annealed during 4 or 5 days, at a red heat in a small reverberatory vault made on purpose. When completely annealed, they are transferred with the utmost expedition into their seat in the fire, by means of powerful tongs supported on the axle of an iron-wheel carriage frame, and terminating in a long lever for raising them and swinging them round. The *pot-setting* is a desperate service, and when unskilfully conducted without due mechanical aids, is the forlorn hope of the glass-founder.

The glass-houses are usually built in the form of a cone from 60 to 100 feet high, and from 50 to 80 feet in diameter at the base. The furnace is constructed in the centre of the area, above an arched or groined gallery which extends across the whole space, and terminates without the walls, in large folding doors. This cavern must be sufficiently high to allow labourers to wheel out the cinders in their barrows. The middle of the vaulted top is left open in the building, and is covered over with the grate-bars of the furnace.

1. *Bottle-glass.*—The bottle-house and its furnace resembles nearly *fig.* 1092. The furnace is usually an oblong square chamber, built of large fire-bricks, and arched over with fire-stone, a siliceous grit of excellent quality extracted from the coal-measures of Newcastle. This furnace stands in the middle of the area; and has its base divided into three compartments. The central space is occupied with the grate-bars: and on either side is the platform or fire-brick *siége* (seat), raised about 12 inches above the level of the ribs upon which the pots rest. Each *siége* is about 3 feet broad.

In the sides of the furnace semi-circular holes of about a foot diameter are left, opposite to, and a little above the top of each pot, called working-holes, by which the workmen shovel in the materials, and take out the plastic gas. At each angle of the furnace there is likewise a hole of about the same size which communicates with the calcining furnace of a cylindrical form, dome-shaped at top. The flame that escapes from the founding or pot-furnace is thus economically brought to reverberate on the raw materials of the bottle-glass, so as to dissipate their carbonaceous or volatile impurities, and convert them into a frit. A bottle-house has generally eight other furnaces or fire arches; of which six are used for annealing the bottles after they are blown, and two for annealing the pots, before setting them in the furnace.

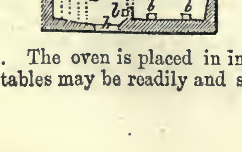
Generally, for common bottles, the common river-sand and soap-boilers' waste are used. About 3 parts of waste, consisting of the insoluble residuum of kelp mixed with lime, and a little saline substance, are employed for 1 part of sand. This waste is first of all calcined in two of the fire arches or reverberatories reserved for that purpose, called the coarse arches, where it is kept at a red heat, with occasional stirring; from 24 to 30 hours, being the period of a journey, or *journée*, in which the materials could be melted and worked into bottles. The roasted soap-waste is then withdrawn under the name of ashes, from its arch, coarsely ground, and mixed with its proper proportion of sand. This mixture is now put into the fire arch, and calcined during the working journey which extends to 10 or 12 hours. Whenever the pots are worked out, that frit is immediately transferred into them in its ignited state, and the founding process proceeds with such despatch that this first charge of materials is completely melted down in 6 hours, so that the pots might admit to be filled up again with the second charge of frit which is founded in 4 hours more. The heat is briskly continued, and in the course of from 12 to 8 hours, according to the size of the pots, the quality of the fuel, and the draught of the furnace, the vitrification is complete. Before blowing the bottles, however, the glass must be left to settle, and to cool down to the blowing consistency by shutting the *cave* doors and feeding holes, so as to exclude the air from the fire-grate and the bottom of the hearth. The glass or metal becomes more dense, and by its subsidence throws up the foreign lighter earthy and saline matters in the form of a scum on the surface, which is removed with skimming irons. The furnace is now charged with coal, to enable it to afford a working heat for 4 or 5 hours, at the end of which time more fuel is cautiously added to preserve adequate heat for finishing the *journey*.

It is hardly possible to convey in words alone a correct idea of the manipulations necessary to the formation of a wine-bottle. Six people are employed at this task; one, called a gatherer, dips the end of an iron tube, about five feet long, previously made red hot, into the pot of melted *metal*, turns the rod round so as to surround it with glass, lifts it out to cool a little, and then dips and turns it round again; and so in succession till a ball is formed on its end sufficient to make the required bottle. He then hands it to the blower, who rolls the plastic lump of glass on a smooth stone or cast-iron plate, till he brings it to the very end of the tube; he next introduces the pear-shaped ball into an open brass or cast-iron mould, shuts this together by pressing a pedal with his foot, and holding his tube vertically, blows through it, so as to expand the cooling glass into the form of the mould. Whenever he takes his foot from the pedal-lever, the mould simultaneously opens out into two halves and falls asunder by its bottom hinge. He then lifts the bottle up at the end of the rod and transfers it to the finisher, who, touching the glass-tube at the end of the pipe with a cold iron, cracks off the bottle smoothly at its mouth-ring. The finished bottles are immediately piled up in the hot annealing arch, where they are afterwards allowed to cool slowly for 24 hours at least.

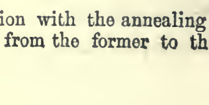
2. *Broad or spread window-glass.*—This kind of glass is called *inferior* window-glass in this country, because coarse in texture, of a wavy wrinkled surface, and very cheap; but on the Continent *spread* window-glass, being made with more care, is much better than ours, though still far inferior in transparency and polish to crown-glass, which has, therefore, nearly superseded it use among us. But Messrs. Chance and Co., of Birmingham, make *British sheet glass* upon the best principles, and turn out an article quite equal, if not superior, to anything of the kind made either in France or Belgium. Their materials are those used in the crown-glass manufacture. The vitrifying mixture is fritted for 20 or 30 hours in a reverberatory arch, with considerable stirring and puddling with long-handled shovels and rakes; and the frit is then transferred by shovels, while red hot, to the melting pots to be founded. When the glass is rightly vitrified, settled, and brought to a working heat, it is lifted out by iron tubes, blown into pears, which, being elongated into cylinders, are cracked up along one side parallel to the axis, by touching them with a cold iron dipped in water, and are then opened out into sheets. The glass cylinders are spread on a bed of smooth stone Paris-plaster, or laid on the bottom of a reverberatory arch; the cylinder being placed on its side horizontally, with the cracked line uppermost, gradually opens out, and flattens on the hearth. At one time, thick plates were thus prepared for subsequent polishing into mirrors; but the glass was never of very good quality; and this mode of making mirror-plate has accordingly been generally abandoned.

The spreading furnace or oven is that in which cylinders are expanded into tables or plates. It ought to be maintained at a brisk red heat, to facilitate the softening of the glass. The oven is placed in immediate connection with the annealing arch, so that the tables may be readily and safely transferred from the former to the latter.

1087



1088

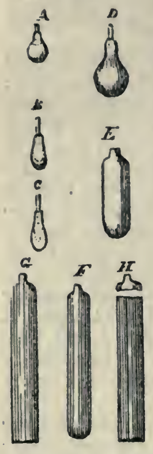


Sometimes the cylinders are spread in a large muffle-furnace, in order to protect them from being tarnished by sulphureous and carbonaceous fumes.

Fig. 1087 represents a ground plan of both the spreading and annealing furnace; *fig.* 1088 is an oblong section in the direction of the dotted-line *x x*, *fig.* 1087.

a is the fire-place; *b b*, the canals or flues through which the flame rises into both furnaces; *c*, the spreading furnace, upon whose sole is the spreading slab. *d*, is the cooling and annealing oven; *e e*, iron bars which extend obliquely across the annealing arch, and serve for resting the glass tables against during the cooling; *f f*, the channel along which the previously-cracked cylinders are slid, so as to be gradually warmed; *g*, the opening in the spreading furnace, for enabling the workmen to regulate the process; *h*, a door in the annealing arch, for introducing the tools requisite for raising up and removing the tables.

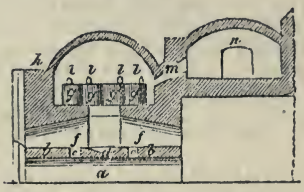
1089



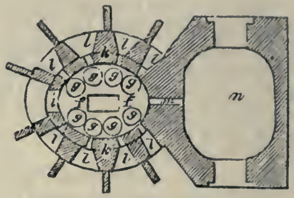
The series of transformations in sheet-glass, already described, is represented in *fig.* 1089, at A, B, C, D, E, F, G, H.

Figs. 1090 and 1091 represent a Bohemian furnace in which excellent white window-glass is founded. *Fig.* 1090 is a longitudinal section of the glass and annealing furnace. *Fig.* 1091 is the ground plan. *a* is the ash pit vaulted under the sole of the furnace; the fire-place itself is divided into three compartments, with a middle slab at *d*, which is hollowed in the centre, for collecting any split glass, and two hearth tiles or slabs *b b*. *c c* are the draught or air-holes; *e e* are arches upon which the bearing slabs *f f* partly rest. In the middle between these arches, the flame strikes upwards upon the pots *g g*, placed as closely together as possible for economy of room. *h* is the breast-wall of the furnace; *i*, *fig.* 1091, the opening through which the pots are introduced; it is bricked up as soon as they are set. *k k* is the base of the cone or dome of the furnace; *l l l*, the working orifices, which are made larger or smaller according to the size of the glass articles to be made. *m* is the flue which leads to the annealing stove *n*, with an arched door. Exterior to this there is usually a drying kiln, not shown in the figure; and there are adjoining stoves, called *arches*, for drying and annealing the new pots before they are set.

1090



1091



The cooling or annealing arch, or leer, is often built independent of the glass-house furnace; it is then heated by a separate fire-place, and constructed like a very long reverberatory furnace.

1092

The leer pans, or trays of sheet iron, are laid upon its bottom in an oblong series, and hooked to each other.

3. *Crown-glass.*—The crown-glass house with its furnace is represented in *fig.* 1092, where the *blowing* operation is shown on the one side of the figure, and the *flashing* on the other. The furnace is usually constructed to receive 4 or 6 pots, of such dimensions as to make about a ton of glass each at a time. There are, however, several subsidiary furnaces to a crown-house: 1, a reverberatory furnace or *calcar*, for calcining or fritting the materials; 2, a blowing furnace for blowing the pear-shaped balls made at the pot-holes, into large globes; 3, a flashing furnace, and bottoming hole for communicating a softening heat, in expanding the globe into a circular plate; 4, the annealing arch for the

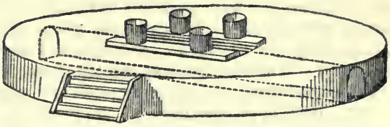
finished tables; 5, the reverberatory oven for annealing the pots prior to their being set upon the founding *siége*.

The materials of crown-glass used to be, fine sand, by measure 5 parts, or by weight 10; ground kelp, by measure 11 parts, or by weight 16½; but instead of kelp, soda-ash is now generally employed. From 6 to 8 cwts. of sand, lime, and soda-ash, mixed together in wooden boxes with a shovel are thrown on the sole of a large reverberatory. Here the mixture is well worked together with iron paddles, flat shovels, and rakes with long handles; the area of this furnace, being about 6 feet square, and the height 2 feet. The heat soon brings the materials to a pasty consistence, when they must be diligently turned over, to favour the dissipation of the carbon, sulphur, and other volatile matters of the kelp or soda-ash, and to incorporate the fixed ingredients uniformly with the sand. Towards the end of 3 hours, the fire is considerably raised, and when the fourth hour has expired, the fritting operation is finished. The mass is now shovelled or raked out into shallow cast-iron square cases, smoothed down, and divided before it hardens by cooling, into square lumps, by cross sections with the spade. These frit-bricks are afterwards piled up in a large apartment for use; and have been supposed to improve with age, by the efflorescence of their saline constituents into carbonate of soda on their surface.

The founding-pots are filled up with these blocks of frit, and the furnace is powerfully urged by opening all the subterranean passages to its grate, and closing all the doors and windows of the glass-house itself. After 8 or 10 hours the vitrification has made such progress, and the blocks first introduced are so far melted down, that another charge of frit can be thrown in, and thus the pot is fed with frit till the proper quantity is used. In about 16 hours the vitrification of the frit has taken place, and a considerable quantity, amounting often to the cwt. of liquid saline matter floats over the glass. This salt is carefully skimmed off into iron pots with long ladles. It is called Sandiver, or Glass-gall, and consists usually of chloride of sodium, with a little sulphate. The pot is now ready for receiving the *topping of cullet*, which is broken pieces of window-glass, to the amount of 3 or 4 cwts. This is shovelled in at short intervals; and as its pressure forces up the residuary saline matter, this is removed; for were it allowed to remain, the body of the glass would be materially deteriorated.

The heat is still continued for several hours till the glass is perfect, and the extrication of gas called the *boil*, which accompanies the fusion of crown-glass, has nearly terminated, when the fire is abated by shutting up the lower vault doors and every avenue to the grate, in order that the glass may settle fine. At the end of about 40 hours altogether, the fire being slightly raised by adding some coals, and opening the doors, the glass is carefully skimmed, and the working of the pots commences.

1093



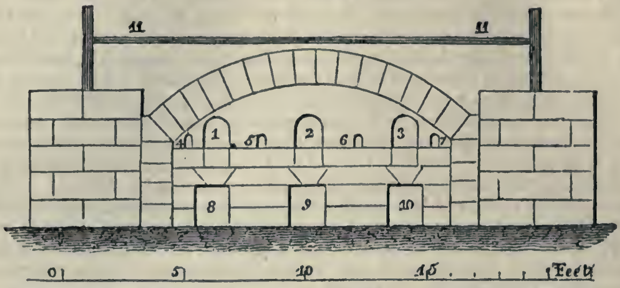
Before describing it, however, we may state that the marginal figure, 1093, shows the base of the crown-house cone, with the four open pots in two ranges, on opposite sides of the furnace, sitting on their raised *siéges* at each side of the grate. At one side of the base the door of the vault is shown, and its course is marked by the dotted lines.

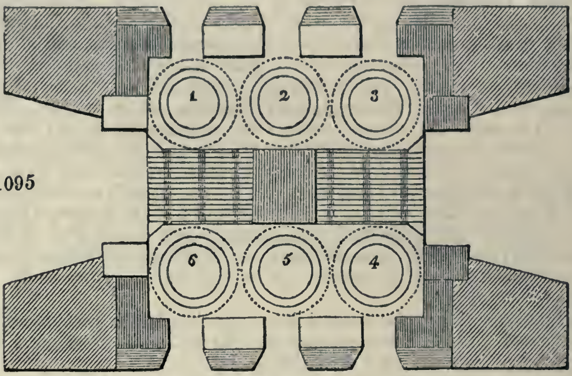
The crown-glass furnace, *figs.* 1094, 1095, is an oblong square, built in the centre of a brick cone, large enough to contain within it two or three pots at each side of the grate room, which is either divided as shown in the plan, or runs the whole length of the furnace, as the manufacturer chooses. *Fig.* 1095 is a ground plan, and *fig.* 1094 a front elevation of a six-pot furnace. 1, 2, 3, *fig.* 1094, are the working holes for the purposes of ventilation, of putting in the materials, and taking out the metal to be wrought. 4, 5, 6, 7, are pipe-holes for warming the pipes before beginning to work with them. 8, 9, 10, are foot holes for mending the pots and *siéges*. 11 is a bar of iron for binding the furnace, and keeping it from swelling.

The arch is of an elliptic form; though a barrel arch, that is, an arch shaped like the half of a barrel cut longwise through the centre, is sometimes used. But this soon gives way when used in the manufacture of crown-glass, although it does very well in the clay-furnace used for bottle-houses.

The best stone for building furnaces is fire-stone; it may be obtained in the neighbourhood of Newcastle from the coal-measures generally, and some of the sandstones of the eastern counties are found to answer the purpose admirably. The great danger in building furnaces is, lest the cement at the top should give way with the excessive heat, and by dropping into the pots, spoil the metal. The top should therefore be built with stones only, as loose as they can hold together after the centres are removed, and without any cement whatever. The stones expand and come quite close together when annealing: an operation which takes from eight to fourteen days at most. There is thus less risk of anything dropping from the roof of the furnace.

1094





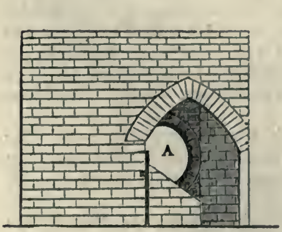
1095

The inside of the square of the furnace is built either of Stourbridge fire-clay annealed, or of fire-stone, to the thickness of sixteen inches. The outside is built of common brick, about nine inches in thickness.

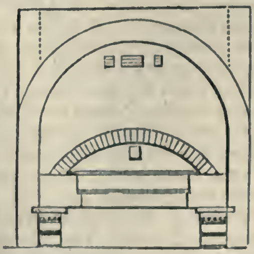
The furnace is thrown over an ash-pit, or cave as it is called, which admits the atmospheric air, and promotes the combustion in the furnace. This cave is built of stone until it comes beneath the grate room, when it is formed of fire-brick. The abutments are useful for binding and keeping the furnace together, and are built of masonry. The furnaces are stoutly clasped with iron all round, to keep them tight. In four-pot furnaces this is unnecessary, provided there be four good abutments.

Fig. 1096 is an elevation of the flashing furnace. The outside is built of common brick, the inside of fire-brick, and the mouth or nose of Stourbridge fire-clay.

1096



1097



1098

Fig. 1097 is the annealing kiln. It is built of common brick, except round the grate-room, where fire-brick is used.

Few tools are needed for blowing and flashing crown-glass. The requisite ball of plastic glass is gathered, in successive layers as for bottles, on the end of an iron tube, and rolled into a pear-shape, on a cast-iron plate; the workman taking care that the air blown into its cavity is surrounded with an equal body of glass, and if he perceives any side to be thicker than another, he corrects the inequality by rolling it on the sloping iron table called a marver (marbre). He now heats the bulb in the fire, and rolls it so as to form the glass upon the end of the tube, and by a dexterous swing or two he lengthens it, as shown in I, *fig.* 1098. To extend the neck of that pear, he next rolls it over a smooth iron rod, turned round in a horizontal direction, into the shape K, *fig.* 1098. By further expansion at the blowing furnace, he now brings it to the shape L, represented in *fig.* 1098.

This spheroid having become cool and somewhat stiff, is next carried to the bottoming hole (like *fig.* 1096), to be exposed to the action of flame. A slight wall erected before one half of this hole, screens the workman from the heat, but leaves room for the globe to pass between it and the posterior wall. The blowing-pipe is made to rest a little way from the neck of the globe, on a hook fixed in the front wall; and thus may be made easily to revolve on its axis, and by giving centrifugal force to the globe, while the bottom of it, or part opposite to the pipe, is softened by the heat, it soon assumes the form exhibited in M, *fig.* 1098.

In this state the flattened globe is removed from the fire, and its rod being rested on the *casher box* covered with coal cinders, another workman now applies the end of a solid iron rod tipped with melted glass, called a *punto*, to the nipple or prominence in the middle; and thus attaches it to the centre of the globe, while the first workman cracks off the globe by touching its tubular neck with an iron chisel dipped in cold water. The workman having thereby taken possession of the globe by its bottom or knobbled pole attached to its punty rod, he now carries it to another circular opening, where he exposes it to the action of moderate flame with regular rotation, and thus slowly heats the thick projecting remains of the former neck, and opens it slightly out, as shown at N, in *fig.* 1098. He next hands it to the *flasher*, who, resting the iron rod in a hook placed near the side of the orifice A, *fig.* 1096, wheels it rapidly round opposite to a powerful flame, till it assumes first the figure O, *fig.* 1098, and finally that of a flat circular table.

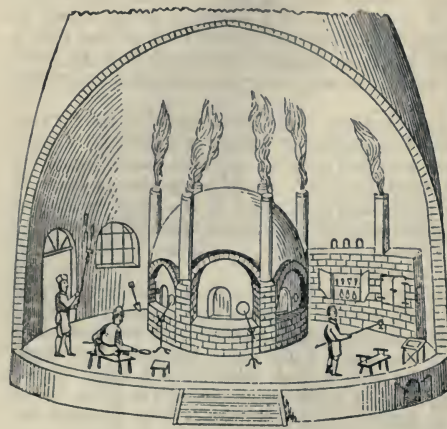
The flasher then walks off with the table, keeping up a slight rotation as he moves along, and when it is sufficiently cool, he turns down his rod into a vertical position, and lays the table flat on a dry block of fire-clay, or bed of sand, when an assistant nips it off from the *punto* with a pair of long iron shears, or cracks it off with a touch of cold iron. The loose table or plate is lastly lifted up horizontally on a double pronged iron fork, introduced into the annealing arch, *fig.* 1097, and raised on edge; an assistant with a long-kneed fork preventing it from falling too rapidly backwards. In this arch a great many tables of glass are piled up in iron frames, and slowly cooled from a heat of about 600° to 100° F., which takes about 24 hours; when they are removed. A circular plate or table of about 5 feet diameter weighs on an average 9 pounds.

4. *Flint-glass.*—This kind of glass is so called because originally made with calcined flints, as the siliceous ingredient. The materials at present employed in this country for the finest flint-glass are, first, sand, calcined, sifted, and washed; second, an oxide of lead, either red lead or litharge; and third, pearlash. Sand for flint-glass manufacture is obtained from the Isle of Wight, Aylesbury, the New Forest, and some other localities in this country. A very beautiful sand is brought from America, and some has been sent home from Australia. The pearl-ash of commerce must however be purified by digesting it in a very little hot water, which dissolves the carbonate of potash, and leaves the foreign salts, chiefly sulphate of potash, and chlorides of potassium and sodium. The solution of the carbonate being allowed to cool and become clear in lead pans, is then run off into a shallow iron boiler, and evaporated to dryness. Nitre is generally added as a fourth ingredient of the body of the glass; and it serves to correct any imperfections which might arise from accidental combustible particles, or from the lead being not duly oxidised. The above four substances constitute the main articles; to which we may add, arsenic and manganese, introduced in very small quantities, to purify the colour and clear up the transparency of the glass. The black oxide of manganese, when used in such quantity only as to peroxidise the iron of the sand, simply removes the green tinge caused by the protoxide of iron; but if more manganese be added than accomplishes that purpose, it will give a purple tinge to the glass. The arsenic is supposed to counteract the injury arising from excess of manganese, but is itself very apt on the other hand to communicate some degree of opalescence, or at least to impair the lustre of the glass.

The raw materials of flint-glass are always mixed with about a third or a fourth of their weight of broken glass of like quality; this mixture is thrown into the pot with a shovel; and more is added whenever the preceding portions by melting subside;

the object being to obtain a pot full of glass, to facilitate the skimming off the impurities and sandiver. The mouth of the pot is now shut, by applying clay-lute round the stopper, with the exception of a small orifice below, for the escape of the liquid saline matter. Flint-glass requires about 48 hours for its complete vitrification, though the materials are more fusible than those of crown-glass; in consequence of the contents of the pot being partially screened by its cover from the action of the fire, as also from the lower intensity of the heat.

1099



1100

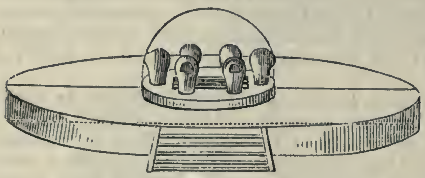


Fig. 1099 represents a flint-glass house for 6 pots with the arch or leer on one side for annealing the crystal ware. In *fig.* 1100, the base of the cone is seen, and the glass pots *in situ* on their platform ranged round the central fire-grate. The dotted line denotes the contour of the furnace, *fig.* 1099.

Whenever the glass appears fine, and is freed from its air-bubbles, which it usually is in about 36 hours, the heat is suffered to fall a little by closing the bottom valves, &c., that the pot may settle; but prior to working the metal, the heat is *somewhat raised* again.

It would be useless to describe the manual operations of fashioning the various articles of the flint-glass manufacture, because they are indefinitely varied to suit the conveniences and caprices of human society.

Every different flint-house has a peculiar proportion of glass materials. The following have been offered as good practical mixtures:—

1.	Fine white sand	300 parts.
	Red lead or litharge	200
	Refined pearl-ashes	80
	Nitre	20
	Arsenic and manganese, a minute quantity.	

2.	Fine sand	50·5
	Litharge	27·2
	Refined pearl-ashes (carbonate of potash, with 5 per cent. of water)	17·5
	Nitre	4·8
		100·0

To these quantities from 30 to 50 parts of broken glass, or cullet, are added, with about a two-thousandth part of manganese and a three-thousandth part of arsenic. But manganese varies so extremely in its purity, and contains often so much oxide of iron, that nothing can be predicated as to its quantity previously to trial.

M. Payen, an eminent manufacturing chemist in France, says that the composition of 'crystal' (the name given in France to their finest flint-glass) does not deviate much from the following proportions:—

	Wood fire.	Coal fire.
Siliceous sand	3	3
Minium	2	2¼
Carbonate of potash	1½	1⅔

The flint-glass *leer* for annealing glass is an arched gallery or large flue, about 36 feet long, 3 feet high, 4 wide; having its floor raised above 2 feet above the ground of the glass-house. The hot air and smoke of a fire-place at one end pass along this gallery, and are discharged by a chimney 8 or 10 feet short of the other end. On the floor of the vault, large iron trays are laid and hooked to each other in a series, which are drawn from the fire-end towards the other by a chain, wound about a cylinder by a winch-handle projecting through the side. The flint-glass articles are placed in their hot state into the tray next the fire, which is moved onwards to a cooler station whenever it is filled, and an empty tray is set in its place. Thus, in the course of about 20 hours, the glass advances to the cool end thoroughly annealed.

Besides colourless transparent glass, which forms the most important part of this manufacture, various coloured glasses are made to suit the taste of the public. The opaline crystal may be prepared by adding to the above composition (No. 2) phosphate of lime, or well-burnt bone-ash in fine powder, washed and dried. The article must be as uniform in thickness as possible, and speedily worked into shape, with a moderate heat. Oxide of tin, *putty-powder*, was formerly used for making opalescent glass, but the lustre of the body was always impaired by its means.

Crystal vessels are made of which the inner surface is colourless, and all the external facets coloured. Such works are easily executed. The end of the blowing-rod must be dipped first in the pot containing colourless glass, to form a bulb of a certain size, which being cooled a little is then dipped for an instant into the pot of coloured glass. The two layers are associated without intermixture; and when the article is finished in its form, it is white within and coloured without. Fluted lines somewhat deeply cut, pass through the coloured coat, and enter the colourless one; so that when they cross, their ends alone are coloured.

For some time past, likewise, various crystal articles have been exhibited in the market with coloured enamel figures on their surface, or with white incrustations of a silvery lustre in their interior. The former are prepared by placing the enamel object in the brass mould, at the place where it is sought to be attached. The bulb of glass being put into the mould, and blown while very hot, the small plate of enamel gets cemented to the surface. For making the white argentine incrustations, small figures are prepared with an impalpable powder of dry porcelain paste, cemented into a solid by means of a little gypsum plaster. When these pieces are thoroughly dried, they are laid on the glass while it is red hot, and a large patch of very liquid glass is placed above it, so as to encase it and form one body with the whole. In this way the incrustation is completely enclosed; and the polished surface of the crystal which scarcely touches it, gives a brilliant aspect, pleasing to the eye.

Optical Glass.—An uniform flint-glass, free from striæ, or *wreath*, is much in demand for the optician. It would appear that such an article was much more commonly made by the English manufacturers many years ago than at present; and that in improving the brilliancy of crystal-glass they have injured its fitness for constructing optical lenses, which depends, not so much on its whiteness and lustre, as on its homogeneous character. Even a potful of pretty uniform glass, when it stands sometime liquid, becomes eventually unequable by the subsidence of the denser portions; so that striæ and gelatinous appearances begin to manifest themselves, and the glass becomes of little value. Gas allowed to cool slowly in mass in the pot is particularly full of wreath, and if quickly refrigerated, that is, in two or three hours, it is apt to split into a multitude of minute splinters, of which no use can be made. For optical purposes, the glass must be taken out in its liquid state, being gathered on the end of the iron rod from the central portion of a recently-skimmed pot, after the upper layers have been worked off in general articles.

M. Guinand, of Brenets near Neufchâtel, a workman in the watch and clock trade, appears to have discovered processes that furnished almost certainly pieces of flint-glass capable of forming good lenses of remarkable dimensions, even of 11 inches diameter, of adequate density and transparency, and nearly free from striæ. Guinand's plan consisted mainly in thoroughly mixing the melted 'metal' with an iron rod. Guinand joined M. Frauenhofer, of Munich, and one of the largest of the lenses produced by them, the diameter of which is 9 inches, is now in the observatory at Dorpat.

M. Cauchoix, the eminent French optician, says, that out of ten object-glasses, 4 inches in diameter, made with M. Guinand's flint-glass, eight or nine turned out very good, while out of an equal number of object-glasses made of the flint-glass of the English and French manufactories, only one, or two at most, were found serviceable.

Guinand was long in communication with the Royal Astronomical Society of London; and he sent over some discs on flint-glass, of which Messrs. Dollond and Herschel made a favourable report. A commission was formed, consisting of Herschel, Dollond, Faraday, and Roget, but owing to the annoying interferences of the Excise officers, notwithstanding the Government had made some special exceptions in favour of these scientific experiments, the results were not practically of that high value which might have been expected. Many of the observations however, were of great value. Amongst other discoveries might be named the remarkable heavy glass, the *Silico-borate of lead*, with which the discovery of the 'so-called' magnetism of a ray of light was made. M. Guinand died, and one of his sons worked with M. Bontemps, while the widow and another son set up works in Switzerland. From their manufactory some examples of lenses were sent to the Great Exhibition of 1851. M. Bontemps was in 1848 prevailed upon to accept the invitation of Messrs. Chance Brothers and Co. to unite with them in attempts they were then making to improve the quality of glass. They succeeded in producing discs of extraordinary dimensions in flint of 29 inches diameter, weighing two cwts. and of crown-glass up to 20 inches. Messrs. Chance, at the recommendation of the Jury, were induced to submit their disc of flint-glass to the operation of grinding, finishing, and other processes necessary in order to ascertain the uniformity of its density throughout, and its superior quality was fully established.

M. Maës of Clichy, near Paris, proposes to manufacture optical glass, with the addition of baryta, magnesia, and oxide of zinc, in combination with boracic acid. The glass manufactured by M. Maës is exceedingly beautiful, but the boracic acid renders it very expensive.

An achromatic object-glass for telescopes and microscopes consists of at least two lenses; the one made with glass of lead, or flint-glass, and the other with crown-glass; the former possessing a power of dispersing the coloured rays relatively to its mean refractive power much greater than the latter; upon which principle, the achromatism of the image is produced, by re-uniting the different coloured rays into one focus. Three plans have been prescribed for obtaining homogeneous pieces of optical glass: 1, to lift a mass of it in large ladles, and let it cool in them; 2, to pour it out from the pots into moulds; 3, to allow it to cool in the pots, and afterwards to cut it off in horizontal strata. The last method seldom affords pieces of uniform density, unless peculiar precautions have been adopted to settle the flint-glass in uniform strata; because its materials are of such unequal density, the oxide of lead having a specific gravity of 8, and silica of 2·7, that they are apt to stand at irregular heights in the pots.

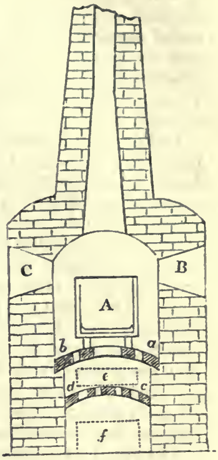
One main cause of these inequalities lies in the construction of the furnace, whereby the bottom of the pot is usually much less heated than the upper part. In a plate-glass furnace the temperature of the top of the pot has been found to be 130° Wedgw., while that of the bottom was only 110°, constituting a difference of no less than 2160° F. The necessary consequence is that the denser particles which subside to the bottom during the fusion of the materials, and after the first extrication of the gases, must remain there not, being duly agitated by the expansive force of heat, acting from below upwards.

The following suggestions, deduced from a consideration of principles, may probably lead to some improvements, if judiciously applied. The great object is to counteract the tendency of the glass of lead to distribute itself into strata of different densities; which may be effected either by mechanical agitation or by applying the greatest heat to the bottom of the pot. But however homogeneous the glass may be thereby made, its subsequent separation into strata of different densities must be prevented by rapid cooling and solidification. As the deeper the pots, the greater is the chance of unequal specific gravity in their contents, it would be advisable to make them wider and shallower than those in use for making ordinary glass. The intermixture may be effected either by lading the glass out of one pot into another in the furnace, and back again, with copper ladles, or by stirring it up with a rouser, and then allowing it to settle for a short time, till it becomes clear and free from air-bubbles. The pot may now be removed from the furnace, in order to solidify its contents in their homogeneous state; after which the glass may be broken in pieces, and be perfected by subjecting it to a second fusion; or what is easier and quicker, we may form suitable discs of glass without breaking down the potful, by lifting it out in flat copper ladles with iron shanks and transferring the lumps after a little while into the annealing leer.

To render a potful of glass homogeneous by agitation is a most difficult task as an iron rod would discolour it, and a copper rod would be apt to melt. An iron rod sheathed in laminated platinum would answer well, but for its expense. A stoneware tube supported within by a rod of iron might also be employed for the purpose in careful hands; the stirring being repeated several times, till at least the glass is suffered to stiffen a little by decrease of temperature. It must then be allowed to settle and cool, after which the pot, being of small dimensions, may be drawn out of the fire.

The second method of producing the desired uniformity of mixture, consists in applying a greater heat to the bottom than to the upper part of the melting pot. *Fig.* 1101 represents in section a furnace contrived to effect this object. It is cylindrical, and of a diameter no greater than to allow the flames to play round the pot, containing from three to four cwts. of vitreous materials. A is the pot resting upon the arched grid *b a*, built of fire-bricks, whose apertures are wide enough to let the flames rise freely, and strike the bottom and sides of the vessel. From 1½ to 2 feet under that arch, the fuel grate *c d* is placed. B C are the two working openings for introducing the materials and inspecting the progress of the fusion; they must be closed with fire-tiles and luted with fire-clay at the beginning of the process. At the back of the furnace, opposite the mouth of the fire-place, there is a doorway, which is bricked up, except upon occasion of putting in and taking out the pot. The draught is regulated by means of a slide-plate, upon the mouth of the ash-pit *f*. The pot being heated to the proper pitch, some purified pearl-ash, mixed with fully twice its weight of colourless quartz-sand, is to be thrown into it, and after the complete fusion of this mixture, the remaining part of the sand, along with the oxide of lead (fine litharge), is to be strewn upon the surface. These siliceous particles in their descent serve to extricate the air from the mass. Whenever the whole is fused, the heat must be strongly urged to insure a complete uniformity of combination by the internal motions of the particles. As soon as the gas has been found by making test phials to be perfectly fine, the fire must be withdrawn, the two working-holes must be opened, as well as the mouths of the fire-place and ash-pit to admit free ingress to cooling currents of air, so as to congeal the liquid mass as quickly as possible; a condition essential to the uniformity of the glass. It may be worth while to stir it a little with the pottery rod at the commencement of the cooling process. The solidified glass may be afterwards detached, by a hammer, in conchoidal discs, which after chipping off their edges, are to be placed in proper porcelain or stone-ware dishes, and exposed to a softening heat, in order to give them a lenticular shape. Great care must be taken that the heat thus applied by the muffle furnace be very equable, for otherwise wreathes might be very readily produced in the discs. A small oven upon the plan of a baker's is best fitted for this purpose, which being heated to dull redness, and then extinguished, is ready to soften and afterwards anneal the conchoidal pieces.

1101



Guinand's dense optical flint-glass of specific gravity 3·616, consists, by analysis, of oxide of lead, 43·05; silica, 44·3; and potash, 11·75; but requires for its formation the following ingredients:—100 pounds of ground quartz; 100 pounds of fine red lead; 35 pounds of purified potash; and from 2 to 4 pounds of saltpetre. As this species of glass is injured by an excess of potash, it should be compounded with rather a defect of it, and melted by a proportionably higher or longer heat. A good optical glass has been made in Germany with 7 parts of pure red lead, 3 parts of finely-ground quartz, and 2 parts of calcined borax.

5. *Plate-glass.*—This, like English crown-glass, has a soda flux, whereas flint-glass requires potash, and is never of good quality when made with soda. We shall distribute our account of this manufacture under two heads:

1. The different furnaces and principal machines, without whose knowledge it would be impossible to understand the several processes of a plate-glass factory.

2. The materials which enter into the composition of this kind of glass, and the series of operations which they undergo; devoting our chief attention to the changes and improvements which long experience, enlightened by modern chemistry, has introduced into the great manufactory of St. Gobain in France, under the direction of M. Tassaert. It may, however, be remarked that the English plate-glass manufacture derives peculiar advantages from the excellence of its grinding and polishing machinery.

The following description given by Dr. Ure refers almost entirely to the manufacture of plate-glass in France. It is retained in nearly its original form, and is, in all respects, applicable to the manufacture of plate-glass in this country.

The clay for making the bricks and pots should be free from lime and iron, and very refractory. It is mixed with the powder of old pots passed through a silk sieve. If the clay be very plastic it will bear its own weight of the powder, but if shorter in quality, it will take only three-fifths. But before mingling it with the cement of old pots, it must be dried, bruised, then picked, ground, and finally elutriated by agitation with water, decantation through a hair-sieve, and subsidence. The clay fluid after passing the sieve is called *slip* (*coulis*).

The furnace is built of dry bricks, cemented with slip, and has at each of its four angles a peculiar annealing arch, which communicates with the furnace interiorly, and thence derives sufficient heat to effect in part, if not wholly, the annealing of the pots, which are always deposited there a long time before they are used. Three of these arches, exclusively appropriated to this purpose, are called pot-arches. The fourth is called the *arch of the materials*, because it serves for drying them before they are founded. Each arch has, moreover, a principal opening called the throat, another called *bonnard*, by the French workmen, through which fire may be kindled in the arch itself, when it was thought to be necessary for the annealing of the pots; a practice now abandoned. The duration of a furnace is commonly a year, or at most 14 months; that of the arches is 30 years or upwards, as they are not exposed to so strong a heat.

In the manufacture of plate-glass, two sorts of crucibles are employed, called the pots and the basins (*cuvettes*). The first serve for containing the materials to be founded, and for keeping them a long time in the melted state. The *cuvettes* receive the melted glass, after it is refined, and decant it out on the table to be rolled into a plate. Three pots hold liquid glass for six small basins, or for three large ones, the latter being employed for making mirrors of great dimensions, that is, 100 inches long and upwards. Furnaces have been constructed with 6 pots and 12 *cuvettes*, 8 of which are small and 4 large; and *cuvettes* of three sizes are made, called *small*, *middling*, and *large*. The small are perfect cubes, the middling and the large ones are oblong parallelopipeds. Towards the middle of their height, a notch, or groove, two or three inches broad, and an inch deep, is left, called the girdle of the *cuvette*, by which part they are grasped with the tongs, or rather are clamped in the iron frame. This frame goes round the four sides of the small *cuvettes*, and may be placed indifferently upon all their sides; in the other *cuvettes*, the girdle extends only over the two large sides, because they cannot be turned up. See *m* T, *fig.* 1102.

The pot is an inverted truncated cone, like a crown-glass pot. It is about 30 inches high, and from 30 to 32 inches wide, including its thickness. There is only a few inches of difference between the diameter of the top and that of the bottom. The bottom is three inches thick, and the body turns gradually thinner till it is an inch at the mouth of the pot.

The large building or factory, of which the melting furnace occupies the middle space, is called the *halle* in French. At Ravenhead in Lancashire it is called the foundry, and is of magnificent dimensions; its length is 339 feet, and its breadth 155. The famous *halle* of St. Gobain is 174 feet by 120. Along the two side-walls of the *halle*, which are solidly constructed of hewn stone, there are openings like those of common ovens. These ovens, destined for the annealing of the newly cast plates, bear the name of *carquaises*. Their soles are raised two feet and a half above the level of the ground, in order to bring them into the same horizontal plane with the casting tables. Their length, amounting sometimes to 30 feet, and their breadth to 20, are required in order to accommodate 6, 8, or even 10 plates of glass alongside of each other. The front aperture is called the throat, and the back door the little throat (*gueulette*). The carquaise is heated by means of a fire-place of a square form, called a *tisar*, which extends along its side.

The founding or melting furnace is a square brick building laid on solid foundations, being from 8 to 10 feet in each of its fronts, and rising inside into a vault or crown about 10 feet high. At each angle of this square, a small oven or arch is constructed, likewise vaulted within, and communicating with the melting furnace by square flues, called *lunettes*, through which it receives a powerful heat, though much inferior to that round the pots. The arches are so distributed as that two of the exterior sides of the furnace stand wholly free, while the two other sides, on which the arches encroach. offer a free space of only 3 feet. In this interjacent space, two principal openings of the furnace, of equal size in each side, are left in the building. These are called tunnels. They are destined for the introduction of the pots and the fuel.

On looking through the tunnels into the side of the furnace, we perceive to the right hand and the left, along the two *free* sides, two low platforms or *siéges*, at least 30 inches in height and breadth. See *figs.* 1093, 1095.

These *siéges* (seats) being intended to support the pots and the cuvettes filled with heavy materials, are terminated by a slope, which ensures the solidity of the fire-clay mound. The slopes of the two *siéges* extend towards the middle of the furnace so near as to leave a space of only from 6 to 10 inches between them for the hearth. The end of this is perforated with a hole sufficiently large to give passage to the liquid glass of a broken pot, while the rest is preserved by lading it from the mouth into the adjoining cuvette.

In the two large parallel sides of the furnace, other apertures are left, much smaller than the tunnels, which are called *ouvreaux*, (peep-holes). The lower ones, or the *ouvreaux en bas*, called *cuvette*-openings, because, being allotted to the admission of these vessels, they are exactly on a level with the surface of the *siéges*, and with the floor of the *halle*. Plates of cast iron form the thresholds of these openings, and facilitate the ingress and egress of the *cuvettes*. The apertures are arched at the top, with hewn stone like the tunnels, and are 18 inches wide when the *cuvettes* are 16 inches broad.

The upper and smaller apertures, or the higher *ouvreaux*, called the *lading* holes, because they serve for transvasing the liquid glass, are three in number, and are placed 31 or 32 inches above the surface of the *siéges*. As the pots are only 30 inches high, it becomes easy to work through these openings either in the pots or the *cuvettes*. The pots stand opposite to the two pillars which separate the openings, so that a space is left between them for one or more *cuvettes* according to the size of the latter. It is obvious that if the tunnels and *ouvreaux* were left open, the furnace would not draw or take the requisite founding heat. Hence the openings are shut by means of fire-tiles. These are put in their places, and removed by means of two holes left in them in correspondence with the two prongs of a large iron fork supported by an axle and two iron wheels, and terminated by two handles which the workmen lay hold of when they wish to move the tile.

The closing of the tunnel is more complex. When it is shut or ready for the firing, the aperture appears built up with bricks and mortar from the top of the arch to the middle of the tunnel. The remainder of the doorway is closed,—1. on the two sides down to the bottom, by a small upright wall, likewise of bricks, and 8 inches broad, called walls of the *glaye*; 2, by an assemblage of pieces called pieces of the *glaye*, because the whole of the closure of the tunnel bears the name of *glaye*. The upper hole, 4 inches square, is called the *tisar*, through which the billets of wood are tossed into the fire. Fuel is also introduced into the posterior openings. The fire is always kept up on the hearth of the tunnel, which is, on this account, 4 inches higher than the furnace-hearth, in order that the glass which may accidentally fall down on it, and which does not flow off by the bottom-hole, may not impede the combustion. Should a body of glass, however, at any time obstruct the grate, it must be removed with rakes, by opening the tunnel and dismounting the fire-tile stoppers of the *glaye*.

Formerly wood-fuel alone was employed for heating the melting-furnaces of the mirror-plate manufactory of St. Gobain; but within these few years, the director of the works makes use with nearly equal advantage of pit-coal. In the same establishment, two melting-furnaces may be seen, one of which is fired with wood, and the other with coals, without any difference being perceptible in the quality of the glass furnished by either. It is not true, as has been stated, that the introduction of pit-coal has made it necessary to work with covered pots in order to avoid the discolouration of the materials, or that more alkali was required to compensate for the diminished heat in the covered pots. They are not now covered when pit-coal is used, and the same success is obtained as heretofore by leaving the materials two or three hours longer in the pots and the *cuvettes*. The construction of the furnaces in which coal is burned is the same as that with wood, with slight modifications. Instead of the close-bottomed hearth of the wood-furnace, there is an iron grate in the coal-hearth through which the air enters, and the waste ashes descend.

When billets of wood were used as fuel, they were well dried beforehand, by being placed a few days on a frame-work or wood called the wheel, placed two feet above the furnace and its arches, and supported on four pillars at some distance from the angles of the building.

The progress of chemistry, the discovery of a good process for the manufacture of soda from sea-salt, which furnishes a pure alkali of uniform power, and the certain methods of ascertaining its purity, have rendered this department of glass-making far more certain than formerly. At St. Gobain no alkali is employed, except artificial crystals of soda, prepared at the manufactory of Chauny, subsidiary to that establishment. The first crop of soda-crystals is reserved for the plate-glass manufacture; the other crystals and the mother-water salts are sold to the makers of inferior glass.

If glass contains much lead it has a yellow tint. If manganese is present it changes by the action of light to a pale rose. Iron imparts a dull greenish tint; therefore the proportions of all those materials should be adjusted with great care.

At the mirror-plate works of Ravenhead, near St. Helen's in Lancashire, soda-crystals, from the decomposition of the sulphate of soda by chalk and coal, have been also tried, but without equal success as at St. Gobain; the failure being unquestionably due to the impurity of the alkali. Hence, in the English establishment, the soda is obtained by treating sea-salt with pearlash, whence carbonate of soda and chloride of potassium result. The latter salt is crystallised out of the mingled solution, by evaporation at a moderate heat, for the carbonate of soda does not readily crystallise till the temperature of the solution falls below 60° Fahr. When the chloride of potassium is thus removed, the alkaline carbonate is evaporated to dryness.

Long experience at St. Gobain has proved that one part of dry carbonate of soda is adequate to vitrify perfectly three parts of fine siliceous sand, as that of the mound of Aumont near Senlis, of Alum Bay in the Isle of Wight, or of Lynn in Norfolk. It is also known that the degree of heat has a great influence upon the vitrification, and that increase of temperature will compensate for a certain deficiency of alkali; for it is certain that a very strong fire always dissipates a good deal of the soda, and yet the glass is not less beautiful. The most perfect mirror-plate has constantly afforded to M. Vauquelin, on analysis, a portion of soda inferior to what had been employed in its formation. Hence, it has become the practice to add, for every 100 parts of cullet, or broken plate, that is mixed with the glass-composition, one part of alkali, to make up for the loss that the old glass must have experienced.

To the above-mentioned proportions of sand and alkali, independently of the cullet which may be used, dry slaked lime carefully sifted is to be added to the amount of one seventh of the sand; or the proportion will be, sand, 7 cwts.; quicklime, 1 cwt.; dry carbonate of soda, 2 cwts. and 37 lbs.; besides cullet. The lime improves the quality of the glass, rendering it less brittle and less liable to change. The preceding quantities of materials, suitably blended, have been uniformly found to afford most advantageous results. The practice formerly was to dry that mixture, as soon as it was made, in the arch for the materials, but it has been ascertained that this step may be dispensed with, and the small portion of humidity present is dissipated almost instantly after they are thrown into the furnace. The coat of glaze previously applied to the inside of the pot prevents the moisture from doing them any harm. For this reason, when the demand for glass at St. Gobain is very great, the materials are neither fritted nor even dried, but shovelled directly into the pot; this is called founding *raw*. Six workmen are employed in shovelling in the materials either fritted or otherwise, for the sake of expedition, and to prevent the furnace getting cooled. One-third of the mixture is introduced at first; whenever this is melted, the second third is thrown in, and then the last. These three stages are called the first, second, and third fusion or founding.

According to the ancient practice, the founding and refining were both executed in the pots, and it was not till the glass was refined that it was laded into the *cuvettes*, where it remained only 3 hours, the time necessary for the disengagement of the air-bubbles introduced by the transvasion, and for giving the *metal* the proper consistence for casting. At present, the period requisite for founding and refining is equally divided between the pots and the *cuvettes*. The materials are left 16 hours in the pots, and as many in the *cuvettes*; so that in 32 hours the glass is ready to be cast. During the last two or three hours the fireman or *tiseur* ceases to add fuel; all the openings are shut, and the glass is allowed to assume the requisite fluidity; an operation called *stopping* the glass, or *performing the ceremony*.

The transfer of the glass into the *cuvettes* is called *lading* (*tréjetage*). Before this is done, the *cuvettes* are cleared out, that is, the glass remaining on their bottom is removed, and the ashes of the firing. They are lifted red hot out of the furnace by the method presently to be described, and placed on an iron plate, near a tub filled with water. The workmen, by means of iron paddles 6 feet long, flattened at one end and hammered to an edge, scoop out the fluid glass expeditiously, and throw it into water; the *cuvettes* are now returned to the furnace, and a few minutes afterwards the lading begins.

In this operation ladles of wrought iron are employed, furnished with long handles, which are plunged into the pots through the upper openings or lading holes, and immediately transfer their charge of glass into the buckets. Each workman dips his ladle only three times, and empties its contents into the *cuvette*. By these three immersions (whence the term *tréjeter* is derived) the large iron spoon is heated so much that when plunged into a tub full of water, it makes a noise like the roaring of a lion, which may be heard at a very great distance.

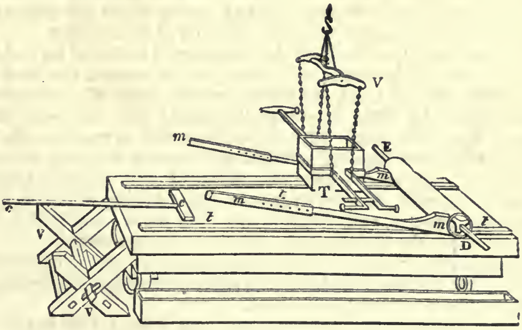
The founding, refining, and *ceremony* being finished, the workmen next try whether the glass be ready for casting. With this view the end of a rod is dipped into the bucket, which is called *drawing the glass*; the portion taken up being allowed to run off, naturally assumes a pear-shape, from the appearance of which they can judge if the consistence be proper, and if any air-bubbles remain. If all be right, the *cuvettes* are taken out of the furnace, and conveyed to the part of the *halle* where their contents are to be poured out. This process requires peculiar instruments and manipulations.

Casting.—While the glass is refining, that is, coming to its highest point of perfection, preparation is made for the most important process, the casting of the plate, whose success crowns all the preliminary labours and cares. The oven or *carquaise* destined to receive and anneal the plate is now heated by its small fire or *tisar* to such a pitch that its sole may have the same temperature as that of the plates, being nearly red hot at the moment of their being introduced. An unequal degree of heat in the *carquaise* would cause breakage of the glass. The casting-table is then rolled towards the front door or throat, by means of levers, and its surface is brought exactly to the level of the sole of the oven.

The table *t, t, t, fig.* 1102, is a mass of bronze, or now preferably cast iron, about 10 feet long, 5 feet broad, and from 6 to 7 inches thick, supported by a frame of carpentry, which rests on three cast-iron wheels. At the end of the table, opposite to that next to the front of the oven, is a very strong frame of timber-work, called the puppet or standard, upon which the bronze roller which spreads the glass is laid, before and after the casting. This is 5 feet long by 1 foot in diameter; it is thick in the metal, but hollow in the axis. The same roller can serve only for two plates at one casting, when another is put in its place, and the first is laid aside to cool; for otherwise the hot roller would, at a third casting, make the plate expand unequally, and cause it to crack. When the rollers are not in action they are laid aside in strong wooden trestles, like those employed by sawyers. On the two sides of the table, in the line of its length, are two parallel bars of bronze, *t, t,* destined to support the roller during its passage from end to end; the thickness of these bars determines that of the plate. The table being thus arranged, a crane is had recourse to for lifting the *cuvette*, and keeping it suspended, till it be emptied upon the table. This raising and suspension are effected by means of an iron gib, furnished with pulleys, held horizontally, and which turns with them.

The tongs, T, *fig.* 1102, are made of four iron bars, bent into a square frame in their middle, for embracing the bucket. Four chains, proceeding from the corners of the frame V, are united at their other ends into a ring, which fits into the hook of the crane. Things being thus arranged, all the workmen of the foundry co-operate in the manipulations of the casting. Two of them fetch, and place quickly in front of one of the lower openings, the small *cuvette*-carriage, which bears a forked bar of iron, having two prongs corresponding to the two holes left in the fire-tile door. This fork, mounted on the axle of two cast-iron wheels, extends at its other end into two branches terminated by handles, by which the workmen move the fork, lift out the tile stopper, and set it down against the outer wall of the furnace.

1102



The instant these men retire, two others push forward into the opening the extremity of the tongs-carriage, so as to seize the bucket by the girdle, or rather to clamp it. At the same time a third workman is busy with an iron pinch or long chisel, detaching the bucket from its seat, to which it often adheres by some spilt glass; whenever it is free, he withdraws it from the furnace. Two powerful branches of iron united by a bolt, like two scissor-blades, which open, come together, and join by a quadrant near the other end, form the tongs-carriage, which is mounted upon two wheels like a truck.

The same description will apply almost wholly to the iron-plate carriage, on which the bucket is laid the moment it is taken out of the furnace; the only difference in its construction is, that on the bent iron bars which form the tail or lower steps of this carriage (in place of the tongs) is permanently fastened an iron plate, on which the bucket is placed and carried for the casting.

Whenever the *cuvette* is set upon its carriage, it must be rapidly wheeled to its station near the crane. The tongs T, above described, are now applied to the girdle, and are then hooked upon the crane by the suspension-chains. In this position the bucket is skimmed by means of a copper tool called a sabre, because it has nearly the shape of that weapon. Every portion of the matter removed by the sabre is thrown into a copper ladle (*poche de gamin*), which is emptied from time to time into a cistern of water. After being skimmed, the bucket is lifted up, and brushed very clean on its sides and bottom; then, by the double handles of the suspension-tongs, it is swung round to the table, where it is seized by the workmen appointed to turn it over; the roller having been previously laid on its ruler-bars, near the end of the table which is in contact with the annealing oven. The *cuvette*-men begin to pour out towards the right extremity E of the roller, and terminate when it has arrived at the left extremity D. While preparing to do so, and at the instant of casting, two men place within the ruler-bar on each side, that is, between the bar and the liquid glass, two iron instruments called *hands*, *m m*, *m m*, which prevent the glass from spreading beyond the rulers, whilst another draws along the table the wiping bar *c c*, wrapped in linen, to remove dust, or any small objects which may interpose between the table and the liquid glass.

Whenever the melted glass is poured out, two men spread it over the table, guiding the roller slowly and steadily along, beyond the limits of the glass, and then run it smartly into the wooden standard prepared for its reception, in place of the trestles V V.

The empty bucket, while still red hot, is hung again upon the crane, set on its plate-iron carriage, freed from its tongs, and replaced in the furnace, to be speedily cleared out anew, and charged with fresh fluid from the pots. If, while the roller glides along, the two workmen who stand by with picking tools perceive *tears* in the matter in advance of the roller, and can dexterously snatch them out, they are suitably rewarded, according to the spot where the blemish lay, whether in the centre, where it would have proved most detrimental, or near the edge. These tears proceed usually from small portions of semi-vitrified matter which fall from the vault of the furnace, and from their density occupy the bottom of the *cuvettes*.

While the plate is still red hot and ductile, about 2 inches of its end opposite to the *carquaise* door is turned up with a tool; this portion is called the *head of the mirror*; against the outside of this head, the shovel, in the shape of a rake without teeth, is applied, with which the plate is eventually pushed into the oven, while two other workmen press upon the upper part of the head with a wooden pole, 8 feet long, to preserve the plate in its horizontal position, and prevent its being warped. The plate is now left for a few moments near the throat of the *carquaise*, to give it solidity; after which it is pushed further in, by means of a very long iron tool, whose extremity is forked like the letter y, and hence bears that name; and is thereby arranged in the most suitable spot for allowing other plates to be introduced.

However numerous the manipulations executed from the moment of withdrawing the *cuvette* from the furnace, till the cast plate is pushed into the annealing oven, they are all performed in less than five minutes.

When all the plates of the same casting have been placed in the *carquaise*, it is sealed up; that is to say, all its orifices are closed with sheets of iron, surrounded and made tight with plastic loam. With this precaution, the cooling goes on slowly and equably in every part, for no cooling current can have access to the interior of the oven.

After they are perfectly cooled, the plates are carefully withdrawn one after another, keeping them all the while in a horizontal position, till they are entirely out of the *carquaise*. As soon as each plate is taken out, one set of workmen lower quickly and steadily the edge which they hold, while another set raise the opposite edge, till the glass be placed upright on two cushions stuffed with straw, and covered with canvas. In this vertical position they pass through, beneath the lower edge of the plate, three girths or straps, each four feet long, thickened with leather in their middle, and ending in wooden handles; so that one embraces the middle of the plate, and the other two the ends. The workmen, six in number, now seize the handles of the straps, lift up the glass closely to their bodies, and convey it with a regular step to the warehouse. Here the head of the plate is first cut off with a diamond square, and then the whole is attentively examined, in reference to its defects and imperfections, to determine the sections which must be made of it, and the eventual size of the pieces. The parings and small cuttings detached are set aside, in order to be ground and mixed with the raw materials of another glass-pot.

The apartments in which the roughing-down and smoothing of the plates is performed, are furnished with a considerable number of stone tables, truly hewn and placed apart like billiard-tables, in a horizontal position, about 2 feet above the ground. They are rectangular, and of different sizes proportional to the dimensions of the plates, which they ought always to exceed a little. These tables are supported either on stone pillars or wooden frames, and are surrounded with a wooden board, whose upper edge stands somewhat below their level, and leaves in the space between it and the stone all round an interval of 3 or 4 inches, of which we shall presently see the use.

A cast plate, unless formed on a table quite new, has always one of its faces, the one next the table, rougher than the other; and with this facing the roughing-down begins. With this view, the smoother face is cemented on the stone table with Paris-plaster. But often instead of one plate, several are cemented alongside of each other, those of the same thickness being carefully selected. They then take one or more crude plates, of about one-third or one-fourth the surface of the plate fixed to the table, and fix it on them with liquid gypsum to the large base of a quadrangular truncated pyramid of stone, of a weight proportioned to its extent, or about a pound to the square inch. This pyramidal muller, if small sized, bears at each of its angles of the upper face a peg or ball, which the grinders lay hold of in working it; but when of greater dimension, there is adapted to it horizontally a wheel of slight construction, 8 or 10 feet in diameter, whose circumference is made of wood rounded so as to be seized with the hand. The upper plate is now rubbed over the lower ones, with moistened sand applied between.

This operation is, however, performed by machinery. The under plate being fixed or imbedded in stucco, on a solid table, the upper one likewise imbedded by the same cement in a cast-iron frame, has a motion of circumrotation given to it, closely resembling that communicated by the human hand and arm, moist sand being supplied between them. While an excentric mechanism imparts this double rotatory movement to the upper plate round its own centre, and of that centre round a point in the lower plate, this plate placed on a moveable platform changes its position by a slow horizontal motion, both in the direction of its length and its breadth. By this ingenious contrivance, which pervades the whole of the grinding and polishing machinery, a remarkable regularity of friction and truth of surface is produced. When the plates are sufficiently worked on one face, they are reversed in the frames, and worked together on the other. The Paris-plaster is usually coloured red, in order to show any defects in the glass.

The smoothing of the plates is effected on the same principles by the use of moist emery washed to successive degrees of fineness, for the successive stages of the operation; and the polishing process is performed by rubbers of hat-felt and a thin paste of colcothar and water. The *colcothar*, called also *crocus*, is red oxide of iron prepared by the ignition of copperas, with grinding and elutriation.

The last part, or the polishing process, is performed by hand. This is managed by females, who slide one plate over another, while a little moistened *putty of tin* finely levigated is thrown between.

Large mirror-plates are now the indispensable ornaments of every large and sumptuous apartment; they diffuse lustre and gaiety around them by reflecting the rays of light in a thousand lines, and by multiplying indefinitely the images of objects placed between opposite parallel planes.

The process of silvering plate-glass will be described under MIRRORS. For the production of the perfectly plane surface required to ensure true reflexion, a process of the most careful polishing is required. It will not differ from the process already described in any respect, beyond that of the extreme care which is required.

Not only is this great exactness of surface required for the production of mirrors of high class, but it is even more necessary in the plates of glass employed in the production of 'the Ghost,' as it is called, which a few years ago excited so much of the public attention at the Polytechnic Institution and elsewhere; this phenomenon being due to the total reflexion of highly-illuminated objects, from the plane surface of highly-polished glass, the objects themselves being hidden from the spectators.

The progress of the plate-glass manufacture is very instructive. Owing to the obstructions of Excise regulations, notwithstanding the reduction of the duty in 1819 to 60*s.* per cwt., the production in 1836 was but about 7,000 feet per week. In the latter year, however, the manufacture ceased to be confined to two houses; new establishments were formed, and in 1845 the production had more than tripled, at a great reduction of price. In 1845 the Excise duties on glass were abolished, and Sir R. Peel, in proposing their abolition, said, 'If you leave the manufacture altogether disburdened, as in France and Belgium, then, with your peculiar advantages of material, the command of alkali and coal, my belief is, you will supply almost the whole world.' And, thanks to the wisdom of that measure, freedom from fiscal regulation has opened the door to extraordinary advantages, by means of which the cost of production has been reduced to a point below that of any other country. In coal the savings effected by unrestricted action are no less than 80 per cent. in quantity alone, involving a corresponding decrease in the cost of furnaces, fire-clay, pots, tools, labour, and also in the erection of buildings that now suffice. The cost of coal, therefore, which, in London, in 1826 exceeded 1*s.* 10*d.* on each superficial foot of glass, is now about 2*d.* per foot. Sand also, which is its base, forming as it does nearly three-fifths of its composition, is obtained near London at 3*s.* 6*d.* and upwards per ton, of a quality superior to Lynn sand formerly used at 18*s.* per ton. The direct charge of labour in 1826 exceeded 1*s.* 6*d.* per foot; now the average rate of wages for skilled labour is higher by 20 per cent. than forty years ago. In 1819 two furnaces, each having a huge chimney-shaft, were required to produce 1,000 feet per week, while at the present time two furnaces, with only one chimney-shaft, suffice for the production of 12,000 feet, with the same, if not a less, consumption of fuel. Similarly, though in a less degree, grinding and polishing benches which then finished 200 feet each per week, now accomplish 500 feet to 700 feet, which, by judicious means, may be still further increased to 1,000 feet and upwards. By these means the whole cost has been reduced to nearly the price of common duty-paid window-glass thirty years ago; and whereas in 1819 the British make was 3,000 feet per week, sold at 20*s.* to 25*s.* per foot, it is now 140,000 feet, selling at 2*s.* and upwards according to quality. The former superior make of this country has, indeed, been greatly neglected, and this has led to a very large increase in the import of the finest fabrics of France and Belgium, so that these imports amounted in 1862 and 1863 to about 16,000 feet per week, and those countries have had a corresponding sale in foreign markets in the absence of such supplies from England; but still the exports of British plate-glass have increased about tenfold since 1849.

At home, glass is now extensively used in slabs for flooring and underground purposes, combining as it does greater strength than the York flag, with the additional advantage of conveying light; and slabs tested at Woolwich dockyard have been found to bear a pressure exceeding a ton weight. Many years ago, a supply of such slabs was required for the purpose of flooring a palace of one of the native princes of India, but the Excise restrictions then prevailing precluded its supply from England at less than 30*s.* per foot; it could now be afforded at 3*s.* to 4*s.* In fact, its true position has yet to be attained, when the resources of this country shall have stimulated that more full development of which it is susceptible, and Great Britain shall, as the author of the freedom of this industry predicted, 'supply almost the whole world.'

Bohemian Glass.—M. Péligot states that the hard glass of Bohemia is composed of 100 parts of silica, 12 parts of quicklime, and only 28 parts of carbonate of potash. These proportions give a glass quite unmanageable in ordinary furnaces; but the addition of a comparatively small quantity of boracic acid is capable of determining fusion, and the result is a glass having all the requisite limpidity at a high temperature, and possessing at the same time a great brilliancy and hardness.

The Bohemian glass is, within certain limits, perfectly elastic, and very sonorous; when well made, it is sufficiently hard to strike fire with steel, and is scratched with difficulty. The lead glasses, on the other hand, have but little hardness, and less in proportion as they contain more oxide of lead; besides which they rapidly lose their brilliancy by use.

The silica which is employed in Bohemia in the manufacture of glass is obtained by calcining crystalline quartz, and afterwards pounding it while dry. When the quartz has been heated to a cherry-red, it is withdrawn from the fire, and thrown immediately into cold water.

Almost all the Bohemian glass is a potash-glass, because soda and its salts give to glass a sensible yellowish tint. The limestone which is used is as white as Carrara marble. The clay employed for the crucibles is very white, and consists of silica, $45\frac{8}{10}$; alumina, $40\frac{4}{10}$; and water, $13\frac{8}{10}$.

The manufacture of glass in Bohemia is of very high antiquity, and the same peculiarities have always belonged to the true Bohemian manufacture.

In our modern times the Bohemian glass has been more especially celebrated for the beautiful varieties of colours which are produced. See Glass, Coloured.

Venetian Glass.—From an early date the city of Venice has been celebrated for its glass: the *reticulated glass*, the *crackle glass*, and the glass paper-weights, or *millefiore*, are all due to the Venetians.

The manufacture of *glass beads* at Murano, near Venice, has been carried on for an indefinite period, and Africa and Asia have been supplied from their glass-houses. The process is most ingeniously simple. Tubes of glass of every colour, are drawn out to great lengths in a gallery adjoining the glass-house pots, in the same way as the more moderate lengths of thermometer and barometer tubes are drawn in our glass-houses. These tubes are chopped into very small pieces of nearly uniform length on the upright edge of a fixed chisel. These elementary cylinders being then put in a heap into a mixture of fine sand and wood-ashes, are stirred about with an iron spatula till their cavities get filled. This curious mixture is now transferred to an iron pan suspended over a moderate fire, and continually stirred about as before, whereby the cylindrical bits assume a smooth rounded form; so that when removed from the fire and cleared out in the bore, they constitute beads, which are packed in casks, and exported in prodigious quantities to almost every country.

The manufacture of *reticulated glass*, for which Venice was equally celebrated, was long lost; it was at length revived by Pohl, and the crackle-glass was in like manner reproduced by the late Mr. Apsley Pellatt in 1851.

The reticulated glass is produced by a kind of network, consisting of small bubbles of air inclosed within the mass, and ranged in regular series crossing and interlacing each other. To produce this ornamental appearance, hollow glass cones or conical tube are kept prepared, containing already this network-arrangement of air-bubbles. These tubes are made by arranging a number of small glass rods round a centre so as to form a cylinder, and fixing them in this position by melted glass. The cylinder is then heated until the single rods stick together, when they are drawn out on the pipe to a long cone, and spirally twisted at the same time, the one half to the right and the other to the left, when one of these hollow cones is inserted into the other, and the two are heated until they fuse together; wherever the little rods cross each other a bubble of air will be inclosed, and this occurring in a very regular manner, the reticulated appearance is produced.

The Venetians were also celebrated for their *filigree*. This glass has of late years been re-introduced in France and in this country. The process of manufacture has been thus described by Mr. Apsley Pellatt, in his *Curiosities of Glass Manufacture*:—

'Before ornaments or vessels can be blown, small filigree-canes, with white or variously-coloured enamels must be drawn. These are first "whetted" off to the required lengths, and then put into a cylindrical mould with suitable internal recesses, and both cane and mould are thus submitted to a moderate heat. The selection of the colour of the canes depends upon the taste of the manufacturer; two to four white enamel-canes are chiefly used, alternately, with about half the number coloured. The blower then prepares a solid ball of transparent flint-glass, which being deposited in contact with the various canes, at a welding heat, occasions them to adhere. This solid ball is then taken from the mould, is re-heated, and "*marvered*" till the adhering projecting ornamental canes are rubbed into one uniform mass; the ball is next covered with a gathering of white glass, which must then be drawn to any size and length that may be required. Should a spiral cane be preferred, the "pucellas" holds the apex in a fixed position, while the ornamental mass, still adhering to the glass-maker's iron, is revolved during the process, till the requisite twist is given. Where vases are formed of alternately coloured and enamelled filigree-canes, the above process is repeated, and the usual mode of blowing is followed.'

The Venetian ball is a collection of waste pieces of filigree-glass conglomerated together without regular design: this is packed into a pocket of transparent glass, which is adhesively collapsed upon the interior mass by sucking up, producing outward pressure of the atmosphere.

Millefiore, or star-work of the Venetians, is similar to the last, only, the lozenges of glass are more regularly placed.

The *Vitro di Trino* of the Venetians is similar to the filigree in many respects; but by closing an outer on the inner case, each containing filigree-canes, a bubble of air is inclosed between each crossing of the canes.

The celebrated frosted glass of the Venetians was re-introduced by Mr. Apsley Pellatt in 1851, who thus describes the process of manufacture:—

'Frosted glass, like *Vitro de Trino*, is one of the few specimens of Venetian work not previously made by the Egyptians and the Romans; and not since executed by the Bohemian or French glass-makers. The process of making it, until recently practised at the Falcon Glass Works, was considered a lost art. Frosted glass has irregularly-varied marble-like projecting dislocations in its intervening fissures. Suddenly plunging hot glass into cold water produces crystalline convex fractures, with a polished exterior, like Derbyshire spar; but the concave intervening figures are caused, first by chilling, and then reheating at the furnace, and simultaneously expanding the reheated ball of glass by blowing; thus separating the crystals from each other, and leaving open figures between, which is done preparatory to forming vases or ornaments. Although frosted glass appears covered with fractures, it is perfectly sonorous.'

Glass, its physical condition and chemical constitution.—So far as may be inferred, from the analysis of ordinary commercial samples of window-glass, this substance has not only a very variable composition, but, worse than this, it is out of all keeping with anything like definite proportion. That it should be full of striæ, and, therefore, refract the rays of light unequally, as it does, so as to produce the most hideous appearances of distortion, is a mere natural consequence of its mechanical composition, which might, and must one day be corrected; but that whole nations should have come to view this defect as an unavoidable peculiarity, is precisely one of those surprising facts which demonstrate the influence of habit over the powers of the mind, and show how easily human reason can reconcile itself to the most gross inconsistencies. If window-glass had one uniform atomic composition, the tendency to form these striæ would nowhere exist in excess; and, therefore, their production would diminish as the skill of the workmen increased; but, with the present variable compound, the glass stretches unequally in different parts, by an equal application of force, and, in spite of human skill, presents a result alternately thick or thin, as accident determines. That these striæ have not the same composition as the parts surrounding them is very obvious, from the circumstance that, if striated glass be cut to an uniform thickness, and polished on both sides, the optical defects remain but little changed, and occasionally they are found to be increased. Again, it is known that the more complex the composition of any glass may be, the greater the liability to this striated structure—of which flint-glass offers an apposite illustration; for here, in addition to the ordinary components of glass, the silicate of lead is superadded. Now the specific gravity of silicate of lead is very high compared with that of silicate of soda, potash, or lime; hence unless employed in the exact quantity to form a chemical combination with the other silicates, a mere mechanical mixture is produced, of very different densities throughout; and the product, under the action of light, displays, permanently, that peculiar fugitive appearance seen when syrup and water, or alcohol and water, are mixed together; that is to say, a series of curved lines are formed by the unequal refraction of the two fluids, which entirely disappear, so soon as perfect admixture has taken place, but which remain in the case of flint-glass, from the utter impossibility of effecting the necessary union between its various parts. Although, however, this cannot be done mechanically, yet, in a chemical way, nature performs such operations with ease and unerring fidelity. The French chemist, Berthier, long ago proved that many neutral salts combine together by fusion in atomic proportions, and form new and definite compounds. Thus, carbonate of potash and carbonate of soda when mixed, atom for atom, unite and produce a compound more easy of fusion than the more fusible of the two; similarly, either of these carbonates will act with carbonate of baryta or strontia; and again, fluor-spar and sulphate of lime, two remarkably infusible substances, when mixed, melt readily, at a low red heat into a fluid as mobile and transparent as water. It is useless to multiply examples of this kind, for thousands exist; and the alkaline and earthy silicates form no exception to this almost universal rule. A mixture of silicate of potash and silicate of soda will, if in atomic ratios, fuse much more readily than either of them alone. But now, let us imagine an attempt to fuse these two bodies together, in any other proportion than that in which they are naturally disposed to combine;—say that the silicate of soda is in excess; then the silicate of potash would unite with exactly sufficient of the silicate of soda to produce the extremely fusible compound above spoken of; whilst the less easily fusible silicate of soda, added in excess, would form a kind of network throughout the mass. It may be said, that a higher heat would overcome this difficulty, by thoroughly liquefying the silicate of soda; and this is really the plan now used with that view; but, independent of the fact, that the mixed silicate of potash and soda would also undergo a corresponding liquefaction, and, therefore, favour the separation of the silicate of soda, yet, as chemical union is impossible, from the very conditions of the experiment, even the most perfect mechanical mixture, under the greatest advantages of fluidity, would never generate a homogeneous body. The striæ might, indeed, be diminished in size; but this would imply a corresponding increase in their number; and, if carried very far, complete opacity would result from such an endeavour to subvert the laws of nature. The power of the workmen to remedy this defect is therefore limited to the capability of modifying its more salient features; he can never remove nor destroy it. What we have here illustrated by the simplest of all assumptions, gathers and accumulates into a formidable evil when several silicates are fused together, having considerable differences of specific weight. Thus, in the case of flint-glass before alluded to, there are generally three, and sometimes five, of these silicates fused together, into, probably, one of the most antagonistic compounds that could be conceived, refracting and dispersing the ray of light in fifty directions, and demonstrating the unfriendly nature of its coerced union, by flying in pieces from the most trivial applications of heat or violence. Yet in flint-glass we are not surpassed, nor indeed equalled, by any other nation; and so thoroughly has this beautiful substance become associated with our industrial reputation, that the British name, flint-glass, has been adopted into several continental languages. Nevertheless, it cannot be doubted that a wide field of improvement is open in this quarter, and that some more solid foundation is needed by our manufacturers in this line, than the prestige of a name, or the force of capital.

In France, as in England, the ingredients are mixed with some care, and introduced into a crucible, heated by a powerful furnace. These ingredients are sand or silica, carbonate of soda, and carbonate of lime, with perhaps a little ground felspar in some cases. The carbonate of soda is first attacked by the silica, and its carbonic acid driven off, whilst the remaining silica and carbonate of lime become imbedded in the vitrifying mass. As the heat increases, a more perfect fusion takes place; and then the carbonic acid of the carbonate of lime makes its way through the fused materials by which they are mechanically mingled together during the effervescence, which is technically termed the 'boil;' and, provided no after-separation ensues from the process of 'settling,' the whole crucible or 'pot' of glass will have a uniform composition. But, as we have seen, this depends altogether upon the relative proportion of the materials towards each other, for an excess of either one or other of the bases will destroy the homogeneous character of the whole, and introduce a plexus of striæ. Now the plate-glass of St. Gobain is almost exactly an atomic compound, and consists of one atom of the trisilicate of soda and one atom of the trisilicate of lime, with a small percentage of alumina. Science must ever take the lead of prejudice and custom.

The examination of English plate-glass fully corroborates the general result deduced from the action of light. There is no approach to an atomic arrangement. The principal constituent is trisilicate of soda, but variable quantities of lime, alumina, and even magnesia, exist in it. Potash is sometimes present, and oxide of iron is invariably so; but in not one single instance, out of 17 samples examined with great care, could so much as a surmise of the doctrine of combining proportions be gathered from the result of the analyses. Similarly fruitless was a research instituted upon flint-glass, both British and foreign. Of 35 samples analysed, no satisfactory evidence could be adduced to favour the opinion that science had been a helpmate to industry, or was at all concerned in this branch of manufacture. There are, however, some points of vast interest associated with the practical working out of this matter. Potash is known to give a more brilliant and harder glass than soda, and alumina seems to tend in the same direction. The Bohemian glass, so celebrated throughout Europe, is a glass of this description, and contains silicate of alumina, silicate of lime, and silicate of potash, but not in chemical proportions. This glass is therefore striated, but it seems to permit of a more perfect decoration by metallic oxides that can be developed in glass of lime and soda. This very probably depends upon the alumina contained in it. From one singular oversight, the use of carbonate of baryta has not yet found its way into the composition of glass, though we can scarcely conceive a more hopeful material. This substance may be had in large quantity in the North of England, of great purity, and at a merely nominal cost as compared with its value for such a purpose as glass-making. That it would fuse readily with a due amount of soda, and give 'a boil' as well as chalk, there can be no doubt; whilst its great density will certainly improve the refractive power of the resulting product, and thus rival the brilliancy of lead- or flint-glass, without imparting that softness and liability to receive scratches which are so objectionable in the latter variety. One difficulty may perhaps reside in the want of information concerning the quantity to be employed. But this is easily adjusted; for it has been demonstrated that, during vitrification, the silicic acid unites to bases in the proportion of three atoms to one: consequently three atoms, or 138 parts, will always require one atom of each base. Therefore, this weight of good dry sand may be set against 54 of dry carbonate of soda, 70 of carbonate of potash, 50 of pure marble or chalk, 99 of carbonate of baryta, and 112 of oxide of lead or litharge. Suppose, then, that the object is to employ carbonate of baryta for the first time, here 6 atoms or 276 parts of sand, 1 atom or 54 parts of dry carbonate of soda, and 1 atom or 99 parts of carbonate of baryta, may be mixed and fused together with every prospect of obtaining a good result; or 9 atoms of silica, 1 of carbonate of potash, 1 of carbonate of soda, and 1 of carbonate of baryta, might be tried without fear of failure. Again, in the case of flint-glass, 112 of litharge, 54 of soda, and 276 of sand, would probably succeed, or an additional atom of trisilicate of potash might be used. For many years past, M. Dumas, now, perhaps, the first chemist in France, has been in the habit of demonstrating to his pupils that glass of all kinds, when properly made, must necessarily be an atomic compound; and yet we scarcely expect to find a single British glassmaker who will admit that his art is susceptible of such decisive and beautiful simplification.

To assist as far as we can in the attainment of this end, we shall proceed to describe a simple means for the analysis of glass, which will enable any person, possessed of even very trifling chemical skill, to determine the composition of any given sample of glass in a comparatively short time. From the nature of the material, it becomes necessary to divide the analysis into two distinct portions; one of which has for its object the estimation of its alkaline ingredients, the other that of the earthy, metallic, and siliceous matters. Having heated a sufficient quantity of the sample in question to dull redness, it must be suddenly thrown, whilst still hot, into a basin containing cold water. In this way it becomes cracked and flawed in all directions, so as to favour its reduction into powder. When dry it must, therefore, be carefully ground in an agate or steel mortar, until it has the appearance of fine flour. Nor is it a matter of indifference whether this takes place in contact with water or not; for glass in this extreme state of comminution readily gives up a part of its alkali to water; and hence, if ground in the presence of that fluid, the resulting analysis would prove incorrect. But we will suppose that a quantity of finely-powdered glass has been obtained as above indicated, and the amount of its alkali is desired; then weigh out 100 grains of the glass, and carefully mix with it 200 grains of pure fluor-spar in a similarly-powdered condition. Place the mixture in a platinum or leaden vessel, and pour over it 500 grains of strong sulphuric acid, stirring the whole well together with a silver spoon, but taking care not to remove any portion of the materials. Next, apply a heat of about 212° Fahr.; and as the process draws to a conclusion, this may be raised as high as 300°. When all evolution of gaseous fumes has ceased, water may be poured on the residuary mass to the extent of four or five ounces, and the mixture thrown on a filter. After the clear fluid has passed through, a little more water must be added to the filter, so as to wash out the whole of the soluble matter; these washings being joined to the original clear fluid, which consists of sulphate of soda or potash, or both, with a quantity of sulphate of lime, and perhaps also of magnesia and alumina. To this an excess of carbonate of ammonia must now be added, to admit of the separation of the earthy salts being effected by filtration. The clear solution is next boiled down to dryness, and the residue is heated red hot for a minute or two. This residue is the soda or potash, or both, formerly contained in 100 grains of the glass, but now united to sulphuric acid. Having ascertained its weight, the relative proportions of potash and soda may be found by testing its content of sulphuric acid with a barytic solution, and calculating the result by the well-known Archimedean equation; or, by dissolving the mixed salt in a small quantity of water, and after adding an excess of tartaric acid, leaving the whole for a few hours covered up in a cool place. Almost the whole of the potash will separate in this way as bitartrate of potash. The quantity of alkali may be determined from the atomic constitution of the alkaline salts. Thus, supposing the dry residue altogether composed of sulphate of soda, then as 72 grains of it indicate 32 of pure soda, the result may be obtained by the rule of proportion. The amount of alkali being known, another portion of the powdered glass must be employed for ascertaining the remainder of the ingredients. That is to say, 100 grains of the sample must be mixed with 200 grains of pure potash, and the whole fused together in a silver crucible, at a red heat, until perfect liquefaction ensues, when the crucible and its contents may be withdrawn from the fire, and, as soon as cool enough, boiled in half a pint of pure water, so as thoroughly to dissolve the fused mass from the crucible. An excess of nitric acid being poured into the solution, the mixture is then evaporated to dryness, by which means the silicic acid is rendered insoluble; consequently, on the application of water, this remains, and may be dried and weighed, whilst the lime, alumina, and lead of the glass may be separated from the soluble portion by the addition, first, of sulphuretted hydrogen, which separates the lead, then of ammonia, which throws down the alumina, and, next, by pouring in carbonate of ammonia, which precipitates the lime as a carbonate. Thus, therefore, the alkaline matters are found by one process, and the silica, earthy, and metallic constituents by another, both of which may be conducted at the same time. It has been recommended to employ carbonate of baryta in the analysis of glass; but the high temperature required with this substance dissipates a portion of the alkaline components, and thus leads to serious errors. Even mere fusion in a glass furnace expels soda from glass, and renders it more and more infusible; but this expulsion is much favoured by the presence of baryta. The above method of analysing glass is, therefore, to be preferred to the baryta plan, by individuals not habitually engaged in manipulative chemistry.—*Ure.*

Glass, for horticultural purposes.—An impression taken up loosely in the first instance from some experiments on the action of the chemical rays of light, when made to permeate coloured glass, has led the public frequently to conceive that glasses which admitted freely the chemical rays were the most adapted to accelerate the growth of plants. No more mistaken view was ever entertained. At different periods in the life of a plant different influences are necessary; at one time the chemical force is required, at another the luminous power, and at another the calorific agent. The solar rays, as we receive them direct from the sun, have those forces exactly adjusted to produce the best possible conditions; but under some of the artificial conditions in which we place plants, it is important to know the conditions of the solar rays best suited to produce a given effect. This we must attempt briefly to explain:—

1. Seeds germinating absorb oxygen, and convert their starch into sugar; this is a purely chemical process, and demands the full power of the *chemical rays* (*actinism*).

2. Wood-forming, from the decomposition of carbonic acid, is a function of the vital power of the plant, excited by *light* (*luminous force*).

3. Flowering and fruiting manifest compound actions, and appear to demand the combined power of *heat* (*calorific power*) and of the chemical rays.

Such are the three chief conditions in the phenomena of vegetable growth. Now *a*, a glass stained blue with cobalt admits the permeation of the chemical rays with great freedom, obstructing both light and heat; *b*, a glass stained yellow with silver, will powerfully obstruct the chemical rays, and allow the luminous rays to pass freely; *c*, deep copper or gold red glasses admit the maximum heat rays to pass freely, and in general allow of the permeation of a small quantity of the chemical rays.

When seed is placed in the soil to germinate, a blue glass placed above the soil will greatly accelerate the process; the first leaves will appear above the soil, in many instances, days before they are seen when the seed is under the ordinary conditions in the soil; but if a plant is allowed to grow under these circumstances, scarcely any wood is produced, but long succulent stalks are formed, with imperfect leaves.

After germination has taken place, if the plant is brought under the influence of the rays permeating yellow glass (*light* separated to a considerable extent from the *chemical power*), wood is formed abundantly, and very healthy plants with dark leaves are produced. For the production of perfect flowers and fruit, the red glass named is the most effective. Plants growing in conservatories which have been glazed with the colourless German sheet-glass, frequently suffer from scorching. To avoid this if possible, the editor of this volume was consulted on the glass which should be employed in glazing the great palm-house at Kew, the problem being to avoid the necessity of blinds, and to secure the plants from the injurious action of the scorching rays. By a long series of experiments it was determined that glass stained with a little of the oxide of copper, and from which there was an entire absence of manganese, entirely effected this end. The great palm-house in the Royal Botanic Gardens at Kew was glazed with glass made on this principle, by the Messrs. Chance Brothers and Co. of Birmingham, and it has now been tested by the sunshine of six-and-twenty summers (1874); and the plants, as every one may observe, grow most luxuriantly, and are entirely free from any indications of scorching on their leaves.

GLASS, COLOURED. Most of the metallic oxides impart a colour to glass, and some non-metallic, and even some substances derived from the organic kingdom have the power of imparting permanent colours to the vitreous combinations of flint and potash. There is much in this subject which still requires examination. M. Bontemps, at the meeting of the British Association at Birmingham, brought forward some very extraordinary facts in connection with the colouring powers of different bodies. Of his communication the following is an abstract:—

In the first place it was shown, that all the colours of the prismatic spectrum might be given to glass by the use of the oxide of iron in varying proportions, and by the agency of different degrees of heat: the conclusion of the author being, that all the colours are produced in their natural disposition in proportion as you increase the temperature. Similar phenomena were observed with the oxide of manganese. Manganese is employed to give a pink or purple tint to glass, and also to neutralise the slight green given by iron and carbon to glass in its manufacture. If the glass coloured by manganese remains too long in the melting-pot or the annealing-kiln, the *purple* tint turns first to a light *brownish-red*, then to *yellow*, and afterwards to *green*. White glass, in which a small proportion of manganese has been used, is liable to become light yellow by exposure to luminous power. This oxide is also, in certain window-glass, disposed to turn pink or purple under the action of the sun's rays. M. Bontemps has found that similar changes take place in the annealing oven. He has determined, by experiments made by him on polygonal lenses for M. Fresnel, that light is the agent producing the change mentioned: and the author expresses a doubt whether any change in the oxidation of the metal will explain the photogenic effect. A series of chromatic changes of a similar character were observed with the oxides of copper, the colours being in like manner regulated by the heat to which the glass was exposed. It was found that silver, although with less intensity, exhibited the same phenomena; and gold, although usually employed for the purpose of imparting varieties of red, was found by varying degrees of heating at a high temperature, and re-casting several times, to give a great many tints, varying from blue to pink, red, opaque yellow, and green. Charcoal in excess in a mixture of silica-alkaline glass gives a yellow colour, which is not so bright as the yellow from silver: and this yellow colour may be turned to a dark red by a second fire. The author is disposed to refer these chromatic changes to some modifications of the composing particles rather than to any chemical changes in the materials employed.

It is not possible in the present essay to enter into the minute details of this beautiful branch of glass-manufacture. In the following statement the materials ordinarily employed to colour glass alone are named.

YELLOW.—*Charcoal* or soot is used for producing the commoner varieties of yellow glass.

The glass of antimony, which is obtained by roasting sulphide of antimony until antimonious acid is formed, and melting it with about 5 per cent. of undecomposed sulphide of the same metal.

The antimonate of potash, a preparation similar to James's powder, is stated to answer the same purpose. Bohemian glass is coloured yellow with glass of antimony, minium, and oxide of iron.

Silver imparts a very beautiful yellow colour to glass; but it requires some caution in its mode of application. It is believed that the presence of alumina is necessary to the production of colour, since a fine yellow cannot be produced unless alumina be present. A mixture of powdered clay and chloride of silver is prepared, and spread upon the surface of the glass; the glass is then re-heated, and the silver penetrates to a certain depth into the glass, before the latter softens. The coating is then scraped off, and the fine yellow colour appears. If the silver yellow glass is held over the flame of burning wood, a peculiar opalescence is produced upon the surface, probably by the oxidation of the silver.

Uranium produces the beautiful canary-yellow, which is found in many articles of an ornamental kind. This glass possesses the very peculiar property of giving a green colour when it is looked *at*, although perfectly and purely yellow when looked *through*. This has been attributed to the presence of iron in the commercial oxide of uranium employed; but the purer the uranium is, the more beautifully will this phenomenon be brought out. It depends upon a very remarkable physical peculiarity belonging to uranium and some other bodies. See FLUORESCENCE.

RED.—A common brownish-red colour is produced in glass by *oxide of iron*, added as ochre, or in the state of pure peroxide. Muller found ancient glass to contain silicic acid, alkalis, lime, magnesia, alumina, protoxide of iron, and suboxide of copper.

Copper is more generally employed in colouring glass red. The use of this metal for such a purpose dates from very high antiquity, and all through the middle ages it was employed to produce the reds which we see in the fine old windows left by our ancestors for our admiration. The ancient *Hæmatinone* was a copper-red glass. Suboxide of copper is used, either in the state of commercial copper-scale, or it is prepared by heating copper-turnings to redness. If, during the fusion of the glass in the pot, the suboxide unites with an additional quantity of oxygen, green and not red is the result. This is avoided by combining some reducing agent with the melted substance. Glass thus coloured does not exhibit its red colour on leaving the crucible; it is nearly colourless, or with a tinge of green even when cold; but if it is then heated a second time it assumes the red colour. H. Rose supposes that a colourless neutral or acid silicate of the suboxide of copper is formed at a high temperature, and that the subsequent softening of the glass at a lower temperature causes the decomposition of this compound and a separation of a portion of the suboxide. We believe that no such chemical change takes place, and that the alteration is due merely to a change in the molecular arrangement of the particles. The suboxide of copper possesses an intense colouring power, so great indeed that glass coloured with even a very small quantity is almost impermeable to light; hence it is usual merely to *flash* colourless glass with this coloured glass, that is, to spread a very thin film of it over the colourless surface. A process for colouring glass red, after its manufacture, with sulphide of copper has been introduced by Bedford.

Gold can, according to circumstances, be made to impart a ruby, carmine, or pink tint to glass. The purple of Cassius was employed; but Dr. Fuss first showed that a mere solution of gold without the presence of tin, as in the salt named, is capable of producing rose and carmine coloured glass.

Similar changes to those already described with copper occur with the salts of gold. Perhaps the glass is colourless in the pot, and it then remains colourless when cold; but when re-heated, the glass quickly assumes a light red colour, which rapidly spreads from the heated point over the whole glass, and increases in intensity until it becomes nearly a black-red. This coloured glass can be again rendered colourless by fusion and slow cooling; its colour is again produced by a repetition of the heating process. If, however, it is suddenly cooled it cannot again be made to resume its ruby colour. This is also an example confirmatory in the highest degree of the view, that no chemical change takes place; but that all the phenomena are due to alterations in molecular structure. The practice of *flashing* colourless glass with the ruby glass from gold is commonly adopted. The beautiful examples of the Bohemian glass manufacture, in which we have a mixture of rich ruby and the purest crystal, are produced in this way. A globe of hot colourless glass is taken from the pot, and a cake of ruby glass, prepared with a composition called *Schmelze,* is warmed and brought into contact with the melted globe; this ruby glass rapidly diffuses itself over the surface, and the required article is blown or moulded with a coating of glass, coloured ruby by gold, of any required thickness.

Schmelze is prepared with 500 parts of silica, 800 of minium, 100 of nitre, and the same quantity of potash. A very small portion of a solution of gold in *aqua regia* is intimately mixed with 500 parts of Schmelze, 43 parts of prismatic borax, 3 or 4 of oxide of tin, and a similar quantity of oxide of antimony. This mixture is heated for twelve hours in an open crucible placed in a flat furnace, and then cooled slowly in an annealing oven. A *Bohemian ruby,* especially so called, is prepared by melting together fulminating gold rubbed in with oil of turpentine, quartz powdered, and fritted minium, sulphide of antimony, peroxide of manganese, and potash. Böhme has given an analysis of a Venetian ruby glass, in which $\frac{1}{20}$th of a grain of gold is combined with about 150 of the ordinary ingredients of glass, with some tin and iron.

Manganese is sometimes employed to give a fine amethystine colour to glass; care is however required to prevent the reduction of the peroxide of manganese in the process.

GREEN.—Green colours may be obtained by a variety of metallic oxides. *Protoxide of iron* imparts a dull green; an emerald-green colour is given by *oxide of copper.* Either copper-scales or verdigris dried and powdered are employed, the colour being much finer with a lead glass, than with one containing no lead. Translucent or *dull glass* is converted into a deep blue or turquoise colour by oxide of copper and not into a green. An emerald green is also produced by the *oxide of chromium.* Two kinds of Bohemian green glass, known respectively as the ancient and modern emerald greens, are prepared from mixtures of the oxides of nickel and of uranium.

BLUE.—The only fine blue is produced by cobalt. The manufacture of *smalt* or *zaffre* is so important that it will be treated of in a separate article. See SMALT and COBALT.

BROWN.—Peroxide of manganese with zaffre yields a fine garnet-like brown.

PINK or FLESH-COLOUR.—Oxide of iron and alumina, obtained by heating a mixture of alum and green vitriol.

ORANGE.—Peroxide of iron with chloride of silver.

JASPER.—A Bohemian glass, generally black, but of fine lustre, prepared by adding forge scales, charcoal, and bone ashes to the ordinary materials for glass.

Amongst the different varieties of glass, artificial gems may be enumerated. For a description of their manufacture, see GEMS, ARTIFICIAL.

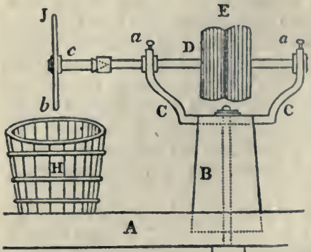
GLASS, STAINED. See GLASS, COLOURED.

GLASS CUTTING AND GRINDING, for common and optical purposes. By this mechanical process the surface of glass may be modified into almost any ornamental or useful form.

1. *The grinding of crystal ware.* This kind of glass is best adapted to receive polished facets, both on account of its relative softness, and its higher refractive power, which gives lustre to its surface. The cutting-shop should be a spacious long apartment, furnished with numerous skylights, having the grinding and polishing lathes arranged right under them, which are set in motion by a steam-engine or water-wheel at one end of the building. A shaft is fixed as usual in gallewses along the ceiling; and from the pulleys of the shaft, bands descend to turn the different lathes, by passing round the driving pulleys near their ends.

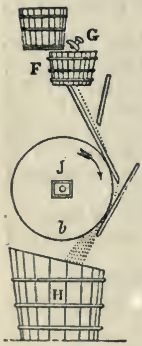
The turning lathe is of the simplest construction. *Fig.* 1103, D, is an iron spindle with two well-turned prolongations, running in the iron puppets *a a,* between two concave boshes of tin or type-metal, which may be pressed more or less together by the thumb-screws shown in the figure. These two puppets are made fast to the wooden support B, which is attached by a strong screw and bolt to the longitudinal beam of the workshop A. E is the fast and loose pulley for putting the lathe into and out of gear with the driving shaft. The projecting end of the spindle is furnished with a hollow head-piece, into which the rod *c* is pushed tight. This rod carries the cutting or grinding disc plate. For heavy work, this rod is fixed into the head by a screw. When a conical fit is preferred, the cone is covered with lead to increase the friction.

1103



Upon projecting rods or spindles of that kind the different discs for cutting the glass are made fast. Some of these are made of fine sandstone or polishing slate, from 8 to 10 inches in diameter, and from ¾ to ½ inch thick. They must be carefully turned and polished at the lathe, not only upon their rounded but upon their flat face, in order to grind and polish in their turn the flat and carved surfaces of glass vessels. Other discs of the same diameter, but only ¾ of an inch thick, are made of cast tin truly turned, and serve for polishing the vessels previously ground; a third set consists of sheet iron from ⅙ to ½ an inch thick, and 12 inches in diameter, and are destined to cut grooves in glass by the aid of sand and water. Small discs of well-hammered copper from ½ to 3 inches in diameter, whose circumference is sometimes flat, and sometimes concave or convex, serve to make all sorts of delineations upon glass by means of emery and oil. Lastly, there are rods of copper or brass furnished with small hemispheres from $\frac{1}{24}$ to ¼ of an inch in diameter, to excavate round hollows in glass. Wooden discs are also employed for polishing, made of white wood cut across the grain, as also of cork.

1104



The cutting of deep indentations, and of grooves, is usually performed by the iron disc, with sand and water, which are allowed constantly to trickle down from a wooden hopper placed right over it, and furnished with a wooden stopple or plug at the apex, to regulate by its greater or less looseness the flow of the grinding materials. The same effect may be produced by using buckets, as shown in *fig.* 1104. The sand which is contained in the bucket F, above the lathe, has a spigot and faucet inserted near its bottom, and is supplied with a stream of water from the stopcock in the vessel G, which, together, running down the inclined board, are conducted to the periphery of the disc as shown in the figure, to whose lowest point the glass vessel is applied with pressure by the hand. The sand and water are afterwards collected in the tub H. Finer markings which are to remain without lustre, are made with the small copper discs, emery, and oil. The polishing is effected by the edge of the tin disc, which is from time to time moistened with putty (white oxide of tin) and water. The wooden disc is also employed for this purpose with putty, colcothar, or washed tripoli. For fine delineations, the glass is first traced over with some coloured varnish, to guide the hand of the cutter.

In grinding and facetting crystal glass, the deep grooves are first cut, for example, the cross lines, with the iron disc and rounded edge, by means of sand and water. That disc is one-sixth of an inch thick and 12 inches in diameter. With another iron disc about half an inch thick, and more or less in diameter, according to the curvature of the surface, the grooves may be widened. These roughly cut parts must be next smoothed down with the sandstone disc and water, and then polished with the wooden disc about half an inch thick, to whose edge the workman applies, from time to time, a bag of fine linen containing some ground pumice moistened with water. When the cork or wooden disc edged with hat-felt is used for polishing, putty or colcothar is applied to it. The above several processes in a large manufactory are usually committed to several workmen on the principle of the division of labour, so that each may become expert in his department.

2. *The grinding of optical glasses.*—The glasses intended for optical purposes being spherically ground, are called lenses; and are used either as simple magnifiers and spectacles, or for telescopes and microscopes. The curvature is always a portion of a sphere, and either convex or concave. This form insures the convergence or divergence of the rays of light that pass through them, as the polishing does the brightness of the image.

The grinding of the lenses is performed in brass moulds, either concave or convex, formed to the same curvature as that desired in the lenses; and may be worked either by hand or by machinery. A gauge is first cut out of brass or copper plate to suit the curvature of the lens, the circular arc being traced by a pair of compasses. In this way both a convex and concave circular gauge are obtained. To these gauges the brass moulds are turned. Sometimes, also, lead moulds are used. After the two moulds are made, they are ground face to face with fine emery.

The piece of glass is now roughed into a circular form by a pair of pincers, leaving it a little larger than the finished lens ought to be, and then smoothed round upon the stone disc, or in an old mould with emery and water, and is next made fast to a holdfast. This consists of a round brass plate, having a screw in its back; and is somewhat smaller in diameter than the lens, and two-thirds as thick. This is turned concave upon the lathe, and then attached to the piece of glass by drops of pitch applied to several points of its surface, taking care, while the pitch is warm, that the centre of the glass coincides with the centre of the brass plate. This serves not merely as a holdfast, by enabling a person to seize its edge with the fingers, but it prevents the glass from bending by the necessary pressure in grinding.

The glass must now be ground with coarse emery upon its appropriate mould, whether convex or concave, the emery being all the time kept moist with water. To prevent the heat of the hand from affecting the glass, a rod for holding the brass plate is screwed to its back. For every six turns of circular motion, it must receive two or three rubs across the diameter in different directions, and so on alternately. The middle point of the glass must never pass beyond the edge of the mould; nor should strong pressure be at any time applied. Whenever the glass has assumed the shape of the mould, and touches it in every point, the coarse emery must be washed away, finer be substituted in its place, and the grinding be continued as before, till all the scratches disappear, and a uniform dead surface be produced. A commencement of polishing is now to be given with pumice-stone powder. During all this time the convex mould should be occasionally worked in the concave, in order that both may preserve their correspondence of shape between them. After the one surface has been thus finished, the glass must be turned over, and treated in the same way upon the other side.

Both surfaces are now to be polished. With this view equal parts of pitch and resin must be melted together, and strained through a cloth to separate all impurities. The concave mould is next to be heated, and covered with that mixture in a fluid state to the thickness uniformly of one quarter of an inch. The cold convex mould is now to be pressed down into the yielding pitch, its surface being quite clean and dry, in order to give the pitch the exact form of the ground lens; and both are to be plunged into cold water till they be chilled. This pitch impression is now the mould upon which the glass is to be polished, according to the methods above described, with finely-washed colcothar and water, till the surface become perfectly clear and brilliant. To prevent the pitch from changing its figure by the friction, cross lines must be cut in it about half an inch asunder, and one-twelfth of an inch broad and deep. These grooves remove all the superfluous parts of the polishing powder, and tend to preserve the polishing surface of the pitch clean and unaltered. No additional colcothar after the first is required in this part of the process, but only a drop of water from time to time. The pitch gets warm as the polishing advances, and renders the friction more laborious from the adhesion between the surfaces. No interruption must now be suffered in the work, nor must either water or colcothar be added; but should the pitch become too adhesive, it must be merely breathed upon till the polish be complete. The nearer the lens is brought to a true and fine surface in the first grinding, the better and more easy does the polishing become. It should never be submitted to this process with any scratches perceptible in it, even when examined by a magnifier.

As to small lenses and spectacle eyes, several are ground and polished together. The pieces of glass are affixed by means of a resinous cement to the mould, close to each other, and are then all treated as if they formed but one large lens. Plane glasses are ground upon a surface of pitch rendered plane by the pressure of a piece of plate glass upon it in its softened state.

Lenses are also ground and polished by means of machinery, into the details of which the limits of this work will not allow us to enter. See LENSES.

(For the *Importations* of glass see Table at top of next page.)

GLASS PAPER and **CLOTH.** Paper and cloth being covered with glue, sand, varying in its degree of fineness, is dusted over it, and of course adheres. These are used for polishing, or removing the rough surfaces of woods and metals.

GLASS, WATER. The term 'water-glass' is applied to those alkaline silicates which, by containing an excess of alkali, are soluble in water. A potash water-glass may be prepared by melting together 45 parts of silica, 30 of potash, and 3 of carbon, in the form of pulverised wood-charcoal. Soda water-glass may be obtained by fusing a mixture of 45 parts of silica, 23 of calcined soda, and 3 of charcoal. Water-glass is used for rendering wood and textile fabrics uninflammable; it is employed in the preparation of Ransome's artificial stone, and was introduced by Von Fuchs in his stereochromatic wall-painting. See STEREOCHROMY; STONE, ARTIFICIAL.

Our *Importations* of glass have been as follow in the years given:—

	1871		1872

GLAUBER'S SALTS (the *Sal cartharticus Glauberi*, or *Sal mirabile Glauberi*). Sulphate of soda was discovered by Glauber in 1658. Its composition is: soda, 19·24; sulphuric acid, 24·76; water, 56·00; total, 100·00.

GLAUCONITE. A mineral occurring generally in the form of dark green grains, which give a colour to certain rocks, especially to the Cretaceous Greensands. The grains are said to be, in many cases, casts of Foraminifera. Glauconite is a hydrous silicate of iron, alumina, potash, &c.

GLAZES. See Pottery.

GLAZIER, is the workman who cuts plates or panes of glass with the diamond, and fastens them by means of putty in frames or window casements. See Diamond, for an explanation of its glass-cutting property.

GLAZING. The process of giving a hard polished surface to bodies. Paper is glazed by the use of resins, gelatine, &c. See Paper. Pottery is glazed by the use of certain fusible materials. See Pottery and Porcelain. Some metals are said to be 'glazed' when, by means of polishing-wheels, the highest finish is put upon their surfaces.

GLIMMER. Many talcose and micaceous minerals were so called by the old miners. Werner applied the term to several varieties of mica; and Haidinger gave it to the species known as *Muscovite.* The terms Glimmer and Glidder are still applied by Cornish miners to the pearly shining surfaces of several minerals and to clays.

GLOVE MANUFACTURE. In February 1822, Mr. James Winter of Stoke-under-Hambdon, in the county of Somerset, obtained a patent for an improvement upon a former patent machine of his for sewing and pointing leather gloves. *Fig.* 1105 represents a pedestal, upon which the instrument called the jaws is to be placed.

Fig. 1106 shows the jaws, which, instead of opening and closing by a circular movement upon a joint, as described in the former specification, are now made to open and shut by a parallel horizontal movement, effected by a slide and screw; *a a* is the fixed jaw, made of one piece, on the under side of which is a tenon, to be inserted into the top of the pedestal. By means of this tenon the jaws may be readily removed, and another similar pair of jaws placed in their stead, which affords the advantage of expediting the operation by enabling one person to prepare the work while another is sewing; *b b* is the moveable jaw, made of one piece. The two jaws being placed together in the manner shown at *fig.* 1107, the moveable jaw traverses backwards and forwards upon two guide-bars, *c*, which are made to pass through holes exactly fitted to them, in the lower parts of the jaws. At the upper parts of the jaws are what are called the indexes, *d d*, which are pressed tightly together by a spring shown at *fig.* 1108, and intended to be introduced between the perpendicular ribs of the jaws at *e*. At *f* is a thumb-screw, passing through the ribs for the purpose of tightening the jaws, and holding the leather fast between the indexes while being sewn; this screw, however, will seldom, if ever, be necessary if the spring is sufficiently strong; *g* is an eye or ring fixed to the moveable jaw, through which the end of a lever, *h* in *fig.* 1105, passes; this lever is connected by a spring to a treadle *i*, at the base of the pedestal, and by the pressure of the right foot upon this treadle the moveable jaw is withdrawn; so that the person employed in sewing may shift the leather, and place another part of the glove between the jaws. The pieces called indexes are connected to the upper part of the jaws by screws passing through elongated holes which render them capable of adjustment.

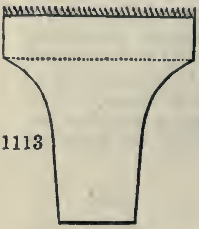
1107

The patentee states that, in addition to the index described in his former patent, which is applicable to what is called round-seam sewing only, and which permits the leather to expand but in one direction, when the needle is passed through it, namely, upwards, he now makes two indexes of different construction, one of which he calls the receding index, and the other the longitudinally-grooved index. *Fig.* 1108 represents an end view, and *fig.* 1109 a top view of the receding index, which is particularly adapted for what are called 'drawn sewing,' and 'prick-seam sewing.' This index, instead of biting to the top, is so rounded off in the inside from the bottom of the cross grooves, as to permit the needles, by being passed backwards and forwards, to carry the silk thread on each side of the leather without passing over it. *Fig.* 1110 represents an end view of the longitudinally-grooved index, partly open, to show the section of the grooves more distinctly; and *fig.* 1111 represents an inside view of one side of the same index, in which the longitudinal groove is shown, passing from *k* to *l*. This index is more particularly adapted to round-seam sewing, and permits the leather to expand in every direction when the needle is passed through it, by which the leather is less strained, and the sewing consequently rendered much stronger.

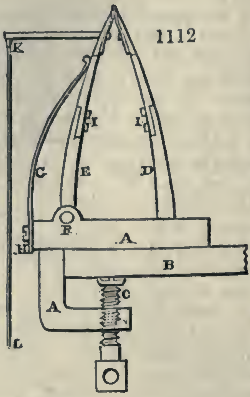
GLOVE-SEWING. The following simple and ingenious apparatus, invented by an Englishman, has been employed extensively in Paris. The instrument is shown in profile ready for action in *fig.* 1112. It resembles an iron vice, having the upper portion of each jaw made of brass, and tipped with a kind of comb of the same metal. The teeth of this comb, only one-twelfth of an inch long, are perfectly regular and equal. Change combs are provided for different styles of work. The vice A A is made fast to the edge of the bench or table B, of the proper height, by a thumb-screw C, armed with a cramp which lays hold of the wood. Of the two jaws composing the machine, the one D is made fast to the foot A A, but the other, E, is moveable upon the solid base of the machine by means of a hinge at the point F. At I I is shown how the upper brass portion is adjusted to the lower part made of iron; the two being secured to each other by two stout screws. The comb, seen separately in *fig.* 1114, is made fast to the upper end of each jaw, by the three screws *n*, *n*, *n*. *Fig.* 1113 is a front view of the jaw mounted with its comb, to illustrate its construction.

The lever K corresponds, by the stout iron wire L, with a pedal pressed by the needlewoman's foot, whenever she wishes to separate the two jaws, in order to insert between them the parallel edges of leather to be sewed. The instant she lifts her foot, the two jaws join by the force of the spring G, which pushes the moveable jaw E against the stationary one D. The spring is made fast to the frame of the vice by the screw H.

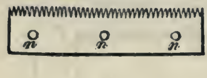
1113



1112



1114



After putting the double edge to be sewed in its place, the woman passes her needle successively through all the teeth of the comb, and is sure of making a regular seam in every direction, provided she is careful to make the needle graze along the bottom of the notches. As soon as this piece is sewed, she presses down the pedal with her toes, whereby the jaws start asunder, allowing her to introduce a new seam; and so on in quick succession.

The comb may have any desired shape, straight or curved; and the teeth may be either larger or smaller, according to the kind of work to be done. With this view, the combs might be changed as occasion requires; but it is more economical to have sets of vices ready mounted with combs of every requisite size and form.

It is estimated that the value of the gloves manufactured in France is between 1,600,000*l.* and 2,000,000*l.*, and is still rapidly increasing. The kid and lamb skins used for glazed gloves are dressed at Paris, Grenoble, Annonay, Romans, and Charlemont. The Paris manufacturers whose gloves are most esteemed employ workmen from Vendôme.

GLUCINA (*Glucine*, Fr.; *Beryllerde*, Ger.) is one of the primitive earths, originally discovered by Vauquelin in 1797 in the emerald of Limoges; he called it glucina from the sweet taste possessed by its salts. Its existence in several other minerals has since been proved: viz., in cymophane or chrysoberyl, phenacite, euclase, gadolinite, leucophane, &c. Its properties have been comparatively little studied, owing to the tedious and expensive processes required for its preparation.

GLUCINUM, the metal of Glucina, has been obtained by M. H. Debray (*Ann. Chem. et Phys.* xliv. 5) by the following process:—Into a wide glass tube are introduced two vessels, one containing chloride of glucinum, and the other sodium, deprived of the greatest part of the adhering naphtha by compression between two sheets of blotting-paper. The glass tube is placed in a combustion-furnace. It is then traversed by a current of hydrogen, passing from the chloride of glucinum to the sodium. The sodium is not placed in the tube until all the air has been expelled by the hydrogen. The tube is then heated just where the sodium is placed, which by this means is deprived of the last particle of naphtha, and fuses. The chloride of glucinum is then heated. The vapour of chloride driven forwards by the hydrogen arrives over the fused sodium. It then swells up, and the heat generated by chemical action is sufficient to raise the contents of the vessel to redness which often breaks the vessel if made of porcelain. The operation is ended when the chloride of glucinum sublimes beyond the sodium vessel. When the tube is cool the vessel is withdrawn, and in the place of the sodium a large quantity of a blackish substance is found, composed of common salt and the metal glucinum in brilliant spangles, and sometimes even in globules. This match is quickly detached and fused in a small crucible, with the addition of some dried common salt, which acts as a flux, and facilitates the union of the globules of metal.

It is a white metal, whose density is 2·1. It may be forged and rolled into sheets like gold. Its melting-point is inferior to that of silver. It may be melted in the outer blowpipe flame, without exhibiting the phenomenon of ignition presented by zinc and iron under the same circumstances. It cannot be set on fire in an atmosphere of pure oxygen, but in both cases is covered with a film of oxide, which seems to protect it from further action. It is not acted on by sulphur, but readily combines with chlorine and iodine by the aid of heat. See Watts's 'Dictionary of Chemistry.'

GLUCOSE. The name given to grape- and starch-sugar by M. Dumas.

GLUE (*Colle forte*, Fr.; *Leim*, *Tischlerleim*, Ger.) is the chemical substance gelatine in a dry state. The preparation and preservation of the skin and other animal matters employed in the manufacture of glue, constitute a peculiar branch of industry. Those who exercise it should study to prevent the fermentation of the substances, and to diminish the cost of carriage by depriving them of as much water as can conveniently be done. They may then be put in preparation by macerating them in milk of lime, renewed three or four times in the course of a fortnight or three weeks. This process is performed in large tanks of masonry. They are next taken out with all the adhering lime, and laid in a layer, 2 or 3 inches thick, to drain and dry, upon a sloping pavement, where they are turned over by prongs two or three times a day. The action of the lime dissolves the blood and certain soft parts, attacks the epidermis, and disposes the gelatinous matter to dissolve more readily. When the cleansed matters are dried, they may be packed in sacks or hogsheads, and transported to the glue-manufactory at any distance. The principal substances of which glue is made are the parings of ox and other thick hides, which form the strongest article, the refuse of the leather-dresser; both afford from 45 to 55 per cent. of glue. The tendons, and many other offals of slaughter-houses, also afford materials, though of an inferior quality, for the purpose. The refuse of tanneries, such as the ears of oxen, calves, sheep, &c., are better articles; but parings of parchment, old gloves, and, in fact, animal skin in every form, uncombined with tannin, may be made into glue.

The manufacturer who receives these materials is generally careful to ensure their purification by subjecting them to a weak lime steep, and rinsing them by exposure in baskets to a stream of water. They are lastly drained upon a sloping surface and well turned over till the quicklime gets mild by absorption of carbonic acid; for, in its caustic state, it would damage the glue at the heat of boiling water. It is not necessary, however, to dry them before they are put into the boiler, because they dissolve faster in their soft and tumefied state.

The boiler is made of copper, rather shallow in proportion to its area, with a uniform flat bottom, equably exposed all over to the flame of the fire. Above the true bottom there is a false one of copper or iron, pierced with holes, and standing upon feet 3 or 4 inches high; which serves to sustain the animal matters, and prevent them from being injured by the fire. The copper being filled to two-thirds of its height with soft water, is then heaped up with the bulky animal substances, so high as to surmount its brim. But soon after the ebullition begins they sink down, and, in a few hours get entirely immersed in the liquid. They should be stirred about from time to time, and well pressed down towards the false bottom, while a steady but gentle boil is maintained.

The solution must be drawn off in successive portions; a method which fractions the products, or subdivides them into articles of various value, gradually decreasing from the first portion drawn off to the last. It has been ascertained by careful experiments that gelatine gets altered over the fire very soon after it is dissolved, if the heat of 212° is maintained, and it ought therefore to be drawn off whenever it is sufficiently fluid and strong for forming a clear gelatinous mass on cooling, capable of being cut into moderately firm slices by the wire. The point is commonly determined by filling half an egg-shell with the liquor, and exposing it to the air to cool. The jelly ought to get very consistent in the course of a few minutes; if not so, the boiling must be persisted in a little longer. When this term is attained, the fire is smothered up, and the contents of the boiler are left to settle for a quarter of an hour. The stopcock being partially turned, all the thin gelatinous liquor is run off into a deep boiler, immersed in a warm water bath, so that it may continue hot and fluid for several hours. At the end of this time the supernatant clear liquid is to be drawn off into congealing boxes, as will be presently explained.

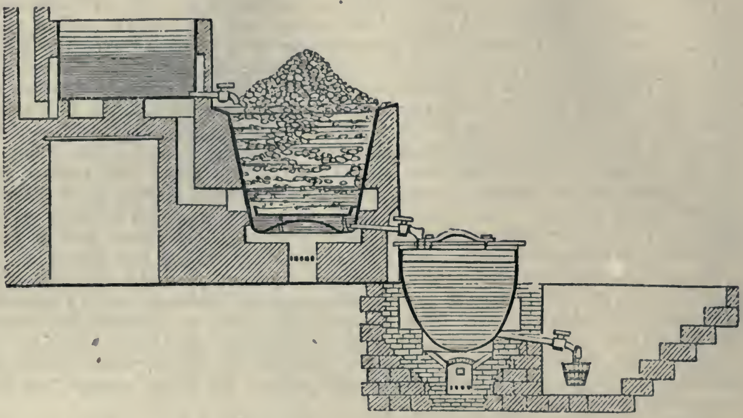
The residue, or undissolved matter in the boiler, is to be again supplied with a quantity of boiling water from an adjoining copper, and are to be once more subjected to the action of the fire, till the contents assume the appearance of dissolved jelly, and afford a fresh quantity of strong glue liquor, by the stopcock. The 'grounds' should be subjected a third time to this operation, after which they may be put into a bag, and squeezed in a press to leave nothing unextracted. The latter solutions are usually too weak to form glue directly, but they may be strengthened by boiling with a portion of fresh skin-parings.

Fig. 1115 represents a convenient apparatus for the boiling of skins into glue, in which there are three coppers upon three different levels: the uppermost being acted upon by the waste heat of the chimney, provides warm water in the most economical way; the second contains the crude materials, with water for dissolving them; and the third receives the solution to be settled. The last vessel is double, with water contained between the outer and inner one; and discharges its contents by a stopcock into buckets for filling the gelatinising wooden boxes. The last-made solution has about one-five-hundredth part of alum in powder usually added to it, with proper agitation, after which it is left to settle for several hours.

The three successive boils furnish three different qualities of glue.

Flanders or Dutch glue, long much esteemed on the Continent, was made in the manner above described, but at two boils, from animal offals well washed and soaked, so as to need less boiling. The liquor being drawn off thinner, was therefore less coloured, and being made into thinner plates was very transparent. The above two boils gave two qualities of glue.

1115



By the English practice, the whole of the animal matter is brought into solution at once, and the liquor being drawn off, hot water is poured on the residuum, and made to boil on it for some time, when the liquor thus obtained is merely used instead of water upon a fresh quantity of glue-materials. The first drawn off liquor is kept hot in a settling copper for five hours, and then the clear solution is drawn off into the boxes.

The boxes are made of deal, of a square form, but a little narrower at bottom than at top. When very regular cakes of glue are wished for, cross grooves of the desired square form are cut in the bottom of the box. The liquid glue is poured into the boxes placed very level, through funnels furnished with filter cloths, till it stands at the brim of each. The apartment in which this is done ought to be as cool and dry as possible, to favour the solidification of the glue, and should be floored with stone flags kept very clean, so that if any glue run through the seams, it may be recovered. At the end of 12 or 18 hours, or usually in the morning if the boxes have been filled over-night, the glue is sufficiently firm for the nets, and they are at this time removed to an upper story, mounted with ventilating windows to admit the air from all quarters. Here the boxes are inverted upon a moistened table, so that the gelatinous cake thus turned out will not adhere to its surface; usually the moist blade of a long knife is insinuated round the sides of the boxes beforehand to loosen the glue. The mass is first divided into horizontal layers by a brass wire stretched in a frame, like that of a bow-saw, and guided by rulers which are placed at distances corresponding to the desired thickness of the cake of glue. The lines formed by the grooves in the bottom of the box define the superficial area of each cake, where it is to be cut with a moist knife. The gelatinous layers thus formed, must be dexterously lifted, and immediately laid upon nets stretched in wooden frames, till each frame be filled. These frames are set over each other at distances of about three inches, being supported by small wooden pegs, stuck into mortise holes in an upright, fixed round the room; so that the air may have perfectly free access on every side. The cakes must moreover be turned upside down upon the nets twice or thrice every day, which is readily managed, as each frame may be slid out like a drawer, upon the pegs at its two sides.

The drying of the glue is the most precarious part of the manufacture. The least disturbance of the weather may injure the glue during the two or three first days of its exposure; should the temperature of the air rise considerably, the gelatine may turn so soft as to become unshapely, and even run through the meshes upon the pieces below, or it may get attached to the strings and surround them, so as not to be separable without plunging the net into boiling water. If frost supervene, the water may freeze and form numerous cracks in the cakes. Such pieces must be immediately re-melted and re-formed. A slight fog even produces upon glue newly exposed a serious deterioration; the damp condensed upon its surface occasioning a general mouldiness. A thunderstorm sometimes destroys the coagulating power in the whole laminæ at once; or causes the glue to *turn* on the nets, in the language of the manufacturer. A wind too dry or too hot may cause it to dry so quickly, as to prevent it from contracting to its proper size without numerous cracks and fissures. In this predicament, the closing of all the flaps of the windows is the only means of abating the mischief. On these accounts it is of importance to select the most temperate season of the year, such as spring and autumn, for the glue-manufacture.

After the glue is dried upon the nets it may still preserve too much flexibility, or softness at least, to be saleable; in which case it must be dried in a stove by artificial heat. This aid is peculiarly requisite in a humid climate, like that of Great Britain.

When sufficiently dry it next receives a gloss, by being dipped, cake by cake, in hot water, and then rubbed with a brush, also moistened in hot water; after which the glue is arranged upon a hurdle, and transferred to the stove-room, if the weather be not sufficiently hot. One day of proper drought will make it ready for being packed up in casks.

The pale-coloured, hard, and solid article, possessing a brilliant fracture, which is made from the parings of ox-hides by the first process, is the best and most cohesive, and is most suitable for joiners, cabinet-makers, painters, &c. But many workmen are influenced by such ignorant prejudices, that they still prefer a dark-coloured article, with somewhat of a fetid odour, indicative of its impurity and bad preparation, the result of bad materials and too long exposure to the boiling heat.

There is a good deal of glue made in France from bones freed from the phosphate of lime by muriatic acid. This is a poor article, possessing little cohesive force. It dissolves almost entirely in cold water, which is the best criterion of its imperfection. Glue should merely soften in cold water, and the more considerably it swells, the better, generally speaking, it is.

Some manufacturers prefer a brass to a copper pan for boiling glue, and insist much on skimming it as it boils; but the apparatus represented renders skimming of little consequence. For use, glue should be broken into small pieces, put along with some water in a vessel, allowed to soak for some hours, and subjected to the heat of a boiling-water bath, but not boiled itself. The surrounding hot water keeps it long in a fit state for joiners, cabinet-makers, &c.

Water containing only one-hundredth part of good glue, forms a tremulous solid. When the solution, however, is heated and cooled several times, it loses the property of gelatinising, even though it be enclosed in a vessel hermetically sealed. Isinglass or fish-glue undergoes the same change. Common glue is not soluble in alcohol, but is precipitated in a white, coherent, elastic mass, when its watery solution is treated with that fluid. By transmitting chlorine gas through a warm solution of glue, a combination is very readily effected, and a viscid mass is obtained like that thrown down by alcohol. A little chlorine suffices to precipitate the whole of the glue. Concentrated sulphuric acid makes glue undergo remarkable changes; during which are produced sugar of gelatine, leucine, an animal matter, &c. Nitric acid, with the aid of heat, converts glue into malic acid, oxalic acid, a fat analogous to suet, and into tannin; so that, in this way, one piece of skin may be made to tan another. When the mixture of glue and nitric acid is much evaporated, a detonation at last takes place. Strong acetic acid renders glue first soft and transparent, and then dissolves it. Though the solution does not gelatinise, it preserves the property of glueing surfaces together when it dries. Liquid glue dissolves a considerable quantity of lime, and also of the phosphate of lime recently precipitated. Accordingly glue is sometimes contaminated with that salt. Tannin, both natural and artificial, combines with glue; and with such effect, that one part of glue dissolved in 5,000 parts of water affords a sensible precipitate with the infusion of nutgalls. Tannin unites with glue in several proportions, which are to each other as the numbers 1, 1½, and 2: one compound consists of 100 glue and 89 tannin; another of 100 glue and 60 tannin; and a third of 100 glue and 120 tannin. These two substances cannot be afterwards separated from each other by any known chemical process.

Glue may be freed from the foreign animal matters generally present in it, by softening it in cold water, washing it with the same several times till it no longer gives out any colour, then bruising it with the hand, and suspending it in a linen bag beneath the surface of a large quantity of water at 60° F. In this case, the water loaded with the soluble impurities of the glue gradually sinks to the bottom of the vessel, while the pure glue remains in the bag surrounded with water. If this softened glue be heated to 92° without adding water, it will liquefy; and if we heat it to 122°, and filter it, some albuminous and other impurities will remain on the filter, while a colourless solution of glue will pass through.

Experiments have not yet explained how gelatine is formed from skin by ebullition. It is a change somewhat analogous to that of starch into gum and sugar, and takes place without any appreciable disengagement of gas, and even in close vessels. Gelatine, says Berzelius, does not exist in the living body, but several animal tissues, such as skin, cartilages, hartshorn, tendons, the serous membranes, and bones, are susceptible of being converted into it. See GELATINE.

GLUTEN (*Colle vegetale* and *Gluten*, Fr.; *Kleber*, Ger.) was first extracted by Beccaria from wheat-flour, and was long regarded as a proximate principle of plants, till Einhoff, Taddei, and Berzelius succeeded in showing that it may be resolved by means of alcohol into three different substances: one of which resembles closely animal albumen, and has been called *Zymome*, or vegetable albumen; another has been called *Gliadine;* and a third, *Mucine.*

Gluten, when dried in the air or a stove, diminishes greatly in size, becomes hard, brittle, glistening, and of a deep yellow colour. It is insoluble in ether, fat and essential oils, and nearly so in water. Alcohol and acetic acid cause gluten to swell and make a sort of milky solution. Dilute acids and alkaline lyes dissolve gluten. Its constituents are not precisely determined, but nitrogen is one of them, and accordingly when moist gluten is left to ferment, it exhales the smell of old cheese.

Some years since, M. E. M. Martin, of Vervins, proposed to extract the starch without injuring the gluten, which then becomes available for alimentary purposes. His process is a mechanical one (resembling that long practised in laboratories for procuring gluten), and consists in washing wheat-flour, made into a paste, with water, either by the hand or machinery.

The gluten thus obtained is susceptible of numerous useful applications for alimentary purposes. Mixed with wheat-flour, in the proportions of 30 parts of flour, 10 of fresh gluten, and 7 of water, it has been employed to produce a superior sort of macaroni, vermicelli, and other kinds of Italian pastes; and MM. Véron Frères, of Paris, have made with it a new sort of paste, which they have termed *granulated gluten* (*gluten granulé*).

GLYCERINE is a sweet substance extracted from fatty substances. It may be prepared in the utmost purity by the following process:—'If we take equal parts of olive-oil and finely-ground litharge, put them into a basin with a little water, set this on a sand-bath moderately heated, and stir the mixture constantly, with the occasional addition of hot water to replace what is lost by evaporation, we shall obtain, in a short time, a soap or plaster of lead. If, after having added more water to this, we remove the vessel from the fire, decant the liquor, filter it, pass sulphuretted hydrogen through it to separate the lead, then filter afresh, and concentrate the liquor as much as possible without burning, upon the sand-bath, we obtain glycerine; but what remains must be finally evaporated within the receiver of the air-pump. Glycerine thus prepared is a transparent liquid, without colour or smell, and of a syrupy consistence. It has a very sweet taste. It specific gravity is 1·27 at the temperature of 60°. When thrown upon burning coals, it takes fire and burns like an oil. Water combines with it in almost all proportions; alcohol dissolves it readily; nitric acid converts it into oxalic acid; and, according to Vogel, sulphuric acid transforms it into sugar, in the same way as it does starch. By yeast it becomes acid by the formation of formic and metacetic acids.'

Its constituents are, carbon 40, hydrogen 9, oxygen 51, in 100.

Glycerine is one of the products of the saponification of fat-oils. It is produced in large quantities in the soap-manufactories in a very impure state, being contaminated with saline and empyreumatic matters, and having a very strong disagreeable odour. In order to obtain glycerine from this source, the residuary liquors are evaporated and treated with alcohol, which dissolves out the glycerine. The alcohol having been separated by evaporation, the glycerine is diluted with water, and boiled with animal charcoal. This process must be repeated several times, or until the result is sufficiently free from smell. It is, however, difficult to obtain pure glycerine from this source, on account of the nature and condition of the ingredients usually employed in making soap, which it is almost impossible to deprive of rancid odour.

The compounds of glycerine with the fatty acids constitute the various kind of fats and oils, but the base does not appear to have the same composition in all. A certain quantity of water appears to separate, and the equivalent of glycerine to be in some fats, but half what it is in others.

Glycerine is now obtained in great quantities from palm-oil, in the process of purification for candles. It is employed with much advantage to preserve soft-bodied animals. It is manufactured into soap, is administered internally, and is supposed to possess highly nutritive properties. It has been employed in cases of deafness, and in diseases of the throat. By some it is used to preserve collodion plates in a state of sensitiveness for many days.

Glycerine has many important uses in the arts. The use of it as a soap, *glycerine soap*, is now familiar to all. It may be used for preserving articles of food, especially such as require to be kept moist, as fruits and the like, in tin cases. Meat is said to keep well in glycerine, and preserve its flavour. It is recommended to modellers for keeping their clay moist. In the *Technologist*, January 1858, a process of madder-dyeing with the aid of glycerine is described. It has been much used in printing processes, especially, for printing receipt and postage stamps. Vasseurs and Houbigant patented an application of glycerine. They dilute it with four or five times its weight of water; with this, paper is moistened, and it retains its moist condition for any length of time. It may be introduced into the paper pulp, or it may be mixed with the ink. In either case copies can be readily taken by pressure. Glycerine never freezes; it is therefore recommended as a lubricant for delicate machinery, and it has been used for floating ships' compasses, as it will not solidify in cold climates, or evaporate in hot ones.

Amongst other purposes to which glycerine has been applied, it has been substituted for lard, as a basis for ointments, by forming a 'plasma' of glycerine and starch. Fifty grains of the *Tous-les-mois* starch are to be rubbed with one ounce of glycerine, and the mixture heated to 240° for a few minutes, or till it becomes translucent. See Watts's 'Dictionary of Chemistry.'

Klever has estimated the solubilities of a number of substances in glycerine. The following are his results:—At the ordinary temperature 100 parts of glycerine dissolve

98 parts of	Carbonate of soda.
60 ,,	Borate of soda.
50 ,,	Arseniate of potash.
50 ,,	Arseniate of soda.
50 ,,	Chloride of zinc.
50 ,,	Tannin.
50 ,,	Urea.
40 ,,	Alum.
40 ,,	Iodide of potassium.
40 ,,	Iodide of zinc.
35 ,,	Sulphate of zinc.
33 ,,	Sulphate of atropine.
33 ,,	Cyanide of potassium.
30 ,,	Sulphate of copper.
27 ,,	Cyanide of mercury.
25 ,,	Bromide of potassium.
25 ,,	Protosulphate of iron.
22·5 ,,	Sulphate of strychnine.
20 ,,	Acetate of morphine.
20 ,,	Acetate of lead.
20 ,,	Arsenious acid.
20 ,,	Carbonate of ammonia.
20 ,,	Chlorate of soda.
20 ,,	Hydrochlorate of ammonia.
20 ,,	Hydrochlorate of morphia.
16 parts of	Lactate of protoxide of iron.
15 ,,	Oxalic acid.
10 ,,	Acetate of copper.
10 ,,	Benzoic acid.
10 ,,	Boracic acid.
10 ,,	Chloride of barium.
8 ,,	Bicarbonate of soda.
8 ,,	Tartrate of iron.
7·5 ,,	Bichloride of mercury.
6·7 ,,	Sulphate of cinchonine.
5·5 ,,	Tartar emetic.
5 ,,	Polysulphuret of calcium.
4 ,,	Nitrate of strychnine.
3·5 ,,	Chlorate of potash.
3 ,,	Atropine.
2·25 ,,	Brucine.
1·90 ,,	Iodine.
1 ,,	Veratrine.
0·50 ,,	Cinchonine.
0·50 ,,	Quinine.
0·45 ,,	Morphine.
0·25 ,,	Tannate of quinine.
0·25 ,,	Strychnine.
0·20 ,,	Phosphorus.
0·10 ,,	Sulphur.

GLYCERINE, NITRO. See Nitro-Glycerine.

GLYOXILINE. See Explosive Agents.

GLYPHOGRAPHY. A process introduced some years since to cheapen wood-engraving. A metal plate was covered with a thick etching-ground, and an etching made through to the metal in the usual manner. Several coats of ink were then applied by means of a small composition roller. This adheres only to the varnish. When the hollows are deep enough, the plate is placed in connection with a voltaic battery, and copper is deposited in the usual way; the result being a plate with the drawing in relief. See Electro-Metallurgy.

GNEISS may be called stratified, or, by those who object to that term, foliated granite, being formed of the same materials as granite, namely, felspar, quartz, and mica.—*Lyell.*

Gneiss might indeed, in its purest and most typical form, be termed schistose granite, consisting, like granite, of felspar, quartz, and mica; but having those minerals arranged in layers or plates, rather than in a confused aggregation of crystals.—*Jukes.*

In whatever state of aggregation the particles of gneiss may have been originally deposited, we know now that it is a hard, tough, crystalline rock, exhibiting curved and twisted lines of stratification, and composed in the main of quartz, felspar, mica, and hornblende. Mineralogically speaking, it differs from the granite rocks with which it is associated chiefly in this, that while the crystals of quartz, felspar, &c., are distinct and entire in granite, in gneiss they are broken, water-worn, and confusedly aggregated. Hence the general belief is, that gneiss or gneissose rocks are but the particles of granite weathered and worn, carried down by streams and rivers, and deposited in the seas of that early period.—*Page.*

GOAF. The waste space left by working a seam of coal, often filled in with refuse sometimes called GOB.

GOBBIN or **GOAFFIN.** The refuse left behind in working coal, and thrown into the goaf.

GOBELIN MANUFACTORY. This establishment, which has long been celebrated for its tapestry, took its name from the brothers Gobelin. Giles Gobelin, a dyer at Paris, in the time of Francis I., had found out an improvement in the then usual scarlet dye; and as he had remarked that the water of the rivulet Bièvre, in the suburbs of St. Marceau, was excellent for his art, he erected on it a large dye-house, which, out of ridicule, was called *Folie-Gobelins* (*Rabelais.*) About this period a Flemish painter, whom same name Peter Koek, and others Kloek, and who had travelled a long time in the East, established, and continued to his death in 1550, a manufactory for dyeing scarlet cloth by an improved process. Through the means of Colbert, minister of Louis XIV., one of the Gobelins learned the process used for preparing the German scarlet dye from one Gluck, whom some consider to be Gulich (who was said to have learned to dye scarlet from one Kuffelar, a dyer at Leyden), and others as Kloek; and the Parisian scarlet dye soon rose into so great repute that the populace imagined that Gobelin had acquired the art from the devil. It is known that Louis XIV., by the advice of Colbert, purchased Gobelin's building from his successors in 1667, and transformed it into a palace, to which he gave the name of *Hôtel Royal des Gobelins,* and which he assigned for the use of first-rate artists, particularly painters, jewellers, weavers of tapestry, and others.—*Beckmann.*

The national manufactory is now alone remarkable for its production in textile manufacture of some of the finest works of art; and not only does it excel in the high character of its designs, but also in the brilliancy and permanence of its *colours.*

GOITRE-STICKS. The stems of the *Sargassum bacciferum,* supposed by some to be useful in curing goître, by virtue of the iodine which they contain.

GOLD. (Eng. and Ger.; *Or,* Fr.) This metal is distinguished by its splendid yellow colour; its great density = 19·3, compared to water 1·0; its pre-eminent ductility and malleability, whence it can be beaten into leaves only 1-282,000th of an inch thick; and its insolubility in any acid menstruum, except the mixture of muriatic and nitric acids, called *aqua regia*—because gold was deemed by the alchemists to be the king of minerals—or in solutions of chlorine.

Gold is almost always found in the metallic state, frequently crystallised in the cube, and its derivative forms.

Mr. J. Arthur Phillips, in his work on 'The Mining and Metallurgy of Gold and Silver,' gives the following modes of occurrence of gold:—

'*Native gold.*—An alloy of gold and silver, associated with small quantities of copper, iron, and other metals.

'*Palladium gold.*—Gold and palladium; porpezite.

'*Rhodium gold.*—Gold and rhodium.

'*Gold-amalgam.*—A native amalgam of gold and mercury.

'*Sylvanite,* or Graphic Tellurium.—An ore, being a telluride of gold and silver.

'*Nagyagite.*—An ore; telluride of lead, containing gold, silver, and copper.'

In addition to these, gold is found associated with copper and iron pyrites; whether in chemical combination, or simply existing in mechanical mixture, does not appear to have been satisfactorily determined.

Native gold is almost always associated with silver. A few examples will show how this native alloy varies.

The *Electrum* of Pliny was not probably found native, although it is often stated to have been so. It seems to have been an alloy, containing at least 20 per cent. of silver.

Gold occurs in threads of various sizes, twisted and interlaced into a chain of minute octahedral crystals; as also in spangled or rounded grains, which, when of a certain magnitude, are called *pepitas.* The small grains are not fragments broken from a greater mass; but they show by their flattened ovoid shape, and their rounded outline, that this is their original state. Humboldt states that the largest *pepita* known was one found in Peru weighing about 12 kilogrammes (26½ lbs. avoird.); but masses have been quoted in the province of Quito which weighed nearly four times as much. Some of the 'nuggets' from Australia have greatly exceeded this. The specific gravity of native gold varies from 13·3 to 17·7.

The mineral formations in which this metal occurs are the crystalline primitive rocks, the compact transition rocks, the trachytic and trap rocks, and alluvial grounds. Sir Roderick Murchison says, in a chapter *On the Original Formation of Gold,* in his 'Siluria':—

'We may first proceed to consider the nature and limits of the rich gold-bearing rocks, and then offer proofs that the chief auriferous wealth, as derived from them, occurs in superficial detritus. Appealing to the structure of the different mountains, which at former periods have afforded, or still afford, any notable amount of gold, we find in all a general agreement. Whether, referring to past history, we cast our eyes to the countries watered by the sources of the Golden Tagus, to the Phrygia and Thrace of the Greeks and Romans, to the Bohemia of the Middle Ages, to tracts in Britain which were worked in old times, and are now either abandoned, or very slightly productive, or to those chains in America and Australia, which, previously unsearched, have in our times proved so rich, we invariably find the same constants in nature. In all these lands, gold has been imparted abundantly to the ancient rocks only, whose order and succession we have traced, or their associated eruptive rocks. Sometimes, however, it is also shown to be diffused through the body of such rocks, whether of igneous or of aqueous origin. The stratified rocks of the highest antiquity, such as the oldest gneiss and quartz rocks (like those, for example, of Scandinavia and the Northern Highlands of Scotland), have very seldom borne gold; but the sedimentary accumulations which followed, or the Silurian, Devonian, and Carboniferous (particularly the first of these three) have been the deposits which, in the tracts where they have undergone a metamorphosis or change of structure by the influence of igneous agency, or other causes, have been the *chief* sources whence gold has been derived.'

Gold is usually either disseminated through the rocks, often in extreme minuteness, or spread out in thin plates or grains on their surface, or, lastly, implanted in their cavities, under the shape of filaments or aborescent crystallisation. The minerals composing gold-bearing veins are either quartz, calcspar, or sulphate of baryta. The ores that accompany the gold in these veins are chiefly iron pyrites, copper pyrites, galena, blende, and mispickel (arsenical pyrites).

In the ores called auriferous pyrites, this metal occurs generally in an invisible form; but though invisible in the fresh pyrites, the gold becomes visible by its decomposition; as the hydrated oxide of iron allows the native gold particles to shine forth on their reddish-brown ground, even when the precious metal may constitute only the five-millionth part of its weight, as at the Rammelsberg in the Hartz. In that state it has been extracted with profit; most frequently by amalgamation with mercury, proving that the gold was in the native state, and not in that of a sulphuret. The iron pyrites of Wicklow and of some of our English mines, contain gold. After the sulphur of the ore has been separated in the process of manufacturing sulphuric acid, the residuary mass, called 'sulphur-cake,' is roasted with common salt. This is thrown into hot water, the copper which is present is dissolved as chloride of copper. The silver present has been converted by the roasting process into a chloride; this is dissolved out with a strong brine, from which the silver is precipitated by zinc. The silver cake obtained in this way is sold from prices varying from 6*s.* to 10*s.* the ounce, the additional sum, above 5*s.* 6*d.* the ounce for pure silver, being given for the gold it contains. See PYRITES.

Principal Gold Mines.

Gold exists in the primitive strata, disseminated in small grains, spangles, and crystals. Brazil affords a remarkable example of this species of gold mine. Beds of granular quartz, or micaceous specular iron, in the Sierra of Cocäes, 12 leagues beyond Villa Rica, which form a portion of a mica-slate district, include a great quantity of native gold in spangles, which in this ferruginous rock replace mica.

The auriferous ores of Hungary and Transylvania, composed of tellurium, silver pyrites, or sulphide of silver, and native gold, lie in masses or veins in a rock of trachyte, or in a decomposed felspar subordinate to it. Such is the locality of the gold ore of Königsberg, of Telkebanya, between Eperies and Tokay in Hungary, and probably that of the gold ores of Kapnick, Felsöbanya, &c., in Transylvania; an arrangement nearly the same with what occurs in Equatorial America. The auriferous veins of Guanaxuato, of Real del Monte, of Villalpando, are similar to those of Schemnitz in Hungary, as to magnitude, relative position, the nature of the ores they include, and of the rocks they traverse. Breislak and Hacquet have described the gold mines of Transylvania as situated in the crater of an ancient volcano. The trachytes which, in some districts, form the principal portions of the rocks including gold, are regarded as of igneous or volcanic origin.

It would seem, however, that the primary source of the gold is not in these rocks, but rather in the syenites and greenstone-porphyries, which in Hungary and Transylvania are rich in great auriferous deposits; for gold has never been found in the trachyte of the Euganean mountains, of the mountains of the Vicentin, or those of the Auvergne; all of which are superposed upon granite rocks.

If it be true that the ancients worked mines of gold in the island of Ischia, it would be another example, and a very remarkable one, of the presence of this metal in trachytes of an origin evidently volcanic.

Gold, from whatever rocks derived, is common in the alluvial deposits near the primitive rocks just described. It is found disseminated in the siliceous, argillaceous, and ferruginous sands of certain plains and rivers, especially in their re-entering angles, at the season of low water, and after storms and temporary floods. It has been supposed that the gold found in the beds of rivers has been torn out by the waters from the veins and primitive rocks, which they traverse. This opinion, suggested at first by Delius, and supported by Deborn, Guettard, Robitant, Balbo, &c., appears to be founded upon just observations: 1. The soil of these plains contains frequently, at a certain depth, and in several spots, spangles of gold, separable by washing. 2. The beds of the auriferous rivers and streamlets contain more gold after storms of rain upon the plains than in any other circumstances. 3. It happens almost always that gold is found among the sands of rivers only in a very circumscribed space. Thus it is known that the Orco contains no gold, except from Pont to its junction with the Po. The Ticino affords gold only below the Lago Maggiore, and consequently far from the primitive mountains, after traversing a lake, where its course is slackened, and into which whatsoever is carried down from these mountains must have been deposited. The Rhine gives more gold near Strasburg than near Basle, though the latter be much closer to the mountains. The sands of the Danube do not contain a grain of gold, while this river runs in a mountainous region; that is, from the frontiers of the bishopric of Passau to Efferding; but its sands become auriferous in the plains below. The same thing is true of the Ems; the sands of the upper portion of this river, as it flows among the mountains of Styria, include no gold; but from its entrance into the plain at Steyer, till its embouchure in the Danube, its sands become auriferous, and are even rich enough to be washed with profit.

The greater part of the auriferous sands in Europe, Asia, Africa, and America, are black or red, and consequently ferruginous; a remarkable circumstance in the geological position of alluvial gold. M. Napione supposes that the gold of these ferruginous grounds is due to the decomposition of auriferous pyrites. The auriferous sand occurring in Hungary almost always in the neighbourhood of the beds of *lignite*, and the petrified wood covered with gold grains, found buried at a depth of 55 yards in clay, in the mine of Vöröspatak near Abrabanya in Transylvania, might lead us to presume that the epoch of the formation of the auriferous alluvia is not remote from that of the lignites. The same association of gold ore and fossil wood occurs in South America, at Moco. Near the village of Lloro have been discovered, at a depth of 20 feet, large trunks of petrified trees, surrounded with fragments of trap rocks interspersed with spangles of gold and platinum. But the alluvial soil affords likewise all the characters of the basaltic rocks; thus in France, the Cèze and the Gardon, auriferous rivers, where they afford most gold, flow over ground apparently derived from the destruction of the trap rocks, which occur *in situ* higher up the country. This fact had struck Réaumur, and this celebrated observer had remarked that the sand which more immediately accompanies the gold spangles in most rivers, and particularly in the Rhone and the Rhine, is composed, like that of Ceylon and Expailly, of black protoxide of iron and small grains of rubies, corundum, hyacinth, &c. Titanium has been observed more recently. It has, lastly, been remarked that the gold of alluvial formations is purer than that extracted from rocks.

Spain anciently possessed mines of gold in regular veins, especially in the province of Asturias; but the richness of the Mexican mines caused them to be neglected. Julius Cæsar is said to have paid his enormous debts, and have added largely to the Roman treasury, from the wealth which he derived from the Spanish mines. The Tagus, and some other streams of that country, were said to roll over golden sands. France contains no workable gold mines; but it presents in several of its rivers auriferous sands. There are some gold mines in Piedmont; particularly the veins of auriferous pyrites of Macugnagna, at the foot of Monte Rosa, lying in a mountain of gneiss; and although they do not contain 10 or 11 grains of gold in a hundred-weight, they have long defrayed the expense of working them. On the southern slope of the Pennine Alps, from the Simplon and Monte Rosa to the valley of Aoste, several auriferous districts and rivers occur. Such are the torrent Evenson, which has afforded much gold by washing; the Orco, in its passage from the Pont to the Po: the reddish grounds over which this little river runs for several miles, and the hills in the neighbourhood of Chivasso, contain gold spangles in considerable quantity.

In the county of Wicklow, in Ireland, in the year 1796, some fine specimens of gold were found,—one mass weighing twenty-two ounces. The gold is found in the *débris* of the valley at the base of Croghan-Kinshela; and it would appear to be derived from the granite of that mountain, or the hornblendic greenstones by which it is traversed. Messrs. Weaver and Mills, however, prosecuted extensive mine-workings in search of the source of the gold without any success. As we have already stated, the pyrites of Wicklow contains gold, but no auriferous veins have been discovered. In Cornwall gold has been found in the tin-streams of Carnon vale, in the Pentuan stream works at Menaccan, and some few other spots; and some of the quartz veins traversing the slate have been found to contain gold. Many of the gossans of the copper lodes are known to have gold in them; but it is only in a few rare instances that the precious metal has been separated.

In Devonshire, near North Molton,—at the Britannia and at the Poltsmore mine,—gold has been found in small quantities, associated with the minerals of the district; but it has never paid the cost of obtaining it. In Scotland also gold has been found. Pennant says: 'In the reigns of James IV. and V. vast wealth was procured in the Lead Hills, from the gold washed from the mountains; in the reign of the latter not less than the value of 300,000*l.* sterling.' We are told that in another locality a piece of gold weighing thirty ounces was found; but we cannot find any good authority for this statement. The gold-bearing districts of Scotland are described at p. 698.

The Gold Mines of North Wales having acquired a large share of attention, it has been thought desirable to insert the following notice from the pen of a gentleman who has most industriously investigated the quartz lodes of Merionethshire.

In North Wales, the older slaty rocks are auriferous. Professor Ramsay has examined and described the district, and especially the mineral and quartz veins of Cwm-eisen-isaf and Dol-y-frwynog, which contain gold. At Gogofau, not far from Llandovery, the Romans worked for gold, the remains of their workings being still to be discovered. Gogofau has been described by Mr. W. Warington Smyth in the 'Memoirs of the Geological Survey.'

The existence of gold in the British Isles was known at a very remote period of history, and it is certain that many adventurers, in crazy craft, came to this country in search of metallic wealth. Julius Cæsar, probably, invaded these islands more for the acquisition of supposed riches than the conquest of a rude and barbarous people. This opinion is strengthened, if not confirmed, by the expression of Galgacus, whilst attacking the Caledonians, 'Britain produces gold, silver, and other metals, the booty of victory.'[1]

A celebrated 'Triad' makes three Welsh chieftains the enviable possessors of *golden cars*, and Meyrick reasonably infers from this, that gold mines were worked by the Welsh (*Cymri*), at a very early period.[2]

---

[1] 'Fert Britannia aurum et argentum et alia metalla, pretium victoriæ; gignit et oceanus margarita sed subfusca et liventia.'—Tacitus, *Vita Agricolæ*, cap. xii.

[2] 'History and Antiquities of the County of Cardiganshire.' 1810.

The style of the golden weapons, torques, bracelets, &c., that have been found at various times is very simple, and quite unlike the style of ornamentation of the early Christian period; it is therefore naturally inferred that they belonged to a time long anterior to that.

It is, however, certain that the Romans actually discovered gold in Wales, and wrought it too: for independently of the statement of Tacitus, just quoted, there are evidences, plenty, of Roman mine-works where gold must have been the principal, if not the sole object of exploration. One of the most remarkable is Gogofau, in Caermarthenshire.[1] This gold-mine is situate on the banks of the Cothy, and forms part of the grounds of Dolau-Cothy. Here a quartz-lode has been 'worked open to the day,' and levels driven 170 feet through the slate. The officers of the Geological Survey discovered gold here, and a *metallurgical workshop.* Amongst other things a beautiful gold necklace was found, which is now in the possession of Mrs. Johnnes, the wife of the gentleman to whom the property belongs. Other instances might be cited, in proof of the former existence of gold in tolerably large quantities in many parts of these islands.[2]

Strabo coincides with Tacitus, as to the precious metals: but Cæsar makes no mention of gold and silver. Cicero (B.C. 106) says: 'In Britannia nihil esse audio neque auri neque argenti,'[3] and, in another Epistle (ad Attic.) he says, 'it was well known that not a single grain of silver could be found in the island.'[4] The statements of Cicero do not, however, tally with subsequent history, and are contradicted by Camden and other modern authorities. Probably there is not, and never was, gold and silver enough discovered in Britain to be, as Tacitus thought, 'the price of victory;' yet the comparative scarcity of precious stones at the time would tend to pre-induce a desire to possess in quantity the next best representatives of value, the precious and the baser metals.

Cimboline, prince of the Trinobantes, had a coinage of gold. This was supposed to be made of British gold, obtained in Essex, but the Essex gold mine is exceedingly problematical.

An idea appears constantly to have prevailed that the gold of this country was by no means of insignificant quantity or value. The 'avarice of kings' and the exigencies of State, as soon as possible, and as a matter of course, laid claim not only to all the gold and silver found, but to all the baser metals as well. These pretensions were, however, subsequently abandoned, and the Crown was divested of all rights in minerals, except gold and silver; these precious metals being retained, as it was said, 'for the purposes of coinage, and to support the dignity of the Crown.'[5] That great legal authority, Sir Edward Coke, laid down the law, 'that *veyns* of gold and silver in the grounds of subjects belong to the king by his prerogative, for they are *Royall* mines,'[6] and the Justices and Barons in the 'Great Case of Mines' (1568) unanimously agreed,[7] 'That by the law, all mines of gold and silver within the realm, whether in the lands of the queen or her subjects, belong to the queen by prerogative, with liberty to dig and carry it away.' And so firmly was the prerogative of the Crown thus established, that it was agreed that a royal mine could not be severed from the Crown; but the judges overruled this. The only doubt existing in the time of Elizabeth was whether, if gold and silver were found intermixed with the baser metals, the whole became a royal mine.

Some contended that any quantity of gold or silver so found was sufficient, whilst others held the opinion that the gold and silver must exceed in value the other metals; but the judges decided that even where the gold or silver in a mine of base metals in the land of a subject was of less value than the base metal, the mere circumstance of its existence makes it a royal mine. The uncertainty of the law, on this decision, caused general distrust, and destroyed to a great extent this kind of enterprise; therefore, in the first year of William and Mary an act was passed (cap. 30.) wherein it was declared that no mine of copper, tin, iron, or lead, shall hereafter be adjudged a royal mine, although gold or silver might be extracted out of the same. This provision, also, was soon considered insufficient, and in the fifth year of William and Mary, an act was passed (cap. 6.) entitled 'An Act to prevent Disputes and Controversies concerning Royal Mines,' wherein it was enacted, that all persons, being subjects of the crown of England, owners of mines within the kingdom of England, dominion of

Wales, or Berwick-upon-Tweed, wherein there is copper, tin, iron, or lead, may enjoy &c. the same, notwithstanding said mines may be pretended, or claimed to be, royal mines. But by the 2nd statute, the Crown, or any other person claiming royal mines under the Crown, has the option of purchasing said ores before removal, other than tin ore, in the counties of Cornwall and Devon, upon payment of a price fixed by the said act, viz. copper 13*l.*; tin, 2*l.*; iron, 2*l.*; and lead, 9*l.* per ton. By the 35 Geo. III. c. 134, the right of preemption which is given to the Crown, and those claiming under the Crown, so far as relates to lead, can only be claimed upon payment of 25*l.* per ton instead of 9*l.* as previously fixed.

From this it would appear—1. That the right of preemption given to the Crown is limited to copper, iron, and lead, wheresoever found, and to tin to be found in England, other than in Cornwall and Devon, if such ores contain gold or silver. 2. That the rights of the Crown to all mines where gold and silver exist intermixed with any substance whatever other than copper, iron, lead, or tin, remain unaffected by either of the statutes of William and Mary. 3. That the rights of the subject to all mines of copper, lead, and tin, even if gold or silver is found therewith, is confirmed by the said statutes, subject only to the right of preemption just stated.[1] But, if any other auriferous ones be discovered, it will be difficult to determine the respective rights of the Crown and the subject to such a mine, unless the 'Great Case of Mines' should be adopted in favour of the Crown. Under any circumstances there is no provision made for such a discovery. Independently of this, the law is not settled, that pure gold and silver, *wherever found*, are the absolute property of the Crown. It is, however, not a little remarkable, that the Crown has *no right of entry* upon private lands to search for its own; nor has it ever exercised its right of preemption as regards lead ore containing silver. But, since the gold discoveries in Wales in 1854, the practice of the office of Woods and Forests has been nearly as follows, viz.:—

1. Where the gold is found in combination with other metals, the *whole* of which, with the necessary easements for working, *are* vested in the Crown, the Crown deals with the case *in the same manner as an ordinary licence to search for minerals*; viz., 30*l.* per annum minimum rent, and one-twelfth royalty on the gold.

2. Where the gold is found in combination with the minerals specified in the acts of William and Mary, and which are *not* vested in the Crown; the Crown *proposes to accept a royalty in lieu of the right of preemption.*

3. Where the gold is found in a virgin state, or secreted in rocks, and not in combination with the ores and minerals specified in those acts, or land where the minerals are *not* vested in the Crown—the Crown requires the parties *to take a licence on payment of a nominal annual rent, and a royalty upon the gold raised.*

The Clogau (Welsh gold) mines are at present working under a royalty to the Crown. There is no mine working under the second. The Castell Carn Dochan mine, on the property of Sir Watkin W. Wynn, Bart. is not working. It is obvious, as a general rule, that the terms exacted by the Crown are far too burdensome to encourage persons in this kind of adventure. It is thought that if the Crown would consent to impose a small annual rental, and, say, a royalty of five per cent. on the net *profits*, it would be paid readily, explorations would be made to a larger extent by private individuals, and the Crown would be a gainer from lands, upon which it has no right of entry to realise its own.

In *England*, gold has been said on very doubtful evidence to exist in quantities of commercial value in the following counties: viz., Cornwall, Devon, Somerset, Gloucester, Worcester, Salop, Bedford, Derby, Chester, Lancaster, Westmoreland, Cumberland, Northumberland, Durham, and York. The tin-streams of Cornwall have yielded a little, and very small quantities of gold have been found in North Devon, especially near North Molton.

In *Scotland*, it has been found in the following counties: viz., Sutherland, Aberdeen, Fife, Perth, Stirling, Linlithgow, Lanark, Dumfries, Ayr, Selkirk, and Kirkcudbright. Lanarkshire is said by Pennant to have yielded 130,000 ounces.

In *Ireland*, the gold-bearing countries are Londonderry, Antrim, Wicklow,[2] Wexford, and Kildare. A nugget weighing 22 ounces was found in Wicklow, and said to be the largest ever found in Europe.[3]

In *Wales*, the known gold-producing counties are Carnarvon, Flint, Cardigan, Caermarthen, Pembroke, and Merioneth. Until recently Cardiganshire, probably, has rendered more service to the State, and profit to the explorers by the production

[3] British Gold, with especial reference to the Gold Mines of Merionethshire.' By R. Hunt, F.R.S. 'Quarterly Journal of Science,' 1865.

of gold than any other Welsh county, although Sir H. Middleton, while ostensibly working for *silver* in the time of Charles I. and his 'most loyal chemist and mineralogist Thomas Bushell,' did not leave on record all their knowledge respecting Welsh *gold* and its associated minerals.[1] But within the last few years, Merionethshire has taken golden honours, sufficient, at least, to make them noteworthy. Hence an especial reference to the gold-mines of that county.

There are several claimants for the honour of having been the earliest of the Welsh gold-finders of later times. Mr. O'Niell, in 1836, is said to have found it at Cae Mawr, and Mr. James Harvey, afterwards, at Berthllwyd. Captain Roberts says he discovered it before either. But, undoubtedly, Mr. Arthur Dean must be allowed to take the lead. In 1843, Mr. Dean discovered some rich gold ores at Cwmheisian, and boldly stated, in the face of national disbelief, that 'a complete system of auriferous veins existed throughout the whole of the Snowdonian or Lower Silurian formations of North Wales.'[2]

Mr. Dean, and after him Mr. Clement, worked about 500 tons of the Cwmheisian minerals, and obtained at the rate of more than half an ounce of gold to the ton. The proprietor Mr. Bruin was unable to carry on the works, and then the gold question slumbered until ten years afterwards, when at the Clogau mine, a pile of 'poor copper ore' was found. This grass-grown refuse was carefully examined by Mr. J. C. Goodman of Dolgelley, who discovered that it really contained less of copper than of gold. Some of the stones, weighing several pounds, had gold disseminated throughout. In one beautiful specimen, now in the possession of Mr. Readwin, there is the mark of a boring-iron, which has passed through the solid gold. Some of this 'poor copper-ore' was put to the test, and Mr. Goodman obtained 14½ ozs. of gold from 100 lbs. weight. A stone weighing 3 cwts. was taken from the lode, stamped and sold for *5s.* per pound weight.[3]

Such novel and interesting facts as these naturally gave rise to the most extravagant expectations as to the ultimate value of the discovery. The quartz-lodes of the district were indiscriminately attacked by the hammers of ardent gold-seekers. The Crown got a small harvest by granting gold-licences, and a good deal of rash speculation and loss was the necessary consequence.

Much weight was attached to Sir Roderick Murchison's Australian prophecy, and that recorded opinion of his, in the *Siluria*, that 'the most usual position of gold is in quartzose vein-stones that traverse altered palæozoic states, frequently near their junction with eruptive rocks, whether of igneous or of aqueous origin.' And it was a remarkable coincidence, that the gold at Clogau was found at the junction of the Cambrian sandstones, and the Lingula flags of the Lower Silurian rocks near an eruptive bar of porphyritic greenstone.

About this time, a valuable paper appeared in the *Transactions* of the Geological Society of London, in which the geology of this problematical district is described at great length by Professor Ramsay, Director-General of the Geological Survey of Great Britain.[4]

Of course, this became an era of joint-stock speculation, and companies were formed for working Clogau, Cwmheisian, and other mines, containing, or supposed to contain, auriferous minerals.

Eventually, the rich Clogau mine became the subject of two Chancery suits, and the other mines, one after another, collapsed, after ineffectual attempts to extract gold by various means of amalgamation.

The vexed question again lay dormant until 1857 and 1858, when the Vigra and Clogau mines were sold by order of the Court of Chancery, and bought by Messrs. Readwin and Williams, who, with a few other enterprising persons, set them to work for copper and gold, with Captain John Parry as mine agent. The Dolfrwynog, the Prince of Wales, and the Cambrian mines were also started to work for gold.

About this time Professor Ramsay, referring to the discoveries of gold at these mines, wrote, 'In the Ural Mountains, South Australia, Canada, and other parts of the world, gold occurs in rocks of the same general age, and apparently under the same circumstances.'[5] There was, however, nothing of importance discovered until the end of 1852, when several bunches of gold were found in the forebreast of a shallow level, on the south side of the gold-lode at Clogau, and early in the following year, the gold appeared associated with yellow copper-ore and telluric bismuth,

generally diffused throughout the lode, and visible from the top of the level to the bottom.

This discovery was the signal for the resuscitation of several dormant gold mines, and the creation of a host of new schemes, all of which have suspended operations, with the exception of Clogau, which has recently been resumed (1874), not so much on account of the paucity of gold, as of the difficulty of extracting it by the means at command.

The neighbourhoods of Dolgelly and Bala at present appear to comprise all the known Merioneth gold mines, and the following particulars thereof are chiefly compiled from papers on this subject in the *British Association Reports*, by Mr. Readwin, who treats of them as being in the Dolgelley and Bala districts.[1] According to this writer, the Dolgelley district is bounded by the river Mawddach, the Great Llawllech or Merioneth anticlinal range, and the river Camlan, to which may be added a continuation of three or four miles further NE., following the junction of the Cambrian sandstones, and the Lower Silurian Lingula-flags of the Geological Survey, and included in the Survey-maps, 75 S.E., and the upper part of 59 N.E.

The geological features of the district are now too well known to require more than a repetition of the general statement, that the rocks are of the Cambrian and Lower Silurian series, forming a junction in a very sinuous course, and frequently cut through by narrow bands of porphyritic greenstone. The district is full of faults, and the metalliferous veins have a general bearing N.E. and S.W., with an underlie to the N.

There is a continuation of rocks of precisely the same character for a distance of six or seven miles, running in a N.E. direction to Castell Carn Dochan in the Bala district.[2]

It may be here noted, that during the various explorations, gold has been found associated with iron-pyrites, blende, galena, heavy spar, copper-pyrites, clay-slate, Silurian shale, quartz, telluric bismuth or tetradymite, carbonate of lime, talcose-schist, iron oxide, grey copper-ore, phosphate and arsenate of lead, and orpiment. It has also been found in *pepitas*, and nearly pure in quartz, or alloyed with from 10 to 20 per cent of silver,[3] and a little copper and platinum.

A number of specimens were exhibited at the International Exhibition 1862, by the Vigra and Clogau Company, and by Mr. T. A. Readwin.

For convenience, the Dolgelley district is divided into the following sections: viz., Cwmheisian, Maesgwm, Berthllwydd, Cambrian, Clogau and Vigra, situate severally in the parishes of Llanfachreth, Trawsfynydd, Llanddwye, Llaneltyd, and Llanaber.

Cwmheisian Section. At the Cwmheisian mine, there is a junction of fourteen lodes nearly forty feet wide, and the whole mass of lode itself is said to contain gold in small quantities. Blende is occasionally found very rich in gold. Mr. Dean extracted 148 ounces from 157½ tons, and Mr. Clement 170 ounces from 300 tons. Some specimens have been found by Mr. Readwin, containing as much as 87 ounces to the ton. Almost all the known methods of gold-extraction have been tried at this mine; but owing to the great preponderance of sulphides in the mineral, none of them succeeded. This is a fact to be regretted, since immense quantities of the lode itself could be actually quarried, and there is plenty of water-power to dress it inexpensively.

Gwynfynydd mine is opposite Cwmheisian. Galena from this mine, though poor in silver, assayed 8 ounces of gold to the ton. But some blende in quartz associated with arsenate and phosphate of lead and orpiment, produced gold at the rate of 156 ounces to the ton. Half-a-ton of mineral from the '*Doubt-me-not-lode*,' gave by amalgamation 9 oz. 13 dwts. of gold. There were a large number of lodes opened on, varying in width from 1 to 66 feet, and gold could be seen in the lodes at the surface in different places. This mine is at an elevation of 300 to 400 feet, and has belonging to it the beautiful waterfalls Pistil-y-Cain and the Rhiadwr Mawddach, one with a fall of 123 feet, the other 87; so that, commanding the water of the two rivers, the Cain and the Mawddach, with an unlimited quantity of mineral procurable by means of adits, large operations, at comparatively little cost, might be carried on here, with the prospect of making a small quantity of gold pay a profit.

From about five tons of lode stuff, 15¾ ounces of gold were extracted in 1862.

Gold has also been found in small quantities at the Hafod-y-Bach, Penmaur, Buarthrae, Doledd, and Penbryn. *Tyddynglwadis* mine is situate exactly at the junc-

[3] List of gold ores from Merionethshire, exhibited by Mr. Readwin, International Exhibition, 1862.

tion of the Cambrian and Lower Silurian rocks, which is distinctly observable at the top of Pistil-y-Cain. This mining sett is full of faults. The galena averages 50 to 60 ounces of silver to the ton, and from 6 to 11 dwts. of gold. A small string of silver-ore was found in the deep level in 1865, containing 2,200 ounces of silver to the ton. Some moss pulled from the river side had specks of gold attached to its roots. It was at this mine that Mr. Readwin first discovered a fragment of the trilobite *Paradoxides*, many more fragments of which were found afterwards by Mr. E. Williamson and Mr. Plant. At *Cefndwddwr*, adjoining Tyddynglwadis, visible gold is found apparently dispersed throughout a fine quartz lode, and has yielded eight ounces of gold from five tons of lode-stuff.

At the old *Dolfrwynog* mine, specimens of decomposed quartz contained over 400 ounces of gold to the ton. One stone weighing fifteen ounces gave twelve ounces of gold.

The *North Dolfrwynog* lode-stuff has assayed 30 dwts. to the ton. About 100 tons of alluvium from the east bank of the Mawddach, on this mine, was washed with the object of ascertaining whether the particles of gold found therein increased in size from the surface to the bed-rock. This was found to be the case. Several ounces of gold were obtained, and it is probable that the whole side of this mountain contains gold, which might be profitably worked on the erection of machinery to economise labour.

West Dolfrwynog adjoins, and is marked on the Ordnance Map 'Turf Copper mine,' from the fact that a few years ago, about 10,000*l*. worth of copper was sold from the ashes of peat, there burnt for the purpose. Quartz and yellow and grey copper-ore from this place have assayed six ounces of gold to the ton, and along the east bank of the Mawddach the alluvium resembles that of North Dolfrwynog.

The *Maesgwm Section* is on the western side of the Trawsfynydd road, nearly opposite Tyddynglwadis, and includes Maesgwm, Ganllwydd, and Coed-cy-fair. At *Ganllwydd* in 1863, several masses of quartz were found to contain visible gold.

The *Berthllwydd Section* includes Berthllwydd (Cefn coch), Goitref, Caegwernog, Caemawr, Benrhos, Tynybenrhos, and Glasdir. *Berthllwydd mine* is on the summit of the lofty ridge behind Tynygroes, on the Trawsfynydd road from Dolgelley. Here is the 'grand champion lode' of the district, which runs N.N.E. and S.S.W. for about a mile. Auriferous blende and galena are the chief products, and some very rich specimens have been found, as well as pepitas and fine gold-dust in the alluvium. The Welsh Gold Company, to whom this and Goitref and Caegwernog mines belong, obtained, in 1866, 666 ounces of gold from 1,982 tons of lode-stuff. At *Caemawr* adjoining, the first visible gold of the district is said to have been discovered. The lode-stuff assays 9 to 11 dwts. of gold to the ton, and the alluvium also contains gold. At *Benrhos* and *Tynybenrhos*, the alluvium contains specks of gold. At *Glasdir*, above 15,000*l*. worth of copper-ore has been quarried, and extraordinarily rich specimens of auriferous copper- and iron-pyrites have been found. At the *Garn* mine rich gold-quartz has been found by Captain John Parry.

The *Cambrian Section* includes the Cambrian mine, the Princess Alice, Moel Ispri, and Cwmabseifian mines, which extend along the road from Dolgelley to Barmouth. The *Cambrian* mine produced some very rich blende; containing at the rate of 350 ounces to the ton. Specimens of Silurian shale have been found with the appearance of having been electro-gilt. This mine has been thoroughly explored, but without producing gold sufficient to pay for working. At Cwmabseifian, Moel Ispri, and the Princess Alice mines, gold has been found in the quartzose lode-stuff, associated with blende and iron-pyrites. At the *Prince of Wales* mine, a few large blocks of blende have been broken, containing at the rate of 456 ounces of gold to the ton. From 5 cwts. of lode-stuff, 17 oz. of gold were obtained. The preponderance of sulphides here renders amalgamation at present wholly inoperative.

The Mawddach river has been examined from Cwmheisian to Llaneltyd Bridge by Mr. Readwin, who found grain-gold with platin-iridium in small quantities. Gold was also previously found by the Hon. F. Walpole and Sir Augustus Webster. Professor Ramsay suggests, with much reason, the possibility of gold being found in the 'marine drift.'

The *Clogau Section* includes Clogau, Garthgell, Hendreforian, West Clogau, Maesclawdd, and Tynycornel.

'The Clogau, St. David, No. 1 mine is certainly the richest gold mine ever worked in the British Islands, and may compare favourably with the quartz-reefs of Australia. Taking this lode as a type of the neighbourhood, it will be well to describe it.

'The lode has an average bearing 15° N.E., and is intersected by a very powerful cross-course bearing 30° N.W. and dipping slightly S.W. The lode traverses beds of indurated Silurian clay-slate, which are interstratified with thick beds of greenstone. There is also a large greenstone dyke, which is traversed by a portion of the lode for a length of about 60 fathoms, until they are intersected by a great cross-course. Behind this cross-course the lode is extremely rich in gold. It should be stated that the lode is composed almost entirely of quartz, with here and there some carbonate of lime. Throughout the quartz, yellow copper-ore is in small quantities, disseminated, as well as gold. Where the gold is most abundant, telluric bismuth in fine silvery-white grains is generally present, and an opinion prevails that whenever that mineral is met with, gold is near at hand. It was commonly supposed that gold is only to be found near the surface. Mr. Dean has favoured us with some notes on this point, which are exceedingly important if all the conditions have been correctly observed. Without comment Mr. Dean's own words are given:—

'The opaque white quartz floors, which are comparatively poor in gold, alternate with others of a greenish white colour, very dense, and of a shining conchoidal fracture; the latter are the rich gold-bearing floors: we have, therefore, alternate rich and poor floors. From the dip of the floors the deposits of gold appear individually to dip eastward, but, as the bands of clay-slate forming the walls of the lode below the greenstone dip westward down to the cross-course, the succession of bunches of gold in the alternate floors of greenish quartz follow the dip of the clay-slate. This is an important point in the relation to the recurrence of rich deposits of gold in depth below the present bottom. This quotation sufficiently indicates the hypothesis that, with a recurrence of the same conditions in depth, rich, or perhaps richer, deposits of gold may be met with. There is a very close analogy between gold and tin. It was an opinion, held with much obstinacy for a long period, that tin would never be found deep in the earth. Experience has now proved the fallacy of this, for the most abundant deposits of tin are now worked at depths of between 200 and 300 fathoms.'[1]

The most remarkable item in Welsh gold statistics is the fact of 9,363 ounces of gold having been obtained from less than 40 tons of quartz. It was here that the 'poor copper-ore' referred to was found, from which some 20 tons had been picked, sampled, and sold as 'copper-ore,' and probably several thousand ounces of gold were contained in it. The St. Helen smelters made no report, but offered an advance of 5*s.* a ton for as much more of it as could be raised. A discovery of rich gold in another lode has been made of a similar character to the St. David's lode.

The gold obtained from this mine to May 30, 1866, was 11,663 ounces from 5,063 tons of quartz, averaging about 42 dwts. to the ton. At *Garthgell* the St. David's lode having been thrown, could not be re-traced; at *Tynycornel* this lode has not been opened on; and at *Hendreforian* and *Maesclawdd*, the lode-stuff is auriferous, but few explorations were made. At *West Clogau* (Llachfraith), 1 ton of lode-stuff gave 17 dwts. of gold. Some profitless work has been done here. Mr. Readwin found visible gold here at nearly 150 fathoms lower than the upper level at St. David's lode.

The *Vigra Section* includes Vigra, Tyddyndu, North Vigra, Nantcoch, Wellington, Fachynys, and Llanaber mines. At all these mines the lode-stuff is auriferous, but it has not been found of commercial value.

Bala district. The gold discovery here was chiefly confined to Castell Carn Dochan mine, near the beautiful lake of Bala (Llyn Tegid) on land belonging to Sir Watkin W. Wynn, Bart.

This mine is situated about five miles from Bala, on the N.W. side of the turnpike-road leading to Dolgelley, and about two miles from the village of Llanuwchllyn. There is one auriferous lode very remarkable. It runs nearly N.E. and S.W. and has a dip to the S. This lode is exposed to view for about twelve fathoms, showing specks of gold nearly the whole distance. The lode-stuff is generally free from sulphides. The quartz, unlike Merioneth quartz, resembles that at Clunes, in Australia, and some boulders have been broken up and found to contain specks of visible gold throughout. The upper portion of the lode appears to have slipped over the lower, and down the face of the hill, leaving behind it a record of where it had been, in characters of gold. Large loose masses of greenstone have been found, having incrustations of quartz spangled with gold. The *débris* yielded gold of equal value with the lode-stuff. This mine has been properly opened, improved reduction machinery erected, and has made regular monthly returns of gold. The

---

[1] 'British Gold, with especial reference to the Gold Mines of Merionethshire,' By Robert Hunt, F.R.S. 'Quarterly Journal of Science,' 1865.

quantity of lode-stuff reduced was 3,500 tons, and the gold produced 1,606 ounces (Dec. 1866).

A brief reference to the various modes of gold-extraction used in Merionethshire will be interesting.

In the earlier stages of gold-mining (1843) at Cwmheisian, the ore was finely stamped and concentrated by washing apparatus, and afterwards amalgamated by *arrastras*, or smelted. After this the gold-mines lay dormant until the Californian discoveries in 1853, when rich gold-quartz was at the same time found at Clogau. The amalgamating machines of Britten and Berdan were then introduced; but it was soon found impossible to work auriferous sulphides indiscriminately by trituration in quicksilver. A good deal, however, of the rich ore at Clogau was treated in this way with very profitable results; but in some cases rich ore yielded only a small portion of its contained gold, and generally much gold was found in the 'tailings.' Washing apparatus was erected at the Cambrian mine, on the Marmata plan, but with no satisfactory results. This method was improved by Mr. Belt at the Prince of Wales mine by the addition of shaking tables, and troughs of quicksilver; but the process only partly succeeded, there being very little gold in the stuff, and that little associated constantly with heavy sulphides. Barrel amalgamation had been previously tried here, at a great cost, but failed for the same reason.

A mode of triturating the ores in quicksilver, having all the vices of Berdan, and none of its virtues, was introduced at the old Dolfrwynog mine, together with an old plan of forcing the ground ore through a body of quicksilver. It is not publicly known whether this proceeding was a total failure or not. No gold appears to have been accounted for, although some of the richest ore in Wales was found at this mine at the time. The sluice-box principle was adopted at North Dolfrwynog on the alluvium, with the object referred to; but it was discovered that much more gold was lost than gained by the pursuit, and it was discontinued.

Mitchell's amalgamators were next introduced at Cwmheisian, which were vessels of quicksilver, through which the ground mineral was intended to be forced by means of a succession of screws, in order that the particles of gold might be presented to the greatest possible surface of quicksilver, and for a long period of time. This plan was found utterly useless with minerals containing sulphides in excess.

Sloper's plan of separating the metals by specific gravity was also tried on the alluvium by the patentee, at North Dolfrwynog, and failed.

In 1862, Mr. Mosheimer introduced his machinery at Garthgell, Clogau, Cwmheisian, and Castell Carn Dochan. After stamping the minerals in the usual way, Mr. Mosheimer at that time proposed to grind them in his horizontal pans with heated quicksilver, adding chemicals, occasionally, for the purpose of liberating the gold from the sulphides. At Cwmheisian this plan was useless because of the sulphides. The quicksilver constantly became 'sick,' dragged in strings after the mullers, and lost apparently all its natural affinity for gold. Only a very small portion of the contained gold was extracted, and the rest left in the tailings.

At Clogau and Castell Carn Dochan, however, the results were very different. The quartz-lodes at these mines are comparatively free from sulphides, there is a little bismuth sulphide found at Clogau, and a little iron sulphide at Castell Carn Dochan—but at both mines, without heating the quicksilver, or introducing chemicals, the gold was practically all extracted; from the richer minerals by Britten's and from the bulk by Mosheimer's machines.

In 1866 the gold reduction works at Castell Carn Dochan were the most complete. There, the ore-stuff as it comes from the mine was taken direct to the stamps, reduced very fine, the metalliferous particles concentrated on blankets, the blanket sand further concentrated, and then amalgamated in the 'Mosheimers' and 'Brittens;' all the waste water, &c. passed into shaking boxes containing quicksilver, and thence through a series of Hungarian pans, such as are used at Schemnitz. The gold here being all free, scarcely a trace of gold was ever found in the tailings. The same plan, with some modifications, was successfully used at Clogau.

A long experience has now elicited that sulphides of lead, arsenic, antimony, zinc, bismuth. &c. will frequently so envelope small particles of gold with a film or tarnish, that quicksilver cannot touch it. The trituration of such sulphides in quicksilver generally destroys its fluidity and amalgamating power, or reduces it to minute globules, which, owing to the tarnish they also have by some means acquired, refuse to re-unite, and are consequently washed away with the tailings. Hence a great loss of both quicksilver and gold, because generally these minute globules, so washed away, are really gold-amalgam. Again, the quicksilver of commerce is very seldom in a fit state for complete amalgamation, even of free gold, and it is well known also that the slightest quantity of greasy matter will tarnish and render useless, until re-distillation, a large quantity of quicksilver.

In 1865, Mr. W. Crookes, F.R.S. the discoverer of thallium, proposed to remedy the evils attendant on the trituration of sulphides and arsenides in quicksilver by the introduction of sodium.

In laboratory-experiments the effects of Mr. Crookes' discovery were very conspicuous:—

1. A small quantity of sodium-amalgam added to ordinary quicksilver greatly increased its brightness and affinity for gold.

2. A bar of gold completely covered with tallow dipped into quicksilver containing sodium was instantly amalgamated.

3. Greasy ('sickened') quicksilver was instantly made bright and clear by the addition of the sodium-amalgam.

4. 'Floured' quicksilver immediately collected on the introduction of a small quantity of the sodium-amalgam.

These novel facts induced Mr. Readwin to put the invention to a crucial test, at the Gwynfynydd mine. He thus writes: 'I have made a series of experimental trials, which have given me some confidence in the utility of Mr. Crookes' invention. I selected for trial such auriferous minerals from Cwmheisian, Tyddynglwadis, North Dolfrwynog, Gwynfynydd, Glasdir, and other places, that have always heretofore either sickened the quicksilver, or refused to give up, by amalgamation, the gold known to be contained in them by analysis. In no one instance, during these experiments (some of which were of 48 hours' duration), did I derange the quicksilver in operation, and in every instance I obtained gold from it, on distillation. The quantities of gold, of course, varied with the samples of minerals treated, and did not in any way affect the value of the experiments, the object of which was chiefly to prove whether heterogeneous minerals could be treated by this method, when they would not submit to other tried methods. The most remarkable, and in my opinion the most important, effect of the sodium, was seen in an experiment on 56 lbs. of mixed minerals from one of the Gwynfynydd lodes. The gold in this lode is often visible and associated with sulphides of lead, zinc, and arsenic. Quicksilver in its ordinary state was first used in this experiment, which shortly became completely 'sickened' by yellow sulphide of arsenic (orpiment), and completely coated the 'Britten' machine with *arsenic-amalgam.* Whilst in this state, sodium-amalgam of about 3 per cent. strength was introduced; the quicksilver soon recovered its fluidity, became quite bright and clear, and on distillation yielded nearly two ounces of gold. I made many other experiments, and in practice I found that, although I was always able to obtain gold by the use of sodium when I could not obtain it otherwise, I discovered that an excess of sodium predisposed the quicksilver to take up other metals, to the partial exclusion of the one most particularly desired; but in all cases the quicksilver was kept quite bright and clear, and on washing out the machines, the subdivided particles were most rapidly re-united, a circumstance of itself of the greatest importance.[1]

Mr. Readwin believes that native lead exists to a considerable extent in some of the minerals, and he shows that the prevalence of galena, &c., is the greatest hindrance in amalgamation. If this be so, and the lead can be taken out of the concentrated ores before amalgamation without losing the gold and silver, the plan may possibly render amalgamation of the residue practicable. Mr. Peter Spence, of Manchester, proposed to calcine the sulphides containing galena till completely oxidised; a portion of the galena is thus converted into sulphate of lead, and a portion into oxide of lead. This oxide and sulphate of lead is then washed in a solution of carbonate of soda, and the sulphate is converted into a carbonate. The calcined ore is then put into a solution of caustic alkali, the mixture is stirred for a short time, the solution taken off, and more solution added whilst the oxide of lead remains; the various solutions added together are allowed to settle, and, when perfectly clear, drawn off into a vessel into which carbonic acid can be thrown into the solution and absorbed by it; as the carbonic acid becomes absorbed by the solution, the soda becomes carbonated, and *white lead* is deposited.

Mr. Spence undoubtedly can convert the sulphide into carbonate of lead, as he proposes, but the process has not in any way affected the value of auriferous and argentiferous minerals. Mr. Spence asserts positively that by his process the lead in any ores can be converted into white lead, leaving the residual and accidental products for after-treatment, according to their nature and value, and this in a rapid and inexpensive manner.

---

[1] Since the above experiments were tried Mr. Crookes has improved his process, and thus avoids the ill effects of an excess of sodium; the improvements met the approval of Dr. W. Allen Miller and other high authorities.

As to the profitable working of auriferous minerals in Wales, Mr. Readwin writes:—

'After several years of experimental effort to work the gold-minerals to a profit, I am more fixed in my opinion than ever, notwithstanding the equivocal position the subject holds as a commercial pursuit, that gold-mining can and will be made remunerative, if certain essential and natural conditions prevail at the respective mines: first, there must be a large and continuous quantity of the auriferous mineral cheaply obtainable by means of adits and tramways; secondly, there must be efficient water-power available on the spot; thirdly, there must be no more cats about the premises than will catch mice. Under such circumstances, provided forty or fifty tons can be raised per diem, a quarter of an ounce of gold to the ton ought to pay all costs of reduction, and I think it would. Many of the difficulties of amalgamation can now be overcome, by the use of sodium or potassium, in some such way as patented by Mr. Crookes.'[1]

It remains to be proved whether, after Mr. Spence's process, the minerals can be further utilised. It seems reasonable to suppose this possible. If the ores containing sulphur are found in quantity, and concentrated so as to lessen the cost of transit, then calcined, the lead-sulphide converted into carbonate, the sulphur collected, the zinc-oxide (if any) made into spelter; the residual products thus obtained at an inconsiderable cost may contain the precious metals in quantity sufficiently valuable to amalgamate either with or without the use of sodium, as proposed by Mr. Crookes. At all events, another step appears to have been gained towards the solution of the problem, 'Can British gold be worked to a profit?'

The following returns of gold raised in Merionethshire were approximately correct up to the end of 1864:—

tons	cwts.	qrs.				oz.	dwts.	grs.
1	4	0	of gold-quartz from	River Mawddach	gave of gold	2	0	0
100	0	0	„	Alluvium	„	5	0	0
5	0	0	„	Cefndwddwr	„	8	0	0

In 1874 explorations at Vigra and Clogau were again commenced.

The Gold-mines of Scotland.—The following remarks on the gold and gold-fields of Scotland are by Dr. W. Lauder Lindsay:—

'Before making general observations on the Scottish gold-fields, or comparing them, as regards their richness or extent, with those of other auriferous countries, which are

---

[1] 'On the Recent Discovery of Gold at Gwyfynydd.' By T. A. Readwin, F.G.S. 'British Association Reports,' 1865.

better known, I propose giving briefly the principal results of my observations and inquiries at and concerning what I may safely denominate the Crawford or *Leadhills gold-field*, the whole of that moorland and hill-region of the southern highlands—Upper Clydesdale—the southern extremity of Lanarkshire, variously known as Crawford, or Crawford Moor, or Crawford-Lindsay, which includes the district now known as the Leadhills, and forms the watershed of the four great southern rivers (the Clyde, Nith, Tweed, and Annan), has repeatedly, and in various ways, proved to be more or less auriferous. Long prior to the modern system of "prospecting," some of the Leadhills valleys were the scene of the far-famed alluvial washings, under Sir Bevis Bulmer in 1578–92, and it was from the produce of such washings that the Scottish regalia were fashioned in 1542, and Kings James IV. and V.'s celebrated bonnet-pieces coined. Bulmer's chief washings are said to have been in the valley of the Elvan, and he is also represented as having washed the whole bed of the Glengonner water. But vestiges of ancient "diggins" are to be met with in many parts of the Leadhills district. For instance, I found the haugh or "flat" on the banks of the Glengonner water above Abington, and immediately below Glencaple Burn, covered with a series of quartz-like mounds, exactly resembling those with which I was familiar in the famous Gabriel's gully at Tuafoka in Otago, and which are said really to mark the site, or one of the sites, of Bulmer's celebrated workings. It was the gold-prospecting in this district, it is said, that led to the discovery of the lead, which has proved so much more permanent a source of prosperity to the district, to which it has, morever, given its distinctive modern name of late years; and at present gold is systematically collected by the Leadhill miners chiefly in certain localities, viz. in the Windgate or Windygate burn, in Langcleuch burn, in Bellgall burn, in the whole course of the Elvan and Glengonner, from the Clyde to their source. The gold occurs chiefly in the gravelly clay, locally known as "till," as this coats the flanks of all the Leadhills valleys; but it is also to be found in the shingle, gravels, or clays of the stream-beds. This gold is invariably what is known as "drift" or "alluvial" gold. There is no present local evidence of the existence of auriferous quartzites. But in 1803 the late Professor Traill of Edinburgh found gold in a vein of quartz *in situ* at Wanlock-Head. All the gold belonging to this district which I have seen is of a granular or nuggety character, and quite comparable with the usual produce of Otago, or other auriferous countries. Some of the "nuggets" found in former times, and preserved in the cabinets of local proprietors, are of very considerable size and value. The cabinet of the late Lord Hopetoun contains two: one of them weighing 2 lbs. 3 oz. = 27 oz. or 12,960 grs., which at the current price of gold in Australia, 4*l.* per ounce, is worth 108*l.*; collected, it is said, about 1502, prior to the systematic workings of Bulmer. The other, weighing 1 oz. 10 dwts., or 720 grs. The first would appear to be by far the largest mass of gold ever found in Scotland. Since, however, systematic gold-workings on a large scale were discontinued, the size of the Leadhills nuggets has been greatly smaller, the largest seldom now exceeding 2 or 3 grs., though they are frequently found of that size. Just previous to my visit, in the autumn of 1863, a nugget of 30 grs. had been found, and another single nugget, whose weight I failed to ascertain, sold for 25*s.* at Abington. More generally the gold occurs here as rough granules, coarser and larger than those constituting what could properly be called "dust," and of this considerable quantities are frequently collected in limited periods for special purposes, such as marriage-gifts, or jewellery, to or for the local proprietors. Thus, in a fortnight, in 1862, 975 grs. were collected for the Countess of Hopetoun; and on another occasion, 600 grs. in six weeks by thirty men at spare hours, fifteen working in the forenoon, and the other half in the afternoon. About Abington, in 1851, similar quantities were collected under similar circumstances to furnish marriage jewellery for Lady Colebrooke. Between May and October 1863, three miners, in the intervals of leisure from their usual work, collected for me 33 grs., which they found in the "till," about forty yards above the bed of the stream, half-way down the Langcleugh burn, between Leadhills and Elvanfoot: their charge was 20*s.*, that is, at the rate of about 15*l.* per ounce, or 7½*d.* per grain. During the last five years the price of crude gold in Australia and New Zealand has averaged from 3*l.* 17*s.* 6*d.* to 4*l.* per ounce, so that the Scottish diggers obtained for their produce nearly four times as much as the New Zealand or Australian diggers got for theirs. The price appears at first sight to be extremely and disproportionally high; but the cases are by no means parallel, for in the case of the Leadhills gold, the collection is made to meet the demands for cabinet specimens, or for jewellery materials under circumstances quite exceptional. The Leadhills miners collect their gold mostly to order; it is thus at once disposed of, and hence gold is seldom to be found there for sale, or only in very small quantity. On one occasion I was offered a sample of 140 to 160 grs. for 5*l.*; that is, at the rate at which I purchased my smaller sample, but the miners have rarely so much in their possession unsold. In the summer of 1862, by way of holiday work, the miners frequently collected quantities of 14 to 54 grs. The able-bodied Leadhills miner never, however, gives up his usual labour, at which he earns 15*s.* per week, for the more precarious gains to be derived from gold-finding. To gold-seeking he devotes only his spare hours, his holiday time, or his periods of sickness or debility. The price he generally more or less readily obtains for his gold varies necessarily with the demand and supply. Sometimes it rises to 7½*d.* per grain, or 15*l.* per ounce, sometimes it falls to 5*d.*, but the more common or average price is 6*d.* per grain, or 12*l.* per ounce, while the average market-price may be quoted at present at 4*l.* per ounce, or 2*d.* per grain. The director of the mines at Leadhills estimates gold-washing at these prices as only capable of yielding, at present wages, 3*d.* per day, while lead-mining gives upwards of 2*s.*, or more than eight times as much, with the great additional advantage of a certain or regular occupation.

'The Scottish gold-fields may be divided geographically or topographically into three: the Northern, Central, and Southern.

'1. The *Northern* comprises the greater part of the counties of Sutherland, Ross, Inverness, and Argyle, north of the Caledonian Canal. It occupies the longitudinal axis of the northern peninsula of Scotland, is second in size only to the Central area, and has yet almost entirely to be explored.

'2. The *Central* lies between the Caledonian Canal and the valley of the Tay; includes a great part of the shires of Inverness (southern half), Aberdeen, Banff. Kincardine, Perth, Forfar, Argyle, Stirling, and Dumbarton. It is by far the largest of the three areas, Like the Southern gold-field, it forms a transverse belt across Scotland, and much of it remains to be explored.

'3. The *Southern* comprises great part of Dumfries, Kirkcudbright, Wigtown, Ayr, Selkirk, Peebles, and Lanarkshire, and includes, more particularly, parts of the districts of Nithsdale, Annandale, Eskdale, Ettrickdale, Tweeddale, and Clydesdale, and the Lammermuirs (in Haddington and Berwick). It is the smallest of the three areas, but is the best known, and, so far as ascertained, the richest.

'At many localities throughout the area which I have assigned to the Scottish gold-fields, actual finds of gold have been made in recent or former times, and this is one of the strongest arguments for their thorough exploration. Of such gold-finds, the following will suffice as illustrations:—

'I. *Northern Gold-Field.* 1. *Sutherlandshire.*—Helmsdale water. A nugget found here in former times weighed 10 dwts., or 240 grs.

'II. *Central Gold-Field.* 1. *Perthshire.*—(A.) *Breadalbane,* area of Loch Tay, and head-waters of the Tay. A nugget found in former times weighed 2 oz., or 960 grs. Sir James Simpson tells me that he was shown a specimen of gold, with its matrix (quartz), by the late Marquis of Breadalbane, from Tyndrum. In 1861 Professor Tennent of London found gold in quartz, associated with iron-pyrites at Taymouth.

'(B.) *Upper Strathearn,* area of Loch Earn, and the head-waters of the Earn. Glen Lednoch (Ritchie); streams falling from the north into Loch Earn (Ritchie); Ardvoirlich (south side of Loch Earn.

'(C.) *Glenalmond* (Mercer); Glenquoich, and other valleys of the Grampians.

'2. *Forfarshire.*—Clova district, areas of Angus, Edzell, and Glenesk.

'3. *Aberdeenshire,* area of the Dee, Braemar, Invercauld, coast about Aberdeen, and in the sea-sand.

'In New Zealand, and other auriferous countries, gold is very commonly associated with *magnetic iron sand,* containing or not titanium, and other minerals, or with iron sulphides. It is of interest to know that the sands of the Dee, which consist, mainly, of the *débris* of granite and gneiss, contain considerable quantities of magnetic iron-sand and iserine, with which are associated smaller amounts of titanium, uranium, and arsenic. The gneiss of Braemar often contains *much* magnetite in place of mica (Nicol), while iron, or oxides, or sulphides, are common in all the schists and granite of Aberdeenshire (Nicol).

'4. *Argyleshire,* Dunoon.

'III. *Southern Gold-Field.* 1. Head-waters of the *Clyde,* including the Ech, Crawford Moor, or Leadhills district; Elvan water, Glengonner, Glencaple, Winloch, Short Cleuch, Lammington burn.

'2. Head-waters of the *Tweed*; Manor water, which flows north to the Tweed; Meggat water, which flows south to St. Mary's loch; other feeders of the Yarrow and Glengaber.

'There are traces of prospecting and digging in former days in Meggatt water valley, similar to those which occur in Leadhills. In the British Museum I saw two specimens of Tweeddale gold: the one nuggety, and in quartz, a very rich sample;

the other granular, rather than nuggety. Griffin prospected St. Mary's loch district, and found gold in dust or granules everywhere.

'3. Head-waters of the *Annan*, Moffatdale; streams falling into Moffat water; Hartfell range, about Dobbs Linn; several small finds of gold were made in the summer of 1863, and one small nugget, weighing about 6 grs., was exhibited in Moffat.'

Sutherland Diggings from 1867 *to* 1869. In 1867 it was noised abroad that gold was abundant in Sutherland, and for a period a considerable number of adventurers were found working, for gold, on the estates of the Duke of Sutherland.

The following are the only returns which have been obtained, as the result of the workings in this district:—

	ozs	dwt	grs		£	*s.*	*d.*
1868. Helmsdale: *Sutherland* . .	577	0	0	valued at	2,000	0	0
1869. Kildonan ,, . .	17	17	8½	,,	61	3	9

The monthly returns of gold from the diggers at Kildonan were declared as follow:—

1869.	ozs.	dwt.	grs.
April	5	8	2
May	3	11	17½
June	2	16	18
July	2	0	3
August	1	8	10
September	1	6	19
October	0	15	12
November	0	8	6
December	0	1	17
	17	17	8½

It is tolerably certain that some gold was obtained, which was not declared by the diggers; but the fact of all the works being abandoned proved that the gold found was insufficient to pay for the labour bestowed upon it. On April 20, 1869, Mr. J. F. Campbell, of Islay, wrote thus in his 'Something from "the Diggins" in Sutherland':—'The Sutherland "diggins" are now established and likely to be worked for some time to come. More than 280 men are paying a pound a month for leave to camp out and work like navvies in claims of 40 feet square; so that they must be earning wages or going crazy. If many men go away, more diggers arise daily, and gold is almost daily found at new spots. It is estimated that 6,000*l.* has been washed from the shingle of two small burns already.'

At Helmsdale, near the mouth of the river, and in the jaws of the glen, are more heaps of stuff like Brora moraines, and the Helmsdale leads back to Beinn Ormen and Clibric again. Gold has been found in burns, which come in from both sides of the Helmsdale strath, in burns which come from the south, and in those which come from the Caithness range on the north. The source of the gold has not yet been found in Helmsdale. The gold is in stuff sorted by modern burns, and it is now worked in watercourses which come down from the Caithness side of the Helmsdale glen. These are branch-burns, which arise amongst bare granite and Silurian rocks, and flow down the side of the main groove towards the main river. These branch-burns have done a good deal of digging and carving on their own account; they have done more than the main river; so they have worked longer. The Kildonan Burn has carved a trench in crystalline Silurian rock from the place where the chief diggings are now carried on down to the farmhouse. It is about 20 feet below the road; it is about 80 feet deep behind the new township, which has been christened Baile'-n-oir, or Golden Town. In this it is like other burns, and marks a gradual rise of land at this spot. Where the fall is rapid, this rock-groove is now washed clean, or left with a few large stones on the bottom. Above this bit of river-cutting is a 'flat,' in which a lot of rolled drift settled probably long before the rock-cut was deepened by the stream below the flat. The water in this 'flat' or 'creek' now meanders through rolled drift, washing it, carrying off the lighter parts and leaving big stones, heavy iron-sand, garnets, and gold. Little gold has been got out of the actual watercourse, but some was found there at first, and that find started the diggings. For about a mile, the whole of this water-worn drift is being turned over and washed in various contrivances, and every-one of these engines is worked on the same principle as the natural engine which washed and sorted this drift.

[1] Òr-méin=gold mine.

The simplest engine is the tin basin. A spadeful of stuff is turned in, and then the pan is dipped into water; the washer shakes the pan, and tosses up the mass; the stuff, being free to move, falls; and the heaviest stuff falls fastest. First, the mud floats away, and lastly, at the bottom of the pan, a small heavy stratum remains, in which a lucky man may find a speck or scale of yellow gold, or a nugget as big as the half of a split pea. The cradle acts on the same principle; so does Long Tom. Each is a contrivance for rocking or raking drift in flowing water with a still pool for the heavy ore to settle in. The long sluice, however, is the best imitation of the burn itself, and the long sluice does most work. It consists of a long wooden trough with a smooth bottom, ending in a bit of crossed grating like the floor of a boat. Beyond this is a longer trough to carry the water down to the burn. A small lead is made, and a small fall comes in at the head of this wooden model of a Highland strath.

Fig. 1116 represents the section of a 'claim' in the Kildonan Burn, drawn by J. F. Campbell, Esq., of Islay. Water-worn drift arranged by running water in a groove carved in the edges of disturbed metamorphosed bent beds of Silurian rocks. Most of the gold is found near the rock amongst the biggest stones, and in chinks of the rock.

1116

Gold in Europe.—There are auriferous sands in some rivers of Switzerland, as the Reuss and the Aar. In Germany no mine of gold is worked, except in the territory of Salzburg, amid the chain of mountains which separates the Tyrol and Carinthia.

The mines of Hungary and Transylvania are the only gold mines of any great importance in Europe; they are remarkable for their position, the peculiar metals that accompany them, and their product, estimated at about 1,430 pounds avoird. annually. The principal ones are in Hungary: 1, those of the Königsberg; the native gold is disseminated in ores of sulphuret of silver, which occur in small masses and in veins in a decomposing felspar rock, amid a conglomerate of pumice, constituting a portion of the trachytic formation; 2, those of Borson, Schemnitz; and 3, of Felsöbanya: ores also of auriferous sulphuret of silver occur in veins of syenite and greenstone-porphyry; 4, those of Telkebanya, to the south of Kaschau, are in a deposit of auriferous pyrites, amid trap rocks of the most recent formation.

In Transylvania the gold occurs in veins, often of great magnitude. These veins have no side plates or wall stones, but abut, without intermediate gangues, on the primitive rock. They consist of decomposing quartz, ferriferous limestone, heavy spar, fluor-spar, and sulphuret of silver. The name of Kapnik deserves notice, where the gold is associated with orpiment, and that of Vöröspatak in granite rocks; those of Offenbanya, Zalatna, and Nagy-Ag, where it is associated with tellurium. The last is in syenitic rock on the limits of the trachyte.

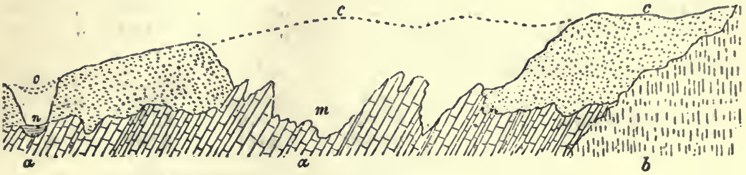
In Italy the only gold mines of importance are in the north of Piedmont. The principal mines are those of Vallanzasca, Val-Toppa, and Pestarena. In 1866 these mines produced 5,952 ounces of gold.

In Sweden, the mine of Edelfors in Småland may be mentioned, where the gold occurs native and in auriferous pyrites; the veins are a brown quartz, in a mountain of foliated hornstone.

In Siberia, native gold occurs in a hornstone at Schlangeberg or Zmeof, and at Zmeino-garsk in the Altai Mountains, accompanied with many other ores.

The gold mine of Beresow in the Ural Mountains has been long known, consisting of *partially-decomposed auriferous pyrites*, disseminated in a vein of greasy quartz. This is, according to Murchison, 'the only work at which subterranean mining in the solid rock is still practised; there the shaft traverses a mass of apparently metamorphosed and crystalline matrix, called "*beresite*," resembling a decomposed granite with veins of quartz, in which some gold is disseminated.' About 1820, a very rich deposit of native gold was discovered on the eastern side of the Ural Mountains, disseminated at some yards deep in an argillaceous loam, and accompanied with the *débris* of rocks which usually compose the auriferous alluvial soils, as greenstone, serpentine, peroxide of iron, corundum, &c. The rivers of this district possess auriferous sands.

1117



At the Soimanofsk mines, south of Miask, great piles of ancient drift or gravel having been removed for the extraction of gold, the eroded edges of highly-inclined crystalline limestones have been exposed, which, from being much nearer the centre of the chain than the above, are probably of Silurian or Devonian age (*fig.* 1117). It is from the adjacent eruptive serpentinous masses and slaty rocks *b*, that the gold shingle *c*, (usually most auriferous near the surface of the abraded rock *a*) has been derived. The tops of the highly-inclined beds *a* are in fact rounded off, and the interstices between them worn into holes and cavities, as if by very powerful action of water. Now here, as at Berezovsk, mammoth-remains have been found. They were lodged in the lowest part of the excavation, at the spot marked *m*, and at about fifty feet beneath the original surface of overlying coarse gravel *c*, before it was removed by the workmen from the vacant space under the dotted line. The feeble influence of the streams *n*, which now flow, in excavating even the loose shingle is seen at the spot marked *o*, the bed of the rivulet having been lowered by *human* labour from its natural level *o*, to that marked *n*, for the convenience of the diggers.—*Murchison.*

It was from the infillings of one of the gravelly depressions between the elevations, south of Miask, that the largest lump of solid gold was found, of which at that time (1824) there was any record. The 'pepita' weighs ninety-six pounds troy, and is still exhibited in the museum of the Imperial School of Mines at St. Petersburg.

The quantity of gold raised in Russia during five years was as follows:—

1847	1700 poods.
1848	1660 „
1849	1530 „
1850	1490 „
1851	1266 „
	7646

Equal to about 296,932 lbs. troy in five years.—*Lectures on Gold, R. Hunt.*

The total production of gold in Russia has of late years been as follows:—

(*Ural, Eastern and Western Siberia*).

	Government Mines. oz.	Private Mines. oz.	Total oz.
1860	111,984	665,986	767,870
1861	105,959	643,159	749,118
1862	102,857	640,885	752,742

	oz.
1847 (the year of maximum production)	961,616
1852 (the year of minimum production)	720,320

The largest single production in 1860 was from the Aurora Steam Works on the

Ojne river, in the Jenesei district, belonging to Messrs. Rjasonow & Co., namely, 54,020 ounces, $\frac{880}{1000}$ to $\frac{890}{1000}$ fine; or at 3*l.* 15*s.* 6*d.* per ounce, value 203,925*l.* 10*s.*

	dwts.	grs.	
In 1823 the sands washed in the Beresow district yielded .	2	5·6	per ton.
1861 ,, ,, ,, ,, .	0	8·1	,,
1828 ,, Bogalousk (N. Ural) .	1	4·7	,,
1830 ,, ,, ,, ,, .	5	18·4	,,
1860 ,, ,, ,, ,, .	0	20·8	,,
1861 (first half year) ,, Mijask ,, ,, .	0	12·3	,,

The force employed was in 1860:—

	Men	Women.	Horses and Mules.	Steam-Engines.
W. and E. Siberia . . .	31,796	919	8,751	—
Ural	20,352	2,181	8,339	4
Total . . .	52,148	3,100	17,090	4

The average payments for royalties in the private mines is 7 per cent.

In Erman's 'Archives' we find that in the year 1851, the gold of the Uralian washing and amalgamation-works produced 332 poods; the Nertschinsk works, 67 poods; the remaining West and East Siberian washings, 1,107 poods; the produce of the Altai Mountains and of Nertschinsk Siberian works, 39 poods; making 1,546 poods.

Gold in Asia.—In Asia, and especially in its southern districts, there are many mines, streams, rivers, and wastes which contain this metal. The Pactolus, a small river of Lydia, rolled over such golden sands, that it was supposed to constitute the origin of the wealth of Crœsus. But these deposits are now poor and forgotten. Japan, Formosa, Ceylon, Java, Sumatra, Borneo, the Philippines, and some other islands of the Indian Archipelago, are rich in gold streams. Those of Borneo are worked by the Chinese in an alluvial soil, on the western coast, at the foot of a chain of volcanic mountains.

Little or no gold comes into Europe from Asia, because its servile inhabitants place their fortune in treasure, and love to hoard up that precious metal.

Numerous gold mines occur on the two slopes of the chain of the Cailas mountains in the Oundès, a province of Little Thibet. The gold lies in quartz veins, which traverse a very crumbling reddish granite. Gold is said to have been found in tolerable abundance in the sands of some of the tributaries to the Amour river.

Gold in Africa.—Africa was, with Spain, the source of the greater portion of the gold possessed by the ancients. The gold which Africa still brings into the market is always in dust, showing that the metal is obtained by washing the alluvial soils. None of it is collected in the north of that continent; three or four districts only are remarkable for the quantity of gold they produce.

The first mines are those of Kordofan, between Darfour and Abyssinia. The negroes transport the gold in quills of the ostrich or vulture. These mines seem to have been known to the ancients, who considered Ethiopia to abound in gold. Herodotus relates that the king of that country exhibited to the ambassadors of Cambyses all their prisoners bound with golden chains.

The second and chief exploitation of gold-dust is to the south of the great desert of Zaara, in the western part of Africa, from the mouth of the Senegal to the Cape of Palms. The gold occurs in spangles, chiefly near the surface of the earth, in the beds of rivulets, and always in a ferruginous earth. In some places the negroes dig pits in the soil to a depth of about 40 feet, unsupported by any props: they do not follow any vein, nor do they construct a gallery; but by repeated washings they separate the gold from the earthy matters.

The same district furnishes also the greater part of what is carried to Morocco, Fez, and Algiers, by the caravans which go from Timbuctoo on the Niger, across the great desert of Zaara. The gold which arrives by Sennaar at Cairo and Alexandria comes from the same quarter. From Mungo Park's description, it appears that the gold spangles are found usually in a ferruginous small gravel, buried under rolled pebbles.

The third spot in Africa where gold is collected is on the south-east coast, between the twenty-fifth and the twenty-second degree of south latitude, opposite to Madagascar, in the county of Sofala. Some persons think that this was the kingdom of Ophir, whence Solomon obtained his gold.

The following account of the Transvaal gold-fields is abstracted from a communication to the 'Times,' dated December 28, 1873:—

'It may be well to explain the origin of the word "Transvaal," which, simple as it is, may not at first be apparent. The "Vaal," which in Boer lingo means, as I understand, "grey," is a magnificent river, taking its rise hundreds of miles away in the Drakensberg mountains, and falling into the still larger and longer Orange river. Some dissatisfied Boers, seceded from the Cape Colony and elsewhere, resolved to form a "South African Republic," took possession of the country on the other side of the Vaal, and christened it the "Transvaal." The river in winter is fordable at frequent intervals; but when in summer it rises, or, as the Boers say, "comes down," it forms a rapid broad stream, very dangerous to cross.

'Before this letter can reach England you will have published some accounts of the finds of gold, so that I shall not now go much into detail. The latest news is that 13¼ lbs. were found in one hour in a single claim, the largest nugget weighing 4 lbs. This gold was brought down to Kimberley diamond-fields on Christmas-day, and has excited much admiration. I know, as facts, of the following finds:—In one week a party dug out 15 oz.; next week, 34 oz.; another party 100 oz. in four weeks, and so on. The present number of diggers is about 500, but fully 800 are now on their road from Kimberley. I have private letters from "Pilgrim's Rest"—the latest rush—also of a highly satisfactory character.

'Now, what does all this portend? The clearest way, perhaps, will be to summarize the situation, as follows:—

'The whole of South Africa is at this moment in a highly prosperous condition; money is plentiful, and, generally speaking, everyone is well off. Our banks, our steamship-companies are flourishing; and although this may not prove to be a second Australia or California, there is a pretty firm conviction that South Africa is likely to be a very important appendage to Her Majesty's empire. Every one is in good spirits, because it is felt that, at length, South Africa will be better appreciated and understood at home.

'The present diggings at Leydenburg are situated in about lat. 25° S., long. 31° E.; Cape Town is in lat. 34° S., long. 18° E.; Algoa Bay, lat. 34° S., long. 26° E.; Natal, lat. 30° S., long. 31° E. So that the approximate distances from the three ports are: Cape Town, 1,200 miles; Algoa Bay, 800 miles; Natal, 400 miles. Delagoa Bay must for the present be left out of the question, until the French arbitration is settled, and until a railway is run through the unhealthy belt.'

It is well known that gold is also found in Western Africa, along the 'Gold Coast,' and some fine examples of nuggets of this gold were brought to this country at the conclusion of the late war (1874). The nuggets were, in most cases, associated with a ferruginous earth, giving a ruddy colour to the gold. An analysis of this Ashantee gold, by Professor Church, is given on p. 687.

Gold in South America.—During the last, and the commencement of the present century, the richest gold mines were found in South America. It occurs there principally in spangles among the alluvial earths, and in the beds of rivers; more rarely in veins.

The gold of Mexico is in a great measure contained in the argentiferous veins, so numerous in that country, whose principal localities are mentioned under the article SILVER. The silver of the argentiferous ores of Guanaxuato contains one 360th of its weight of gold; the annual product of the mines being valued at from 2,640 to 3,300 pounds avoirdupois.

Oaxaco contains the only auriferous veins explored as gold mines in Mexico; they traverse the rocks of gneiss and mica slate.

All the rivers of the province of Caracas, to ten degrees north of the line, flow over golden sands.

Peru is not rich in gold ores. In the provinces of Huailas and Pataz, this metal is mined in veins of greasy quartz, variegated with red ferruginous spots, which traverse primitive rocks. The mines called *pacos de oro*, consist of ores of iron and copper oxides, containing a great quantity of gold.

Most of the gold furnished by New Grenada (New Columbia) is the product of washings established in alluvial grounds. The gold exists in spangles and in grains, disseminated among fragments of greenstone and porphyry. At Choco, along with the gold and platinum, hyacinths, zircons, and titanium occur. There has been found, as already stated, in the auriferous localities, large trunks of petrified trees. The gold of Antioquia is 20 carats fine, that of Choco 21, and the largest lump or *pepita* of gold weighed about 27½ pounds avoirdupois. The gold of Chili also occurs in alluvial formations.

Brazil does not contain many gold mines, properly so called; for the veins containing the metal are seldom worked. Dr. Walsh says gold was first known to exist in the Brazils in 1543. The Indians made their fishing-hooks of it, and from them it was discovered that it was found in the beds of streams, brought down from the mountains.

But the first ore found by a white man in that country was in the year 1693; this discovery led to the colonisation of the Minas Geräes, and to all those evils resulting from 'the cursed lust of gold,' with details of which the history of South America abounds.

It was in the sands of the Mandi, a branch of the Rio Dolce, at Catapreta, that the auriferous ferruginous sands were first discovered in 1682. Since then they have been found almost everywhere at the foot of the immense chain of mountains, which runs nearly parallel with the coast, from the 5th degree south to the 30th. It is particularly near Villa Rica, in the environs of the village Cocäes, that the numerous washings for gold are established. The *pepitas* occur in different forms, often adhering to micaceous specular iron. But in the province of Minas Geräes, the gold occurs also in veins, in beds, and in grains, disseminated among the alluvial loams. It has been estimated in annual product, by several authors, at about 2,800 lbs. avoirdupois of fine metal.

Almost all the gold formerly brought into the market was from alluvial lands, and had been extracted by washing; but now numerous veins of auriferous quartz and deposits of auriferous pyrites are worked. The Morro Velho mine, belonging to the St. John del Rey Company, is perhaps the most important Brazilian gold mine.

Gold in North America.—Californian Gold Mines. The accident which first revealed the golden treasures of the soil of California is thus related by a writer in the 'Quarterly Review' for September 1852:—

Captain Suter, the first white man who had established himself in the district where the Americanos joins the Sacramento, having erected a saw-mill on the former river, whose tail-race turned out to be too narrow, took out the wheel, and let the water run freely off. A great body of earth having been carried away by the torrent, laid bare many shining yellow spangles, and on examination Mr. Marshall, his surveyor, picked up several little lumps of gold. He and Captain Suter then commenced a search together, and gathered an ounce of the ore from the sand without any difficulty; and with his knife the captain picked out a lump of an ounce and a half from the rock. A Kentuckian workman employed at the mill had espied their supposed secret discovery, and when, after a short absence, the gentlemen returned, he showed them a handful of the glittering dust. The captain hired a gang of fifty Indians, and set them to work. The news spread, but the announcement of the discovery was received with incredulity beyond the immediate neighbourhood. But presently, when large and continuous imports of gold from San Francisco placed the matter beyond doubt, there ensued such a stir in the States, as even in that go-ahead region is wholly without parallel: numbers of every age, and of every variety of occupation, pushed for the land of promise. Many were accompanied by their families, and most under the excitement of the hour overlooked their physical unfitness, and their inability to procure necessaries. The waters of the Humboldt, from their head to their 'sink,' a space of nearly 300 miles, are in the dry season strongly impregnated with alkali, and it was here that they first began to faint. Some died from thirst, others from ague, others fell beneath the burdens they attempted to carry when their last animal dropped into the putrid marsh, which grew thicker at every step. Beyond the 'sink' the diminished bands had to encounter sixty or seventy miles of desert, where not a blade of herbage grew, and not a drop of pure water could be procured; and those who pushed safely through this ordeal had still to ascend the icy slopes of Sierra Nevada, where the rigours of winter were added to all other difficulties. At different points, one being almost in sight of the golden land, overwearied groups had formed encampments, in case perhaps some help might reach them. It is to the credit of the settlers that, on hearing this, they strained their resources to the utmost to afford relief. Yet, when all was done, a sick, destitute, most wretched horde of stragglers was all that remained of the multitude who, full of hope and spirits, had commenced the prairie journey.

The development of the gold-fields of California has been so remarkable, that it appears necessary to devote some space to a consideration of the conditions under which the auriferous treasures are discovered. This cannot be better done than by quoting Professor Blake's remarks on the 'Geognosy of the Gold-Drift of California.'

With the exception of the diluvial strata, the whole geological formation of the Sierra range consists of igneous and metamorphic rocks; the former are mostly porphyritic in the lower hills, whilst higher up trachytic rocks are more frequently met with. The metamorphic rocks consist of micaceous schists, slates both talcose and micaceous, metamorphic sandstones and limestones, with occasional beds of conglomerate. The stratified rocks have been much displaced: it is rare to find them with a dip of less than 70°, and they are generally very nearly perpendicular. The strike of the beds in that section to which Professor Blake's observations have been confined (between the Stanislaus and Yuba rivers) is extremely uniform, being from 5° to 10°

W. of N. and E. of S. The extent of the diluvial deposits is commensurate, or nearly so, with that of the gold-bearing region, in that part of the country which he has examined. They are found in a belt of land from thirty to sixty miles broad, and running parallel with the axis of the range; and, from facts that he has ascertained from others, he states that he has no doubt but that they exist throughout all the gold-bearing region, both north and south. These diluvial deposits are met with as we advance towards the lower hills of the Sierra, extending frequently some miles into the plain. On ascending from the lower hills towards the mountains, the diluvial beds no longer occupy the same relative position: occasionally deposits of rounded stones can be found in the valleys and on the sides of the hills, but when this is the case, their origin can always be traced to deposits existing on the tops of the surrounding hills, from which they have been brought down by the action of the causes now at work. As we ascend towards the axis of the chain, these deposits become more extensive, and at a distance of twenty or thirty miles from the lower hills, they are found occupying the crests of almost all the highest ridges in the country; but besides being found on the crests of the ridges, where their extent frequently does not exceed a few yards in breadth, they are also met with covering the extensive elevated flats which exist on the benches between the different watercourses, forming continuous beds of some miles in extent, which are rarely interrupted by the protrusion of any of the older rocks. Where found in elevated positions, the lower hills and valleys are entirely free from them; frequently a large section of the country will be enclosed with two high ridges capped by deposits, and diverging from a common point; in the intervening space will be seen many secondary ridges, sometimes fifteen or eighteen hundred feet high, formed entirely of the older rocks, no traces of deposits being found on their surface, nor in the ravines that lead from them.

The depth of these deposits is extremely variable. Sometimes nothing more than a trace of them in the presence of a few round pebbles lying on the top of a ridge is found; the valleys and ravines in the neighbourhood containing their disintegrated elements in considerable quantities. In other instances, particularly where spread out over the elevated flats, they are of a moderate and pretty uniform thickness for a considerable distance, varying from two to three feet to a few inches, and this, too, in positions where the surface could not have been exposed to any great amount of denudation. They are again found many hundred feet in thickness, composed of superimposed strata of different mineralogical constitution, generally horizontal and conformable with each other.

The localities where the deposits are met with most extensively disclosed, and that have been worked, are at Nevada and at Mokelumne hill. At the former place they form the crest of a high mountain, called the Sugar-loaf, full 2,000 feet above the level of Deer Creek, the upper 600 feet being formed entirely of diluvial strata. At Mokelumne hill they are also 200 feet deep, forming here also the summit of a high and isolated mountain. The elements of which they are composed differ considerably in different localities, although there are through the whole series many points of resemblance. In the lower valleys and flats between the ranges of the lower hills, they appear to consist of beds of gravel, containing occasional boulders of quartz and the harder rocks. On the elevated flats higher up in the mountains, the surface of these deposits is generally covered by a reddish loam, mixed with small gravel; whilst reposing on the bed-rock, and a few inches above it, is found a stratum containing large boulders and gravel, the boulders being principally quartz. On the tops of the hills and the crests of the ridges, where they generally attain their greatest thickness, we find them composed of many distinct strata lying nearly horizontal and conformable with each other, and generally also with the surface of the underlying rocks. In these situations the most superficial stratum is composed of a mass of extremely hard conglomerate, containing principally trachytic rocks, imbedded in a hard argillaceous cement. It is this hard stratum that has undoubtedly preserved the underlying beds from the destructive influence which has so powerfully acted on the surrounding rocks.

At other points the whole series consists of conglomerates and soft friable sandstone. In the lower strata quartzose conglomerates, with an argillaceous cement, or loose quartzose gravel, always prevail, with large boulders of quartz, weighing frequently two or three tons, having their surface worn smooth and the angles rounded. The deposits of the heavier rocks have been formed on spots which were evidently lower than the level of the surrounding rocks; whilst on those parts which were higher at the time the deposits were formed, the higher trachytic rocks are found. As far as Professor Blake's researches have extended, the more quartzose conglomerates have been invariably found on the erupted rocks, whilst the stratified rocks which they had upheaved were only covered by the trachytic conglomerates. The pebbles of which these conglomerates are composed present specimens of all the harder rocks: metamorphic sandstones, clinkstone, trap, porphyries, and quartz, make up the larger part of the mass. They are all perfectly rounded, but in the lower deposits are so soft that, with the exception of the trap and quartz, they generally fall to pieces on exposure to the air. The strata, as before observed, are nearly horizontal and conformable; if they have any dip, it appears to have been owing to the slope of the surface of the rock on which they were deposited; in fact, no displacement seems to have taken place in this country since the time of their formation. They lie perfectly horizontal over the almost vertical edges of the upheaved slate-rocks.

As regards the mineral riches of these deposits, it would appear that gold is found wherever they exist. The ravines coming from the ridges on which they are found are generally extremely rich, and always contain gold, even in places where the deposits themselves have been worked without success. In some places where they have been worked as much as thirty thousand dollars have been taken from a claim of fifteen feet square; and there are many instances where ten and fifteen thousand dollars have been taken from claims of the same size. But few of these rich spots have, up to the present time, been opened, yet there can be no doubt but that many still remain to be discovered. Where the deposits are found extending over a large surface on the elevated flats, gold is always met with, generally diffused through the gravel immediately above the rock on which they rest.

A recent Blue-book gives some important information on the subject of Californian mines. It states that the short supply of water during the past year has interfered materially with mining operations, both in Canada and Nevada. Many of the quartz-mills in this State have been idle for many months, and hydraulic mining has had to be suspended altogether in many localities, both from want of water for hydraulic use and from the accumulation of the 'tailings.' Every year new capital is brought to bear on mining enterprise; and it is no longer difficult to find the requisite means to work a mine, if the prospects are at all encouraging.

During the past year, notwithstanding the limited supply of water, there have been more enterprises started or increased in magnitude than in any previous year. Hydraulic mining is the most attractive, and as the course of the old river-channels are more surely traced, this interest will be enormously extended. The State geologist has had, during the past two years, some of his staff employed in tracing the course of these rivers, and the result of these scientific researches will be to facilitate the action of the mines materially. In a semi-official report he says:—

'In the prosecution of this work a large amount of valuable information has already been collected, both of a geographical and geological character. It is confidently expected that the working-up of all materials collected, with the accompanying maps and sections, will exhibit the phenomenon of gravel deposits—in regard to which there has been so much discussion and such a multiplicity of opinions—in a new light, and that many difficulties which have hitherto perplexed the miners will be solved. He desired the work to be continuously prosecuted until a full and detailed map and report on the whole region have been prepared, which he thought would be accomplished the next session if the pecuniary means are forthcoming.'

Hydraulic mining is becoming more general through the mining districts. It was for some years mainly confined to the counties of Yuba, Nevada, Placer, El Dorado, and Butte, but it is spreading to Mariposa in the south, and Trinitio, Klamath, and Liskyon counties, in the north. Yuba and Nevada, always the leading counties in hydraulic mining, still maintain the ascendency. From one small district in the former county nearly 100,000*l*. were received, and the yield from the completion of tunnels will be much greater this year. Tuolumne has added to the counties known to possess old river-channels. A large ditch is nearly completed to bring water from the Tuolumne river to a very extensive gravel-deposit near La Grange, which is said to be unusually rich and free from cement. The great hindrance to the working of these mines has generally been the want of drainage-capacity, which has compelled the construction of long and expensive tunnels, a work of great labour and time.

The large ditches now furnishing water for hydraulic purposes supply hydraulic power from nozzles of 7 inches in diameter, and the force is tremendous. Two or three years ago a 3-inch nozzle was the largest in use. A great many very fine quartz-mills have been built, with all the improvements that science and practical experience have taught; and though labour has not depreciated sensibly in value, quartz of a much lower grade can be profitably worked than heretofore.

The two leading quartz-mines of California—the Amador, in Amador county, and the Eureka, in Nevada county—have paid in dividends respectively 172,000*l*. (since it has been an incorporated company) and 354,800*l*. The total yield of the California gold mines is estimated at 3,000,000*l*. Extraordinary developments have been made in the great 'Comstock lead' of Nevada, and the yield has reached 2,200,000*l*., fully one-third more than the product of 1870. The more recent discoveries have been in the 'Crown Point' and 'Belcher' mines, which have proved so flattering as to send the value of their stock far above what it has ever before reached. The latter has heretofore paid in dividends but little over the assessment, but it recommenced paying dividends in January 1871, by one payment of 10 dollars per cent. per share, equal to 28,000*l.* The following are the dividends paid by four of the leading mines of this lode:—Chollar Potosi, 330,400*l.*; Crown Point, 168,000*l*; Hale and Norcross, 32,000*l.*; Yellow Jacket, 88,800*l.*

The coinage of gold at the San Francisco mint was as follows:—

1867.	1868.	1869.	1870.
Dols.	Dols.	Dols.	Dols.
17,370,535	17,365,000	14,365,550	20,355,000

Gold produced in the States and Territories west of the Missouri river during 1871: from Raymond's 'Mining Statistics West of the Rocky Mountains.' Gold bullion, amalgam, or dust:—

	Dols.
Arizona	163,739,93
British Columbia	1,349,580,83
Colorado	2,605,681,50

Montana	4,031,502,00
Oregon	1,693,602,15
Utah	221,262,14
Washington	320,107,09
Total	28,024,026,90

Professor Raymond gives his estimate of the gold and silver productions in the United States for the year 1871 as follows, as compared with former years:—

	1869	1870	1871
	dollars	dollars	dollars
Arizona	1,000,000	800,000	800,000
California	22,500,000	25,000,000	20,000,000
Colorado	4,000,000[1]	3,675,000	4,663,000
Idaho	7,000,000	6,000,000	5,000,000
Montana	9,000,000	9,100,000	8,050,000
Nevada	14,000,000	16,000,000	22,500,000
New Mexico	500,000	500,000	500,000
Oregon and Washington	3,000,000	3,000,000	2,500,000
Wyoming	...	100,000	100,000
Utah	...	1,300,000	2,300,000
Other sources	500,000[2]	525,000	250,000
Total	61,500,000	66,000,000	66,663,000

[1] Including Wyoming. [2] Including Utah.

The estimated production of gold and silver for the five years ending 1871 in the United States, based upon the coinage of the mints and the foreign exports, according to the commerce and navigation reports, was as follows:—

Years	Gold	Silver	Total production
	£	£	£
1867	7,700,000	3,800,000	11,500,000
1868	7,000,000	3,000,000	10,000,000
1869	6,500,000	2,800,000	9,300,000
1870	6,000,000	3,200,000	9,200,000
1871	5,600,000	4,400,000	10,000,000

Statement of Deposits and Coinage at the Mint of the United States and Branches during the year ended December 31, 1871.

	Gold deposits	Silver deposits	Total deposits
	dollars	dollars	dollars
United States Mint, Philadelphia	2,884,645,61	2,124,924,26	5,009,569,87
Branch Mint, San Francisco	24,960,122,61	1,247,567,05	26,207,689,66
„ Carson City	2,515,132,79	2,994,456,17	5,459,597,96
„ Denver	1,020,223,37	2,937,67	1,023,161,04
Assay office, Charlotte	16,122,37	164,52	16,286,89
Total	31,396,246,75	6,320,058,67	37,716,305,42

About one-third of the value of the silver-production is also gold, which should be deducted from the second column and added to the first, to show the exact proportion of each metal produced. The above statement does not embrace the gold and silver exported in the form of ore.

Gold in Canada.—In the Progress Report, Mr. Henry G. Vennor of the Geological Survey of Canada, after referring to notices of gold in former reports, says:—

The portion of the townships of Madoc and Marmora, in which the only mines now (1872) being worked for gold are situated, is that immediately surrounding the granite area known as the Huckleberry Rocks. These rocks occupy a very large part of the south-western quarter of Madoc and the south-eastern quarter of Marmora, extending north-westward on the boundary line between these townships as far as the middle of the eighteenth lot, with a breadth of about four miles, the river Moira, in Marmora, forming their western limit.

In the talcoid slates are found large bedded quartz-veins, holding sulphurets of iron and copper, and native gold. A uniform relation between the gold- and iron-bearing zone is shown as probable. The gold in Madoc and Marmora occurs:—

1. In bedded metalliferous lodes.
2. In slate bands, impregnated with sulphurets.
3. In nests, or bunches, with quartz and sulphurets in dolomite.
4. In cross or fissure veins (of minor importance).

Seven mines were worked for gold in 1871, in the province of Ontario; the gold produced in 1871, being 500 ounces from Cook Mine. Mr. Charles Robb of the Canadian Geological Survey says:—'Within the last three years most important discoveries of auriferous veins have been made, and operations commenced for developing them on an extensive scale and with good prospects of success.'

In the *Province of Quebec* the following quantities of gold were obtained:—

1869	1050½ ounces,	value	18,909$
1870	581 „	„	10,467
1871	115 „	„	2,070

Gold exported from Canada.

	1866[1]	1867[1]	1868[1 2]	1869[1 2]	1870[1 2]	1871
Coin and Bullion,	499,498*l.*	607,507*l.*	1,013,785*l.*	878,793*l.*	1,647,608*l.*	1,372,292*l.*

The Gold-Fields of British Columbia.—That the auriferous deposits of this region are spread over a considerable scope of country is apparent from the fact that paying diggings have already been found on the Fraser river, extending from Fort Hope almost to Fort Alexander, a continuous distance of nearly 400 miles. Among the tributaries of this stream, Thompson and Bridge rivers are known to be auriferous. Extensive works are established, and large quantities of gold are produced, but returns of quantities cannot be obtained.

The return of gold mining generally throughout the Province is:—

1869	value	1,824,871$
1870	„	1,333,745
1871	„	1,349,581

Gold Mines of Nova Scotia.—The production of gold in Nova Scotia has been as follows:—

---

[1] Years ending June 30.

[2] Exclusive of exports to other Provinces of the Dominion.

Australian Gold-Mines.—The discovery of the great gold-field in Australia to the westward of Bathurst, about 150 miles from Sydney, was officially made known in Great Britain, by a despatch from Sir C. A. Fitzroy to Earl Grey, on the 18th September 1851, many persons with a tin dish having obtained from one to two ounces per day. On May 25th, he writes that lumps have been obtained, varying in weight from one ounce to four pounds. On May 29th, he writes that gold has been found in abundance, that people of every class are proceeding to the locality, that the field is rich, and, from the geological formation of the country, of immense area. By assay the gold is found to consist of 91·1 of that metal, and about 8·333 of silver, with a little base metal; or of 22 carats in fineness. July 17th, a mass of gold weighing 106 lbs. was found imbedded in the quartz-matrix, about 53 miles from Bathurst; and much more, justifying the anticipations formed of the vast richness and extent of the gold-field in this colony. This magnificent treasure, the property of Dr. Kerr, surpassed the largest mass found in California, which was 28 lbs.; and that in Russia, which was 70 lbs., now in the Museum at St. Petersburg. One party of six persons got at the same time 400*l.* in ten days, by means of a quicksilver machine; and a party of three, who were unsuccessful for seven days, obtained in five days more than 200 ounces.

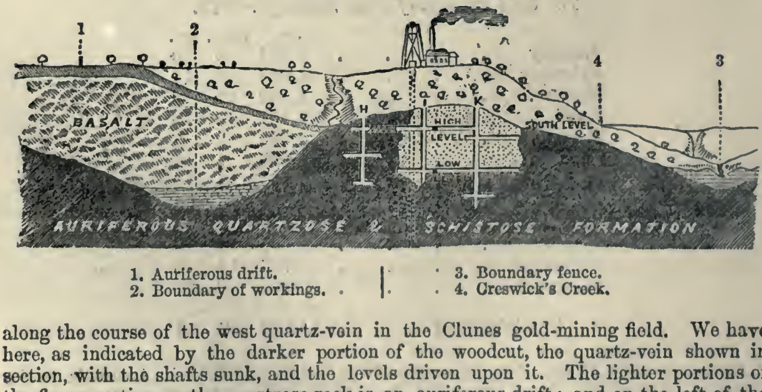
Numerous claims have been made by persons who have thought that they had given the first indications of gold in Australia. To the late Sir Roderick Murchison is, however, due the merit of pointing out that gold might probably be found in Australia, long before it was known in Europe that gold existed in that important colony. Sir Roderick Murchison thus gives us the facts :—

'Having in the year 1844 recently returned from the auriferous Ural mountains, I had the advantage of examining the numerous specimens collected by my friend Count Strzelecki along the eastern chain of Australia. Seeing the great similarity of the rocks of those two distant countries, I could have little difficulty in drawing a parallel between them; in doing which I was naturally struck by the circumstance that no gold had *yet* been found in the Australian range, which I termed in anticipation the 'Cordillera,' impressed with the conviction that gold would, sooner or later, be found in the great British colony. I learnt in 1846 with satisfaction that a specimen of the ore had been discovered. I thereupon encouraged the unemployed miners of Cornwall to emigrate, and dig for gold as they dug for tin in the gravel of their own district. These notices were, as far as I know, the first printed documents relating to Australian gold.'

August 25th, 1851, Lieutenant-Governor C. J. Latrobe announced to Earl Grey from Melbourne, the discovery of large deposits of gold in that district of the colony. In a second Parliamentary blue-book, issued February 3rd, 1852, it is stated that 79,340 ounces of gold, worth 257,855*l.* 7*s.*, had been previously forwarded to England; and that the gold-fields of the colony of Victoria rival, if they do not exceed in value, the first-discovered gold-fields of New South Wales; the total value being then 300,000*l.*; and but a little time afterwards about half a million sterling. Mr. E. Hargreaves, Commissioner for Crown lands, announced from Bathurst, that no part of California which he had seen had produced gold so generally and to such an extent as Summerhill Creek, the Turon River, and its tributaries.

For the purpose of conveying a correct idea of the conditions under which the greatest quantity of the Australian gold occurs, three plans have been selected from different districts. The first of these (*fig.* 1118) represents a longitudinal section along the course of the west quartz-vein in the Clunes gold-mining field. We have here, as indicated by the darker portion of the woodcut, the quartz-vein shown in section, with the shafts sunk, and the levels driven upon it. The lighter portions of the figure resting on the quartzose rock is an auriferous drift; and on the left of the section the great basaltic formation is shown.

1118

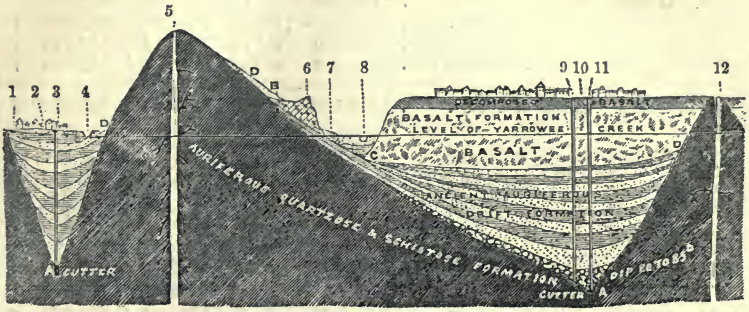


1. Auriferous drift.
2. Boundary of workings.
3. Boundary fence.
4. Creswick's Creek.

Fig. 1119 is a section of a portion of the Ballarat gold-field. It is an east and west section from the Red Streak-lead across Post-Office Hill, White Flat, the township of Ballarat West, and the quartz-reef west of the township; and it shows the auriferous drift, schist, quartz, and basalt formations of the district.

In those two sections we have, therefore, all the conditions shown of the processes of mining on the quartz-lodes and in the alluvial deposits.

1119



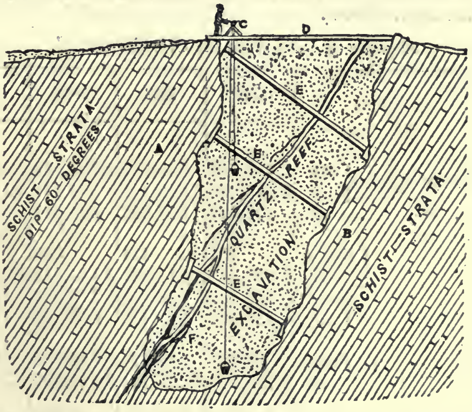
1. The town of Ballarat East.
2. The main road.
3. The Red-Streak lead.
4. The creek.
5. Old Post-office hill, with quartz-reef.
6. Basalt escarpment south of Golden Point.
7. White flat recent auriferous alluvial deposit.
8. Yarrowee Creek.
10. The Gravel-Pits lead.

9 and 11 are two shafts sunk into the ancient auriferous alluvial deposit.
12. Quartz-reef beyond the town of Ballarat West, shown in the drawing.
B is the remains of a lava stream, interrupted by the schist and clay-slate hills.
D·D is the gravel strata which invariably rest on the side of the schist hills which surround the Ballarat basin.

Fig. 1120 is a section from the Boroondara and Bulleen gold mines, a few miles from the capital of Victoria. It is the east and west section of the Carlton Estate quartz-reef, and is mainly given to illustrate the unskilful and dangerous condition of many of the workings undertaken by men who have no experience in subterranean operations. The shaft, if such it can be called, is about 40 feet deep; and the reef dips with the solid strata at an angle of about 60 degrees to the horizon.

The wall of the shaft at A is not supported on the footwall by props and proper timbering, which it should be, as indicated by E E E. The windlass at C, and the framework at D, are both exceedingly insecure. This is the mode of proceeding in a very important working, where almost every piece of quartz broken out contains gold, and also antimony and iron. At the point F the quartz-reef was exceedingly rich, and there it branches off into small strings, yielding 22 ounces of gold to the ton.

1120



It is not necessary here to trace the progress of gold-mining in this colony. The quantity of gold discovered and exported has been enormous. Some exceedingly large 'nuggets' have been found; one in Forest Creek, weighing 27 lbs. 6 oz. 15 dwts., and the Welcome Nugget, weighing 2,217 oz. 16 dwts.

The following are the returns made by the inspector to the government of *Victoria* in the years given:—

	Alluvial		Quartz		Total

The imports of Australian gold into the United Kingdom in 1873 exhibited a large increase as compared with 1872, having amounted to 9,471,601*l.* as compared with 6,014,621*l.* in 1872, and 6,919,480*l.* in 1871.

Gold in New Zealand.—Dr. Hector in the 'Geological Survey Progress Report' gives the following account:—'Gold had been long known to exist at Coromandel, a little north of the Shortland District, in 1852, and it had been regularly worked there since 1862. Rumours had also long existed that gold was plentiful in the Thames Valley, and several Maoris and Europeans had brought specimens to Auckland at various times from 1865. In July 1867, a native chief, named Taipari, stimulated by the offer of the Provincial Government of a reward of 5,000*l.* for any one who should discover a payable gold-field, employed several men, both Europeans and Natives to prospect his land; and gold was obtained by sluicing in the Karaka and Hope Creeks. This was taken to Auckland and shown to the Deputy Superintendent and the Native Commissioner, and at the same time Taipari offered to throw open his lands as a gold-field. Satisfactory arrangements having been made with him, the result was that a block of land from the Hope to the Pukehinan Creeks, known as the Karaka block, was proclaimed a gold-field on August 1, 1867, and a town was laid out at the mouth of the Kawaeranga, and named Shortland. Parties at once set to work sluicing on the Karaka, Waiotahi, and Moauataiari, but with indifferent results; when on August 17, four men discovered the gold *in situ* in the Kuranni on the face of a waterfall, on the spot now so well known as Hunt's Reef. This led to further exploration for quartz veins, and in a month gold had been found in about a dozen places. Further discoveries quickly followed. Sluicing was abandoned, and quartz-mining recognised as the true industry of the field. So satisfactorily did this turn out that, at the end of December 1868, or seventeen months after the first proclamation of the field, not only had two other distinct districts, Tapu and Puriri, been started, but about 1,200 claims had been taken up near Shortland, between 800 and 850 of which were then actually working, and probably 600 of the number had seen gold in greater or less quantities. Twenty-seven crushing machines were on the ground, and thirteen others were going up. The yield of gold had exceeded 83,000 ounces, valued at more than 200,000*l.*; and the population numbered about 18,000 souls.

'Gold is now being worked at Puriri—in the district between Shortland and Tararu, and at Tapu. It has also been found in one or two places between Tararu and Tapu; and as the same geological structure extends over the whole district, there is every probability of its existing much more extensively than has yet been discovered.

'The quality of the gold differs considerably in different parts of the field, and even from the same claim, it often varies a good deal. Out of twenty-eight assays from various parts of the Shortland District, furnished by the assayer of the Union Bank of Australia the highest gave 19·5, and the lowest 9·625 carats fine, both being from the Waiotahi Creek; while, from the Lord Derby claim, also on the Waiotahi, some stone yielded nearly pure silver, being only 2·75 carats fine, and worth only 9*s.* 8*d.* an ounce. The average of the 28 assays is 15 carats fine.

'The following table gives the result of these assays separated into districts; and although they are much too few to give any decided results, they show an unmistakeable tendency towards a poorer gold, that is, one containing more silver, as they go northward:—

Locality	Highest carats	Lowest carats	Average carats	Number of assays
Karaka	16·094	16·062	16·078	2
Waiotahi	19·500	9·625	16·094	4
Moauataiari	17·594	14·687	15·937	8
Kuranni	16·594	13·937	15·000	8
Ponga Flat	16·656	12·000	14·328	2
Head of Madman's Gully . .	14·031	13·656	13·781	3
Tararu	...	...	13·968	1

'The gold is very widely distributed through the district, although certain parts appear at present to contain it in more considerable quantities than others; but the mines have not yet been long enough worked to pronounce with much certainty on this point. The fact before mentioned, that probably 600 out of 1,200 claims had seen gold, shows well how widely it is distributed through the country, for it must be borne in mind that, unlike most quartz-mining districts, the reefs here are not continuous for far, and that the greater part are but thin irregular veins; so that the country was not taken up along lines of leads only, but *en masse*, nearly the whole of the country between the Hope and Tararu being pegged off. It follows from this, that nearly one-half of the surface of the country contains more or less gold *in situ*. Major Heaphy informs me that he has had thirty-one assays made of quartz from the same number of veins from various localities in the Opitomoko and Tararu

Creeks, all of which gave more or less indications of gold. Two only showed a trace: while the three highest were 3 oz. 6 dwts.; and 3 oz. 10 dwts.; and 3 oz. 18 dwts. to the ton respectively, the average of the whole being 1 oz. 15 dwts. 8 grs. In none of them could gold be seen with the naked eye. Out of 1,200 claims that have been taken up in the Shortland District I estimate that about 150, or 12 per cent., have found gold in sufficient quantity to justify the expectation that they will turn out permanently payable mines, and I have no doubt but that, as time goes on, many more will be added to the number. As nearly the whole of the Shortland District has been taken up, and more or less proved it follows that about an eighth of its surface, which is about 2,000 acres, contains payable auriferous quartz-veins.'

The Report gave the following return of the yield of gold from the Thames district up to March 31, 1869, taken from the Customs' Returns:—

Quarter ending March 31, 1869 . . .	41,674 ozs.,	value 131,273*l.*
The yield previous to March 31, 1868 . .	81,035 „	„ 250,405*l.*
Making a total yield for Thames and Coromandel district to March 31, 1869 . . .	122,709 „	„ 381,678*l.*

The total yield of gold from all parts of New Zealand up to the same date was 4,549,952 ozs., value 17,674,532*l.*

The total value of gold exported from New Zealand in 1871 was 2,787,520*l.*, produced from the several gold-fields to the following amounts. The total value of the gold exported in 1870 being 2,157,585*l.*, showing an increase of 629,935*l.*:—

	1870	1871
The produce of gold-field in Provinces of *Auckland* .	£319,146	£1,188,708
„ „ *Marlborough* .	7,408	7,468
„ „ *Nelson* . .	591,510	439,936
„ „ *Wellington* .	120	...
„ County of *Westland* . .	578,707	531,648
„ Province of *Otago*, including *Southland* . . .	660,694	619,760

The total value of gold exported from New Zealand from April 1, 1857, to December 31, 1871, was 6,272,878 ounces; the total value being 24,352,999*l.*

The statistics of New Zealand, 1871, give the exports of *gold-dust* as follow:—

Gold, Metallurgic Treatment of.—The gold found in the sands of rivers, or in auriferous soils, need not be subjected to any metallurgic process, properly speaking. The gold seekers separate it from the sands, by washing them first upon inclined tables, sometimes covered with a cloth, and then by hand in wooden bowels of a particular form. The methods of working vary in different localities. The people called Bohemians, Cigans, or Tchinganes, who wash the auriferous sands in Hungary, employ a plank with 24 transverse grooves cut in its surface. They hold this plank in an inclined position, and put the sand to be washed in the first groove; they then throw water on it, when the gold, mixed with a little sand, collects usually towards the lowest furrow. They remove this mixture into a flat wooden basin, and by a peculiar sleight of hand separate the gold entirely from the sand. The richest of the auriferous ores consist of the native gold quite visible, disseminated in a gangue, but the veins are seldom continuous for any length. The other ores of this district are auriferous metallic sulphides, such as sulphides of copper, silver, arsenic, &c., and particularly iron.

The stony ores are first ground in the stamping mill, and then washed in hand-basins, or on wooden tables.

The auriferous sulphides are much more common, but much poorer than the former ores; some contain only one 200,000th part of gold, and yet they may be worked with advantage, when treated with skill and economy.

The gold of these ores is separated by two different processes; namely, by fusion and amalgamation.

The auriferous metallic sulphides are first roasted; then melted into *mattes*, which are roasted anew; next fused with lead, whence an auriferous lead is obtained, which may be refined by the process of cupellation.

When the gold ores are very rich, they are melted directly with lead, without preliminary calcination or fusion. These processes are however little practised, because they are less economical and certain than amalgamation, especially when the gold-ores are very poor.

If these ores consist of copper pyrites, and if their treatment has been pushed to the point of obtaining auriferous rose-copper, or even black copper including gold, the precious metal cannot be separated by the process of liquation, because the gold having more affinity for copper than for lead, can be but partially run off by the latter metal. For these reasons the process of amalgamation is far preferable. This process being the same for silver, we reserve its full description for that metal. See SILVER.

The rich ores in which the native gold is apparent, and merely disseminated in a stony gangue, are directly triturated with quicksilver, without any preparatory operation. As to the poor ores, in which the gold seems lost amid a great mass of iron, sulphide of copper, &c., they are subjected to a roasting process before being amalgamated. This process seems requisite to lay bare the gold enveloped in the sulphurets. The quicksilver with which the ore is now ground seizes the whole of its gold, in however small quantity this metal may be present.

The gold produced by the refining process with lead is free from copper and lead, but it may contain iron, tin, or silver. It cannot be separated from iron and tin without great difficulty and expense, if the proportion of gold be too small to admit of the employment of muriatic acid.

By cupellation with lead, gold may be deprived of any antimony united with it.

Tin gives gold a remarkable hardness and brittleness; a piece of gold, exposed for some time over a bath of red-hot tin, becomes brittle. The same thing happens more readily over antimony, from the volatility of this metal. A two-thousandth part of antimony, bismuth, or lead destroys the ductility of gold. The tin may be got rid of by throwing some corrosive sublimate or nitre into a crucible, containing the melted alloy. By the first agent, perchloride of tin is volatilised; by the second, stannate of potash forms, which is carried off in the resulting alkaline scoriæ.

Gold treated by the process of amalgamation contains commonly nothing but a little silver. The silver is dissolved out by nitric acid, which leaves the gold untouched; but to make this *parting* with success and economy on the great scale, several precautions must be observed.

If the gold do not contain fully two-thirds of its weight of silver, this metal, being thoroughly enveloped by the gold, is partially screened from the action of the acid. Whenever, therefore, it is known by a trial on a small scale, that the silver is much below this proportion, we must bring the alloy of gold and silver to that standard by adding the requisite quantity of the latter metal. This process is called quartation.

This alloy is then granulated or laminated; and from twice to thrice its weight of sulphuric or nitric acid is to be boiled upon it; and when it is judged that the solution has been pushed as far as possible by this first acid, it is decanted, and new acid is poured on. Lastly, after having washed the gold, some sulphuric acid is to be boiled over it, which carries off a two or three thousandth part of silver, which nitric acid alone could not dissolve. Thus perfectly pure gold is obtained.

The silver held in solution by the sulphuric or nitric acid is precipitated in the metallic state by copper, or in the state of chloride by sea-salt. See SILVER.

Gold has less affinity for oxygen than any metal. When alone, it cannot be oxidised at any degree of heat with contact of air, although in combination with other oxidised bodies, it may pass into a state of an oxide, and be even vitrified. The purple smoke into which gold-leaf is converted by an electric discharge is not an oxide, for it is equally formed when the discharge is made through it in hydrogen gas. There are two oxides of gold; the first or protoxide is a green powder, which may be obtained by pouring, in the cold, a solution of potash into a solution of the metallic chloride. It is not durable, but soon changes in the menstruum into metallic gold and peroxide. Its constituents are 96·13 metal and 3·87 oxygen. The peroxide is best prepared by adding magnesia to a solution of the metallic chloride; washing the precipitate with water till this no longer takes a yellow tint from muriatic acid; then digesting strong nitric acid upon the residuum, which removes the magnesia, and leaves the peroxide in the form of a black or dark brown powder, which seems to partake more of the properties of a metallic acid than a base. It contains 10·77 per cent. of oxygen. For the curious combination of gold and tin, called the purple precipitate of Cassius, see PURPLE OF CASSIUS; COLOURS.

GOLD AND SILVER REFINING. Since the object of this book is to treat more especially of the application of scientific processes to commercial undertakings, it will not be out of place to give some account of the processes by which gold and silver are refined, or rendered free from other metals. In the laboratory, where chemical manipulation has reached a great way to perfection, the precious metals are separated by nitric acid and other agents, but the processes are far too expensive and tedious to admit of being used upon a large scale.

For the purposes of rendering gold containing foreign metals sufficiently pure for the operations of coining, the late Mr. Warrington described a process by which fused gold is treated with black oxide of copper, with a view to oxidising those metals which render gold too brittle for manufacture into coin. Mr. Warrington proposed to add to fused gold, which is found to be alloyed with tin, antimony, and arsenic, 10 per cent. of its weight of the black oxide of copper, which, not being fusible, is capable of being stirred up with the fused mass of gold, just as sand may be stirred up with mercury, but with this great advantage, that the oxide of copper contains oxygen, with which it parts readily to oxidise any metal having a greater affinity for oxygen than itself. The metals, once oxidised, become lighter than the fused metal, and mixing mechanically, or combining chemically with the black oxide of copper, float to the surface and are removed. In the execution of Mr. Warrington's proposition, it is imperative to use crucibles free from reducing agents, such as carbon, and it is found that half an hour is sufficient time to allow the contact of the oxide of copper with the fused gold.

It has been generally stated by those supposed to be acquainted with the subject, that gold containing tin, antimony, and arsenic is so brittle as to render it wholly unfit for coining. This requires modification, for although these metals, as well as lead, render gold so brittle that it will readily break between the fingers, yet it is not true to say that it renders gold so brittle as to be incapable of being coined. In June and July 1859, some brittle gold, to the extent of about 64,000 ounces, passed through the Mint. The bars were so brittle that they broke with the slightest blow from a hammer, but by special treatment the gold was coined into the toughest coins ever produced. It may now be stated that if the system of manufacture be changed to suit the requirements of the case, gold cannot be found too brittle for the purpose of coining. This is simply a matter of fact, but the expense of coining brittle gold is undoubtedly very great; it is therefore wise that Mr. Warrington's plan should be adopted for all gold containing the volatile metals or tin. Osmium-iridium does not render gold brittle. Dr. Percy and Mr. Smith have demonstrated that all metallic substances found in commerce contain traces of gold, which can be separated by carefully-conducted chemical processes, and it is found that silver is peculiarly liable to be in alloy with gold, and gold with silver; hence a process of refining which shall effect the separation of as little as one five-hundredth part of gold from its mass of silver, is a matter of the utmost commercial importance.

It is with regret that it is stated that the refineries of London are conducted with such secrecy as to render a full description of any one of them impossible, while the ignorance which will induce the proprietors of these establishments to attempt such quietude is much to be pitied, for, except so far as regards details of interior arrangement, their processes are as well known and understood as it is possible for any manufacture to be.

In Paris (the London refiners are known to use the 'French process'), the plan adopted is founded on the fact, that at a high temperature sulphuric acid parts with one equivalent of its oxygen to oxidise an atom of a metal, while the atom of oxide so formed at once combines with another atom of sulphuric acid to form a sulphate. The atom of sulphuric acid which has parted with its atom of oxygen passes off as gaseous sulphurous acid.

If mercury be boiled with sulphuric acid (commonly called oil of vitriol), it is found that it entirely loses its metallic existence, and assumes the form of a dense white salt. This change takes place at the expense of the sulphuric acid, and is shown by the following equation. For explanation sake, call mercury Hg, and sulphuric acid SO^3; if now it is assumed that one part or atom of Hg be boiled with two parts or atoms of SO^3, we have $Hg + SO^3 + SO^3$, and for elucidation we may write SO^3 as equal to $SO^2 + O$; then we have $Hg + O + SO^3 + SO^2$, which, under the influence of heat, become $\underbrace{HgOSO^3}_{\text{a white salt.}} + \underbrace{SO^2}_{\text{gas.}}$

If now the mind substitutes silver for mercury, and so writes Ag instead of Hg, the whole matter will be understood. The silver is dissolved in sulphuric acid just as sugar would be in water, and in this fact we have a valuable means of separating it from gold. If for a moment one imagines a mass of silver alloyed with gold to be represented by a piece of sponge filled with water and frozen, it is well known that if the mass be warmed the ice is melted, and in the form of water filters from the sponge; just so, if a mass of the alloy of the precious metals be boiled in sulphuric acid, the silver is dissolved or washed away, leaving the gold in the form of a sponge, which, as it becomes exposed to the bubbling of the acid, is detached and falls to the bottom of the vessel in which it is boiled.

If by assay the silver to be refined is found to be very rich in gold, it is better to fuse the mass with more silver, so as to produce a mass containing at least 3 of silver to 1 of gold, and this alloy, in its fluid state, should be poured into cold water, by which the falling stream is suddenly chilled, and the particles become what is technically called 'granulated.' The stream should fall some distance (not less than 2 feet) through the air before it reaches the water, that the copper (if any be present) may be as much as possible oxidised, with a view to saving sulphuric acid.

In all cases the alloyed metals should be granulated, because the extended surface of metal presented to the hot acid saves much time.

Silver containing less than $\frac{1}{500}$ part of its weight of gold is found not to pay for separation, but any which contains this amount or more is treated as follows:—

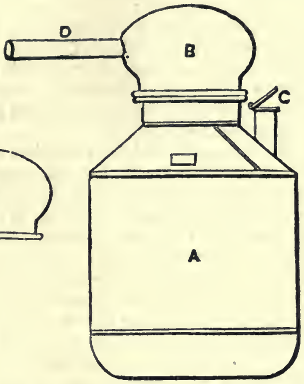
Vessels of platinum were formerly used and were deemed indispensable, but experiment has proved that these may be safely replaced by cast-iron vessels; in both cases the boilers or retorts are provided with tubes passing from the top into chambers which receive the acid gases and vapours.

The platinum vessels used by Mr. Mathison and subsequently by Messrs. Rothschild for many years are now out of use; but as sketches of the vessels actually used cannot be obtained, it is deemed wise to give a sketch of the platinum vessels, which weigh 323·40 troy ounces, and contain, if filled to the neck, 8 gallons of water. A, the retort or boiler; B, the head, provided with a tube of platinum, D, to which is joined at the time of use a long tube of lead. C is a tube terminating on the shoulder of the boiler, and provided with a lid, and is of service to allow of the occasional stirring of the silver during solution, and of the addition of the small quantity of acid at the termination of the chemical action. The vessels became much coated with gold, which was removed with difficulty and at great risk of attacking the platinum.

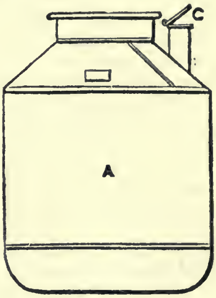
The sketches (*figs.* 1121, 1122, and 1123) are on a scale of 1 inch to a foot.

According to convenience and requirements, the retort or boilers may be multiplied as to number, but about 5 or 6 would seem to be a convenient set for operations. Independently of the smaller prime cost of cast-iron retorts or boilers (now used in place of platinum), there is the advantage of being able to use acid which is not free from impurities, because the cost of the retorts is practically not worth consideration, if taken in relation to the extra price which must be paid for pure acid. Besides these facts, it is found that owing to some influence (is it chemical or catalytic ?) which the iron exerts, less acid is required to be used in proportion to the precious metals than was used when platinum vessels were believed to be necessary.

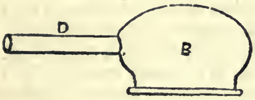
1121



1122



1123



A charge for one boiler varies from 1,130 to 1,300 troy ounces of the granulated mixed precious metals, and is heated with about twice or twice and a half times its weight of sulphuric acid of sp. gr. 1·7047. The heat is gradually raised until effervescence takes place, and it is then regulated with care, while at last, the temperature is raised nearly to the boiling point. As in the case of mercury so in the case of silver, it is better not to rise quite to the boiling point, else sulphuric acid distils off with the escaping sulphurous acid. According to the care with which the granulating has been effected, each charge is heated from 3 to 4 hours. When the elimination of sulphurous acid ceases, the operation is known to be terminated, and chemical examination shows that exactly equivalent quantities of sulphate of silver and sulphate of copper are formed to account for the sulphuric acid. In practice the sulphurous acid is frequently lost, although in all refineries it should be used for the re-composition of sulphuric acid.

Leading from the top of the boiler or retort is a horizontal leaden tube from 8 to 10 yards long, terminating in a leaden chamber, in which sulphuric and sulphurous acids accumulate with some sulphate of silver, mechanically carried over by the violence of the chemical action. It is found that the acid which accumulates in this leaden chamber has a sp. gr. of from 1·3804 to 1·4493. The reduced strength of the acid from 1·7047 to this point is readily understood if the fact be remembered that sulphuric acid is really a compound of anhydrous sulphuric acid and water, and that only the anhydrous sulphuric acid is concerned, although the water performs the friendly part of leading it into action on the silver; the action having commenced, the water is done with, and passes off with the sulphurous acid as it is eliminated; but independently of this cause, it is found that sulphuric acid, by boiling, parts with water, and concentrates itself, until by and by the anhydrous acid itself distils off, and when this is seen, it is at once known that the operation is carried rather too far. When the action has quite terminated, it is customary to add to each boiler or retort from 60 to 80 troy ounces of sulphuric acid of sp. gr. 1·6656, procured from the liquor which has deposited sulphate of copper (presently described); then to pour the whole into a leaden boiler, and boil it for a few minutes; afterwards withdraw the fire, and allow to stand for half an hour, during which time the gold is precipitated. The object in adding this amount of sulphuric acid is to form a clear solution, that the gold may be enabled to settle to the bottom; water could not be added, because it would probably cause an explosion by the heat evolved in its combination, and because sulphate of silver is not very soluble in water, while it is soluble to a very large extent in hot sulphuric acid. At the end of half an hour the clear liquor, containing in solution the silver and copper as sulphates, is decanted and mixed with so much water as shall reduce it to a sp. gr. of from 1·2080 to 1·2605, and well stirred. Copper plates are then introduced, while the solution is kept hot or boiling by a jet of steam.

The silver salt is decomposed by the copper plates, and the copper passes into solution as sulphate of copper, so that at the end of the precipitation the solution contains the copper of the original alloy, as well as the copper which has been used to precipitate the silver. The silver precipitates or falls to the bottom in a finely divided or spongy form, and it is commonly thought that the whole of the silver is thrown down when a portion of the solution is not rendered turbid by a solution of chloride of sodium; but in the presence of a strongly acid solution this test is not to be relied on for minute quantities; therefore, in some refineries, the solution is allowed to rest for days together in leaden cisterns in which copper plates are placed, so that by these means the last traces of silver are obtained.

If the amount of gold be very minute, the original solution is well stirred and then allowed to settle for some time; when finely-divided gold, mechanically mixed with crystals of sulphate of silver and crystals of sulphate of copper, is found at the bottom. This deposit is boiled with water, and is then transferred to a vessel in which it is kept hot, and is brought into contact with suspended copper plates, by which the silver is rendered metallic, and falling to the bottom of the vessel, mixes with the gold. The mixed precipitate of silver and gold is then dried, melted, and granulated, and treated with sulphuric acid, as in the process already described. By this extra process the gold becomes concentrated by the removal of the silver, and is then thrown down in larger and more easily collected particles. When the gold is finely divided and precipitates slowly, the following plan is sometimes adopted:—The whole precipitate, containing finely-divided gold mixed with sulphate of silver, is washed well with warm water, and left to rest. The sulphate of silver is dissolved, whilst the gold settles to the bottom of the vessel, but it is still mixed with a minute quantity of sulphate of silver. It is drained and placed in the retort or boiler of cast iron, and boiled with sulphuric acid; this boiling is twice repeated, and at last a very diluted solution of sulphate of silver is obtained; but by the boiling the gold has assumed a form which enables it to precipitate rapidly; in fact, the flocculent sponge becomes a mass of dense particles, which fall readily to the bottom, are collected and well washed, to free them from silver, and are then dried ready for melting.

The solution of sulphate of silver is evaporated in leaden vessels by the agency of steam, until it becomes saturated, and is then allowed to stand for an hour that all the gold may separate, and is afterwards drawn off either by a tap placed about half an inch from the bottom of the vessel, or by a siphon, and is then treated with copper plates, as already detailed.

In all cases the precipitated spongy silver is carefully washed to free it from sulphate of copper, and dried by heat or by hydraulic pressure; but if dried by pressure the masses obtained are found to contain from 8 to 10 per cent. of water, and are therefore dried by a gentle heat to avoid the breaking-up of the masses, from the sudden formation of steam, as well as to save the chance of destroying the pot of Picardy clay in which the silver is melted when it has been dried.

After melting, the silver is found to retain traces of gold, which are so minute as to be overlooked, since the cost of recovery would exceed the value of the gold to be recovered; but the silver is found to be alloyed with from 5 to 6 thousandths of its weight of copper, which appears to be left in the form of sulphate, notwithstanding the washings to which the silver has been subjected. It is practically impossible to wash away the last traces of sulphate of copper. This small amount of copper is of little importance, since it amounts to but 5 parts of copper alloyed with 995 parts of silver, yet this may be removed by fusion and treatment with nitrate of potassa.

During the whole process, even if copper be not present in the original mass of metal to be refined, it is to be observed that copper plates are used for precipitating the silver; therefore sulphate of copper is formed in considerable quantities, and as this salt has a high commercial value as giving the base for many colours used in painting and paper-hangings, as well as for agricultural purposes, it becomes desirable to obtain this salt in a saleable form. The solution is therefore evaporated to a sp. gr. of 1·3804, and allowed to cool, when crystals deposit; but since sulphate of copper deposited from strongly acid solutions is mixed with the anhydrous salt, the whole mass of crystals is re-dissolved in warm water, and allowed to stand in leaden vessels about

6 ft. long, 3 ft. deep, and 3 ft. wide, that the crystals may deposit slowly, as slow formation produces large crystals, which are more easily collected. The sulphate of copper is represented by $CuO,SO^3,5HO$ ($\mathbf{CuSO^4,5H^2O}$). The mother-liquors are evaporated and returned to the works, being in fact free sulphuric acid, with a small amount of sulphate of copper in solution. The parts of the hydraulic presses which come in contact with the silver at the time of pressing are coated with a compound of tin and lead, hardened by mixture with antimony. Cast iron is very little attacked by concentrated sulphuric acid, but it is necessary to avoid wrought iron in any shape, and copper vessels would of course be rapidly destroyed.

The floors should be covered with lead of tolerable thickness. The melting-pots used in France are made of Picardy clay, and hold from 2,200 to 2,600 troy ounces of silver. The pots cost from 4*d.* to 6*d.* each, and if dried and used with care, very seldom crack or break.

The total cost of refining silver in Paris, inclusive of the loss by melting, is stated to be 15 centimes for 32 troy ounces; but it must be understood that the loss of silver by melting is absolutely very minute, because the flues are swept, and the sweepings so obtained are made to yield the silver which has been volatilised, while the pots, &c., are ground and made to yield their absorbed silver.

In the event of the mass containing much copper and little silver, it is usual to granulate the mass and roast the granulated particles to oxidise the copper; the oxide of copper is then dissolved out by diluted sulphuric acid, and the remaining mass of silver, with a smaller amount of copper, is treated in the ordinary way.

If the gold contains platinum, it is found that it is apt to retain from 4 to 5 per cent. of silver, which must be separated by mixing the precipitated gold with about a fourth of its weight of anhydrous sulphate of soda (which is preferred to sulphate of potassa, on account of its greater solubility in water), and to moisten this mass with concentrated sulphuric acid, using about 6 or 7 parts of acid to every 10 parts of sulphate of soda. The moistened mass is then heated till sulphuric acid ceases to distil off, and the heat is then raised till the whole mass melts; and by extracting the sulphate of silver and sulphate of soda the gold will be found to contain 99·40 per cent. of gold; but if the process be repeated, the gold is obtained of a purity of 99·90.

When the silver has been removed, the gold is fused with nitre, which oxidises and removes the platinum; but the potash salt formed is found to contain gold, so that the gold and platinum are obtained from the potash salt mixed with fused nitre by the process of cupellation, for which see SILVER.—G.F.A.

A simple process of refining gold by means of chlorine gas was introduced a few years ago by Mr. F. B. Miller, of the Sydney branch of the Royal Mint. It consists in passing chlorine through the melted gold, by thrusting into the molten metal a small clay tube connected with the stoneware vessel in which the chlorine is generated. The evolved chlorine combines with the silver in the alloy, and the chloride of silver thus formed floats on the surface of the purified gold. Miller's processs is now extensively used, and may always be advantageously applied when the proportion of silver in the gold does not much exceed ten per cent.

The following remarks on the 'Hall-Marking of Gold' is from the pen of Mr. Wm. Chaffers, the author of 'Hall-Marks on Plate.'

The guarantee of the quality of gold and silver as stamped by the Government Assay Offices is a matter of such great importance to the public that any doubt thrown upon it ought immediately to be thoroughly investigated.

The standard of the precious metals has been insisted on by the laws of the land for more than 600 years, and the assaying of them was a privilege conferred, as early as the year 1300, by Edward I., upon the Goldsmiths' Company, who stamped them with the Leopard's Head, as a sign to the public that a piece of gold or silver was actually of the quality thereby signified. It was ordained in 1327 that in all cities and towns in England where goldsmiths reside, one or two of the craft for the rest of the trade should come to London and have the stamp of a puncheon of a Leopard's Head marked upon their work, as of ancient time it has been ordained, and at that early date it was enjoined that three stamps should be put upon the plate: 1. The goldsmith's mark who made it. 2. The mark of the assayer (a letter of the alphabet denoting the year). 3. The mark of the Goldsmiths' Hall (a Leopard's Head crowned). Another mark of a lion passant, denoting that the piece was standard, was added about 1545. . . . In 1423 other towns were privileged to mark plate; but as many had discontinued, another act was passed in 1700, by which York, Exeter, Bristol, Chester, and Norwich were formally appointed. In 1702 Newcastle was added to the list, and in 1773 Birmingham and Sheffield were also privileged to assay and stamp silver plate, each town placing a stamp of their arms for the purpose of identification.

These two standards of plate—gold of 22 carats, and silver of 11 oz. 2 dwts.—or sterling have remained unchanged, except for a short period of 25 years, when a purer quality of gold was introduced called the new standard, but it was found too soft for general use.

In 1798 a lower standard of gold, consisting of 18 carats pure gold out of the 24, was allowed by the Act, indicated by the stamp of a crown and 18 instead of the lion passant. In 1854 inferior qualities of gold were legalised to be stamped in figures setting forth the fineness—viz. 15, 12 and 9 carats pure gold out of the 24.

It may be well to state for the information of the public, and to put people on their guard in purchasing gold—that whether of the best or worst quality, it is still termed so and sold as warranted gold, although the value ranges from 85*s.* to 30*s.* per oz.—that 24-carat, or pure gold, is worth 4*l.* 4*s.* 11½*d.* per oz.; 22-carat, or standard, is worth 3*l.* 17*s.* 10½*d.* per oz.; 20-carat (Ireland only) is worth 3*l.* 10*s.* 9½*d.* per oz.; 18-carat is worth 3*l.* 3*s.* 8½*d.* per oz.; 15-carat is worth 2*l.* 13*s.* 1*d.* per oz.; 12-carat is worth 2*l.* 2*s.* 5¾*d.* per oz.; 9-carat is worth 1*l.* 11*s.* 10½*d.* per oz.

Hence any purchaser may tell by the stamp the intrinsic value of the article offered for sale, to which must necessarily be added the cost of manufacturing. The marks thus affixed to the article by the Government Assay Offices afford the surest guarantees, and have never before been questioned. It is true a slight variation of a few grains may be detected in assaying a finished piece such as a watch-case, but this arises from the solder employed in putting the object together.

GOLD ASSAYING.—This may be conveniently divided into: 1. The assaying of gold ores; 2. The assaying of gold alloys.

1. *The Assaying of Gold Ores.—a. Quartz and Earthy Substances containing Gold.*—The ore is reduced to fine powder and passed through a sieve of 80 holes to the linear inch, and any residual gold is carefully collected, rolled up in a convenient quantity of lead, cupelled (for a description of the process of cupellation and the furnace employed, see SILVER), and the resulting button of metal treated in the same manner as those subsequently obtained from the assay of the sifted portion. The total weight of the sample is ascertained in order that the proportion of gold and silver obtained from the residual metal may be calculated. The sifted portion is well mixed and submitted to assay as follows:—From 500 to 1,000 grs. of the ore are weighed out and mixed with from 600 to 1,200 grs. of dried carbonate of soda, 500 grs. of litharge or red lead, and 20 grs. of charcoal-powder. The mixture is placed in a Cornish or earthen crucible, and then submitted to a gradually increasing heat in an air-furnace, heated with coke or other suitable fuel, until fusion is completed in from 20 to 30 minutes. Considerable effervescence will occur at the first part of the operation, from the escape of carbonic acid gas; when tranquil the crucible is removed from the furnace and its contents poured into an iron ingot-mould (*fig.* 534, Art. COPPER), and when cold the slag is detached from the button of lead. The lead is cupelled (see SILVER), and the button of gold and silver weighed in a balance, turning with $\frac{1}{1000}$th of a grain. After weighing, the button is rolled up along with 2½ times its weight or less of silver, in from 10 to 50 grains of lead, re-cupelled, and the alloy obtained flattened out under a hammer, parted, and the gold weighed. After correction for the silver contained in the litharge or red lead used for the assay, the amount of silver present is ascertained by deducting the weight of the gold from the weight of the silver and gold previously found. For fusion, part of the carbonate of soda may be replaced by calcined borax; the boro-silicates produced being more fusible than silicates.

b. Auriferous Pyrites with or without Vein-Stuff and Earthy Matters.—1,000 grs. of the finely-powdered ore are to be taken, and calcined in a *roasting-dish* in a muffle, or in an earthen crucible, in an open air-furnace. The heat is carefully regulated at first to prevent softening of the particles or clotting, and the calcination continued, with frequent stirring, until the smell of sulphurous acid ceases. When cold, the calcined ore is mixed with about 500 grs. of dried carbonate of soda, from 300 to 400 grs. of calcined borax, 500 grs. of litharge or red lead, and from 30 to 60 grs. of charcoal-powder, according to the proportion of oxide of iron present. Fusion is conducted in an earthen crucible, and the assay completed as previously described (*a*). Sand may be used in place of borax, and is cheaper. When arsenic is present, it is only partly expelled by calcination. A piece of iron is therefore added during fusion, and the *speiss* obtained detached from the button of lead before cupellation. When copper pyrites is present the addition of more litharge or red lead is required for fusion to remove the copper during cupellation. In England and Australia the gold and silver results obtained from the assay are reported to ounces, pennyweights, and grains troy upon the statute ton of 2,240 lbs.

c. Assay in the 'Washing-bowl,' Tin-dish, or other Vessel.—This method is often resorted to in prospecting at the diggings, and under other circumstances, to ascertain the approximate quantity of gold (native gold) present in a sample of quartz or other ore. The ore is finely powdered, and from 1,000 to 7,000 grs. (= 1 lb. avoid.) are thrown upon the washing vessel, and thoroughly wetted with water. The muddy portion is first removed, and the washing repeated with successive portions of water, and with a shaking motion, which can only be acquired by practice, so as to finally collect the gold in the lower part of the vessel. When the earthy matters have been removed, the gold is carefully dried, collected, and weighed, or in some cases mercury is added to collect the gold, and the amalgam afterwards heated to drive off the mercury, and the residual gold weighed. When pyrites is present, it remains for the most part with the gold. To separate it, the residue is roasted or calcined, and the resulting oxides of iron and copper removed by submitting it to a washing process, with or without the addition of mercury.

2. *The Assaying of Gold Alloys.*—*a. Gold-parting.*—Bar-gold, and alloys used for monetary and other purposes, are assayed by this method. 10 grs., or other convenient quantity, of the sample is weighed out on a balance turning with $\frac{1}{1000}$th of a grain. To the weighed metal is added 2½ times its weight. or less of silver, and both are rolled up in 60 grs. or more of lead-foil, according to the quantity of copper present, and cupelled, in order to alloy the gold with the silver, and remove the copper or other metallic impurities. When cold the resulting button is removed from the cupel, cleansed, and flattened out under the hammer, or rolled out into a riband or fillet of from 2½ to 3 inches in length. The fillet is annealed by heating it to dull redness, and then rolled up into a loose coil. The coil is transferred to a parting flask, and boiled for 15 minutes in nitric acid, of specific gravity 1·2 (about 1 part by measure of acid to 2 of water). The acid is carefully poured off, the cornet washed with warm distilled water, and then boiled for 20 minutes in nitric acid, of specific gravity 1·3 (about 1 part by measure of acid to 1 of water), a fire-clay pea, or a small piece of well-burnt charcoal, being placed in the flask to prevent the ebullition taking place irregularly and with sudden bursts, which would be liable to break the *cornet*, or eject a portion of the liquid from the flask. The acid is poured off, the cornet washed with water, and the clay pea removed. The cornet is transferred to a small clay crucible, by dexterously inverting the flask previously filled with water. The water is drained off from the crucible, and the cornet dried, annealed, or heated to dull redness, and weighed. A very small portion of silver is retained by the gold. In order to ascertain the amount of error due to the surcharge or the *correction* for this silver when several assays are made, a number of *proofs* or *checks* are passed through the process along with the alloys. These proofs consist of weighed portions of pure gold, to which is added a proportion of copper equal to that estimated to exist in the alloy to be assayed. The excess of weight finally obtained in these proofs gives the amount to be deducted. It generally varies from 0·1 to 0·5 in 1,000. The amount of *correction* will depend on the weight of alloy submitted to assay, the proportion of silver added, the care in *firing*, the strength of the nitric acid used, and the time employed in the first and second boilings. The cornets are sometimes boiled a third time in nitric acid. In accurate assaying of gold bullion and other alloys of gold, it is absolutely necessary that the acids should be pure, and that the silver used is most carefully freed from the traces of gold which it usually contains.

The last traces of silver may be removed from the cornet by treating it before the final annealing with fusing bisulphate of potash in a porcelain crucible. When sufficiently cool, the whole is heated with hot water containing a little sulphuric acid, and the cornet dried and ignited. By this means gold may be obtained of almost absolute purity, or $\frac{1000}{1000}$, as it is termed. The following results obtained by the late Mr. T. H. Henry will serve for illustration:—Ten grains of pure gold, alloyed with three times its weight of silver, cupelled, and boiled with acid at 22° B., and 32° B., once, weighed 10·016. Ten grains of a half-sovereign, with silver, &c., and acid at 22°, and twice at 32° B., gave 915·4; again, 915·6. With acid, as before, and bisulphate of potash, 915·2; again, 915·2.

Pure gold alloyed with copper, to bring it to standard, cupelled with silver and lead, and treated with acids and bisulphate, gave in one case precisely the same as was taken originally, or $\frac{1000}{1000}$, and in another 999·98.

The assays are reported on 1,000 parts to ⅓rd of a thousandth. The assays are also returned on the 24 parts or *carats*; pure gold is said to be *fine*. Thus—if 18 parts by weight of gold are obtained from 24 parts of the alloy submitted to assay, it is said to be 18-carats fine. For jewellers and others the assays are also reported in relation to British Standard. Standard gold contains 22 parts of gold in 24. If the assay result of gold is less than this amount it is said to be *worse*, or if more is said to be *better*. than standard. For example, 23 parts in 24 would be reported 1 carat better, or 21 parts would be reported 1 carat worse than standard.

Where a number of assays have to be made, a series of flasks are heated simultaneously over a number of gas-burners arranged in rows. In order to save time and to diminish the amount of manipulation. several methods have more recently been devised. At the Sydney Mint each fillet coil is impressed with a number, and 16 of them are boiled with acid in one flask. The plan which is now being generally adopted, consists in placing the fillet coils in a series of platinum cups or thimbles, each cup being provided with several fine slits. These cups are then arranged in rows in a perforated platinum tray, and the whole placed in a vessel of platinum or other material containing nitric acid. After boiling in acid for a given time, the tray is lifted out, dipped in water, and then transferred to a vessel containing a stronger acid; after boiling, the tray containing the gold cornets is then removed, washed in water, dried, and carefully heated in a muffle. The cornets are then removed and weighed.

The platinum cups are made of various sizes, according to the quantity of alloy operated on, and the platinum trays constructed to receive from 16 or more of the cups as may be desired. A tray to hold 49 cups is about 4 inches square, and each cup ⅝ths of an inch in depth and ½ inch in diameter at the top. The use of platinum cups is a modification of the plan first introduced by Mr. T. H. Henry and Mr. C. Tookey in 1854. They constructed glass tubes, provided at the lower part with perforated discs of platinum, and having a rim near the upper end. In the assay process a fillet coil was placed in each tube. A number of these tubes were supported by a porcelain plate having circular holes, the holes and tubes being numbered. Thus arranged, a number of them could be boiled at one time in a vessel containing nitric acid, and readily removed for subsequent treatment. The platinum cups and parting apparatus were first manufactured and introduced by Messrs. Johnson and Matthey.

At the Mint Conference held at Vienna in 1857 the following process was agreed upon:—Add to 1 part of gold supposed to be present 2½ parts of silver, wrap up in paper, and introduce into a cupel in which the requisite amount of lead is just fusing. After cupellation, the button of gold and silver is flattened out by hammering or rolling, then ignited, and rolled into a coil. The coils are then treated, first, with nitric acid of 1·2 sp. gravity, afterwards with nitric acid of 1·3 sp. gravity, and lastly it is washed with water, ignited and weighed.

The process recommended in the old French official report is as follows:—Twelve grains of the gold intended to be assayed must be mixed with thirty grains of fine silver, and cupelled with 108 grains of lead. The cupellation must be carefully attended to, and all the imperfect buttons rejected. When the cupellation is ended, the button must be reduced, by lamination, into a plate of 1½ inch, or rather more, in length, and four or five lines in breadth. This must be rolled up upon a quill, and placed in a matrass capable of holding about three ounces of liquid, when filled up to its narrow part. Two ounces and a half of very pure aquafortis, of the strength of 20 degrees of Baumé's aerometer, must then be poured upon it; and the matrass being placed upon hot ashes, or sand, the acid must be kept gently boiling for a quarter of an hour: the acid must then be cautiously decanted, and an additional quantity of 1½ ounce must be poured upon the metal, and slightly boiled for twelve minutes. This being likewise carefully decanted, the small spiral pieces of metal must be washed with filtered river-water, or distilled water, by filling the matrass with this fluid. The vessel is then to be reversed, by applying the extremity of its neck against the bottom of a crucible of fine earth, the internal surface of which is very smooth. The annealing must now be made, after having separated the portion of water which had fallen into the crucible; and lastly, the annealed gold must be weighed. For the certainty of this operation, two assays must be made in the same manner, together with a third assay upon gold of twenty-four carats, or upon gold the fineness of which is perfectly and generally known.

No conclusion must be drawn from this assay, unless the latter gold should prove to be of the fineness of twenty-four carats exactly, or of its known degree of fineness; for, if there be either loss or surplus, it may be inferred that the other two assays, having undergone the same operation, must be subject to the same error. The operation being made according to this process by several assayers, all the assayers must have obtained an uniform result without communication with each other.

M. Vauquelin recommends to boil 60 parts of nitric acid at 22° Baumé, on the spiral slip, or cornet of gold and silver alloy, for twenty-five minutes, and replace the liquid afterwards by acid of 32°, which must be boiled on it for eight minutes. This process is free from uncertainty, when the assay is performed upon an alloy containing a considerable quantity of copper. But this is not the case in assaying finer gold; for then a little silver always remains in the gold. The surcharge which occurs here is 2 or 3 thousandths. M. Claudet recommends the following process:—He takes 0·500 of the fine gold to be assayed; cupels it with 1·500 of silver and 1·000 of lead; forms, with the button from the cupel, a riband or strip three inches long, which he rolls into a cornet. He puts this into a matrass with acid at 22° B., which he boils for 3 or 4 minutes. He replaces this by acid of 32° B., and boils for ten minutes; then decants off, and boils again with acid of 32°, which must be finally boiled for 8 or 10 minutes. He washes the cornet, and puts it entire into a small crucible permeable to water; heats the crucible to dull redness in the muffle, when the gold assumes the metallic lustre and the cornet becomes solid. It is now taken out of the crucible and weighed.

When the alloy contains platinum, the assay presents greater difficulties. In general, to separate with accuracy the platinum from the gold, we must avail ourselves of a peculiar property of platinum; when alloyed with silver, it becomes soluble in nitric acid. Therefore, by a proper quartation of the alloy by cupellation, and boiling the button with nitric acid, we may get a residuum of pure gold. If we were to treat the button with sulphuric acid, however, we should dissolve nothing but the silver. The copper is easily removed by cupellation.

The examination may also be employed for assay purposes to indicate the quantity of silver necessary for quartation or parting.

b. Silver Parting.—This method is employed for estimating gold in certain varieties of silver. When an alloy of silver and gold contains about 65 per cent. or more of silver, the silver may be completely removed by the action of nitric acid. 20 grs. of the silver are to be weighed out, transferred direct to the parting flask, and boiled in the first and second nitric acids for about the same time and in the same manner as for *gold parting*. The residual gold, which is generally left in the state of fine powder, is very carefully washed with water, transferred to a crucible, dried, ignited and weighed. If the silver under examination contains lead, antimony, and other impurities, it is first cupelled with lead and the button afterwards cleaned, and flattened out, before submitting it to the parting process.

c. Assay by the Touchstone or the Touch.—This method is used by jewellers and others to ascertain the approximate fineness or quality of gold trinkets, &c., and to prevent fraud. It depends on comparing the colour and other properties of a minute portion of the metal tested, with those of small bars of alloys, the composition of which is known. For this purpose we require a *Touchstone* of a black colour, consisting of Lydian stone, pottery, or other substance; and a series of *needles* or alloys of gold and copper, gold and silver, or gold silver and copper, &c. Thus the set of gold and copper needles may consist of pure gold; 23½ carats of gold with ½ carat of silver; 23 carats of gold with 1 carat of silver; 22½ carats of gold with 1½ carat of silver; and so on, till the silver amounts to four carats; after which the addition may proceed by whole carats. A *Test acid*, consisting of nitric acid, or of nitric acid with about 2 per cent. of hydrochloric acid, is used. The examination may be made as follows:—First remove the superficial coating of gold, by rubbing or otherwise. Then compare the streak produced by rubbing the article upon the touchstone with those produced from the alloys. When the one is found which most closely corresponds in colour, both streaks are tested with the acid, and a judgment formed therefrom.

The attentive assayer compares not only the colour of the stroke made upon the touchstone by the metal under examination with that produced by the needle, but will likewise attend to the sensation of roughness, dryness, smoothness, or greasiness, which the texture of the rubbed metal excites when abraded by the stone. When two strokes perfectly alike in colour are made upon the stone, the test acid will affect them very differently if they are not of similar compositions. The stone itself may also be made red-hot by the fire, or by the blowpipe, if thin black pottery be used; in which case the phenomena of oxidation will differ according to the nature and quantity of the alloy.

GOLD, ALLOYS OF. See ALLOY.

GOLD-AMALGAM. See AMALGAM.

GOLD-BEATERS' SKIN. This skin is prepared from the external or peritoneal coat of the cæcum or blind gut of neat cattle. The workman separates and turns over the portion which encircles the junction of this pouch with the rest of the intestines, and draws it off inverted from the other coats to the length of 25 or 30 inches. It is then immersed a short time in a weak solution of potash, and is cleaned by straying upon a board with a knife. When thus well cleaned, and by soaking in water, the piece is stretched upon a kind of frame from 40 to 50 inches in length and 11 inches wide, and made up of two uprights held together by two cross-pieces having longitudinal grooves two and a half lines in width. The surface of the membrane, which was outside in the animal, is placed in contact with the upper part of the frame; it is stretched in every direction, and is glued to its rim. Another membrane is then stretched above the first, with its external surface placed upwards, and is attached to it by glueing around the edges. When dry, the membranes are separated by running a sharp knife along the grooves. Each strip is then glued upon a frame similar to the first one, but without a groove, and is washed over with a solution composed of alum, 1 ounce; water, 2 quarts.

When the surface is dried, a sponge dipped in a concentrated solution of fish-glue in white wine, rendered aromatic by cloves, nutmegs, or camphor, is passed over it. When this coating is dried, it is covered with a coat of white of eggs, and the strip is cut in pieces 5½ inches square, which are then smoothed out under a press, and made up into leaves.

A body is given to the pieces of gut; that is, they are moistened with an infusion of cinnamon, nutmeg, and other warm and aromatic ingredients, in order to preserve them: an operation repeated after they have been dried in the air. When the leaves of skin are dry, they are put in a press, and are ready for use. After the parchment, vellum, and gut-membrane have been a good deal hammered, they become unfit for work, till they are restored to proper flexibility, by being placed, leaf by leaf, between leaves of white paper, moistened sometimes with vinegar, at others with white wine. They are left in this condition for three or four hours, under compression of a plank loaded with weights. When they have imbibed the proper humidity, they are put between leaves of parchment 12 inches square, and beat in that situation for a whole day. They are then rubbed over with fine calcined gypsum, as the vellum was originally. The gut-skin is apt to contract damp in standing, and is therefore dried before being used.

GOLD-BEATING. This is the art of reducing gold to extremely thin leaves, by beating with a hammer. The processes employed for this purpose may be applied to other metals, as silver, platinum, and copper. The Romans used to gild the ceilings and walls of their apartments; and Pliny tells us, that from an ounce of gold forming a plate of 4 fingers square, about 600 leaves of the same area were hammered. At the present day, a piece of gold is extended so as to cover a space of 651,590 times greater than its primary surface when cast.

The gold employed in this art ought to be of the finest standard. Alloy hardens gold and renders it less malleable; so that the fraudulent tradesman who should attempt to debase the gold would expose himself to much greater loss in the operations than he could derive of profit from the alloy.

The average thickness of common gold-leaf is $\frac{1}{282000}$ of an inch.

Four principal operations constitute the art of gold-beating:—1. The casting of the gold ingots. 3. The lamination. 2. The hammering. 4. The beating.

1. *The casting.*—The gold is melted in a crucible along with a little borax. When it has become liquid enough, it is poured out into an ingot-mould previously heated, and greased on the inside. The ingot is taken out and annealed in hot ashes, which both soften it and free it from grease, The moulds are made of cast iron, with a somewhat concave internal surface, to compensate for the greater contraction of the central parts of the metal in cooling than the edges. The ingots weigh about 2 ounces each, and are ¾ of an inch broad.

2. *The forging.*—When the ingot is cold, the French gold-beaters hammer it out on a mass of steel 4 inches long, and 3 broad. The hammer for this purpose is called the forging hammer. It weighs about 3 pounds, with a head at one end and a wedge at the other, the head presenting a square face of 1½ inch. Its handle is 6 inches long. The workman reduces the ingot to the thickness of ⅛th of an inch at most; and during this operation he anneals it whenever its substance becomes hard and apt to crack. The English gold-beaters omit this process of hammering.

3. *The lamination.*—The rollers employed for this purpose should be of a most perfectly cylindrical figure, a polished surface, and so powerful as not to bend or yield in the operation. The ultimate excellence of the gold-leaf depends very much on the precision with which the riband is extended in the rolling press. The gold-beater desires to have a riband of such thinness that a square inch of it will weigh 6½ grains. Frequent annealings are requisite during the lamination.

4. *Beating.*—The riband of gold being thus prepared uniform, the gold-beater cuts it with shears into small squares of an inch each, having previously divided it with compasses, so that the pieces may be of as equal weight as possible. The squares are piled over each other in parcels of 150, with a piece of fine calf-skin vellum interspersed between each, and about twenty extra vellums at the top and bottom. These vellum leaves are about 4 inches square, on whose centre lie the gold laminæ, each of an inch square. This packet is kept together by being thrust into a case of strong parchment open at the ends, so as to form a belt or band, whose open sides are covered in by a second case drawn over the packet at right angles to the first. Thus the packet becomes sufficiently compact to bear beating with a hammer of 15 or 16 pounds weight, having a circular face nearly four inches in diameter, and somewhat convex, whereby it strikes the centre of the packet most forcibly, and thus squeezes out the plates laterally.

The beating is performed on a very strong bench or stool, framed to receive a heavy block of marble, about 9 inches square on the surface, enclosed upon every side by wood-work, except the front, where a leather apron is attached which the workman lays before him to preserve any fragments of gold that may fall out of the packet. The hammer is short-handled, and is managed by the workman with one hand; who strikes fairly on the middle of the packet, frequently turning it over to beat both sides alike;

a feat dextrously done in the interval of two strokes, so as not to lose a blow. The packet is occasionally bent or rolled between the hands to loosen the leaves and secure the ready extension of the gold; or it is taken to pieces to finish the gold, and to shift the central leaves to the outside, and *vice versâ*, that everything may be equalised. Whenever the gold plates have extended under this treatment to nearly the size of the vellum, they are removed from the packet, and cut into four equal squares by a knife. They are thus reduced to nearly the same size as at first, and are again made up into packets, and enclosed as before, with this difference, that skins prepared from ox-gut are now interposed between each gold-leaf, instead of vellum. The second course of beating is performed with a smaller hammer, about 10 pounds in weight, and is continued till the leaves are extended to the size of the skins. During this period, the packet must be often folded, to render the gold as loose as possible between the membranes; otherwise the leaves are easily chafed and broken. They are once more spread on a cushion, and subdivided into four square pieces by means of two pieces of cane cut to very sharp edges, and fixed down transversely on a board. This rectangular cross being applied on each leaf, with slight pressure, divides it into four equal portions. These are next made up into a third packet of convenient thickness, and finally hammered out to the area of fine gold-leaf, whose average size is from 3 to 3½ inches square. The leaves will now have obtained an area 192 times greater than the plates before the hammering began. As these were originally an inch square, and 75 of them weighed an ounce (= 6½ × 75 = 487½), the surface of the finished leaves will be 192 × 75 = 14,400 square inches, or 100 square feet per ounce troy. This is by no means the ultimate degree of attenuation, for an ounce may be hammered so as to cover 160 square feet; but the waste incident in this case, from the number of broken leaves, and the increase and nicety of the labour, make this an unprofitable refinement; while the gilder finds such thin leaves make less durable and satisfactory work.

The finished leaves of gold are put up in small books made of single leaves of soft paper, rubbed over with red chalk to prevent adhesion between them. Before putting the leaves in these books, however, they are lifted one by one with a delicate pair of pincers out of the finishing packet, and spread out on a leather cushion by blowing them flat down. They are then cut to one size by a sharp-edged square moulding of cane, glued on a flat board. When this square-framed edge is pressed upon the gold, it cuts it to the desired size and shape. Each book commonly contains 25 gold-leaves.

We must now describe some peculiarities of the French practice of gold-beating. The workman cuts the laminated ribands of an inch broad into portions an inch and a half long. These are called *quartiers*. He takes 24 of them, which he places exactly over each other, so as to form a thickness of about an inch, the riband being ½ of a line, or $\frac{1}{24}$th of an inch thick; and he beats them together on a steel slab with the round face (*panne*) of the hammer, so as to stretch them truly out into the square form. He begins by extending the substance towards the edges, thereafter advancing towards the middle; he then does as much on the other side, and finally hammers the centre. By repeating this mode of beating as often as necessary, he reduces at once all the *quartiers* (squares) of the same packet, till none of them is thicker than a leaf of grey paper, and of the size of a square of 2 inches each side.

When the *quartiers* are brought to this state, the workman takes 56 of them, which he piles over each other, and with which he forms the first packet (*caucher*) in the manner already described; only two leaves of vellum are interposed between each gold-leaf. The empty leaves of vellum at the top and bottom of the packet are called *emplures*. They are 4 inches square, as well as the parchment pieces.

The packet thus prepared forms a rectangular parallelopiped; it is inclosed in two sheaths, composed each of several leaves of parchment applied to each, and glued at the two sides, forming a bag open at either end.

The block of black marble is a foot square at top, and 18 inches deep, and is framed as above described. The hammer used for beating the first packet is called the flat, or the enlarging hammer; its head is round, about 5 inches in diameter, and very slightly convex. It is 6 inches high, and tapers gradually from its head to the other extremity, which gives it the form of a hexagonal truncated pyramid. It weighs 14 or 15 pounds.

The French gold-beaters employ besides this hammer, three others of the same form; namely, 1. The *commencing hammer*, which weighs 6 or 7 pounds, has a head 4 inches in diameter, and is more convex than the former. 2. The *spreading hammer*, (*marteau à chasser*); its head is two inches diameter, more convex than the last, and weighs only 4 or 5 pounds. 3. The *finishing hammer*; it weighs 12 or 13 pounds, has a head four inches diameter, and is the most convex of all.

The beating processes do not differ essentially from the English described above.

GOLD, CHLORIDE OF. Trichloride of gold. This salt is formed when gold is dissolved in nitro-muriatic acid. It is much used in photography.

GOLD COINAGE. The current gold coins of the United Kingdom are the sovereign and the half-sovereign. See Mint; Sovereign.

GOLD LACE. Gilt silver wire, woven into a lace.

GOLD-LEAF. See Gold-Beating.

GOLD, MANNHEIM. A brass composed of from 3 to 4 ounces of zinc to 1 pound of copper. See Brass.

GOLD, MOSAIC. A brass of very fine colour used in common jewellery. Hamilton and Parker's patent Mosaic gold consists of 16½ ounces of zinc to 16 ounces of copper. It is of a dark colour when first cast, but on dipping assumes a beautiful golden tint. The patentees say, 'when cooled and broken, all yellowness must cease, and the tinge vary from reddish fawn or salmon colour, to a light purple or lilac, and from that to whiteness.' See Brass; Alloys.

GOLD-PURPLE. See Purple of Cassius.

GOLD, SALTS OF. The bromide, cyanide, iodide, phosphide, sulphide, and some other salts of gold which are rarely used in the arts, are fully described in Watts's 'Dictionary of Chemistry.'

GOLD OF PLEASURE. A plant cultivated on the Continent for its seeds, which yield a fine oil, while its fibres can be employed in the manufacture of sail-cloth, packing, and other coarse articles. It is the *Camelina sativa* of botanists. It has not attracted much attention in this country.

GOLD THREAD, or *spun gold*, is a flatted silver-gilt wire, wrapped or laid over a thread of yellow silk by twisting with a wheel or iron bobbins. By the aid of a mechanism like the braiding machine, a number of threads may thus be twisted at once by one master wheel. The principal nicety consists in so regulating the movements that the successive volutions of the flatted wire on each thread may just touch one another, and forms a continuous covering. The French silver for gilding is said to be alloyed with 5 or 6 pennyweights, and ours with 12 pennyweights, of copper in the pound troy. The gold is applied in leaves of greater or less thickness, according to the quality of the gilt wire. The smallest proportion formerly allowed in this country by Act of Parliament was 100 grains of gold to one pound, or 5,760 grains of silver; but more or less may now be used. The silver rod is incased in the gold-leaf, and the compound cylinder is then drawn into round wire down to a certain size, which is afterwards flatted in a rolling mill, such as is described under Mint.

The liquor employed by goldsmiths to bring out a rich colour on the surface of their trinkets is made by dissolving 1 part of sea-salt, 1 part of alum, 2 parts of nitre, in 3 or 4 of water. The pickle or sauce, as it is called, takes up not only the copper alloy, but a notable quantity of gold; the total amount of which in the Austrian Empire has been estimated annually at 47,000 francs. To recover this gold the liquor is diluted with at least twice its bulk of boiling water, and a solution of very pure green sulphate of iron is poured into it. The precipitate of gold is washed upon a filter, dried, and purified by melting in a crucible along with a mixture of equal parts of nitre and borax.

GOLD-THREAD. The bitter root of the *Coptis trifoliata*, used in North America as a tonic.

GOLD WIRE is formed by drawing a cylindrical rod of the metal, as pure as may be, through a series of holes punched in an iron plate, diminishing progressively in size. The gold, as it is drawn through, becomes hardened by the operation, and requires frequent annealing.

GOLDEN MARCASITE. A name given at one time to the metal zinc. Albertus Magnus calls it *Marchasita aurea*. 'This was properly a stone, the metallic particles of which were so entirely sublimated by fire, that nothing but useless ashes remained behind. It contained fixed quicksilver, communicated a colour to metals, on which account it was well known to the alchemists, burned in the fire, and was at length entirely consumed. It was found in various parts, but that at Goslar was the best, because the copper it contained seemed to have in it a mixture of gold. To give this copper, however, a still greater resemblance to gold, some tin was added to it, by which means it became more brittle. This *marchasita* also rendered copper white as silver. Thus far Albertus. It obtained without doubt the name of *Marchasita aurea* because zinc communicates a yellow colour to copper; and for the same reason the Greeks and the Arabians called *Cadmia* golden, or *aurea*.'—*Beckmann.*

GOLDEN SULPHURET OF ANTIMONY. *Stibium Sulphuratum Aurantiacum.* The pentasulphide of antimony, a golden yellow powder, its formula being SbS^{5} (**$Sb^{2}S^{5}$**). See Antimony.

GONG-GONG, or *Tam-tam* of the Chinese. A kind of cymbal made of a copper-alloy. See Copper.

GONIOMETER. An instrument employed to measure the angles of crystals. The most perfect instrument is the reflecting goniometer of Wollaston. The angle of the crystal is measured by determining through what angular space the crystal must be turned so that two rays reflected from two surfaces successively shall have the same direction. A simpler form of the instrument consists merely of a semicircular graduated scale of degrees with a moveable and a fixed radius. It is a most important instrument to the scientific mineralogist.

GOOSEBERRY. The fruit of the *Ribes grossularia*, a plant belonging to the natural order *Ribesiaceæ* or *Grossulariaceæ*.

GOOSEBERRY-GARNET. A name for Grossularia. See GARNET.

GOSLARITE. Native hydrous sulphate of zinc, named from its occurrence in the Rammelsberg mine, near Goslar, in the Hartz.

GOSSAN, *a Cornish mining term.* An oxide of iron, mixed with other matters. Gossans are found on the upper portions of lodes, and according to their characters are regarded by the miners as favourable or unfavourable indications. The gossans are probably the result of the slow decomposition of the sulphate of iron from the fluid in which the metalliferous matter, deposited in the lode, has been precipitated, or of the sulphides which may have been previously formed. The gossans are frequently very rich in silver, and sometimes they contain gold.

GOSSYPIUM. The cotton-tree. See COTTON.

GOULARD LOTION or **WATER.** A solution of the acetate of lead. See LEAD, ACETATE OF.

GOURDS. The hard integument of the fruit of several species of cucurbitaceous plants, used in the East for vessels, musical instruments, &c. See CALABASH.

GOVERNOR. A mechanical arrangement, usually attributed to Watt, for regulating the motion of a steam-engine.

GRADUATOR. A vessel employed in vinegar-manufacture. See ACETIC ACID.

GRAINS OF PARADISE. The fruit of several zingiberaceous plants; sometimes it is called *Mallaguetta pepper.* Pereira distinguishes between the two; but it appears that they commonly pass for the same in commerce. Grains of paradise are imported in casks, barrels, and puncheons from the coast of Guinea. They are used to give a factitious strength and pungency to beer and cordials.

By 56 Geo. III. c. 58, no brewer or dealer in beer shall have in his possession or use grains of paradise, under a penalty of 200*l.* for each offence: and no druggist shall sell it to a brewer under a penalty of 500*l.* for each offence.

GRAIN TIN. The purest kind of metallic tin. See TIN.

GRAMMATITE. A variety of Tremolite. See HORNBLENDE.

GRANITE, in the common and original acceptation of the term, denotes a rock, composed of felspar, quartz, and mica. It oftentimes contains, in addition to these, some other minerals.

These component minerals of granite, both essential and accidental, are united together by a confused crystallisation, not only mutually penetrating and interfering with each other, but sometimes the small crystals of one are completely enveloped in the large crystals of a different kind of mineral, and it is a very common occurrence for one or even more of these minerals to be developed in large crystals, in a granular basis of the whole, so as to constitute a porphyritic granite. This character is generally imparted by the felspar, and rarely by the quartz or mica.—*Boase.*

The chemical composition of ordinary granite is generally as follows:—

Silica	72·3
Alumina	15·3
Alkalis	7·4
Lime, magnesia and iron	5·0

This rock consists generally of about 40 per cent. of felspar, 30 or 40 per cent. of quartz, and from 10 to 20 per cent. of mica.

The granites of Cornwall and Devonshire have been long celebrated for their exceeding durability. Sir Henry de la Beche thus describes the situation of the workable granites:—

'There is much good granite on Dartmoor, though it is not always sufficiently accessible to be carried long distances: the chief places where it is worked in large quantities and afterwards exported are, Hey or High Tor on the east, and near King Tor on the west. The granite from the former place is conveyed by a tram-road to the Stover canal, down which it is carried in boats, and afterwards down the Teign to Teignmouth, to be shipped for its destination. That from the west side of the moor is conveyed by the Prince's Town and Plymouth tram-road to the latter place and shipped.

'The continuation of the Hingston Down granite is worked up the Tamar near New Bridge and exported from Morwellham. A very hard variety is obtained upon the higher part of the Down, and has been employed advantageously for pavements. . . . The chief quarries in the eastern or hard part of the Hensborough mass of granite are those of (the late) Mr. Austin Treffry, up the Par Valley, commonly known as Lostwithiel granite. Extensive quarries are there worked, and the stone is brought to the head of the canal near Pons-mill, upon which it is conveyed to Par harbour, and there shipped. . . . The Carn Menelez mass has furnished the granite most commonly known as Cornish. It is nearly altogether shipped at Penryn, where it is brought variable distances from different quarries in the vicinity, many situated in the parish of Mabe;'—also in Constantine, Budock, and Stithians.

Since the above report was written, the quarries at Cheeswring near Liskeard have been opened, and stone of a beautiful quality is raised and exported in large quantities. The Lamorna quarries have also been worked; the stone obtained from them is of excellent quality, and it can be obtained of almost any size.

The following great works, amongst many others, have been constructed entirely, or in part, of Cornish granites. The Penryn and Lamorna granites have supplied Portland Breakwater; Keyham Docks for the Steam Navy; Commercial Docks, London; the Hull, Great Western, and Birkenhead Docks, and the National Works at Chatham and Portsmouth, together with the Scutari Monument. The plinth for the railings of the British Museum was from the Carnsew quarries, and the towers, including the lodge, for gates, &c., from Constantine. From Lamorna blocks of 12 feet square are readily obtained; these quarries produce about 60,000 feet per annum; some stones have been raised 25 feet in length and 11 feet in diameter.

The Wellington Memorial, erected at Strathfieldsaye, from the design of the Baron Marochetti, is constructed of granite entirely from the Constantine quarries. This monument contains stones of unusual character, the die being a single stone 9 ft. 6 in. high and 7 ft. square, weighing nearly 40 tons. The shaft of the column is 30 ft. in height in one stone, and some of the mouldings are in stones of nearly 11 ft. square. The whole of the surfaces above the plinth are finely polished, and have all the appearance of being carved from a single block.

The Cheeswring granite has been used in the London Docks, Westminster Bridge, the Thames Embankment, Rochester Bridge, the Docks at Copenhagen, the Great Basses Lighthouse near the island of Ceylon, and for the Tomb of the Duke of Wellington in the crypt of St. Paul's Cathedral. These quarries produce from 8,000 to 10,000 tons of stone per annum, and about a similar quantity is annually shipped from the quarries near Par.

The granites of Scotland are chiefly produced from the county of Aberdeen.

The granite of Aberdeen, especially from the quarries of Dancing Cairn, Rubislaw, and Tyrebagger, is much used in the metropolis for kerb and paving stones; some red granite is also quarried. Around Peterhead the red granite prevails, hence it is usually distinguished as the *Peterhead granite*. The principal quarries are those of Black Hill, four miles west of Peterhead, belonging to the Governors of the Merchant Maiden Hospital of Edinburgh; those on the estates of the Earl of Errol—at Boddam, at Longhaven, at Cairngall, and at Rova. The Sheerness Docks were built mostly with stone from these quarries. The Stirling Hill quarries, at Boddam, furnished the pillar of the Duke of York's Monument; the Seafield quarries the abacus. The beautiful pillars in the library of the British Museum were obtained from Longhaven; the cost for transport, at the time they were worked, being something almost fabulous, so great were the difficulties attending their removal. The pillars in Fishmongers' Hall are from the Stirling quarries, as are also the bases of the monuments of Pitt and Fox; and the polished pillars of the Carlton Club House, in Pall Mall, are from the quarries near Peterhead.

Granite of excellent quality is obtained in Argyleshire, especially in the island of Mull, where it may be obtained in blocks of enormous size. The quarries are situated on the west side of the island; a fine pink granite being worked at North Bay, and a dark red variety at Tormor. The Mull granites are especially adapted, by their beauty of colour and uniformity of grain, for purposes of ornament; and have been largely employed in the construction of the Albert Memorial, recently erected in Hyde Park.

Granite is also worked to a limited extent in several of the islands round our coast. In the Isle of Man, the grey granite of South Barrule forms a gigantic boss penetrating the surrounding schistose rocks, and furnishing a stone worked for local consumption; in Lundy Island, which consists almost entirely of granite, quarries have recently been opened; and in the Channel Islands, certain syenitic varieties have long been worked, and are largely employed as London road-metal.

The granites of Ireland.—The most extensive granite district in Ireland stretches south from Dublin, through the counties of Wicklow and Carlow into Kilkenny; it occurs on the south-eastern coast of Down, and around Newry; the range of the Mourne mountains is granite, which again appears in small and isolated protrusions in Derry and Tyrone, and in Cavan. In the western portion of Donegal there is a large extent of this rock, which here partakes of a gneissose character; and again, in the west of Galway, granite covers a considerable area. The granite of the Wicklow range is the most extensively used. It varies in its quality, that near Kingston being coarse and hard, while that from Ballyknocken, or Golden Hill, is much finer, and therefore fitted for ornamental work. The granite of Down is of a darker colour and finely crystallised. It is extensively quarried at Newry, and sent by water to the north of Ireland.

The Galway granite is of a reddish colour, containing large crystals of flesh-red felspar. That of Mayo is of a dark bluish grey colour, while that of Tyrone is reddish.

The Irish granite averages 170 lbs. per cubic foot, its extreme weights being 143 lbs. and 176 lbs. After 88 hours' immersion in water, it was found that a cubic foot of the granite of Newry and Kingston absorbed about ¼ lb., that of Carlow nearly 2 lbs., and the granite of Donegal 4 lbs. of that fluid. These facts are important in connection with the use of these rocks for building purposes.—*Wilkinson's Practical Geology and Ancient Architecture of Ireland.—Sir R. Kane's Industrial Resources of Ireland.—Hull's Building and Ornamental Stones.*

Granite is worked to a small extent at Shap Fell in Westmoreland, and at Mount Sorrell in Leicestershire. The rocks worked as and called the Grooby granite may perhaps more properly be termed Syenites, in some cases assuming the character of a syenitic granite, in others of a syenitic greenstone. These are worked extensively for 'pitching' and for macadamising roads.

Until recently it was an opinion almost universal among geologists that granite had been formed by igneous fusion, and had solidified from a molten condition, under enormous pressure; the theory being supported partly by the crystalline and unstratified character of the rock, but chiefly by the fact that almost every large mass of granite gives off numerous ramifications or veins which penetrate the surrounding rocks, and which appear to have been formed by injection of the molten granite into neighbouring fissures. Evidence has, however, accumulated during the last few years tending to modify this theory very materially. Thus, it has been found that the specific gravity of quartz which has undergone fusion is never higher than 2·3, whilst that of the quartz in granite reaches 2·6; but it should be remembered that the pressure under which granite has evidently been formed must, as Dr. Haughton has pointed out, tend to increase the density of the silica. Again, many minerals occurring in granite, either as essential or as accessory constituents, are such as could not have existed at a high temperature; some of them, indeed, containing a notable proportion of water. Many of these minerals, moreover, are so highly basic that it is difficult to understand how they could have been fused in the presence of free quartz without entering into chemical combination with the silica. Finally, the constituent minerals of granite have, in most cases, not solidified in the order of their relative infusibility; the quartz, which is the most infusible, having evidently solidified last, since it commonly bears the impress of the felspar crystals.

Much light has also been thrown upon the probable origin of granite by the researches of Mr. H. C. Sorby on the microscopical structure of crystals: a subject which has been followed up by Dr. Zirkel and other observers. The crystals of many minerals contain cavities partially filled with liquid, which has evidently been caught up and mechanically enclosed during the formation of the crystal: a phenomenon frequently witnessed in the crystallisation of artificial salts in the laboratory. From the nature of their formation, it is evident that such cavities must be entirely filled with liquid at the temperature at which they have been formed; any vacuities that afterwards appear being due to subsequent contraction, resulting usually from a reduction of temperature. If the crystal, therefore, be exposed to heat until the liquid, by its expansion, entirely fills the cavity, the temperature at which the crystal was originally formed will be at once indicated. Such results will, however, require considerable modification if the mineral should have been formed under the effects of great pressure, as was certainly the case with granite. As crystals deposited from aqueous solution contain *fluid*-cavities, so those obtained by sublimation enclose bubbles of vapour, giving rise to *gas-* or *vapour*-cavities; whilst substances solidifying from fusion, such as glass or slag, contain portions of solid matter, in what are termed *glass-* or *stone*-cavities, according to the nature of the enclosed solid. Now, when the constituent minerals of granite are subjected to microscopical examination, they exhibit numerous cavities, of which some contain liquids, others enclose solids, and a few merely vapour. These cavities are most abundant in the quartz, some varieties of which contain more than a thousand millions to the cubic inch. Since the presence of fluid-cavities indicates formation by the wet way, whilst stone-cavities point to fusion, and gas-cavities to sublimation, the co-existence of all these varieties in granite leads Mr. Sorby to believe that this rock has been formed under highly complex physical conditions, 'combining at once both igneous fusion, aqueous solution, and gaseous sublimation. The proof of the operation of water is quite as strong as that of heat.'

GRANITITE. A granite, containing oligoclase, orthoclase, quartz, and a magnesian mica.

GRANULATION is the process by which metals are reduced to minute grains. It is effected by pouring them, in a melted state, through an iron cullender, pierced with small holes, into a body of water; or directly upon a bundle of twigs immersed in water. In this way copper is granulated into bean-shot, and silver-alloys are granulated preparatory to refining. It has recently been proposed to granulate pig-iron before introducing it into Danks's rotatory puddling-furnace.

GRAPES. The fruit of the grape-vine (*Vitis vinifera*). They are largely used as fruit, both fresh and dried; forming, in the latter case, raisins and currants. The juice of the grape yields wine, brandy, wine-vinegar, &c. The residue of the expression of the juice is known as *marc*, and is used in the preparation of verdigris, or acetate of copper. Oil is prepared from the seed of the grape, whilst the lees are burnt for the sake of the potash they contain.

GRAPE SUGAR. A sugar so called from its being produced in the grape; but it also occurs in many other fruits, and it forms the crystalline portion of honey. A great quantity of grape-sugar is now prepared from starch. The formula of grape-sugar is $C^{12}H^{12}O^{12}.2HO$ ($\mathbf{C^6H^{12}O^6.H^2O}$).

GRAPHIC GRANITE. A peculiar form of granite, in which some of the crystalline constituents are so disposed in the matrix as to suggest a resemblance to some forms of oriental characters.

GRAPHIC TELLURIUM. A name applied to sylvanite, in allusion to the curious forms in which its crystals are generally arranged. See SYLVANITE.

GRAPHITE, *Plumbago*, or *Black-lead.* (*Plombagine*, Fr.; *Reissblei*, Ger.) A mineral substance of a lead or iron-grey colour, a metallic lustre, soft to the touch, and staining the fingers with a lead-grey hue. H = 1 to 2. Specific gravity, 2·08 to 2·45. It is easily scratched or cut, and affords a black streak, displaying the metallic lustre in its interior. B.B. infusible both alone and with reagents; but burns with great difficulty in the outward flame without flame or smoke, generally leaving a residue of oxide of iron. It consists of carbon in a peculiar state of aggregation, with an extremely minute and apparently accidental impregnation of iron. Graphite occurs in gneiss, mica slate, and their subordinate clay-slates and limestones, in the form of masses, veins, and kidney-shaped disseminated pieces. It has been found also among the coal-strata, as near Cumnock in Ayrshire. This substance is employed for counteracting friction between rubbing surfaces of wood or metal, for making crucibles and portable furnaces, for giving a gloss to the surface of cast iron, &c.

The following report of the late Von Haidinger and others, of Vienna, on the origin of graphite, contains much that is valuable.

Iron, after long remaining buried in the earth, at last entirely decomposes, leaving a black, porous, eminently combustible residuum, known as graphite or pure carbon. Haidinger's report on the ferruginous masses of Kokitzau and Gotta, near Dresden, masses of uncertain origin, lends support to this general fact.

One word on the formation, still so little known, of graphite. The presence of graphite in granite, gneiss, and diorite, has renewed the disputes between the Neptunists and Plutonists. Graphite is well known to be nearly pure carbon, for it leaves in burning but a very small quantity of ash. Now, if these primitive crystalline rocks are of igneous formation, it is impossible to explain how graphite could co-exist with silicates of protoxide of iron without having reduced these salts. Judging merely by what takes place in blast-furnaces, carbon reduces all oxides of iron at a high temperature. It must, then, be admitted that granite, gneiss, and diorite did not contain graphite when the mineral elements of these rocks, such as mica, hornblende, and other ferrous silicates, were in a state of fusion. Graphite, then, must have been subsequently introduced into these rocks, but when and how? Questions such as these are very difficult to answer satisfactorily. The most plausible hypothesis is that graphite has been introduced by the wet way into the crystalline rocks, and substituted for one of the mineral components. Thus in the gneiss of Passau (Bavaria) it takes the place of mica.

Graphite is frequently to be met with in granular limestone, a fact particularly interesting to geologists. Is limestone a product of eruption, or is it a sediment transformed by the action of heat? The presence of graphite is explicable by neither hypothesis. For, at a certain temperature, which need not be very high, carbon decomposes carbonate of lime. This salt may, no doubt, under strong pressure, be heated to the melting-point without losing its carbonic acid; this is a laboratory experiment often cited by the Plutonists. But it is quite a different thing with a mixture of carbon and carbonate of lime at a high temperature. If we reject the Neptunian origin of granulated limestone, we must then, as with crystalline rocks, suppose that graphite has been introduced by the wet way at a more recent period. The same remark applies to magnetic pyrites (sulphide of iron), often very rich in plumbago kerns.

Does graphite, like all carbon, belong to the organic kingdom? It is certain that anthracite, lignite, and coal are the result of a slow decomposition of an enormous quantity of vegetables, the impressions found on them often indicate the kind of vegetables, most of them extinct, which have contributed to these carbonaceous formations. Graphite, if not formed in precisely the same way as coal and anthracite, nevertheless bears signs of an organic origin. The formation of nuclei and veins of graphite in crystalline rocks is sufficiently explained by the decomposition of carburetted hydrogen gas at a high temperature; this gas, disengaged from organic matters, and penetrating the fissures of the burning rock, would undergo decomposition into hydrogen and carbon.

It is this deposited carbon which forms graphite. If in our laboratories we do not obtain exactly the same product, it must be remembered that Nature has means at her command which escape our researches. We find it impossible to make coal from wood. The wood may be carbonised by the dry or by the wet way. In the first case the carbonisation is very rapid; in the latter it is extremely slow, as is shown by the blackened points of piling sunk in water.

Finally, graphite has been found in meteorites and aerolites. Attempts have been made to explain its presence here by the continuance of these stones in soil more or less rich in carbonised principles. But with regard to newly-fallen stones, this explanation is inadmissible. If it be maintained that graphite is an organic product, it must be admitted that in the case of newly-fallen meteorites it can proceed only from organic matters belonging to another world than our own.

In his report on Alibert graphite, M. Dumas presents some considerations on the probable origin of graphite and of the diamond. M. Despretz and others ascribe to fire the change of carbon into diamond. Newton ascribed it to the coagulation of a fatty or oily body; Liebig says the diamond is slowly formed by processes which determine the prolonged putrefaction of a liquid body rich in carbon and in water; then, contrary to M. Despretz's method, a high temperature would be unfavourable to a successful attempt. Adopting Newton's hypothesis, M. Göppert states, in a 'Memoir on the solid bodies entering into the composition of the diamond, and considered with regard to their organic or inorganic origin,' that he is disposed to class the diamond among the produce of the decomposition of organic matters. All these hypotheses M. Dumas rejects; according to him the diamond is crystallised carbon, at the moment of its production, and in the midst of a mass which has been exposed merely to the heat necessary to soften it, provided this condition is sufficiently prolonged.

Finally, M. Dumas frankly admits that nothing positive is known as to the true origin of the diamond, though the substance most allied to it, silicium, is perfectly known, and very beautiful crystals of it are obtained.

However, it is positively ascertained that the diamond and graphite have not the same origin, and that the residue of every carboniferous substance, treated at a high temperature, proves to be but a variety of graphite. The graphite found by M. Alibert in the mines of Marinski, situated at the summit of Batougol, on the Siberian frontiers, is, then, a graphitoid carbon of the most beautiful kind, formed by volcanic phenomena. M. Jaquelain, after carefully comparing the external characteristics of Alibert graphite with that obtained by his process, concludes that the conditions under which they are produced must be analogous.

In fact, on comparing the texture of the two carbons, they will be found sometimes of a metallic, mirror-like lustre; at another time the surface will be of shining steel-grey, mammillated as if it had been half fused, and had passed through a pasty stage. This appearance is similar to that of oxide of iron, nodular, brilliant, with mammillated surface, known by the name of brown hematite.

M. Jaquelain is inclined to admit that tarry and pyrogenated products, transformed in immense proportions into carbon and hydrogen under the influence of igneous rocks, become accumulated in rents and excavations, causing an aggregation of carbon and inducing a fusion analogous to that of carbon in retorts for lighting gas, and of graphitoid carbon destined to form the pencils used for the electric light.

On this point M. Jaquelain narrates one of his own recent experiments. On decomposing some sulphide of carbon in a porcelain tube in presence of pure copper, heated to about 800°, sulphide of copper and graphite were formed, the latter externally similar to natural graphite.—*Cosmos*, 1864, pp. 720, 725.

Some of the latest researches of Gustav Rose, published just before his death in 1873, were directed to the natural forms of carbon, including graphite. For these the reader may be referred to the 'Proceedings of the Berlin Academy of Sciences.'

GRAPHOTYPE. By this new process of engraving (discovered in the summer of 1860 by Mr. De Witt Clinton Hitchcock) the artist becomes his own engraver, and thus overcomes the difficulties met with in most other processes, arising from the impossibility of two individuals working out the same idea in exactly the same way. A short description of the circumstance which led to this discovery will give a good idea of the nature of the new method called 'Graphotype.' Mr. Hitchcock was engaged in making a drawing on boxwood, and finding it necessary to erase a portion of his work and re-whiten his block, he took a visiting-card (the white material used for the surface of the wood engraver's block being of the same composition as the enamel of the said card) and commenced rubbing off the enamel with the aid of a brush and water, when, to his astonishment, he found the printed letters remained in relief. The ink in combining with the enamel had become sufficiently hard to resist the action of the brush, and thus he had accidentally prepared a sort of block upon which the letters stood out. This circumstance led him to the discovery that by taking a slab of chalk, reducing its surface to as smooth a condition as possible, drawing on it with an ink composed of silicate of potash (water-glass) and indigo, then, when the sketch was dry, by brushing away the surface with a dry brush (the lines of the drawing being virtually converted into stone, they will withstand the friction of the brush, while the intervening particles are easily removed), and saturating the mass of chalk with liquid glass, he had a block ready for printing from in the ordinary way of burnishing.

This experiment was successful, and after several trials the following method has been adopted as the most perfect:—A chalk surface upon a metallic plate is now adopted. French chalk is ground to the finest powder, then the coarser particles separated from the finer by being thrown into water, the sediment which first subsides is removed and ground again; this is repeated several times. Next, the powder is repeatedly passed through a wire cloth which contains 10,000 holes to the square inch, and is then laid between a smooth metallic (zinc) plate and a smooth steel plate, and submitted to intense hydraulic pressure, then, after the chalk-surface is sized, it is ready for the artist. The pencils employed by the artist are of sable-hair, and the ink is composed of lamp-black and glue. When the drawing is finished the surface is gently rubbed with silk velvet, or fitch hair-brushes, until the chalk between the inked lines is all removed to the depth of about the eighth of an inch. After this the block has only to be hardened, which is done by soaking it into a solution of an alkaline silicate (water glass); by this means the whole of the chalk is converted into stone.

This petrified block is not used to print with, as it would not stand the wear and tear it would be subjected to in the printing press, but a mould is taken of it, from which a type-metal cast (a stereotype) is made, and it is this stereotype from which the impressions are taken.

One of the great merits of this new process is the extreme delicacy and precision with which the finest lines are produced, and the accuracy and rapidity of production are the two great recommendations of the graphotype. A sketch made in the morning may be multiplied by thousands by the evening. The graphotype is a most valuable invention; and it seems probable that it will supersede the old wood-engraving to a considerable extent: it is cheaper, more accurate, and more rapid of production, but still it possesses all the advantages of the ordinary block.

GRASS-OIL. A fragrant oil which is extracted from a peculiar Indian grass; it is generally called the *grass oil of Nemaur*. Grass-oil, on account of its odour, is often termed lemon-grass or verbena; it is derived from the *Andropogon Nardus*, a species of grass which is now regularly cultivated in Ceylon for the sake of the essential oil which it yields by distillation, about 10,000 lbs. of which are imported annually. *A. citratum* has been considered to be the source of the oil of lemon-grass.

GRATE, *a mining term.* A metal plate pierced with small holes: it is fixed in front of the stamps in which the ore is pounded, and through the holes the finely-divided matter makes its escape.

GRAUWACKE or **GREYWACKE.** (*Grau*, grey; *wacké*, clay.) A German name, often adopted by geologists for some of the most ancient fossiliferous strata. The rock is often of a grey colour, hence *grau*, German for *grey*; *wacké* being a provincial miner's term. Although at one period, the term *grauwacké* or *greywacké*, was employed to include the Cambrian and Silurian slates, the term has now nearly dropped out of the geological nomenclature.

GRAVE-WAX. A familiar term for adipocere. See ADIPOCERE.

GRAVITY. The term usually applied to the action of the earth's gravitation.

GRAVITY, SPECIFIC. The specific gravity of a body is represented by the ratio which the weight of a given volume of the body bears to the weight of an equal volume of a certain substance chosen as a standard of comparison. Water is the standard for solids and liquids, and air the common standard for gases, but modern chemists frequently refer the specific gravity of gases to hydrogen as unity. If, therefore, the specific gravity of platinum is stated to be 19·5 (water = 1), or 19500 (water = 1000), it is simply meant that a given bulk—say a cubic inch—of platinum will weigh 19½ times as much as a cubic inch of water weighs. In like manner the specific gravity of oxygen is said to be 1·1056 (air = 1), or 16 (hydrogen = 1), by which is meant that a certain volume of oxygen weighs $1\frac{1056}{10000}$ times greater than the same volume of air, or 16 times as much as an equal bulk of hydrogen; all the weights being determined under like conditions of temperature and pressure. Specific gravity is sometimes called 'relative weight,' and is commonly regarded as the same thing as 'density.' For a description of the several methods by which the specific gravity of any body, either solid, fluid, or aeriform, may be determined, we must refer to Watts's 'Dictionary of Chemistry,' or to any works treating of the manipulatory details of physics or chemistry. The following Table may be found useful:—

Table of Specific Gravities.

Metals				Stones, Earths, &c.			
Names	Weight, water being 1000	Number of cubic inches in a lb.	Weight of a cubic inch, in lbs.	Names	Weight, water being 1000	Number of cubic feet in a ton	Weight of a cubic foot, in lbs.

GREBE. A water-bird, *Podiceps cristatus*, the great crested or tippet grebe. It is about the size of a goose, and a native of England, being found in the fens of Shropshire, Cheshire, and Lincolnshire, where they are called gaunts. The bird, which is valued for the plumage of its breast, so much admired by ladies for muffs, and used for trimmings, is a large Swiss and Central European species.

GREEN EARTH. An earthy mineral occurring in cavities in amygdaloidal melaphyres, especially at Monte Baldo, near Verona, whence it is procured for use as a pigment, being sold under the name of *Terre verte de Verone.*

GREEN EBONY of Jamaica. This is a wood of a brown-green colour. It is derived from the *Amerimnum Ebenus*, and is used in turnery and for marquetry-work. See MARQUETRY; PARQUETRY.

GREENHEART. A wood brought from Jamaica and Guiana, the produce of the *Laurus chloroxylon.* It is used in shipbuilding. Bancroft, in his 'Guiana,' thus describes it: 'The Sipiera or Greenheart tree is in size like the locust-tree, about 60 or 70 feet high; there are two species, the black and the yellow, differing only in the colour of their bark and wood.'

GREEN IRON ORE. A native phosphate of iron. See DUFRENITE.

GREEN LEAD ORE. An arsenio-phosphate and chloride of lead. See Pyromorphite.

GREEN LINNETS. A miner's name for green lead-ore or pyromorphite.

GREENOCKITE. Native sulphide of cadmium. It occurs in small, but very perfect and brilliant, short hexagonal crystals, in a porphyritic greenstone, on prehnite, and associated with calcite. It has been found in a railway-cutting at Bishopstown, near Paisley, and at Bowling, near Old Kirkpatrick. It was first observed by the late Lord Greenock, afterwards Earl Cathcart, hence its name. See Cadmium.

GREEN PAINTS. (*Couleurs vertes*, Fr.; *Grüne Pigmente*, Ger.) Green, which is so common a colour in the vegetable kingdom, is rare in the mineral. There is only one metal, copper, which affords in its combinations the various shades of green in general use. The other metals capable of producing this colour are, chromium in its sesquioxide, nickel in its hydrated oxide, as well as its salts, the selenate, arsenate, and sulphate; titanium in its prussiate; and some of the salts of uranium.

GREEN PIGMENTS. Under the name of 'green cinnabar,' Vogel described a new colour. Prussian blue is dissolved in oxalic acid, chromate of potash is added to this solution, which is then precipitated with acetate of lead. The precipitate, well washed, dried and levigated, gives a fine green powder. By varying the proportions of the three solutions, different shades of green may be produced. Another method has been given by Dr. Elsner. Make a solution of yellow chromate of potash and another of yellow prussiate of potash; then mix the two, dissolve separately in water some acetate of lead and iron, and add this solution to the others. By precipitating the first two solutions by the third, a green deposit is obtained, the tint depending on the proportions employed.

Green pigments are prepared also by the mixture of yellows and blues; as, for example, the green of Rinman and of Gellert, obtained by the mixture of cobalt-blue and flowers of zinc; that of Barth, made with yellow lake, prussian blue, and clay; but these paints seldom appear in the market, because the greens are generally extemporaneous preparations of the artists.

Mountain green consists of the hydrate, oxide, or carbonate of copper, either factitious or as found in nature.

Bremen or *Brunswick green* is a mixture of carbonate of copper with chalk or lime, and sometimes a little magnesia or ammonia. It is improved by an admixture of white lead. It may be prepared by adding ammonia to a mixed solution of sulphate of copper and alum.

Frise green is prepared with sulphate of copper and sal-ammoniac.

Mittis green is an arsenate of copper, made by mixing a solution of acetate or sulphate of copper with arsenite of copper. It is in fact *Scheele's green.*

Sap green is the inspissated juice of buckthorn berries. These are allowed to ferment for 8 days in a tub, then put in a press, adding a little alum to the juice, and concentrated by gentle evaporation. It is lastly put up in pigs' bladders, where it becomes dry and hard. See Colours, *Table of.*

GREENSAND. The term 'Greensand' applies to the strata lying between the Chalk and the Wealden deposits. They are of marine origin, as is denoted by the presence throughout their entire thickness of sea-shells, and are divided into an upper and lower series, separated by a stratum of clay, called gault. The *Upper Greensand*, which underlies the Chalk Marl, is composed chiefly of calcareous sand in the lower, and of sandstone and layers of chert (a compact flinty rock) in the uppermost part. The sandstone affords a good and durable building stone. The chert is well adapted from its toughness for making roads, and the sandy portion, in addition to its usefulness as a component of mortar, furnishes an excellent agricultural soil, from the calcareous matter it contains, in addition to the large percentage of soluble silica entering into its composition, which sometimes amounts to more than 40 per cent. In Sussex, Surrey, and Kent, the land based upon the Upper Greensand is known by the name of malm, and produces the greater part of the hops for which those counties are celebrated. In the neighbourhood of Godstone and Merstham, in Surrey, extensive quarries are driven into the hills, at the base of the chalk downs, for the purpose of procuring the soft and chalky stone which occurs there in the higher portion of the Upper Greensand, for which there is a large demand in London, for cleaning door-steps and stonework in the fronts of houses, under the name of *hearthstones.* A plentiful supply of pure water is borne up by the impermeable strata, forming the uppermost part of the Upper Greensand, which finds its way out of the ground near the base of the Chalk, and forms the sources of many streams and rivers.

The *Lower Greensand* consists of alternations of sands, sandstones, and clays, which are often very ferruginous, so much so sometimes as to constitute a siliceous ore of iron, as is the case of Seend in Wiltshire, and Shotover in Oxfordshire. The ferruginous sands form the iron-sand of Dr. Smith. The Lower Greensand, also, contains beds of Fuller's Earth, which are worked at Reigate, and they furnish a durable and useful building stone, known by the name of Kentish Rag, and quarried extensively in the neighbourhood of Maidstone.

The term 'Greensand,' though applied to deposits of considerable thickness, is, in fact, only strictly applicable to certain minor portions of them, which are marked by the presence of minute grains of green silicate of iron (the *glauconite* of American mineralogists), These impart a colour to the beds in which they occur, which has given the name to the entire formation.—H.W.B. See Chert; Firestone; Gault.

GREEN, SCHEELE'S. An arsenite of copper. See Copper.

GREEN SLOKE. *Ulva latissima*, the broad green laver. See Algæ.

GREENSTONE. 'Greenstone is a dark and heavy blackish green or brownish rock, consisting of felspar and hornblende; it usually has a crystalline texture, but is sometimes compact.'—*Dana.* The term has been loosely applied by geologists to a number of rocks of similar general appearance, but of different mineralogical composition. See Diabase; Diorite.

GREEN ULTRAMARINE. This is artificially prepared in France and Germany, and employed, instead of the arsenical greens, for printing upon cotton and paper. See Ultramarine.

GREEN VITRIOL. Sulphate of iron, or copperas. See Iron, Sulphate of.

GREISEN. A rock composed of a granular mixture of quartz and mica—generally lithia-mica—in fact, a granite without felspar, or a mica-schist in composition, but without foliation. It is frequently associated with tin-ore in the mining districts of Saxony and Bohemia.

GRENADA COCUS or **GRENADILLO.** This wood, imported from the West Indies, is called red ebony by the French cabinet-makers.

GREY ANTIMONY. The native trisulphide of antimony. See Antimony.

GREY COPPER. A native disulphide of copper. See Copper.

GREY DYE. (*Teinture grise*, Fr.; *Graufärbe*, Ger.) The grey dyes, in their numerous shades, are merely various tints of black, in a more or less diluted state, from the deepest to the lightest hue.

The dyeing materials are essentially the tannic and gallic acid of galls or other astringents, along with the sulphate or acetate of iron, and occasionally wine-stone or crude tartar. *Ash-grey* is given for 30 pounds of woollen stuff, by one pound of gall nuts, ½ lb. of wine-stone, and 2½ lbs. of sulphate of iron. The galls and the wine-stone being boiled with from 70 to 80 pounds of water, the stuff is to be turned through the decoction at a boiling heat for half an hour, then taken out, when the bath being refreshed with cold water, the copperas is to be added, and, as soon as it is dissolved, the stuff is to be put in and fully dyed. Or, for 36 pounds of wool; 2 pounds of tartar, ½ pound of galls, 3 pounds of sumach, and 2 pounds of sulphate of iron are to be taken. The tartar being dissolved in 80 pounds of boiling water, the wool is to be turned through the solution for half an hour, and then taken out. The copper being filled up to its former level with fresh water, the decoction of the galls and sumach is to be poured in, and the wood boiled for half an hour in the bath. The wool is then taken out, while the copperas is being added and dissolved; after which it is replaced in the bath, and dyed grey with a gentle heat.

If the grey is to have a yellow cast, instead of the tartar, its own weight of alum is to be taken; instead of the galls, one pound of old fustic; instead of the copperas, ¾ of a pound of Salzburg vitriol, which consists, in 22⅝ parts, of 17 of sulphate of iron, and 5⅝ of sulphate of copper; then proceed as above directed. Or the stuff may be first stained in a bath of fustic, next in a weak bath of galls with a little alum; then the wool being taken out, a little vitriol (common or Salzburg) is to be put in, previously dissolved in a decoction of logwood; and in this bath the dye is completed.

Pearl-grey is produced by passing the stuff first through a decoction of sumach and logwood (2 lbs. of the former to 1 of the latter), afterwards through a dilute solution of sulphate or acetate of iron; and finishing it in a weak bath of weld containing a little alum. *Mouse-grey* is obtained when, with the same proportions as for ash-grey, a small quantity of alum is introduced.

For several other shades, as tawny-grey, iron-grey, and slate-grey, the stuff must receive a previous blue ground by dipping it in the indigo vat; then it is passed first through a boiling bath of sumach with galls, and lastly through the same bath at a lower temperature, after it has received the proper amount of solution of iron.

For dyeing silk grey, fustet, logwood, sumach, and elder-tree bark, are employed instead of galls. Archil and annotto are frequently used to soften and beautify the tint.

The mode of producing grey dyes upon cotton has been explained in the articles Calico-Printing and Dyeing.

GREYWACKE, *Grauwacke.* A German term, used to designate the coarse slaty strata of the transition rocks. It is now employed to designate the brecciated beds which occur in those formations.

GRINDING AND CRUSHING MACHINERY. See Dressing of Ores.

GRINDSTONE. Grinding-stones or grit-stones are varieties of sandstone, most of those which are celebrated being obtained from the sandstones and millstone grits of the coal-measures. Mr. Knight describes the best known varieties, which are the following:—

Newcastle Grindstones.—These abound in the coal districts of Northumberland, Durham, Yorkshire, and Derbyshire. They are selected of different degrees of coarseness and density, according to the work for which they are required.

Bilston Grindstone is a similar description of stone, of great excellence, of a lighter colour, much finer, and of a very sharp nature, and at the same time not too hard. It is confined to a small spot of limited extent near Bilston in Staffordshire, where it lies above the coal.

Wickersley Grindstones.—These are obtained from a village about nine miles east of Sheffield, and are much used for the finer description of edge-tools.

Sheffield Grindstone.—A hard, coarse gritstone, used for grinding large files and the like; it is obtained from Hardsley, about fourteen miles north of Sheffield.

Devonshire Batts are obtained near Collumpton.

Yorkshire Grit and *Congleton Grit* are other varieties from which grindstones are manufactured.

Burr Stones.—These are very celebrated; they are found at La Ferté-sous-jouarre (Seine et Maine), and are said to be unequalled for grist-mills. The combined roughness and hardness of this tertiary quartz-deposit give it immense advantages. The stones formed of this rock are usually pieced, which renders them very expensive.

Artificial grindstones have been successfully made of late by Ransome's method of manufacturing artificial stone. They are said to form excellent and economical substitutes for the natural grindstones.

GRIS-PERLE. The name given by the French dyers to a grey produced by the action of sulphuric acid on aniline violet. It is much used in dyeing silk. See Aniline.

GRIT. A peculiar hard sandstone. See Millstone Grit.

GROATS, EMBDEN. When oats are deprived of their integuments, they are called *groats*, and when these are crushed, they are known as *Embden groats.* Oatmeal is prepared by grinding the grains.

GROS DE NAPLES. A plain silk fabric woven of organzine silk, prepared with much neatness and care.

GROSSULARIA. Gooseberry-garnet. See Garnet.

GROUND IVY. *Nepeta Glechoma.* The leaves of this plant were formerly thrown into a vat with ale, to clarify it and give it a flavour.

GROVE or **GROOVE.** A mining term in Derbyshire. 'The mine, or work that a man is employed in. Hence it is, if a question be asked, Where is Tom today?—He is gone to the groove, he is at the groove. Sometimes it is used for the shaft, and mines are commonly called *groovers.*'—*Hooson's Miner's Dictionary.*

GROWAN. A local term applied in Cornwall to granite in an imperfect state, either through decomposition, or irregular formation. It is said that the term is sometimes applied to the solid granite. We have never heard it so used, and the miners and the quarrymen draw a well-defined line between a granite and a growan.

GUAIACUM. (*Gaïac*, Fr.; *Guajaharz*, Ger.) Both the wood and resin are imported; they are used medicinally. It is known that, after the discovery of the New World, when the first syphilitic diseases showed themselves in Europe, the origin of which was erroneously ascribed to Santo Domingo, the guaiacum wood was considered as specific against this disease. The historian Herrera informs us that one pound of the wood was at that period paid in Spain with seven piastres. The gum which exudes from the wood, and possesses, as it may be conceived, the medicinal qualities in a much higher degree, is now valued at 7*d.* per pound.

GUANINE. $C^{10}H^5N^5O^2$ ($\mathbf{C^5H^5N^5O}$). An organic base, found by Unger in guano. Guano contains about 6 per cent of it.

GUANO. This extraordinary excrementitious deposit of certain sea-fowls, which occurs in immense quantities upon some parts of the coasts of Peru, Bolivia, and Africa, has lately become an object of great commercial enterprise, and of intense interest to our agricultural world. More than thirty years ago it was exhibited and talked of merely as a natural curiosity, but the quantity imported into England alone rose from 30,000 to 350,000 tons (in 1858), the value of which was estimated at no less than 3,000,000*l.* But during the last few years the quantity imported has somewhat diminished, and hence the rise in price from 11*l.* to 14*l.* per ton.

Our importations of guano since 1868 have been as follow:—

	1868		1869		1870

The conditions essential for the preservation of these excrements appear to be the existence of a soil consisting of a mixture of sand and clay, in a country where the birds are allowed to live for ages undisturbed by man or man's works, and where, moreover, the climate is very dry, free not only from rain, but also from heavy dews.

These conditions appear to have been combined to a remarkable extent on the coasts of Peru and Bolivia, between latitudes 13° north and 21° south of the equator, for although beyond this region the flocks of cormorants, flamingoes, cranes and other sea-fowl, appear to be equally numerous, yet the excrement is rapidly carried away by the rain or dew.

It is then the dryness of the climate chiefly which has permitted the guano to accumulate on these coasts, for, says Mr. Darwin [1]—'In Peru real deserts occur over wide tracts of country. It has become a proverb that rain never falls in the lower part of Peru.' And again:—'The town of Iquique contains about 1,000 inhabitants, and stands on a little plain of sand at the foot of a great wall of rock, 2,000 feet in height, the whole utterly desert. A light shower of rain falls only once in very many years.' Indeed, since three-fifths of the constituent parts of guano are soluble in

---

[1] 'Researches in Geology and Natural History,' p. 421.

cold water, Prof. Johnstone very justly observes[1] that, 'A single day of English rain would dissolve out and carry into the sea a considerable portion of one of the largest accumulations; a single year of English weather would cause many of them entirely to disappear.'

Such being the case, we might expect to find similar accumulations in other hot and dry climates, as in Egypt, and in Africa, *e. g.* in the neighbourhood of the Great Desert; and only a few years since a considerable deposit of guano was found in the Kooria Mooria Islands.

In Peru the natives have employed it as a manure from the remotest ages, and have by its means given fertility to the otherwise unproductive sandy soils along their coasts. While Peru was governed by its native Incas, the birds were protected from violence by severe laws. The punishment of death was decreed to the persons who dared to land on the guaniferous islands during the breeding period of these birds, and to all persons who destroyed them at this time. Overseers were appointed by the Government to take care of the guano districts, and to assign to each claimant his due share of the precious dung. The celebrated Baron Von Humboldt first brought specimens to Europe in 1804, which he sent for examination to Fourcroy, Vauquelin, and Klaproth, the best analytical chemists of the day; and he spoke of it in the following terms:—'The guano is deposited in layers of 50 or 60 feet thick upon the granite of many of the South-sea islands off the coasts of Peru. During 300 years the coast birds have deposited guano only a few lines in thickness. This shows how great must have been the number of birds, and how many centuries must have passed over in order to form the present guano beds.'

There appear to be three varieties in Peru: the white, grey, and red, the first being the most recent, and the last the oldest; and in the midst of the great accumulations of the last kind, bones and feathers of birds are found (*Frezier*), as if to remove any doubt which might still remain as to its origin.

Cincha Island Guano.—Much of the so-called Peruvian guano is exported from the Cincha Islands. They are three in number, and lie in one line from north to south about half a mile apart. Each island is from 5 to 6 miles in circumference, and consists of granite covered with guano in some places to a height of 200 feet. in successive horizontal strata, each stratum being from 3 to 10 inches thick, and varying in colour from light to dark brown. No earthy matter whatever is mixed with this vast mass of excrement. At Mr. Bland's visit to these islands in 1842, he observed a perpendicular surface of upwards of 100 feet of perfectly uniform aspect from top to bottom. In some

1124

---

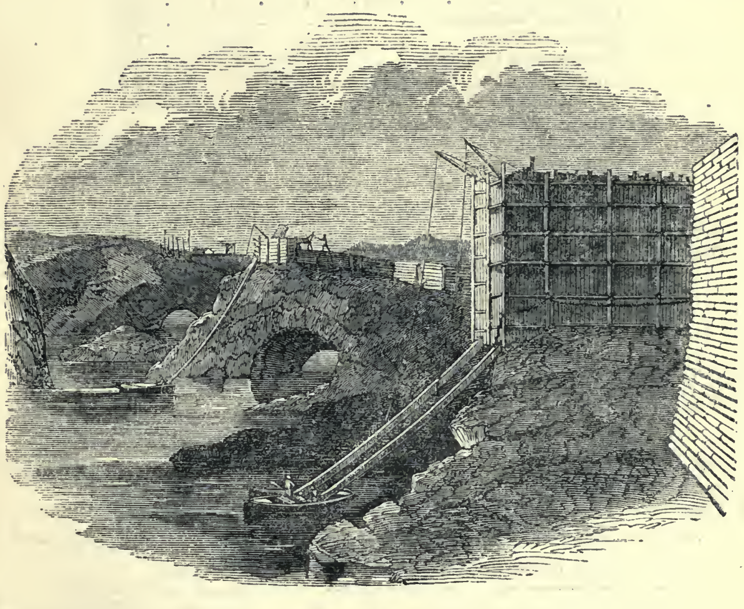
[1] 'On Guano.' 'Journal of the Agricultural Society of England,' vol. ii. p. 315.

parts of these islands, however, the deposit does not exceed 3 or 4 feet in thickness. In several places, where the surface of the guano is 100 feet or more above the level of the sea, it is strewed here and there with masses of granite, like those from the Alpine mountains, which are met with on the slopes of the Jura chain. These seem to indicate an ancient formation for the guano, and terraqueous convulsions since that period. No such granite masses are found imbedded within the guano, but only skeletons of birds.

The accompanying wood-cut, *fig.* 1124, shows the nature of the formation.

The export of the guano has not increased during the last few years: between 200,000 and 400,000 tons are the annual amount, which is effected by the aid of 900 working hands, 320 of them being Chinese, who enter into contracts to serve their employer (the Government contractor), for about 4 dollars a month, renewing it, if they choose, with the increase of 4 dollars monthly, and a bonus of 120. Those who work on their own account are paid 8 and 10 rials, 4 and 5 shillings, for each cart that they load. They live in a collection of dirty huts made of bamboo and mud; they, nevertheless, appear to be happy and contented, and in general are well conducted. The men with pickaxes work their way into the guano, leaving a sort of wall on either side; here it is so hard that it requires a heavy blow to remove it. It is then conveyed in wheelbarrows, either direct to the mouths of the shoots on the edge of the cliffs, or to the huge carts running on tramways for the same purpose. The colour varies very much—in some parts being as dark as warm sepia, and in others as light as that of a Bath brick.

1125



The smell of ammonia is said to be very powerful, so much so, in fact, as to affect the eyes of the workmen; crystalline deposits of various ammoniacal salts are also found amongst the guano. The guano heaps are surrounded by a high fence to prevent its being blown away by the wind, near the mouths of the canvas tubes or shoots, which are sometimes 70 feet long, through which it is conducted to the boats. See *fig.* 1125.

As in Peru, the surface of the guano is covered with skeletons of birds and bones of seals. It is also perforated by numberless holes, running in every direction, like a rabbit-warren. These are made by a bird about the size of a pigeon, which remains hidden during the day, sallying forth at dark to fish. Gold and silver ornaments are also discovered occasionally, having been buried by the ancient inhabitants more than three centuries ago.

It is quite unnecessary here to insist on the value of guano as a manure. This is a point established beyond all question by nearly every agriculturist in the kingdom;

and recorded by all classes of writers on agricultural subjects. It has been the means, moreover, of converting the sandy desert around Lima into a soil capable of raising abundant crops of maize; hence the Peruvian proverb, 'Huano, though no saint, works many miracles.'

Commercial varieties.—The following appear to be the chief:—

1. Peruvian.
2. Augamos.
3. Ichaboe.
4. Patagonian.
5. Saldanha Bay.
6. Kooria Mooria.
7. African.
8. Indian.

Chemistry.—Guano being an article of so great value to the agriculturist as a manure, and being liable not only to adulteration to a very great extent, but also varying when genuine considerably in quality, it is highly important to have some means of ascertaining its value. This cannot be done satisfactorily by ever so experienced a dealer by mere inspection, and therefore, both for the buyer and the seller, resort is necessary, for a knowledge of its compound parts, to the analysis of the chemist.[1] Such being the case, we must first ascertain the composition of genuine guano, and then inquire upon which of its several constituents its value as a manure depends.

The following is one of the earliest analyses by Fourcroy and Vauquelin, of a sample of guano presented to them by Baron Von Humboldt, showing the composition in 100 parts:—

Urate of ammonia	9·0
Oxalate of ammonia	10·6
Oxalate of lime	7·0
Phosphate of ammonia	6·0
Phosphate of ammonia and magnesia	2·6
Sulphate of potash	5·5
" soda	3·3
Sal-ammoniac	4·2
Phosphate of lime	14·3
Clay and sand	4·7
Water and organic matter	32·2

But perhaps the *constitution* of guano is better exhibited by the following analysis of three sorts by Denham Smith:—

AMERICAN GUANO.—*Analysis of three sorts by Denham Smith.*

1. *Constituents soluble in hot water* (*in* 100 *parts of Guano*).

	I.	II.	III.
Phosphate of lime	0·186	...	0·110
" soda	0·120	...	...
" ammonia and magnesia	0·564	0·784	0·133

Humus	2·636	0·862	0·826
Organic matter	3·456	...	...
Water	...	4·974	...
Loss	0·044	0·498	...

We may also quote the following analysis by Dr. Ure, of guano, imported from Bolivia, by the 'Mary Anne,' being the first cargo thence imported.

It was of a pale yellow-brown colour, dry, partly pulverulent, partly concreted, in small lumps. Its mean specific gravity was 1·63.

The *soluble* portion was found to contain :—

Urea	5·0
Sulphate of potash	7·9
Chloride of sodium	5·0
Phosphate of ammonia	5·5
Oxalate of ammonia	0·6
	24·0

The *insoluble* portion contained :—

Silica	2·25
Phosphate of lime	9·00
Phosphate of magnesia and ammonia	1·25
Urate of ammonia	15·27
Undefined nitrogenised organic matter, yielding by combustion with soda-lime 17·05 parts of ammonia	41·73
	69·50

The total quantity of ammonia yielded by it was 20·95 per cent.

Analysis of Cincha Island Guano. (*Ure.*)

		Ammonia
Matter soluble in water	47·00	
consisting of—		
Sulphate of potash, with a little sulphate of soda	6·00	
Muriate of ammonia	3·00	0·95
Phosphate of ammonia	14·32	4·62
Sesquicarbonate of ammonia	1·00	0·34
Sulphate of ammonia	2·00	0·50
Oxalate of ammonia	3·23	0·89
Water	8·50	
Soluble organic matter and urea	8·95	
	47·00	
Matter insoluble in water	53·00	
consisting of—		
Silica	1·25	
Undefined organic matter	9·52	
Urate of ammonia	14·73	1·23
Oxalate of lime	1·00 ?	
Subphosphate of lime	22·00	
Phosphate of magnesia and ammonia	4·50	0·32
	53·00	8·35

Valuable as these elaborate analyses are in a scientific point of view, they are quite unnecessary for practical purposes in ascertaining the value of any given sample, for on which of these various constituents does the chief efficacy of guano depend?

Ammonia.—Undoubtedly *one of the most*, if not *the most*, important constituents of guano is the *ammonia*. Authors differ as to the precise manner in which ammonia and its salts act in promoting the growth, and especially in the development of the nitrogenised compounds of plants; but the fact is placed beyond dispute, whether it be that the ammonia contained in the air is decomposed by the leaves, or that the salts of ammonia are absorbed by the spongioles of the roots in solution in water. Now, it is quite possible that, in the mysterious economy of the life of the plant, the ammonia may perform a slightly different function when in different states of combination, either with hydrochloric, sulphuric, nitric, phosphoric, carbonic, uric, humic, or oxalic acids; and although, as a general rule, we should be inclined to yield the palm in point of utility to the more soluble combinations, yet all experience goes to show that the value of an ammoniacal manure may be measured chiefly, if not entirely, by the *quantity* of that compound present, and is in a great measure independent of its state of combination.

The *amount of ammonia* corresponding to the total quantity of nitrogen in the *several varieties of guano* ranges as follows:—

	Maximum	Minimum	Mean
1. *Peruvian.*			
(From 9 analyses by Way[1]) of samples imported in 1847–8	18·94	16·40	17·67
From Mr. Way's analyses of 10 samples imported in 1848–9	17·81	15·98	16·189
From Mr. Way's analyses of 14 samples imported in 1849	18·94	16·82	17·88
Mean	...	...	17·246
So that the average quantity of ammonia, either existing in, or capable of being yielded by genuine Peruvian guano, may be estimated at about 17 per cent.			
2. *Angamos* guano.			
Ammonia (actual and potential) from two analyses by Dr. Ure	20·89	20·40	20·64
So that this variety is slightly richer in ammonia and nitrogenised compounds than the Peruvian.			
3. *Ichaboe* guano.			
Ammonia (actual and potential) from 11 analyses by Dr. Ure and Mr. Teschemacher	9·5	4·5	7·3
Showing that this variety, as far as regards nitrogenised compounds, is far inferior to the preceding; and the same remark applies to the succeeding varieties, *e.g.*:—			
4. *Patagonian* guano.			
From analyses of 14 samples by Dr. Ure and Mr. Teschemacher	4·68	1·60	2·54
5. *Saldanha Bay* guano.			
From results of analyses of 9 samples by Mr. Way	2·49	0·94	1·68
From results of 9 analyses by Dr. Ure and Mr. Teschemacher	2·10	1·25	1·56
6. *Kooria Mooria.*			
From results of 3 analyses by Mr. Nesbit	0·34	0·17	0·25
From results of 3 analyses by Mr. Apjohn	0·318	0·127	0·22

So that the average quantity of ammonia in the several varieties is—

Peruvian	17 per cent.	Patagonian	2·5 per cent.
Angamos	20 „	Saldanha Bay	1·5 „
Ichaboe	7 „	Kooria Mooria	0·25 „

---

[1] 'On the Composition and Money Value of the different kinds of Guano.' By S. Thomas Way, &c. 'Journal of the Agricultural Society of England,' p. 202, &c.

Dr. Ure drew a distinction between what he called the *actual* and *potential* ammonia, *i.e.* between ammonia and ammoniacal salts ready formed, and compounds, such as uric acid, which during their decay are gradually converted into ammonia. It appears that recent guano contains from 3 to 5 per cent. of uric acid, whilst the older deposits contain generally less than 1 per cent. No doubt the guano at the time of its deposition consisted chiefly of uric acid; and it is this uric acid which has become converted into salts of ammonia; for the excrements of birds which live chiefly on fish are found to contain from 50 to 80 per cent. of uric acid. It is also an established truth in agricultural chemistry that a manure which contains bodies capable of *gradually* yielding up any valuable compound, such as ammonia, are more useful than those which contain that compound ready formed, and in the state of soluble combinations, which the first storm of rain may wash away from the roots of the plants, where they are required. Nevertheless, admitting the truth of all this, the writer is of opinion (and he believes this is the general experience of agriculturists) that the importance of this distinction between *actual* and *potential* ammonia has been rather exaggerated; and that generally it is enough for all practical purposes, in estimating the value of a guano, to determine the total quantity of nitrogen present in every form, and to consider it as representing an equivalent quantity of ammonia '*in esse*' or '*in posse*.'

Potash.—Of the two alkalis, potash and soda, the soil usually contains more than sufficient soda for the supply of vegetation; it is therefore chiefly potash which it is necessary to add in the form of manure.

Besides, even the best guano always contains a considerable quantity of common salt, viz. from 1·0 to 2·5 and even 5 per cent.

Mr. Way, in his valuable paper, 'On the Composition and Value of Guano,' only gives the quantity of alkaline salts, not having determined the potash; but the average quantity of potash in genuine guano may be seen by referring to the analyses before given in detail, and will be found to vary from 3 to 4 per cent.

However, in estimating the value of guano the knowledge of the quantity of potash is by no means of the same importance as of the ammonia, or of the phosphoric acid.

Phosphoric acid.—The phosphoric acid is second in importance to no other constituent than the ammonia; being essential for the development of the seeds and all those parts of the vegetable organism which serve as foods in the production and restoration of the flesh and bones of animals. It exists in the guano (as is shown by the preceding detailed analyses) in combination with ammonia, potash, soda, and lime.

In most analyses the quantity of phosphate of lime, $3CaO,PO^5$, is given instead of phosphoric acid, PO^5 or $3HO,PO^5$; but 156 parts of phosphate of lime ($3CaO,PO^5$) correspond to 72 of phosphoric acid (PO^5), or as 13 to 6.

The amount of phosphate of lime in the several varieties of guano is as follows:—

	Maximum	Minimum	Mean
Peruvian.			
From analyses of 9 samples by Way, imported in 1847–8	34·45	19·46	26·95
From Mr. Way's analyses of 10 samples, imported in 1848–9	25·30	21·31	23·30
From Mr. Way's analyses of 14 samples, imported in 1849	28·98	21·28	25·13
Angamos.			
From 2 analyses by Dr. Ure	22·00	18·50	20·25
Ichaboe.			
From 11 analyses by Dr. Ure and Mr. Teschemacher	37·00	26·00	31·50
Patagonian.			
From analyses of 14 samples by Dr. Ure and Mr. Teschemacher	65·5	29·3	47·4
Saldanha Bay.			
From analyses of 9 samples by Mr. Way	60·96	49·01	54·98
From analyses of 9 samples by Dr. Ure and Mr. Teschemacher	62·5	51·0	56·7
Kooria Mooria.			
From analyses of 3 samples by Mr. Nesbit	25·50	2·80	14·15
From analyses of 3 samples by Mr. Apjohn	28·50	5·84	17·17

So that the average quantity of phosphate of lime in the several specimens is as follows:—

Peruvian	25·12	Patagonian	47·4
Angamos	20·25	Saldanha Bay	55·84
Ichaboe	31·50	Kooria Mooria	15·66

These facts are very suggestive as showing how guano, by exposure to air and moisture, has the ammoniacal salts washed out, at the same time, as a consequence, increasing the *ratio* of phosphates.

Organic Matter.—The amount of organic matter in guano, other than ammonia and its salts, is of no great importance in estimating its value as a manure. Not unfrequently the amount of organic matter, containing uric acid or ammoniacal salts, is stated in analyses, as organic matter '*rich in*' or '*containing ammonia*;' but it is obvious such analyses are nearly worthless, the value of the guano depending essentially on the quantity of *nitrogen*, either existing as ammoniacal salts or capable of being converted into them. Good guano contains on an average about 50 per cent. of ash (mineral matter) and 50 per cent. of combustible (organic) matters.

Sand.—The knowledge of the proportion of sand in a guano is of some importance as determining its purity or otherwise. It is easy to understand how a deposit like guano, existing often near the sea-shore, and frequently on a sandy soil, should contain a certain admixture of sand. Some specimens are almost free from it, and few genuine specimens contain more than from 1 to 2 per cent.

Common salt.—The presence of common salt in a guano need not surprise us. It is doubtless derived from the sea, partly through the medium of the birds themselves, and partly from the evaporation of the salt spray continually driven upon the coasts by the wind. It is variable in quantity, as we should expect from a knowledge of its origin, ranging in samples of genuine guano from 1 to 5 per cent. Although common salt has been shown[1] to possess a certain power of absorbing ammonia, yet this is but transient, and the efficacy of guano cannot be said to depend to any extent upon the sea-salt present in it. The knowledge of its amount is of great importance, since the guano is not unfrequently adulterated with salt.

Water.—Obviously the greater the amount of water present in guano, the smaller will be the proportion of valuable constituents in a given weight. Genuine guano contains on an average from 10 to about 20 per cent. of water. Many of the salts in guano are likewise deliquescent, so that it has a tendency to become moist by exposure to the air: and this tendency to absorb moisture is an element of value in the manure, especially in dry seasons.

Calculation of the money value of guano from the results of analyses.—In a most important and interesting paper 'On the Value of Artificial Manures,'[2] Mr. Way arrives at certain money values for ammonia, phosphoric acid, and the various constituents of guano and other manures, by a comparison with the cost of these several compounds in their ordinary commercial salts. These numbers will be found most valuable to the agriculturist in drawing his own conclusions respecting the value of a guano or other manure from the results of analysis furnished to him by the chemist. They are as follows:—

	£	
Ammonia	56	per ton.
Potash	31	,,
Phosphate of lime (insoluble)	7	,,
Phosphate of lime (soluble)	32	,,
Organic matter	1	,,

and the following example of their application may prove useful.

Calculation of the money value of guano, as deducted from the cost of its several constituents in their commercial salts, applied to the mean composition of Peruvian guano deduced by Mr. Way from 78 analyses:—

100 tons contain		£		£
Ammonia	16·5	at 56	per ton	930
Organic matter	52·0	,, 1	,,	52
Potash	3·5	,, 31	,,	108
Insoluble phosphate of lime	23·0	,, 7	,,	161
Soluble phosphate of lime	7·0	,, 32	,,	224
		Value of 100 tons		£1,475

Or, per ton . . 14*l.* 15*s.*

---

[1] A. B. Northcote, on the Function of Salt in Agriculture, Phil. Mag. x. 179.

[2] Agricultural Journal, xvi. 533.

Hence it is obvious that whilst guano was selling at 11*l.* per ton, it was more economical and convenient to employ it than to make an artificial mixture of its chemical constituents; but now that the price has risen, it becomes a question whether it will not be possible to produce an artificial compound having equal value as a manure which will compete in price with the guano.

Impurities and adulterations.—In consequence of the high price of guano, the great demand for it, and the ease with which the unwary farmer may be imposed upon, guano is adulterated with various substances, and to a great extent. Impositions even have been practised by selling as genuine guano artificial mixtures, made to look so much like guano that the farmer would scarcely detect it. The writer recollects examining a guano which contained 50 per cent. of sand, and no less than 25 per cent. of sea-salt; and Dr. Ure gives the following analysis of an article sent to him, which had been offered to the public by advertisement as Peruvian guano, which contained—

Common salt	32·0
Sand	28·0
Sulphate of iron	5·2
Phosphate of lime	4·0
Organic matter (from bad guano, to give it smell)	23·3
Moisture	7·5
	100·0

In fact, so numerous and various are the tricks played with guano, that unless a sample is submitted to a skilful chemist for analysis before purchase, we would strongly recommend the agriculturist to purchase of no one but dealers of unquestionable honour.

Professor Johnstone observes:—'Four vessels recently sailed hence for guano stations, ballasted with gypsum, or plaster-of-Paris. This substance is intended for admixture with guano, and will enable the parties to deliver from the vessel, a nice-looking and light-coloured article. The favourite material for adulterating guano at the present moment is umber, which is brought from Anglesea in large quantities. The rate of admixture is, we are informed, about 15 cwts. of umber to about 5 cwts. of Peruvian guano, from which an excellent-looking article, called African guano, is manufactured.'

Analysis of Guano.

The following is Dr. Ure's method for the complete analysis of guano:—

1. In every case I determine, first of all, the specific gravity of the guano; which I take by means of spirits of turpentine, with a peculiar instrument contrived to render the process easy and precise. If it exceeds 1·75 in density, water being 1·0, it must contain sand impurities, or has an excess of earthy phosphates, and a defect of azotised animal matter.

2. I triturate and digest 200 grains of it with distilled water, filter, dry the insoluble matter, and weigh it.

3. The above solution, diffused in 2,000 gr. measures, is examined as to its specific gravity, and then with test-paper, to see whether it is acid or alkaline.

4. One half of this solution is distilled along with slaked lime in a matrass connected with a small quintuple globe condenser, containing distilled water, and immersed in a basin of the same. As the condensing apparatus terminates in a water-trap, no part of the ammonia can be lost; and it is all afterwards estimated by a peculiar meter, whose indications make manifest one hundredth part of a grain.

5. The other half of the solution is mixed with some nitric acid, and divided into three equal portions:

a, the first portion, is treated with nitrate of baryta, and the resulting sulphate of baryta is collected, ignited, and weighed.

b, the second portion, is treated with nitrate of silver, and the resulting chloride of silver ignited and weighed.

c, the third portion, has a certain measure of a definite solution of ferric nitrate mixed with it, and then ammonia in excess. From the weight of the precipitated subphosphate of iron after ignition, the known amount of oxide used being deducted, the quantity of phosphoric acid in the soluble portion of the guano becomes known.

d, the three above portions are now mixed, freed by a few drops of dilute sulphuric and hydrochloric acids from any baryta and silver left in them, and then tested by nitrate of lime for oxalate of ammonia. The quantity of oxalate of lime obtained determines that point.

6. The last liquor filtered, being freed from any residuary particles of lime by oxalate of ammonia, is evaporated to dryness and ignited, to obtain the fixed alkaline matter. This being weighed, is then dissolved in a little water, neutralised with acid, and treated with soda-chloride of platinum. From the quantity of potash-chloride of platinum, which precipitates, after being filtered, dried, and weighed, the amount of potash present is deducted; the rest is soda. These bases may be assigned to the sulphuric, hydrochloric, and phosphoric acids, in proportions corresponding to their respective affinities.

7. The proportion of organic matter in the above *solution* of guano, is determined directly by evaporating a certain portion of it to dryness, and igniting. The loss of weight, minus the ammonia and oxalic acid, represents the amount of organic matter.

8. A second portion of a solution of the guano is evaporated to dryness by a gentle steam heat, weighed, inclosed in a stout well-closed phial along with alcohol of 0·825, and heated to 212°. After cooling, the alcoholic solution is decanted or filtered clear, evaporated to dryness by a gentle heat, and weighed. This is urea, which may be tested by its conversion into carbonate of ammonia, when heated in a test-tube or small retort. In this way I have obtained from Bolivian guano 5 per cent. of urea; a certain proof of its entire soundness.

9. *Analysis of the insoluble matter.*—One third of it is digested with heat in abundance of borax-water, containing $\frac{1}{100}$ of the salt, filtered, and the filter dried by a steam heat. The loss of weight indicates the amount of uric acid, which is verified by supersaturating the filtrate with acetic or hydrochloric acid, thus precipitating the uric acid, throwing it upon a filter, drying, and weighing it. This weight should nearly agree with the above loss of weight, the small difference being due to soluble organic matter, sometimes called geine and ulmic acid. The uric acid is evidenced, 1, by its specific gravity, which I find to be only 1·25, as also that of the urate of ammonia; 2, by its affording fine purple *murexide* when heated in a capsule along with nitric acid, and then exposed to the vapour of ammonia from a feather held over it; 3, by its dissipation when heated, without omitting an empyreumatic odour.

10. Another third of the solid matter is distilled along with half its weight of slaked lime, and 10 times its weight of water, in the apparatus already described, and the ammonia obtained from it estimated.

11. The remaining third having been ignited, is digested with a gentle heat in weak hydrochloric acid, and the undissolved silica and alumina washed on a filter, dried, and weighed. To the hydrochloric solution, dilute sulphuric acid is added, and the mixture is heated till all the hydrochloric acid be expelled, with the greater part of the water. Alcohol of 0·850 is now poured upon the pasty residuum, and the whole, after being well stirred, is thrown upon a filter. The phosphoric acid passes through, as also the magnesia in union with sulphuric acid. The sulphate of lime, which is quite insoluble in spirits of wine, being washed with them, is dried, ignited, and weighed. From the weight of sulphate of lime, the quantity of phosphate of that earth that was present becomes known.

12. Ammonia in excess is now added to the filtrate, which throws down the granular phosphate of ammonia and magnesia. After washing and drying this powder at a heat of 150°, its weight denotes the quantity of that compound in the guano.

13. To the filtered liquor (of 12), if a little ammonia be added, and then chloride of magnesium be slowly dropped in, phosphate of ammonia and magnesia will precipitate, from the amount of which the quantity of phosphoric acid may be estimated.

14. The proportion of oxalate of lime is determined by igniting the washed residuum (of 9), and placing it in an apparatus for estimating the quantity of carbonic acid given off in dissolving carbonate of lime. I have rarely obtained more than ½ gr. of carbonic acid from the insoluble residuum of 100 gr. of good guano, and that corresponds to less than 1½ per cent. of oxalate of lime in the guano. Sometimes no effervescence is at all to be perceived in treating the washed residuum with acid after ignition.

15. The carbonate of ammonia in guano is readily determined by filtering the solution of it in cold water, and neutralising the ammonia with a test or alkalimetrical acid.

16. Besides the above series of operations, the following researches must be made to complete our knowledge of guano. The insoluble residuum (of 10), which has been deprived by two successive operations of its uric acid and ammonia, may contain azotised organic matter. It is to be therefore well dried, mixed with 5 times its weight of the usual mixture of hydrate of soda and quicklime, and subjected to gentle ignition in a glass or iron tube closed at one end, and connected at the other with an ammonia-condensing apparatus. The amount of ammonia, being estimated by a proper ammonia-meter, represents the quantity of azote, allowing 14 of this element for 17 of ammonia, being the potential ammonia corresponding to the undefined

animal matter. In a sample of Peruvian guano I obtained 5 per cent. of ammonia from this source.

17. The whole quantity of ammonia producible from guano is to be determined by gently igniting 25 gr. of it well dried, and mixed with 10 times its weight of the mixture of hydrate of soda and quicklime (2 parts of the latter to 1 of the former). The ammonia disengaged is condensed and measured, as described above.

18. The ready-formed ammonia is in all cases determined by distilling a mixture of 100 gr. of it with 50 gr. of slaked lime, condensing the disengaged ammonia, and estimating it exactly by the meter.

19. The relation of the combustible and volatile to the incombustible and fixed constituents of guano, is determined by igniting 100 gr. of it in a poised platinum capsule. The loss of weight denotes the amount of combustible and volatile matter, including the moisture, which is known from previous experiments.

20. The insoluble matter is digested in hot water, thrown upon a filter, dried, and weighed. The loss of weight is due to the fixed alkaline salts, which, after concentrating their solutions, are investigated by appropriate tests: 1, nitrate of baryta, for the sulphates; 2, nitrate of silver, for the chlorides and sulphates; and 3, bichloride of platinum, for distinguishing the potash from the soda salts.

21. The insoluble matter (of 20) is digested with heat in dilute nitric or hydrochloric acid, and the whole thrown upon a filter. The silica which remains on the filter is washed, ignited, and weighed. The lime, magnesia, and phosphoric acid may be determined as already pointed out.

If, however, the remarks made in an earlier part of this article be correct, it is altogether unnecessary, in order to ascertain the commercial value of a sample of guano, to perform so elaborate a series of operations as that described above.

The following points are all that are required to be investigated:—

The amount of water; organic matter; nitrogen; proportion of ash; analysis of the ash as to phosphoric acid and alkalis—potash and common salt; sand.

1. *Water.*—The most delicate and troublesome operation is perhaps the determination of the amount of water. If the substance be dried in the water-oven, as is the usual practice, at 212° F., a very large quantity of ammonia is expelled: so that it becomes necessary to desiccate by protracted exposure under a bell-glass, over a vessel of sulphuric acid. Even in this manner, the error is not entirely eliminated, and Mr. Way suggests treating the specimen in a shallow platinum dish, with a few drops of hydrochloric acid, which is allowed to soak through the whole: he states, that it may then be dried at 212° F., without loss.

2. *Organic matter.*—The proportion of organic matter is determined in the usual way, by burning it off in an open platinum crucible, until nothing is left but the white or brownish white ash, which is then weighed.

3. *Determination of nitrogen.*—This is best performed by Will and Varrentrapp's process. See Watts's 'Dictionary of Chemistry.'

4. *Phosphoric acid.*—The phosphoric acid in the ash of the guano is determined by conversion into perphosphate of iron, and then separation as ammonia-magnesia phosphate, in the usual way. Under the head of ASH OF ORGANIC BODIES, in Watts's 'Dictionary of Chemistry,' will be found the general method for the complete analysis of the ashes of organic bodies, which, if it be thought desirable, may be carried out, *in extenso*, in the case of the ash of guano.

5. *Alkalis.*—This is, however, scarcely necessary, so long as the alkalis are determined to ascertain the amount of the valuable alkali potash, and the extent of contamination with common salt.

6. *Sand.*—The quantity of sand is determined by treating a portion of the dried guano with hydrochloric acid and water, till nothing more is dissolved, then igniting, and weighing the residue.

Statistics of the guano trade at Peru.—We extract the following from an article published in the official journal at Lima:—The exportation of guano began in 1841, under the contract with the house of Messrs. Quiros, Allier, and Co. Up to the end of 1856, the exportation from the Cincha Islands has been 1,967,079 tons, of which 1,626,405 tons were sold, and 23,885 were lost at sea. The stock in hand of the company was 316,789 tons. The gross proceeds of all these sales came to $100,263,518; the charges amounted to $ 61,008,881, leaving net proceeds, $ 39,254,647; say at 1*l.* per $ 5—7,850,927*l.* In the year 1857 the exportation amounted to 472,965 tons, which, added to 316,789 tons, left on hand in the previous year, gives 789,754 tons; of these 304,589 tons were sold, and 19,156 were lost at sea, leaving 466,009 tons. The net profit that year was $ 12,531,016, or at $ 5 per 1*l.*—2,507,703*l.*

In addition to the importation of guano already given on p. 741, the Trade and Navigation Returns for 1872 give the following statement under the head of 'Manures unenumerated,' which will evidently comprehend some guanos—the remainder being chiefly phosphates of lime:—

	Tons	Value £
From Germany.	38,592	102,737
„ France	13,905	52,641
„ Portugal, Azores, and Madeira	15,656	61,498
„ Spain	1,649	5,894
„ United States of America .	35,446	88,811
„ Dutch West India Islands .	3,131	12,080
„ Hayti and St. Domingo . .	11,269	41,241
„ British West India Islands .	8,305	33,173
„ Other countries . . .	3,983	22,664
Total . . .	131,936	420,739

GUARANIN. In the preparation of caffeine from guarana, an alkaline compound was obtained, to which this name was given. See CAFFEINE.

GUAVA. This fruit is a native of the two Indies and the Brazils. There are two well-known varieties, the *Psidium pomiferum*, or apple-fruited guava; and the *P. pyriferum*, the pear-fruited variety. The pulpy fruits of these trees make, with sugar, excellent preserves, which are imported as Guava jelly.

GUIGNET'S GREEN. A basic hydrate of chromium, used as a pigment. See CHROMIUM.

GUINEA CORN. The grain of *Holcus Sorghum*.

GUINEA PEPPER. Another name for the Grains of Paradise.

GUIPURE. A lace made at Limerick by cutting out the pattern from cambric; the flowers and ornamental parts being formed of the cambric, and the open part of stitches which resemble the antique lace.

GUM (*Gomme*, Fr.; *Gummi, Pflanzenschleim*, Ger.) is the name of a proximate vegetable product, which forms with water a slimy solution, but is insoluble in alcohol, ether, and oils. It is converted by strong sulphuric acid into oxalic and mucic acids.

There are six varieties of gum: 1, gum arabic; 2, gum senegal; 3, gum of the cherry and other stone-fruit trees; 4, gum tragacanth; 5, gum of Bassora; 6, the gum of seeds and roots. The first five spontaneously flow from the branches and trunks of their trees, and sometimes from the fruits in the form of a mucilage which dries and hardens in the air. The sixth kind is extracted by boiling water. In commerce, under the name of gum, very different substances are confounded; thus we have *gum elemi* and *gum copal*, which are true resins; and *gum ammoniacum*, which is a gum resin; and *gum elastic* (caoutchouc), which is a peculiar body, differing from either.

Gum arabic and gum senegal consist almost wholly of the purest gum called *arabine* by the French chemists; our native fruit-trees contain some *cerasine*, along with arabine; the gum of Bassora and gum tragacanth consist of arabine and bassorine.

Gum arabic, flows from the *Acacia arabica*, and the *Acacia vera*, which grow upon the banks of the Nile and in Arabia. It occurs in commerce in the form of small pieces, rounded upon one side and hollow upon the other. It is transparent, without smell, brittle, easy to pulverise, sometimes colourless, sometimes with a yellow or brownish tint. It may be bleached by exposure to the air and the sunbeams, at the temperature of boiling water. Its specific gravity is 1·355. Moistened gum arabic reddens litmus-paper, owing to the presence of a little supermalate of lime, which may be removed by boiling alcohol; it shows also traces of the chlorides of potassium and calcium, and the acetate of potash. 100 parts of good gum contain 70·40 of arabine, 17·60 of water, with a few per cents. of saline and earthy matters. Gum arabic is used in medicine, as also to give lustre to crapes and other silk-stuffs. See ACACIA.

Gum senegal is collected by the negroes during the month of November, from the *Acacia senegal*, a tree 18 or 20 feet high. It comes to us in pieces about the size of a partridge's egg, but sometimes larger, with a hollow centre. Its specific gravity is 1·436. It consists of 81·10 arabine; 16·10 water; and from 2 to 3 of saline matters. The chemical properties and uses of this gum are the same as those of gum arabic. It is much employed in calico-printing.

Cherry-tree gum consists of 52·10 arabine; 34·90 cerasine; 12 water; and 1 saline matter. It is used by hatters for smoothing the nap.

Gum tragacanth is gathered, about the end of June, from the *Astragalus tragacantha* of Crete and the surrounding islands. It has the appearance of twisted ribands; is white or reddish; nearly opaque, and a little ductile. It is difficult to pulverise, without heating the mortar. Its specific gravity is 1·384. When plunged in water, it dissolves in part, swells considerably, and forms a very thick mucilage. 100 parts of it consist of 53·30 arabine; 33·30 bassorine and starch; 11·0 water; and from 2 to 3 parts of saline matters. It is employed in calico-printing, and by shoemakers.

Gum of Bassora. See Bassorine.

Gum of seeds, as linseed, consists of 52·70 arabine; 28·9 of an insoluble matter; 10·3 water; and 7·11 saline matter. Neither bassorine nor cerasine seems to be present in seeds and roots.

GUM, BRITISH. See Dextrine.

GUM ELASTIC. See Caoutchouc.

GUM LAC. See Lac.

GUM-RESINS. (*Gomme-résines*, Fr.; *Schleimharze*, Ger.) When incisions are made in the stems, branches, and roots of certain plants, a milky juice exudes, which gradually hardens in the air; and appears to be formed of resin and essential oil, held suspended in water charged with gum, and sometimes with other vegetable matters, such as caoutchouc, bassorine, starch, wax, and several saline matters. The said concrete juice is called a gum-resin; an improper name, as it gives a false idea of the nature of the substance. They are all solid; heavier than water; in general opaque and brittle; may have an acrid taste, and a strong smell; their colour is very variable. They are partially soluble in water, mostly soluble in alcohol; and the solution in the former liquid seldom becomes transparent. Many of the gum-resins are medicinal substances, and but little employed in the arts and manufactures. The following is a list of such:—assafœtida; gum ammoniac; bdellium; euphorbium; galbanum; gamboge; myrrh; olibanum or frankincense; opoponax; and scammony. The gum-resins which are employed in the arts or manufactures are described in this work under their peculiar names.

The following Tables give our importations of Gum and Gum-Resins from 1868 to 1870:—

Gum	1868		1869		1870	
	Cwts.	Value	Cwts.	Value	Cwts.	Value

GUM-WOOD. *Eucalyptus piperata*, or blue-gum tree of New South Wales. The wood is sent over in large logs and planks; the colour of dark Spanish mahogany, with a blue and sometimes a greyish cast. See EUCALYPTUS.

GUN BARRELS. See FIRE ARMS.

GUN COTTON. (Syn. *Pyroxyline; Fulmicoton*, Fr.) In 1833 M. Braconnot discovered that starch, by the action of monohydrated nitric acid, became converted into a peculiar substance which dissolved in excess of the acid, and was re-precipitated in a granular state on the addition of water. This substance, known as xyloidine, when washed and dried, was found to explode on contact of a light, and even if heated to 356°. It also exploded if subjected to a smart blow. The subsequent researches of M. Pelouze indicated this singular body to be starch, $C^{12}H^{10}O^{10}$ ($\mathbf{C^6H^{10}O^5}$), in which one equivalent of hydrogen is replaced by peroxide of nitrogen, or hyponitric acid. The formula of xyloidine would consequently be $\left.\begin{matrix} C^{12}H^{9} \\ NO^{4} \end{matrix}\right\} O^{10}$ [$\mathbf{C^6H^9(NO^2)O^5}$]. On the supposition of this being the correct formula, 100 parts of starch should yield 127·7 of xyloidine, and M. Pelouze obtained from 128 to 130. About thirteen years subsequently to the discovery of xyloidine, M. Schönbein announced his discovery of gun-cotton. Chemists immediately saw the analogy between the two substances, for while xyloidine appears to be derived from starch by the substitution of one equivalent of hyponitric acid for one of hydrogen, gun-cotton is derived from cellulose, $C^{12}H^{10}O^{10}$ ($\mathbf{C^6H^{10}O^5}$), isomeric with starch, by the substitution of two or three equivalents of hyponitric acid for the same number of equivalents of hydrogen.

4½ ounces pure dry nitre in fine powder.
30 drams (fluid measure) sulphuric acid, sp. gr. 1·845.
120 grains of well-carded cotton.

The cotton is to be well pulled out and immersed in the mixture of the nitre and sulphuric acid. The contact with the acid, &c., is to be insured by stirring and pulling out the cotton with two glass rods. As soon as perfect saturation is effected, which, with good management, will be in about a minute, the cotton is to be thrown into a large pan of water, and well rinsed. The vessel is to be continued under a tap until litmus-paper is no longer reddened. The cotton is to be squeezed in the folds of a clean towel, and exposed (after being again well pulled out) to a gentle heat to dry. It is curious that the most soluble cotton is often the least explosive, although there is reason to believe that the most soluble cotton is that which nearest approaches in constitution to tri-nitro-cellulose.

M. Schönbein recommends a mixture of one measure of nitric acid with three measures of sulphuric acid as the best bath for the cotton. The liquid is to be allowed to cool previous to its immersion. He also saturates the cotton with nitrate of potash, by immersing it in a solution of that salt before drying. Cotton prepared in this manner is not adapted for photographic purposes, but it is highly explosive, and therefore well fitted for blasting rocks.

The true constitution of gun-cotton is by no means well established. It appears to be very liable to differ in composition according to the method of preparation. According to M. Béchamp it is essential, in order to obtain a cotton both fulminating and soluble in ether, to operate upon the mixture of nitre and sulphuric acid before the temperature (which rises on the ingredients being mingled) has fallen. If cooling has taken place previous to the immersion of the cotton, the resulting pyroxyline is fulminating, but insoluble in ether.

The analyses of MM. Domonte and Ménard, and also of M. Béchamp, agree best with bi-nitro-cellulose; while those of Gladstone, Vankerchoff, and Reuter, Schmidt, and Hecker, and Pelouze are more in accordance with a tri-nitro-cellulose. To add to the difficulty of forming a conclusion on the subject, M. Péligot's analyses agree best with the expression $\left.\begin{matrix} C^{12}H^{10} \\ (NO^4)^2 \end{matrix}\right\} O^{12}$, which is that of bi-nitro-glucose.

According to M. Béchamp xyloidine and pyroxyline are acted on by protoacetate of iron, the original substance being regenerated. Thus xyloidine affords starch, and pyroxyline cotton. The regenerated cotton was analysed with the following result:—

Experiment		Calculation		
Carbon .	. 43·35	C^{12} =	72	44·44
Hydrogen	. 6·31	H^{10}	10	6·17
Oxygen .	. 50·34	O^{10}	80	49·39
	100·00		162	100·00

Béchamp (and others) regarded gun-cotton as containing nitric acid. The former supported his views with numerous experiments; but there are several disturbing influences preventing the products of the decomposition of gun-cotton by alkalis, &c., being regarded as sufficiently known to enable us to express a decided opinion as to its true constitution, It may be mentioned in evidence of this that during the action of caustic potash upon gun-cotton, M. Béchamp observed sugar to be produced. The latter chemist, in common with many others, doubles the formula which we, following M. Gerhardt, have provisionally adopted for cellulose; he, moreover, formulates the latter substance and its nitro-derivatives thus:—

$C^{24}H^{17}O^{17},5NO^5,2HO$ = pentanitric cellulose.
$C^{24}H^{16}O^{16},4NO^5, HO$ = tetranitric cellulose.
$C^{24}H^{17}O^{17},3NO^5$ = trinitric cellulose.
$C^{24}H^{20}O^{20}$ = cellulose.

Explosive substances analogous to gun-cotton may be prepared from many organic bodies of the cellulose kind, by immersing them in the same bath as for gun-cotton. Among these may be mentioned paper, tow, sawdust, and calico.

When collodion is wanted for an application to cut surfaces, and the cotton is with difficulty soluble in alcoholic ether, a solution may easily be obtained if the cotton be first moistened with acetic ether, and the alcoholic ether be afterwards added.

Several of the nitro-derivatives of starch and cellulose undergo spontaneous decomposition when kept for some time in stoppered bottles (*Gladstone*).—C. G. W.

When cotton wool is immersed in a mixture of strong nitric and sulphuric acids, substitution takes place immediately, and the product has only to be freed from adhering acid by washing with water, and then dried. But in order to insure the uniform production of the most highly nitrated compound, Von Lenk adopts several precautions, the most important of which are:—

1. The cleansing and perfect desiccation of the cotton previously to its immersion in the mixed acids.

2. The employment of the strongest acids procurable in commerce.

3. The steeping of the cotton in a fresh strong mixture of acids after the first immersion and partial conversion into gun-cotton.

4. The continuance of the steeping for forty-eight hours.

5. The thorough purification of the gun-cotton thus produced from every trace of free acid, by washing the product in a stream of water for several weeks; subsequently a weak solution of potash may be used, but this is not essential.

The prolonged application of these processes is absolutely necessary to ensure the thorough nitration of the cotton, and the subsequent purification of the product; for each cotton fibre is a long narrow tube, often twisted and even doubled up, and the acid has first to penetrate to the inmost depths of these tubes and afterwards to be soaked out of them; hence the necessity of time.

Sometimes, to render the gun-cotton less spontaneously explosive, and to remove the last lingering traces of free acid, it is impregnated with a solution of silicate of soda (soluble glass) which is forced into it by means of a centrifugal machine, having a central tube for supplying the solution. It is then dried by exposure to the air, whereby carbonate of soda is formed, and silica separated, and the carbonate of soda is afterwards washed out with water while the silica remains attached to the fibres.

Sometimes, again, to render the fibres soft, and diminish the danger of explosion from violent friction, the gun-cotton, after being treated with soluble glass, is immersed in a soap-ley, the excess of which is then squeezed out, and the gun-cotton finally dried.

Gun-cotton was prepared on a large scale by a process essentially the same as that of Von Lenk, at the manufactory of Messrs. Prentice at Stowmarket, previous to its destruction by fire. Preparations are now (1874) being made for resuming the manufacture in this place.

Gun-cotton prepared by Von Lenk's process is not liable to explosion by percussion; it may detonate between iron and iron if a heavy blow be struck, but only that part explodes which is hit, without communicating ignition to the surrounding particles. If a heavy blow be struck on gun-cotton with an iron hammer, upon bronze or any other comparatively soft metal, no detonation takes place. Otto found, on the other hand, that pyroxyline, prepared with nitric acid alone, explodes like fulminating mercury when struck with a hammer.

The temperature at which gun-cotton explodes has been very accurately determined by Baron von Ebner, who fixes the lowest temperature at 136° C. (2770° Fahr.); but the heat required is usually stated to be greater than this. According to Melsens, gun-cotton which has been washed with soda and retains a small quantity of the alkali, does not explode till heated to 180° C., and similar observations have been made by Payen, Pelouze, Piobert, Vankerchoff, and others.

Von Lenk's system of manufacturing gun-cotton is briefly as follows:—

'1. The carded cotton is spun into a loose yarn, varying in size and strength according to the applications it is to receive; and the yarn is made up into hanks of convenient size (weighing about three ounces).

'2. The cotton is submitted to preliminary purification, by boiling it for a few minutes in a solution of potassic carbonate, of specific gravity 1·02, separating the alkaline liquid by means of a centrifugul extractor, and washing the cotton thoroughly in water.

'3. The cotton is perfectly dried by artificial heat, immediately before its treatment with acid.

'4. The acid used for the production of the gun-cotton is prepared by mixing one part by weight of nitric acid (of specific gravity 1·52) with three parts of sulphuric acid (of specific gravity 1·84). This mixture is allowed to become perfectly cold before use.

'5. The dry cotton is immersed by small quantities (about six ounces, or two hanks at one time) in a bath of the mixed acids, which is kept as cool as possible. When the cotton has become thoroughly saturated, and has been moved about in the acid for a few minutes, it is removed from the bath to a ledge placed over it, where a portion of the acid absorbed is separated by gentle pressure. The hanks are then transferred to small covered stoneware vessels, in which they are preserved for forty-eight hours; the proportion of acid with which they are allowed to remain saturated for that period being 10·5 parts by weight to 1 of the original cotton. The vessels containing the gun-cotton and acid are kept as cool as possible by being surrounded with water.

'6. The acid removed from the bath by each successive quantity of cotton immersed is replaced by the addition of a corresponding quantity of the fresh mixture, before another quantity of cotton is treated.

'7. After the lapse of forty-eight hours, the acid is separated from the gun-cotton, as completely as possible, by mechanical means (*i. e.*, by means of the centrifugal extractors). The expressed acids are not employed again.

'8. The hanks are then drenched with water, singly, as rapidly as possible; they are afterwards washed by hand till no longer acid to the taste, and are afterwards placed in crates or perforated boxes, and kept immersed in flowing water for about three weeks.

'9. At the expiration of that time, the water is separated mechanically from the gun-cotton, and the moist skeins are boiled for fifteen minutes in a solution of potassic carbonate (of specific gravity 1·02). When the alkaline liquor has been expressed, the skeins are once more immersed, in flowing water, for a few days. The finished gun-cotton is then dried by exposure to air.

'10. It is afterwards allowed to soak for about one hour in a cold solution of sodic silicate (of specific gravity 1·072). The liquid is then expressed from the hanks in the usual manner; after which they are allowed to dry thoroughly, again washed, for five or six hours, in running water, and finally by hand. The thorough desiccation of the gun-cotton then completes its manufacture.

'The employment of the cotton in the form of hanks of loosely-spun yarn, instead of simply in the loose carded condition, considerably facilitates its conversion and purification. The proper impregnation of the cotton by the acids is more rapidly accomplished with the hanks; such manipulations as attend the separation of the main quantity of acid from the converted material, and its first rapid and complete immersion (while still saturated with the concentrated acids) into water, and are much more readily carried out with the cotton in the spun form; and, again, the exposure of the latter to the full purifying effects of a current of water, is much more simply and perfectly effected than if carded cotton be used, while the mechanical loss of wool and of gun-cotton, in the several operations of washing and expressing, is much reduced.'

Professor Abel perfectly satisfied himself of the advantages just pointed out, by operating upon considerable quantities of carded cotton wool. In these experiments it was found impracticable, moreover, except by application of very powerful pressure, to reduce the proportion of the acid which the wool retained after immersion (and which had to be left in contact with it, as prescribed) below that of fourteen parts to one of cotton; whereas with the yarn there is no difficulty in reducing the quantity, by moderate pressure, to ten parts, or even lower. The consumption of acid is therefore economized by using the cotton in a spun form.

'The preparation of the mixture of nitric and sulphuric acids, as directed by Von Lenk, involves no important point of novelty. The necessity of employing the mixture cold, and therefore of either submitting it to refrigeration before use, or of preparing a stock of the mixture some time before it was required, was well known to the earlier operators.[1]

'In the treatment of the cotton with the mixed acids, the following precautions, namely, the immersion of uniform quantities of the perfectly dry cotton in the bath of acid, the adherence to a fixed proportion in weight between the cotton and the acid with which it is left in contact, and the regular replacement of the acids removed from the bath at each successive immersion of the cotton, by a corresponding quantity of fresh mixture, combine to exert no unimportant influence upon the uniformity of the product. That such is the case has been established by manufacturing experiments. For example, on one occasion some hanks of cotton were immersed in the bath of acids without addition to the latter, of the quantity of fresh acid proportionate to the amount removed in the previous operation of immersion. The resulting product, which was in all other respects treated as usual, exhibited a decided difference, both in its composition and its explosive powers, when compared with gun-cotton previously produced, strictly according to rule, in the same bath of acids.'

Effects of heat upon gun-cotton.—The behaviour of gun-cotton under exposure,

---

[1] An observation made by Béchamp, in his Papers on Pyroxylin, that the production of a soluble or insoluble product was determined simply by conditions of temperature when the conversion was effected by means of sulphuric acid and saltpetre, induced me to ascertain by experiment whether the solubility, in alcohol and ether, of the product obtained with the employment of the prescribed mixture of nitric and sulphuric acids, increased, if the temperature of the latter was raised to about 70° C. That temperature was fixed upon for the experiment as being the average of the freshly-prepared mixture of nitric and sulphuric acids, usually employed for producing gun-cotton for photographic purposes, and which, in experiments instituted, furnished soluble gun-cotton, yielding transparent collodion. The products obtained by the action of the warm mixture upon the cotton wool exhibited no difference as regards its insolubility from the ordinary products furnished by the cold mixture. Neither was insoluble gun-cotton rendered at all soluble by being submitted to treatment with the warm mixture. Hadow has shown that a more dilute mixture of acids, which when cold, furnishes an almost insoluble product, will, if employed at a temperature of 55° C., yield perfectly soluble gun-cotton, giving a fluid transparent collodion.

even to comparatively high temperatures, is subject to very considerable modifications, which may be in great measure determined by the conditions of treatment. Illustrations of this were obtained at an early period of these investigations, in experiments instituted with the view to ascertain the average temperature at which gun-cotton explodes.

The following is a summary of the observations made on this head by Mr. Abel.

Exploding-point of gun-cotton.—The apparatus employed in the experiments on this subject consisted of a small air-bath, fitted with a thermometer, and closed with a mica-plate, having a circular opening in the centre, through which the gun-cotton might be introduced, and which was kept closed, when not in use. The mode of operating was modified in various ways. In the first instance, the gun-cotton was combed out into a very loose condition, and allowed to rest upon metal in the air-bath. The temperature of the latter was then raised very gradually from 15° C. to 204° or 205° C. When the time occupied in the passage to the maximum temperature was two hours and upwards, the gun-cotton did not explode at all (in six experiments), but gradually became dark brown, quite friable, and deprived of all explosive properties. When a considerably shorter time (about one hour) was occupied in the attainment of the maximum temperature, the gun-cotton exploded on one or two occasions, but not until its temperature had reached 205° C.

In the next experiments, the gun-cotton was employed in very small compact masses, and resting upon a wooden support, was exposed to a continuously-increasing temperature. The passage from 15° C. to the exploding-point ranged in these experiments from 45 minutes to 2 hours.

Temperature at commencement of experiment = 26° C.

No. of Experiment	Time occupied	Exploding-Point
8	45 minutes	137°·5 C.
9	1 hour 25 minutes	136°.
10	1 hour	137°·5 C.
11	1 hour	138°·5 C.
12	2 hours	138°.

Another series of experiments was instituted for ascertaining in what particular mechanical condition the gun-cotton exploded most readily, and at most uniform temperatures; and ultimately the material was employed in the form of pieces of loosely-twisted strand about 20 millimeters long, and its exploding-point was determined by first raising the atmosphere of the air-bath to 105° C., then allowing the specimen to fall upon a diaphragm of wire gauze in the air-bath, at once increasing the temperature as rapidly as possible; and carefully reading the thermometer until the explosion occurred. The results of eight observations thus conducted were as follow:—

No. of Experiments	Exploding-Point
13	151°·5 C.
14	151°
15	151°
16	150°·5 C.
17	150°·5 C.
18	148°·5 C.
19	151°
19*a*	147°

These last experiments, which appear the most trustworthy, indicate that the average temperature at which the gun-cotton explodes, when in a condition most favourable to its rapid heating, is about 150° C. For two observations, in which the gun-cotton was in a very open condition, the temperature being raised more rapidly than usual, the explosions occurred when the thermometer indicated 145° and 143°·5 C.; and in the experiments preceding these, which were differently conducted, compact gun-cotton being exposed to heat for a considerable time, the point of ignition ranged between 136° and 138°·5 C. Schrötter, Redtenbacher, and Schneider, in their report upon Von Lenk's gun-cotton, mention that 136° C. is the *lowest* temperature fixed by Von Ebner, at which this material explodes.

Action of light on gun-cotton.—The following are the results obtained up to the present time by exposure to light, under various circumstances, of gun-cotton prepared and purified, according to Von Lenk's directions.

Exposure to strong daylight and to sunlight, either in the open air, or in confined spaces for a few days (two or four), developes in the gun-cotton a very faint aromatic odour; and if litmus-paper be allowed to remain in close contact with the confined material, it acquires a rose-coloured tinge similar to that produced by carbonic acid, and recovers its original colour after brief exposure to air. If, after exposure to light in open air for some days, the gun-cotton be placed in the dark, in cases which are not air-tight, the odour becomes gradually fainter, and the effect upon litmus-paper slighter; if the packages containing the gun-cotton are air-tight, the odour and action upon litmus do not increase during storage for several years (the actual experience gained at Woolwich extends over nearly four years).

If the gun-cotton be exposed for protracted periods to daylight with free access of air, it speedily loses all odour and power of affecting litmus. If exposure to diffused daylight in confined spaces be continued, the first results of the action of light are, of course, retained; but up to the present time no single indication of their increase has been observed; indeed, the very faint acid reaction described, which was developed at first, has frequently disappeared, probably in consequence of the neutralising action of small quantities of earthy carbonates contained in the gun-cotton.

But if the material be exposed continuously in a perfectly confined space to the action of sunlight or strong daylight, it furnishes, after a time much greater evidence of change than that already described. The acidity gradually becomes more manifest; the odour increases, and becomes in time somewhat pungent, and indicative of the presence of very small quantities of nitrous acid; and litmus-paper, if confined in a vessel with gun-cotton thus exposed, becomes entirely bleached after two or three months. Although specimens of gun-cotton always undergo some spontaneous change under these very special circumstances, the decomposition proceeds with extreme slowness; and the results of the observations are, therefore, in this respect quite at variance with those recently published by De Luca, who states that the specimens operated upon by him decomposed upon exposure to sunlight, some on the first day of the experiment, others after several days' exposure.

The advantages arising from the reduction of gun-cotton fibre to a state of fine division are thus explained by Mr. Abel:—

Abundant proofs have been obtained that the long-continued wasting and the treatment with an alkaline liquid to which gun-cotton is submitted, do not completely separate from it products of the partial oxidation of organic impurities retained by the cotton up to the time of its conversion. This is unquestionably due in great measure to the tubular structure of the fibre. If the impurities were merely upon the surface of the fibre, their perfect removal by the action of solvents should be accomplished without difficulty; but it does not appear that even long-continued digestion of gun-cotton in alcohol has the effect of completely freeing it of the impurities soluble in that liquid which are locked within the fibre. The action of a warm or cold alkaline liquid upon the material might perhaps eventually result in the complete removal of these bodies; but the loss of product and destructive effect upon the fibre, resulting from any other than a brief digestion in a very dilute alkaline bath, are too considerable to admit of such a treatment. The following experiments may be quoted in illustration of this:—

A quantity of gun-cotton, which had already been submitted to the usual purification with water and a hot alkaline bath, was boiled for ten minutes in a solution of potassic carbonate, of the strength usually employed (of specific gravity 1·02). By this treatment the material sustained a loss of 3·7 per cent.; the bath having assumed an amber colour. Upon being again boiled for twenty minutes in the same alkaline bath, which thereby became considerably deepened in colour, the sample sustained a further loss of 12·09 per cent. The strength of the fibre had been considerably reduced by this treatment.

6·5 grms. of gun-cotton and 0·4 grm. of sodic carbonate were placed together with 50 cubic centims. of water in a flask, to which a vertical condenser was attached, and were heated to 100° for twelve hours. The alkali was then found to have become nearly neutralised, and the dark brown liquid contained sodic nitrate in abundance. The gun-cotton was washed and twice treated in the same manner, the alkali being neutralised on each occasion, as in the first instance.

But though it is evident that the treatment of gun-cotton with warm alkaline baths cannot be advantageously extended, satisfactory proof has been obtained that the stability of gun-cotton which has been purified as far as is possible by the present system, may be importantly increased by submitting the material to a special process of washing.

In the experiments instituted upon the application of gun-cotton as a substitute for gunpowder, some very advantageous results have attended the conversion of the material into homogeneous masses of any desirable form or density by preparing it according to the method commonly employed for converting rags into paper. In reducing the material to a very fine state of division by means of the ordinary beating and pulping machines, the capillary power of the fibres is nearly destroyed, and the gun-cotton is for a considerable period very violently agitated in a large volume of water. It would be very difficult to devise a more perfect cleansing process than that to which the gun-cotton is thus submitted; and the natural result of its application is that the material thus additionally purified acquires considerably increased powers of resisting the destructive effects of heat. Samples of the pulped gun-cotton, even in the most porous condition have been found to resist change perfectly upon long-continued exposure to temperatures, which developed marked symptoms of decomposition in the gun-cotton purified only as usual.

The pulping process applied to gun-cotton affords, therefore, important additional means of purifying the material, the value of which may be further enhanced by employing a slightly alkaline water in the pulping machine.

Shortly after the discovery of gun-cotton in 1846, attempts were made to increase the explosive force of that substance by impregnating it with a solid oxidising agent such as saltpetre. The preparations of gun-cotton were saturated in a solution of the salt, and the water was subsequently evaporated, but the quantity of the 'nitrate' or 'chlorate' which could be introduced by this, the only practical mode of treatment, was so small as to be of little value. The system of reducing gun-cotton to a fine state of division by the pulping process has, however, afforded the means of readily incorporating this substance with an agent sufficiently rich in oxygen to oxidise the whole of the carbon in the gun-cotton preparation. This requires a comparatively large proportion of saltpetre, or other analogous salt, and Mr. Abel succeeded in obtaining some very promising results in this direction.

The general mode of producing 'nitrate' or 'chlorate' preparations of gun-cotton may be briefly described as follows:—

The requisite proportion of the oxidising agent, such as saltpetre, is reduced to a very fine powder, and is then intimately mixed with the finely-divided or pulped gun-cotton, by steeping the latter in a saturated solution of the salt. The mixture is then granulated or compressed into any desired form by the usual method employed in the preparation of Abel's compressed gun-cotton.

The products obtained in this way, especially in the disc or compressed state, possess several important advantages over ordinary compressed gun-cotton. The nitrated material forms very hard masses, which are much less liable to break up or give off dust when roughly handled than the ordinary substance. This comparative hardness is probably due to the particles of the mass becoming firmly cemented together by the crystallisation of the salt on the evaporation of the water during the process of drying. Indeed, it has been found that the application of considerably less pressure than is required to produce very compact cakes of ordinary gun-cotton suffices to furnish masses decidedly superior both in hardness and compactness. Moreover, the cakes, or discs, of the nitrated preparation, when dry, are found to have become coated with a hard film of the salt, which acts as an additional protective against mechanical injury and renders the surface less dusty, and thus less readily inflammable, than the ordinary kind.

Again, it has been conclusively demonstrated by several experiments, continued for considerable periods, that the nitrated preparation is more stable when exposed to the action of high temperatures than the unimpregnated gun-cotton.

So far, therefore, as concerns the question of storage and transport, the nitrated material possesses several important advantages over ordinary compressed gun-cotton, but, on the other hand, it has two drawbacks.

It has now been decided—wisely, we think—to store all large supplies of gun-cotton in the wet state, in which condition the material is perfectly uninflammable by ordinary heat. For this purpose the discs of gun-cotton are packed in large wooden waterproof tanks, fitted with means of drainage. A tank holds a ton of gun-cotton discs, each disc being three inches in diameter by about two inches in depth, and the ordinary material is wetted by simply filling the tank with water, and allowing the latter to drain off.

With the nitrated preparation, however, it is desirable that a weak solution of saltpetre instead of pure water should be used in wetting the gun-cotton.

We do not urge this as a serious drawback; but it is evident that the process of wetting, and re-wetting when necessary, a store of ordinary gun-cotton is a comparatively simple process, whereas the same operation might, in the case of nitrated gun-cotton, be attended with more or less difficulty under certain circumstances of storage.

Again, the wet nitrated preparation does not dry so readily as the ordinary material; but, on the other hand, this objection is almost negatived by the fact that wet gun-cotton, whether nitrated or not, can be detonated, and made to produce equal, if not superior, effects to the substance in the dry state. Gun-cotton has been detonated with most destructive effect under water, by simply filling a bag net with discs, and exploding them by means of one dry disc enclosed in a waterproof envelope. The detonating fuse is inserted in the dry disc, and its detonation determines that of all the remaining discs, although the latter are absolutely immersed in, and in contact with, the water.

In comparing the explosive action of equal weights of compressed gun-cotton and of the 'nitrate' mixture, it must be borne in mind that a considerable percentage of the total mass of the latter is formed of a material of about one-sixth the cost of pure gun-cotton. Thus a 'nitrate' mixture, prepared with the full theoretical proportion (about 38 per cent. by weight) of the oxidising agent, will not quite equal the effects obtained from the same total weight of ordinary compressed gun-cotton. In other words, the force of the explosion of, say, 100 lbs. of a material which consists of 38 lbs. of nitre and 62 lbs. of gun-cotton will not equal that of 100 lbs. of pure gun-cotton. Here the loss of force due to the replacement of about one-third of the gun-cotton by the salt used is not fully compensated for by the extra work obtained from the complete oxidation of the remaining two-thirds of gun-cotton. If, however, about three-fourths of the theoretical amount of the salt be employed, the mixture will, weight for weight, equal ordinary compressed gun-cotton in explosive effect, although, as we have said, a considerable proportion of the gun-cotton has, in the nitrated preparation, been replaced by a comparatively inexpensive substance. Thus the use of nitrated gun-cotton will be attended by material advantage in point of economy.

But if equal *volumes* of highly-compressed gun-cotton, and of the 'nitrate' or 'chlorate' mixture, similarly compressed, are compared, the explosive force of the latter will be found to be much greater. Chlorated gun-cotton is decidedly more violent in its action than the nitrated mixture, but it is more costly to manufacture, and more dangerous to store and use. The 'chlorate' salt is comparatively high in price, and more of it is required to furnish the requisite amount of oxygen; it is, moreover, very susceptible of ignition by friction or percussion, and is, therefore, comparatively dangerous. For these reasons it does not compare favourably with the 'nitrated' preparations. Of the latter the best is that in which saltpetre is used. It is the most readily prepared, and its tendency to absorb moisture is not appreciably greater than that of ordinary compressed gun-cotton.

Important experiments have been instituted jointly by the Special Committee on Gun-cotton, the Torpedo Committee, and the Royal Engineers Committee, on the comparative explosive properties of ordinary gun-cotton, both in the dry and wet states, and of nitrated gun-cotton under similar conditions.

Some of these experiments are made by exploding under water equal weights of the several substances under identical circumstances, and registering the resulting pressure or blow by a 'crusher' gauge somewhat similar to the pressure gauge used by the Committee on Explosives in determining the explosive force of gunpowder in the chamber of a gun.

Experiments have also been made to ascertain the rapidity of detonation; in other words, the rate at which a string or row of gun-cotton discs placed close to one another will successively explode if detonated at one extremity. For this purpose the beautiful chronoscope invented by Captain Andrew Noble, F.R.S., has been successfully employed. This instrument is designed to measure very minute portions of time, and by arranging the primary conducting wires at equal intervals along a long row of gun-cotton discs a register is obtained of the time occupied in successively breaking the wires as the explosive wave flashes along the row. It has thus been ascertained that the rapidity of the detonation of gun-cotton is about 20,000 feet per second.

The expansive velocity of the gases generated by the explosion of gunpowder has been reckoned at about 7,000 feet per second, so that, according to this estimate, gun-cotton has about three times the explosive rapidity of gunpowder. It is probable that the destructive force of an explosive substance bears a close analogy to the rapidity with which the explosion is transmitted, and the experiments we allude to may furnish most interesting and valuable results. But, whatever may be the method followed in experiments, the considerable advantage which the nitrated gun-cotton possesses, both in point of cost and power, added to the fact that it is so readily susceptible of ignition by detonation, renders it highly probable that this preparation of gun-cotton will be largely substituted for the ordinary compressed material in many of its applications.

Moreover, the circumstance that carbonic oxide, a poisonous gas which is produced in considerable amount upon the explosion of ordinary gun-cotton, is present in the products of explosion of nitrated gun-cotton in scarcely higher proportion than in those of gunpowder, appears likely to remove that objection to the employment of gun-cotton in military mines, which arose from the large quantity of carbonic oxide developed when heavy charges of gun-cotton were exploded.

Abel has made a series of ingenious experiments on the combustion of gun-cotton. He finds that when quantities of gun-cotton, varying from one to two grains, in the form of a loose twist laid double, are ignited by means of a platinum wire in highly rarefied atmospheres, they burn very slowly, presenting by daylight an appearance as if they smouldered. The pressure in the case described must not exceed 8 inches of mercury, but the rarefaction necessary for the result varies with the quantity of gun-cotton, its mechanical condition, its position with reference to the source of heat, the quantity of heat applied, and the direction of its application.

Gun-cotton, when ignited in small quantities in rarefied atmospheres, may exhibit during its combustion three distinct luminous phenomena. In the most highly rarefied atmospheres, the only indication of combustion is a beautiful green glow, or phosphorescence, which surrounds the extremity of the gun-cotton, as it is slowly transformed into gases or vapours. When the pressure of the atmosphere is increased to one inch (with the proportion of gun-cotton indicated), a faint yellow flame appears at a short distance from the point of decomposition; and as the pressure is increased, this pale yellow flame increases in size, and eventually appears quite to obliterate the green light. Lastly, when the pressure of the atmosphere and consequent proportion of the oxygen in the confined space is considerable, the cotton burns with the ordinary bright yellow flame. There can be no doubt that this final result is due to the almost instantaneous secondary combustion, in the air supplied, of the inflammable gases evolved by the explosion of the gun-cotton. The pale yellow flame will take place in rarefied nitrogen.

In a series of experiments made under gradually-diminished pressures, oxygen being used, instead of air, it was found that the gun-cotton exploded instantaneously with a bright flash until the pressure was reduced to 1·2 inch; from this pressure to that of 0·8 inch, it still burned with a flash, but not instantaneously, and at pressures below 0·8 inch, it no longer burned with a bright flash, but exhibited the comparatively slow combustion, accompanied by the pale yellow flame. In atmospheres of carbonic anhydride, carbonic oxide, hydrogen, and coal-gas, this pale yellow flame is seen as in nitrogen; but the two latter gases have a great tendency to extinguish the combustion, doubtless on account of their high cooling power by convection.

The slow kind of combustion of gun-cotton, in the form of twist, may be obtained also in a powerful current of atmospheric air, if the thread of cotton be placed in a somewhat narrow glass tube. Indeed, it was found that if, even for the briefest space of time, the gases resulting from the first action of heat on gun-cotton upon its ignition in open air are impeded from completely enveloping the burning extremity of the gun-cotton twist, their ignition is prevented, and the gun-cotton continues to burn in the slow and imperfect manner, undergoing a transformation similar in character to destructive distillation. By proper arrangements, these gases may be burnt at the mouth of a tube while the gun-cotton is burning in the interior. There is little doubt that these products of decomposition vary as greatly as the phenomena themselves; thus, in the instance of the most imperfect metamorphosis of gun-cotton, the products included a considerable proportion of a white vapour, slowly dissolved by water, as also small quantities of nitrous acid, and a very large proportion of nitric oxide; cyanogen, too, is always found. This contrasts strongly with the simpler products of decomposition found by Karolyi when the gun-cotton was exploded under the pressure of a confined space.

Abel considers that the remarkable facility with which the combustion of gun-cotton in the air or other gases may be modified, might be taken advantage of to produce a variety of mechanical effects; and he states, that by enclosing in suitable cases solid cords made up of two or more strands of gun-cotton more or less compactly twisted, he has succeeded in producing fuses and slow-matches, the time of burning of which may be accurately regulated. See Watts's 'Dictionary of Chemistry.'

GUN-METAL. The Austrians introduced a gun-metal, called, from its inventor, *Aich metal.* It is composed of copper, 600 parts; zinc, 382 parts; iron, 88 parts. Its tenacity is said to be excessive; it is easily forged and bored; when cold, it may be bent considerably without breaking, and we are told its resistance is far greater than iron of the best quality. See BRASS and COPPER.

GUNNERY. Under the heads of ARTILLERY and FIRE-ARMS, we have included all which appears necessary in a work of this description.

GUNNY CLOTHS or **BAGS.** The coarse sacking made in India, which is used for wrapping rice, spices, &c. The Bengal gunny cloth is made of the fibre of a species of *Corchorus*, while that of Bombay and Madras is manufactured from different kinds of sunn fibre, the *Crotolaria juncea.—Simmonds.*

GUNPOWDER. The discovery of gunpowder has been claimed for Roger Bacon and Schwartz. The ground for this appears to be no more than this. In their writings the earliest recorded mention of the discovery is made in any European language. Roger Bacon, unquestionably antecedent to his German rival, was born 1214 and died 1292; and his work, 'De Nullitate Magiæ,' appears to have been writen about 1270, while Kircher's account gives 1354 as the date of the discovery by Schwartz. It appears, however, that an Arabic manuscript exists in the collection of the Escurial which unmistakeably describes gunpowder and its properties, the date of which is anterior to 1250.—*Mallet.*

This-well known composition is employed for charging the numerous varieties of fire-arms. Its use depends upon the fact that, at the moment of ignition, violent deflagration takes place, accompanied by the evolution of a large volume of gas. It is evident that if the explosion occurs in a limited space, a vast pressure accumulates and becomes a propulsive force. The gas produced by the explosion of good gunpowder occupies nearly 900 times the volume of the powder itself; but, owing to the high temperature, the space occupied by the gas at the moment of formation is probably nearly 2,700 times greater than the volume of the powder. One of the most popular errors regarding the projectile force of explosive substances arises from the extremely vague meaning generally attached to the words strong, powerful, and other equivalent terms. It is this which leads so many to imagine the possibility of attaining marvellously long ranges by means of the various fulminating substances known to chemists. The latter are unfit for use in fire-arms, owing to a variety of circumstances. One of them is the extreme rapidity of their explosion. The whole mass appears to be converted into gas at once, whereas in gunpowder the ignition proceeds from particle to particle. The action of fulminates is also too local; if a portion of any of the more violently explosive substances be fired on a piece of metal, the latter will be perforated or depressed exactly at the spot occupied by the substance, and if it be attempted to use it to charge fire-arms, they will be destroyed, and yet, in all probability the bullet not projected. Moreover, it is impossible to use fulminates successfully for charging shells, because the latter, instead of being blown into pieces of moderate size, capable of inflicting large wounds and throwing down buildings, become converted into fragments so small as to be far less destructive.

It has been found that no composition fulfils so many requisites for charging fire-arms as a mixture, in due proportions, of sulphur, nitre, and charcoal. It is this composition which, in the form of small grains, more or less polished, constitutes gunpowder. The latter should possess several properties which, although sometimes tending in opposite directions, are not entirely incompatible, and may therefore be nearly attained in practice. Some of the principal of these are the following:—1. The proportions should be so adjusted that the combustion may be complete, and little residue be left after explosion. 2. The powder should be as little hygrometric as possible. 3. It should be sufficiently, but not too explosive. 4. It should be hard and dense enough to bear carriage without breakage of the grains.

Too great a proportion of carbon and sulphur will cause rapid fouling of the gun, and the explosive force will be less than it should be; too small a proportion of sulphur will render the powder too hygrometric. The presence of soda or chloride of potassium in the nitre will lead to the same fault. The powder must be sufficiently stamped, or it will not possess the fourth requisite.

The history of gunpowder may be conveniently studied under the following heads:—

Preparation of the ingredients.
Mixture and granulation.
Modes of estimating projectile force.
Analysis of gunpowder.

PREPARATION OF THE INGREDIENTS.

Preparation of the Nitre.—The nitre employed for powder is always in a state of almost absolute purity, especially as regards the presence of the chlorides of potassium or sodium. The crude nitre of commerce contains several impurities, among which are found nitrates of soda and lime, chlorides of potassium and sodium, and sulphates of potash and soda. They are all removed by crystallisation. The principal impurity is common salt. The process of purification is founded on the fact, that the latter substance is almost equally soluble in hot or cold water, whereas nitre is far more soluble in hot than in cold water. The following is the French mode of refining saltpetre:—1,200 kilogrammes are gently heated with 600 litres of water in a copper boiler. The solution is constantly stirred and skimmed, and more nitre is added, until the total quantity is 3,000 kilogrammes. As soon as the whole is added, and it is presumed that all the nitre is dissolved, the common salt is removed from the bottom of the boiler. The solution is now to be clarified with glue. For this purpose 400 litres of water are added by small portions, and then 1 kilogramme of the glue dissolved in hot water. The scum, which soon rises, is removed, and the fluid is boiled until clear. The whole is then allowed to cool to about 194°, and the solution of nitre is carefully decanted from the layer of common salt into the crystallising vessel. The latter is a large shallow pan with sloping sides. The fluid is constantly stirred as it cools, in order that the crystals formed may be very small; this is done in order to facilitate the washing process, and also because the fine powdery crystals are well adapted for admixture with the other ingredients. When the crystallising solution is cold, the nitre is removed to boxes containing false bottoms, pierced with holes. The aperture in the bottom of the box (below the false bottom) being closed, a saturated solution of pure nitre is poured on the crystals to dissolve out the chloride of sodium. Being already saturated, it is evident it cannot dissolve any of the nitre. After remaining two hours in contact with the nitre, the solution is allowed to run off, and when the dropping has almost entirely ceased, the process of washing is repeated, substituting pure water for the solution of nitre. The product is dried at a gentle heat, being constantly stirred to enable it to retain the pulverulent form. The power (above alluded to) possessed by a saturated solution of nitre, of dissolving other salts, has been taken advantage of in one of the processes for analysing saltpetre. Some manufacturers fuse the nitre after it has been purified by crystallisation; this process has several disadvantages, among others that of necessitating machinery to reduce it again to a pulverulent state.

Preparation of the Sulphur.—Sulphur may be purified for the gunpowder-maker by two processes. In the first the crude article is fused in an iron pot, so contrived that the fire does not play directly on the bottom, but only round its sides. The lighter impurities are to be removed by skimming, while the heavier sink to the bottom. The temperature should not be allowed to rise much above 232°, for it then becomes sluggish, and at 320° it is so thick as to prevent the impurities from being removed.

Sulphur may be more readily and economically purified by distillation. The apparatus for the purpose is exceedingly simple in principle; but the process requires care, and is not entirely free from danger. As it is not intended to obtain the sulphur in the state of flowers, the apparatus for condensation is not required to be kept cold; in fact, the still is purposely placed so near to the chamber of condensation that the sulphur may be received in the fluid state. There are several points which must be attended to in the construction of an apparatus for the distillation of sulphur; they are as follow:—1. The crude sulphur must be capable of being introduced, and the refined product removed easily, without air being, at the same time, permitted to enter the still or condenser. 2. Free means of egress for the heated air must be provided. 3. The contrivance for the latter purpose must not allow fresh air to return. 4. The process must be continuous. The still and condenser employed in France for the purification of crude sulphur fulfils all these conditions. The still is in the form of a very wide-necked tubulated retort, made of cast iron. It is set in brickwork over a furnace, and opens into a square brick chamber surmounted by a dome. The latter has a rather short chimney over it, containing a valve opening upwards to permit escape of the heated air, but not allowing anything to return. Over what may be termed the tubulature of the retort or still, is placed an iron pot with a tube communicating with it. The pot is heated by the same fire that works the still. The crude sulphur is placed in the pot, where it melts, and by raising a plug, which closes the tubulature, may be made to enter the still. The pipe forming the tubulature rises a short distance above the bottom of the iron supply-pot. This is in order that any heavy mechanical impurities may sink to the bottom, and not enter the still, and unnecessarily clog it. If the pot be always kept full of melted sulphur, and the latter is permitted to enter by raising the plug, it is evident that no air will find its way into either the retort or condenser. It is exceedingly important that this should be the case, because violent explosions are liable to occur if the highly-heated vapour of sulphur comes in contact with an oxidising medium, such as atmospheric air, which would convert it into sulphurous acid. The melted sulphur which collects on the floor of the chamber is allowed to flow out when desired, by means of an iron plug attached to a rod of the same metal. The sulphur is not allowed to run out entirely, so as to permit air to enter, for the reason stated above. The loss occurring during the purification is owing partly to oxidation, resulting in the formation of sulphurous acid, and partly to the fixed impurities contained in the crude material. See also the article SULPHUR.

Preparation of the Charcoal.—Of the three ingredients of gunpowder, the most important is generally considered to be the charcoal. Unfortunately the woods which are best adapted for the production of pyroligneous acids are not fitted for the manufacture of gunpowder; the charcoal must, therefore, be prepared specially. The following are the essential properties of good charcoal for powder:—1. It should be light and porous. 2. It should yield little ashes. 3. It should contain little moisture. The woods yielding good powder-charcoals are black alder, poplar, spindle tree, black dogwood, and chestnut. Hemp-stalks are said to yield good charcoal for gunpowder.

The operation of preparing the charcoal naturally divides itself into three processes:— 1. The selection of the wood. 2. Preparation of the wood previous to carbonisation. 3. The carbonisation.

In selecting the wood, care is to be taken to avoid the old branches, as the charcoal made from them would yield too much ashes. The bark is to be rejected for the same reason. The wood is then cut into pieces from 4½ feet to 6 feet long. If the branches used are more than ¾ of an inch in diameter, they are to be split. If the wood be too large, great difficulty will be found in uniformly charring it.

There are two methods employed in the charring of wood for gunpowder. In one, the operation is conducted in pits; but the process more commonly resorted to is distillation in cylindrical iron retorts. There are certain advantages in the pit-process, but they are more than counterbalanced by the convenience and economy of distillation. The stills used are about 6 feet long and 2 feet 9 inches in diameter. The ends of the cylinders are closed by iron plates, pierced to admit tubes of the same metal. Some of the latter are for the introduction during the carbonisation of sticks of wood, which are capable of being moved to indicate the stage of the decomposition, while another communicates with the condenser. The more freely the volatile matters are allowed to escape, the better the quality of the resulting charcoal. If care be not taken in this respect, especially as the distillation reaches its close, the tarry matters become decomposed, and a hard coating of carbon is deposited on the charcoal, which greatly lowers its quality. The process of burning in pits is considered to yield a superior coal, owing to the facility with which the gases and vapours fly off.

The degree to which the burning distillation is carried, materially influences the nature of the resulting powder. If the operation be arrested before the charcoal becomes quite black, so that it may retain a dark brownish hue, the powder will be more explosive than it would be if it were pushed until the charcoal had attained a deep black colour. When it has been found that no more volatile products are being given off, the fire is damped, and in a few hours the contents of the cylinders are transferred to well-closed iron boxes to cool. See Carbon.

Mixture and Granulation.

A very considerable number of methods have been employed at various times, for effecting that thorough incorporation of the ingredients necessary for the production of a good powder. The oldest method consists in stamping the materials in wooden mortars. The pestles are square shafts of wood ending in brass beaters. The mortars are of wood, and so shaped that any of the composition which may be forced upwards by the blows of the stampers, falls back to the bottom. In order to prevent fracture of the mortars, a piece of wood of the toughest kind should be let in on the spot where the pestle falls. The pestles are raised by means of cogs fixed on a shaft, driven by a water-wheel or steam-engine.

One of the many methods adopted to mix the nitre, sulphur, and charcoal, is by means of drums containing metallic balls; but this arrangement is inferior to that where edge-stones are employed. This last is superior to all others, the product being not only very dense and, therefore, capable of enduring, without becoming pulverulent, the motion unavoidable in carrying it about; but it is also thoroughly incorporated. It is, of course, essential that the stones, and the bed on which they work, should not strike fire during work. To secure this, they are sometimes made of calcareous stone, and sometimes of cast iron. Previous to being subjected to the action of the mill, the ingredients must be pulverised and mixed. The pulverisation may conveniently be effected in wooden drums, containing metallic balls. The pulverised materials, after being sifted or bolted, and weighed out in the proper proportions, are to be inserted in a mixing drum, containing on its inside pieces of wood projecting inwards, so that, as it revolves, complete admixture gradually takes place. The product of the last operation is now ready to be laid on the bed of the mill. During the grinding, the cake is kept moist by the addition, at proper intervals, of enough water to make it cohere. As the stones revolve, a scraper causes the material to take such a position that it cannot escape their action. The cake produced by the action of the stones is ready for graining or corning. For this purpose the cake is subjected to a powerful pressure, by means of a hydraulic press. The mass is then broken up and transferred to a species of sieve of skin or metal pierced with holes. A wooden flail is placed on the fragments, and the sieves are violently agitated by machinery. By this means the grains and dust produced by the operation fall through the holes in the skin or metal discs, and are afterwards separated by sifting. Sometimes the machinery is so arranged that the graining and separation of the meal-powder are effected at one operation. The meal powder is re-worked, so as to convert it into grains. The next operation to which the powder is subjected is glazing. Its object is to render it less liable to injury, by absorption of moisture or disintegration during its carriage from place to place. The glazing is effected by causing the grained powder to rotate for some time in a wooden drum or cylinder, containing rods of wood running from end to end. The grains as they rub against each other and against the wooden ribs, have their angles and asperities rubbed off, and at the same time the surface becomes harder and polished. It is finally dried by exposure to a stream of air, heated by means of steam.

A vast number of experiments have been made, at various times, to discover the proportions of nitre, sulphur, and charcoal best adapted for the production of gunpowder. It has been found, as might have been anticipated, that no general rule can be given, no admixture can be made which shall fulfil every requirement. Those powders which contain the largest quantities of charcoal are, it is true, as powerful as others in projectile force; but they have the disadvantage of attracting more humidity from the air. It is very singular that all nations appear to have found, by trial, the proportions most generally useful for ordinary purposes, and it is worthy of remark, that they all approximate to the percentages required by the very simple formula, $KO,NO^5 + S + 3C$. In fact, the Prussian powder approaches so closely the theoretical numbers, that they fall within the limits of the errors of analysis, thus:—

Prussian powder.		Theoretical proportions.		
Nitre	75·0	KO,NO^5	93 or 1 equivalent	74·8
Sulphur	11·5	S	16 ,, ,,	11·9
Charcoal	13·5	C	18 or 3 equivalents	13·3
	100·0		127	100·0

When a powder constituted as above is fired, the decomposition is probably as follows (represented in symbols):—

$$KO,NO^5 + S + 3C = 3CO^2 + N + KS.$$

$$[\mathbf{2(KNO^3) + S + 3C = 3CO^2 + 2N + K^2S}]$$

That is to say, the explosion of one equivalent of powder results in the formation of three equivalents of carbonic acid, one of nitrogen, and one of sulphide of potassium. It is evident that these theoretical relations are not *absolutely* the true expression of the phenomena; because, in the first place, gunpowder is merely a mechanical mixture, and not a definite chemical compound; and, in the next, the charcoal is represented by the symbol C as if it were pure carbon, whereas, in fact, even the purest and best-made charcoals contain variable amounts of hydrogen, ashes, and oxygen. The hydrogen is partly converted into water and partly into hydrosulphuric acid (sulphuretted hydrogen).

The following are the proportions of the ingredients used in various countries:—

Table of the Composition of various Gunpowders.

	Nitre	Sulphur	Charcoal
English war-powder	75	10	15
,, sporting ditto . . .	77	9	14
French war-powder	75	12·5	12·5
,, sporting ditto	76·9	9·6	13·5
,, blasting ditto	62	20	18
,, ,, ditto (another kind) .	65	20	15
United States war-powder . . .	75	12·5	12·5
Prussian war-powder	75	11·5	13·5
Russian ,, ,, ...	73·8	12·6	13·6
Austrian ,, ,, ...	75	10	15
Spanish ,, ,, ...	76·5	12·7	10·8
Swedish ,, ,, ...	75	16	9
Chinese ,, ,, ...	75·7	14·4	9·9

Blasting powders contain less nitre than others, the combustion is therefore less perfect, and if used for artillery or small arms, not only is the piece very soon rendered foul, but the ball is projected to a much less distance than is required in practice. In France, where a heavy tax is laid on sporting powders, this difference of composition prevents the cheap blasting powder from being used in fowling-pieces.

MODES OF ESTIMATING THE PROJECTILE FORCE OF GUNPOWDER.

The usual mode of determining the propulsive force of powder is by ascertaining the distance to which it can throw a ball of known weight. The instrument used in this country for this purpose consists of an 8-inch mortar charged with 2 ounces of powder, the balls being in each case of the same size and weight. The French use for the purpose an iron mortar, elevated at an angle of 45°. The mortar is 7·5 inches in diameter. The ball is of bronze, and is only 0·067 inch smaller than the bore of the gun; the windage is, consequently, very small. The charge of powder being 3·2 ounces, and the weight of the ball 65 lbs., the latter should be thrown not less than 437·5 yards.

The force of powder may also be estimated by means of an instrument, called a pendulum-gun. It consists of a gun-barrel hung at the lower end of a pendulum, so arranged that the amount of angular deviation caused by the recoil may be measured; the balls may also be fired into a cup suspended to a similiar pendulum. The data obtained serve to enable the rapidity of motion of the ball, at the moment of discharge, to be calculated by means of formulæ contrived for the purpose.

ON THE ANALYSIS OF GUNPOWDER.

Several methods have been given by various chemists for the analysis of gunpowder: the following, on the whole, appears the most effective:—The percentage of water is, in the first place, to be determined by drying *in vacuo* over sulphuric acid, until no more diminution of weight occurs. The dried powder, or a fresh quantity, is then to be washed on a filter with boiling water, until nothing more is dissolved out. The residue is to be dried below 212° and weighed; the loss is the nitre. If preferred, the solution of the nitre may be evaporated to dryness, and the residue weighed. The mixture of charcoal and sulphur is then to be digested in a stoppered flask, with bisulphide of carbon; this will dissolve out the sulphur, and leave the charcoal. The loss of weight of the dry mixture of sulphur and charcoal will enable the percentages of sulphur and charcoal to be calculated. If it be desired to know the quality of the charcoal, a combustion of it may be made with a mixture of chromate of lead and bichromate of potash. Ordinary charcoal contains from 69 to 74 of carbon, 3·9 to 5·5 hydrogen, 0·5 to 3·0 per cent. ashes. It has been attempted to dissolve out the sulphur with sulphite of soda, or caustic potash; but these methods involve several sources of error.

Good gunpowder should not lose more than 1 per cent. of moisture on drying. It should not leave alkaline globules, when exploded on a clean metallic plate. The specific gravity of a good powder should not be less than 1·755; it is sometimes as high as 1·840. The denser the powder the better it endures transportation. As the density cannot be taken in water, owing to the solubility of the nitre, turpentine or benzole must be substituted, a correction being made for the difference in density of the fluid medium.

Horsley's and Erhardt's Gunpowder.—In the 'Chemical News,' August 16, 1862, we find a short paper 'On an Explosive Compound,' by John Horsley, F.C.S. 'If nine parts of well-dried and finely-powdered chlorate of potash be mixed with three parts of fine powdered galls, a highly explosive compound is formed, which needs no granulation. As it will not admit of trituration in a mortar, the mixture should be made on paper by means of a bone spatula, or by passing it through a fine brass sieve. The strength of common gunpowder may be increased by working up with the powdered meal about 12 per cent. of powdered galls, and regranulating it. I have been acquainted with this for several years, but never published it before.'

Dr. Erhardt has yet more recently patented a powder, the peculiarity of which is that the ingredients are kept apart until they are required for use. This appears to be in one packet (chlorate of potash), and in the other, tannin. These are mixed together in certain proportions, and diluted with powdered anthracite, according to the purpose for which it may be required. As a blasting powder in quarries, Dr. Erhardt's powder is said to possess extraordinary power.

Schultze's White Gunpowder is a tri-nitro-cellulose, prepared from sawdust by the following process. The sawdust is first boiled for three or four hours with a weak solution of soda, and then boiled a second time with a fresh lot of the same solution. It is then washed in running water, afterwards steamed for fifteen minutes, and then again washed in running water for twenty-four hours. It is now bleached with chlorine or chloride of lime, boiled in water, once more washed in a stream, and then dried. The sawdust is now ready to be treated with nitric acid. For this purpose a mixture of 40 parts strong nitric acid (1·48 to 1·50) is mixed with 100 parts of sulphuric acid (1·84); and the mixture is allowed to stand two hours to cool. One hundred parts of this mixture are then placed in an iron vessel, around which a stream of cold water circulates, and six parts of the sawdust are gradually added, stirring all the time. The sawdust is allowed to remain in the acid two or three hours, the stirring being continued. After this time the whole is transferred to a centrifugal machine, and the acid separated. The wood is then washed for two or three days in cold water, afterwards boiled in a weak soda solution, again well washed in cold water, and then dried. It is now ready for the final operation, which consists in soaking it for ten or fifteen minutes in a solution of 26 parts of nitrate of potash in 220 parts of water. After this it is carefully dried at a temperature not exceeding 44° C.; the very fine dust is then separated by means of a drum sieve, and the remainder is ready for market.—'Chem. Central Blatt.,' No. 44, p. 704.

About six years since, M. Hochstädter made a comparatively safe application of chlorate of potash to explosive purposes. Unsized paper was thoroughly soaked in, and coated with, a thin paste consisting of chlorate of potash, finely-divided charcoal, a small quantity of sulphide of antimony, and a little starch, gum, or some similar binding material, water being used as the solvent and mixing agent. The paper was rolled up very compactly, and dried in that form. In this manner very firm rolls of an explosive material are obtained, which burns with considerable violence in the open air, and the propelling effect of which in small arms, has occasionally been found greater than that of a corresponding charge of rifle-powder. Moreover, the material, if submitted in small portions to violent percussion, exhibits but little tendency to detonation. But as no reliance can be placed on a sufficiently uniform action of these explosive rolls in a fire-arm, this alone sufficed to prevent their competing with powder. The same description of explosive preparation, differing only from that of Hochstädter in a trifling modification of its composition, has recently been brought forward in this country by M. Reichen and Mr. Melland.

An explosive composition was patented in this country, in which spent tan broken into small fragments was saturated with the oxidising agents, nitrate and chlorate of potash, and then dusted over with sulphur. This composition deflagrates slowly when ignited in the open air, but when confined in blast holes it exhibits sufficient explosive force to do good work.—See Abel's Lecture 'On Recent Progress in the History of Proposed Substitutes for Gunpowder,' Royal Institution, May 4, 1866, and Watts's 'Dictionary of Chemistry.'

Gunpowder rendered non-explosive: Mr. Gale's Patent. The rapidity of burning of gunpowder—which is only another name for its degree of explosiveness—depends, *cæteris paribus*, upon the facility afforded to the propagation through the mass of the heated gases generated by the first ignited portion. The requisite facility is afforded in ordinary gunpowder by breaking it up into grains, thus creating a number of crevices through which the gases can pass from grain to grain with a rapidity proportioned to the size and number of the interstices. Mr. Gale's process—which is not, we believe, employed in any country—consisted merely in filling up these crevices with finely-powdered glass or other suitable substances, thus shutting off the communication between the grains, and destroying the explosive character of the powder. He diluted the powder with so much incombustible dust as may be required to prevent the gunpowder from burning; and he restored its explosive character by simply sifting out the diluent and once more opening the pores of the powder.

Considering that nobody acquainted with the nature of gunpowder was ignorant of the simple facts upon which Mr. Gale's process was based, and that these facts were experimentally proved on a large scale by M. Piobert as far back as 1835, and by the Russian chemist Fadeieff between 1841–4; that the results of these experiments are detailed in Piobert's *Traité d'Artillerie*, and that similar experiments have been made more recently in this country, Mr. Gale could hardly claim for this proposition the originality which was at first popularly supposed to attach to it. Indeed, it seems that his process differed from that of Piobert and Fadeieff only in the employment of a different quality and larger quantity of protective powder. But the question of the probable value of the process is distinct from that of its originality. While hesitating to pronounce an opinion as to its possible occasional value for the storage of merchants' or mining powder, we may confidently assert what we believe to be the opinion of the majority of naval and military men, that for military purposes or for the treatment of powder on board our ships of war, the discovery had no practical value. It was at once open to the very definite objection that it entailed an increase of storage room to three and a half times that ordinarily required, while the transport of so much additional dead weight, whether on sea or on land, was regarded as absolutely impracticable. Such experiments as were made, moreover, exhibited a decided tendency to unmix in travelling; in other words, a tendency on the part of the powder, resulting from the different size of its grain as compared with the grains of glass-dust, to resume to a dangerous extent its explosive character; and there is little doubt that the delicate surface of powder is liable to be sensibly affected and fouled by the protective medium, while strong doubts are expressed as to the keeping qualities of the mixture, which lengthy and careful experiments alone could solve. It would always be necessary also, on service, to keep so large a supply of powder ready for immediate use as to render quite insignificant the degree of additional security which might be afforded by having the remainder non-explosive. The formidable objection to the process on the score of its entailing a considerable amount of extra manipulation of gunpowder, which would always be attended with more or less danger, delay, and uncertainty, has never, that we are aware, been satisfactorily disposed of; and officers whose opinions are entitled to every consideration object generally to a system which tends to establish in men's minds a feeling of security about a substance which, however harmless it may temporarily be rendered, must finally and frequently be handled in its explosive form.

How far, or how many of, these objections may apply to the process for civil use cannot be decided without reference to the particular circumstances of each case; but, together, they certainly appear sufficiently formidable to preclude the employment of the process for military or naval powders, either in transport or in store.

An experiment made in 1866 in a martello tower near Rye, with five tons of gunpowder rendered non-explosive by the process proposed by Mr. Gale, attracted sufficient attention to render acceptable these few words on the rationale of this so-called discovery and its probable value for military or other purposes.

The magnitude of the Rye experiment gave it a specious importance, to which it had no real claim. But when five tons of gunpowder are seen slowly burning away without any explosive effect, it is difficult to make people understand that a great practical result has not been achieved. And this was the sight by which visitors to Pett Level near Rye were rewarded. Five tons of cannon powder had been mixed with twenty tons of glass-dust, and stowed in barrels in the magazine and on the basement-floor of a martello tower. An attempt was first made to cause an explosion or a conflagration by firing one barrel, and when this failed, a sort of bonfire was ignited within the tower, which rapidly communicated from barrel to barrel, and burnt steadily, with a dense acrid smoke from the door and windows of the tower. But there was no explosion—nothing more than an occasional dull, muffled puff as the contents of a fresh barrel caught fire.

The experiment placed beyond doubt the efficiency of the method of protection proposed, even for a large mass closely stowed in a confined space; but it left the question of the wisdom of adopting that particular method precisely where it was before.

The above remarks, which completely embrace the question, are borrowed from an excellent article in the 'Pall Mall Gazette.' Little need be added to them. It will be gathered from the first paragraph that the gunpowder is not rendered really non-explosive, but that its rate of combustion is retarded. Confined in a cask or any vessel preventing the escape of the gases formed, the result would be, after a little time, an explosion.

This mixture of powdered glass with gunpowder has been recommended also for protecting gunpowder from damp; it having been forgotten that all porous bodies, and powdered glass especially, have the property of condensing moisture from the atmosphere within their pores.

Our gunpowder *Exports* have been as follow:—

Years	Lbs.	Value
		£
1868	16,721,002	394,458
1869	15,453,576	368,320
1870	17,357,668	427,229
1871	18,678,487	438,782
1872	19,889,628	485,434

GUNPOWDER, GERMAN. See EXPLOSIVE AGENTS.

GUNPOWDER, WHITE. See EXPLOSIVE AGENTS.

GUTTA-PERCHA. Although the trees yielding this substance abound in the forests of the Indian Archipelago, the first notice taken of it appears to have been by Dr. W. Montgomerie, in a letter to the Bengal Medical Board, in the beginning of

1843, wherein he recommends the substance as likely to prove useful for some surgical purposes, and supposes it to belong to the fig-tribe. In April 1843 the substance was taken to Europe by Dr. D'Almeida, who presented it to the Society of Arts of London, but it did not at first attract much attention, as the Society simply acknowledged the receipt of the gift; whereas, its value becoming known, they awarded a gold medal to Dr. W. Montgomerie.

The gutta-percha tree, or gutta turban, as it ought more properly to be called, according to Mr. Oxley, belongs to the natural family *Sapoteæ*, but differs much from all described genera, having alliance with both *Achras* and *Bassia*, yet differing in some essentials from both. It is the *Isonandra gutta* of Hooker, and is described in the 'London Journal of Botany,' 1848, where it is figured, and in Pereira's *Materia Medica.*

The tree is of a large size, from 60 to 70 feet in height, and from 2 to 3 in diameter. Its general appearance resembles the genus *Durio*, or well-known *Doorian*, so much so as to strike the most superficial observer. The under surface of the leaf, however, is of a more reddish and decided brown than in the durio, and the shape is somewhat different.

Only a short time ago the gutta-percha tree was tolerably abundant on the island of Singapore; but already all the large timber has been felled, and few, if any, other than small plants, are now to be found. The range of its growth, however, appears to be considerable, it being found all up the Malayan Peninsula, as far as Penang. The tree also occurs in Borneo, and, there is little doubt, is to be found in most of the islands adjacent.

The localities it particularly likes are the alluvial tracts along the foot of hills, where it flourishes luxuriantly, forming, in many spots, the principal portion of the jungle. But, notwithstanding the indigenous character of the tree, its apparent abundance and wide-spread diffusion, the gutta will soon become a very scarce article, if some more provident means be not adopted in its collection than those at present in use by the Malays and Chinese.

Montgomerie says, 'a magnificent tree of 50, or more probably 100 years' growth, is cut down, the bark stripped off, and the milky juice collected and poured into a trough formed by the hollow stem of the plantain-leaf; it quickly coagulates on exposure to the air; but from one tree I am told not more than 20 lbs. or 30 lbs. are procured.'

The mode in which the natives obtain the gutta is by cutting down the trees of full growth, and ringing the bark at distances of about 12 to 18 inches apart, and placing a cocoa-nut shell, spathe of a palm, or such like receptacle, under the fallen trunk, to receive the milky sap that immediately exudes upon every fresh incision. This sap is collected in bamboos, taken to their houses, and boiled, in order to drive off the watery particles and inspissate it to the consistence it finally assumes. Although the process of boiling appears necessary when the gutta is collected in large quantities, if a tree be freshly wounded, a small quantity allowed to exude, and it be collected and moulded in the hand, it will consolidate perfectly in a few minutes, and have all the appearance of the prepared article.

When it is quite pure the colour is of a greyish white; but, as brought to market, it is more ordinarily found of a reddish hue, arising from chips of bark that fall into the sap in the act of making the incisions, and which yield their colour to it. Besides these accidental chips, there is a great deal of intentional adulteration by sawdust and other materials. Some specimens brought to market do not contain much less than ¼ lb. of impurities: and even in the purest specimens, one pound of the substance yielded, on being cleansed, one ounce of impurities. Fortunately, it is not difficult to detect or clean the gutta of foreign matter, it being only necessary to boil it in water until well softened, roll out the substance into thin sheets, and then pick out all impurities, which is easily done, as the gutta does not adhere to anything, and all foreign matter is merely entangled in its fibres, not incorporated in its substance. The quantity of gutta-percha obtained from each tree varies from 5 to 20 catties, so that, taking the average at 10 catties, which is a tolerably liberal one, it will require the destruction of ten trees to produce one picul. How much better would it, therefore, be to adopt the method of tapping the tree, practised by the Burmese in obtaining the caoutchouc from the *Ficus elastica* (viz. to make oblique incisions in the bark, placing bamboos to receive the sap which runs out freely). True, they would not at first get so much from a single tree, but the ultimate gain would be incalculable, particularly as the tree seems to be one of slow growth; by no means so rapid as the *Ficus elastica.*

Properties of the Gutta-percha.—This substance, when fresh and pure, is of a dirty white colour, and of a greasy feel, with a peculiar leathery smell. It is not affected by boiling alcohol, but dissolves readily in boiling spirits of turpentine, also in naphtha and coal-tar. A good cement for luting bottles and other purposes is formed by boiling together equal parts of gutta and coal-tar and resin. When required for use, it can always be made plastic by putting the pot containing it over the fire for a few minutes. The gutta-percha itself is highly inflammable; a strip cut off takes light, and burns with a bright flame, emitting sparks, and dropping a black residuum in the manner of sealing-wax, which in its combustion it very much resembles. But the great peculiarity of this substance, and that which makes it so eminently useful for many purposes, is the effect of boiling water upon it. When immersed for a few minutes in water above 150° Fahr. it becomes soft and plastic, so as to be capable of being moulded to any required shape or form, which it retains upon cooling. If a strip of it be cut off and plunged into boiling water, it contracts in size both in length and breadth.

It is this plasticity when plunged into boiling water that has allowed of its being applied to so many useful purposes, and which first induced some Malays to fabricate it into whips, which were brought into Singapore, and led to its further notice. The natives subsequently extended their manufactures to buckets, basins, and jugs, shoes, traces, vessels for cooling wines, and several other domestic uses. Its easy plasticity and power of retaining any shape given to it when cool, at once pointed it out as suitable for the manufacture of bougies; and accordingly Dr. W. Montgomerie availed himself of this, made several of the above instruments, and recommended the use of it to the Bengal Medical Board. It also answers very well for the tubes of syringes, which are always getting out of order in hot climates, when made of caoutchouc.

Mr. T. Oxley, surgeon, Prince of Wales Island and Malacca, whose remarks are of much value from his acquaintance with the production of which he writes, says:—

'I observed in the "Mechanics' Magazine" for March 1847, a notice of several patents taken out for the working of this article by Mr. Charles Hancock, in which an elaborate process is described for cleaning the gutta, as also mention of its having a disagreeable acid smell. The gutta, when pure, is certainly slightly acid, that is, it will cause a very slight effervescence when put into a solution of soda, but is unaffected by liquor potassæ. The smell, although peculiar, is neither strong nor unpleasant, so that the article experimented on must have been exceedingly impure, and possibly derived a large portion of its acidity from the admixture and fermentation of other vegetable substances. Again: it appears to me that, if the gutta be pure, the very elaborate process described as being necessary for cleaning it, is superfluous. The gutta can be obtained here in a perfectly pure state by simply boiling it in hot water until well softened, and then rolling it out into thin sheets, when all foreign matter can be easily removed. I would recommend that the manufacturers at home should offer a higher price for the article if previously strained through cloth at the time of being collected, when they will receive the gutta in a state that will save them a vast deal more of trouble and expense than the trifling addition necessary to the original prime cost.'

In February 1847, Mr. Charles Hancock obtained a patent for improvements in the manufacture of gutta-percha. In the first place, for the construction of a slicing machine, consisting of a circular iron plate, formed with three radial slots, in which knives are fixed in a similar manner to the irons of an ordinary plane or spokeshave; the shaft which carries the plate is caused to rotate by steam or other power. The lumps of gutta-percha drop against the knives, by which they are cut into slices, of a degree of thickness corresponding to the projection given to the knives. These slices are then soaked in a vessel of hot water till they become pliable. Instead of a circular revolving cutter, a vertical cutter or chopper may be used; curved knives may be had recourse to for refractory lumps. The softened slices are next subjected to the action of breakers or rollers with serrated blades, which are mounted transversely over the tank. In front of each breaker there is a pair of fluted feeding-rollers; and the pieces of gutta-percha are passed to the rollers of the first breaker. There is an inclined endless web mounted upon two rollers, the front one of which is immersed in the water, and the other is situated opposite the space between the feeding-rollers of the second breaker. There is a second inclined web placed before the third breaker. There is also a mincing-cylinder, with radial blades working partly in the water. The feeding-rollers, and the carrying-rollers of the endless webs, are made to revolve in a forward direction, while the breakers, the mincing-cylinder, and the agitator, are made to revolve in the opposite direction. The breakers and mincing-cylinder should revolve at the rate of from 600 to 800 revolutions per minute, but the feeding-rollers and endless webs need not move faster than about one-sixth of that rate. Thus, the substance is reduced to fragments and washed in the water, the heavy impurities falling to the bottom of the tanks, and the light purer matter floating. The water should be used cold. When the gutta-percha has a fetid smell, it is treated with carbonate of soda or chloride of lime. The same apparatus may be used for purifying caoutchouc.

Mr. Hancock combined sulphur with gutta-percha in the following manner:—He found that if a minute portion of sulphur be used along with a sulphide, the best result is obtained; the proper proportions being 6 parts of sulphide of antimony, or hydrosulphide of lime, and 1 part of sulphur to 48 parts of gutta-percha. When these materials have been mixed, the compound is put into a boiler and heated under pressure to a temperature of from 260° to 300° Fahr., and it is to be left in this state for a period varying from half an hour to two hours, according to the thickness of the materials. He prefers, for effecting the union of the sulphurous constituent, the following method to the masticating machine:—1. He subjects the purified gutta-percha to the combined action of steam and the fumes of orpiment and sulphur mixed in the proportions stated, in a metal chamber, provided with a steam-tight cover secured by screw-bolts. There is also a steam-boiler connected therewith, and when the heat in it is raised to about 280° Fahr., a fire is lighted beneath the pot containing the sulphurising materials. But the gutta-percha, &c., should be heated with the steam before it is sulphurised. In from half an hour to two hours the sulphurising is finished. Or, the gutta-percha may be rubbed strongly over with the sulphurous mixture and then heated, either dry or with the aid of steam, or it may be coated in the form of a paste.

Another of Mr. Hancock's inventions is to expose the gutta-percha to the deutoxide of azote (nitric oxide), or to chloride of zinc, concentrated and boiling hot, and then washing with an alkaline solution or mere water. Gutta-percha thus treated by the action of the gas, as it is evolved from nitric acid and copper, iron, or zinc, becomes exceedingly smooth, and of a lustre approaching to metallic; the same effect is produced upon common unsulphurised caoutchouc. Gutta-percha is thus also freed from all stickiness; and if sulphurised it acquires under this treatment the downy softness of velvet. Chloride of zinc and nitrous gas remove the smell of vulcanised caoutchouc in a great measure, especially if it be afterwards washed.

Another invention is that of masticating gutta-percha in the proportion of 6 parts with 1 of chloride of zinc; which compound may be afterwards sulphurised. A further modification consists in producing a spongy gutta-percha for stuffing sofas, &c. 48 parts of it moistened with oil of turpentine, coal-naphtha, bisulphide of carbon, or other proper solvent; 6 parts of hydrosulphide of lime, sulphide of antimony, or other analogous sulphide; 10 parts of carbonate of ammonia, carbonate of lime, or other substance that is either volatile or capable of yielding a volatile product; and 1 part of sulphur. Mr. Hancock mixes these materials together in a masticator, and then subjects them to a high degree of heat, observing the same conditions which are stated in the former description, except only that the heat may be pushed with advantage several degrees higher, say from 260° to 300°.

Various articles are manufactured of ordinary gutta-percha, such as single and double texture waterproof fabrics, boots, galoshes, belts, bandages, trowsers and other straps, capes, life-preservers, tubes, knapsacks, caps, cups and other vessels of capacity, hammer-cloths, cotton-spinning rollers, backs of cards for carding wool, pianoforte-hammers, paper-holders, springs, trusses, &c. By taking the gutta-percha after it has been sulphurised, and brushing it with a solution of resin in boiling oil (linseed?), placing it in a chamber heated to from 75° to 100° Fahr., and afterwards polishing it by the means usually employed by the japanners, it acquires the lustre of japanned wares.

Mr. Hancock has also contrived a machine for cutting gutta-percha into strips or riband, threads, or cord of any required shape. It consists of two grooved rollers of iron or steel, mounted in a suitable framework. The grooves of each roller are semicircular, and the projecting divisions between the grooves are made with knife-edges, so as to divide readily any sheet or mass of gutta-percha presented to them. The under roller is flanged at both ends, and the upper roller is made to fit inside of these flanges, in order to keep the cutting-edges from shifting or being damaged. To cut thin sheets of gutta-percha with this machine into strips or ribands, the material is passed through it in a cold state, and only the cutting-edges are brought into operation. To make round cord or thread by means of it, either a sheet of gutta-percha of a thickness equal to the diameter of the holes formed by the grooves, and at a temperature of 200° Fahr. (produced by supplying it from a feeding-chamber heated to that degree) is passed through the machine, and the threads or cords are received in a tank of cold water, from which they are led away to be wound on reels or drums; or the gutta-percha is employed in a plastic state, and passed under a gauge before it enters the machine. If it be desired to produce a cord of a semicircular form in the transverse section, a plane-roller is substituted for the lower grooved-roller; or should cord of a square, triangular, or hexangular, or any other form, be required, the two rollers must be shaped to suit.

Gutta-percha Tubes.—A series of interesting experiments have been made at the Birmingham Waterworks, relative to the strength of gutta-percha tubing, with a view to its applicability for the conveyance of water. The experiments were made (under the direction of Henry Rose, Esq., engineer), upon tubes, ¾ and ⅛th of an inch diameter, of gutta-percha. These were attached to the iron main, and subjected for two months to a pressure of 200 feet head of water, without being in the slightest degree deteriorated. In order to ascertain, if possible, the maximum strength of the tubes, they were connected with the Water Company's hydraulic proving-pump, the regular load of which is 250 lbs. on the square inch. At this point the tubes were unaffected, and the pump was worked up to 337 lbs., but to the astonishment of every one the tubes still remained perfect. It was then proposed to work the pump up to 500 lbs., but it was found that the lever of the valve would not bear this weight. The utmost power of the hydraulic pump could not break the tubes.

The gutta-percha being somewhat elastic, allowed the tubes to become slightly expanded by the extraordinary pressure which was applied, but on its withdrawal they resumed their former size.

This tubing is such an extraordinary conductor of sound, that its value, not only to deaf persons, but to the public generally, has been fully appreciated. It has been fitted up in dwelling-houses, in lieu of bells. As speaking-tubes for giving and receiving messages in mines, railway stations, prisons, workhouses, hotels, and all large establishments, it is invaluable.

Properties of Common Gutta-percha.—The gutta-percha, purified for manufacturing purposes, is of a reddish brown colour; it readily becomes electrical by friction and is a bad conductor of both electricity and heat. At the ordinary temperature of our climate, say from 32° to 77°, it possesses about as much tenacity as thick leather, with rather less flexibility; it softens and becomes sensibly doughy towards 120°, although still very tough. Its ductility is such, at a temperature of from 110° to 241°, that it is readily extended into thin sheets, or drawn into threads or tubes; its flexibility and ductility diminish as the temperature becomes lower. It does not possess at any temperature the peculiar elastic extensibility which characterises caoutchouc. Exposed for an hour to a temperature of 14°, its flexibility is slightly diminished.

In its various forms, gutta-percha possesses a peculiar porosity, as may be shown in the following manner:—A drop of its solution in sulphuret of carbon is to be placed on a glass slip; the spontaneous evaporation soon reduces this solution to a whitish plate; if it be then examined with the microscope, the numerous cavities with which it is pierced may be distinctly perceived. These cavities may be rendered still more visible by means of a drop of water; the liquid gradually insinuates itself, the mass appears more opaque, and by means of the microscope the cavities are seen to be enlarged.

Similar results are obtained by keeping thin transparent laminæ, obtained by the evaporation, by heat, of a solution of gutta-percha, immersed in water for a considerable time.

The preceding observations lead us to think, that this substance retaining, in consequence of its porosity, a great many minute particles of air, owes to this circumstance its appearance of possessing a less density than that of water, namely 0·979. In fact, on stretching gutta-percha under strong pressure, and immediately cutting the strips thus produced into very small pieces under water, the greater part of the fragments fall to the bottom of the vessel—some immediately, others after absorbing a certain quantity of water. The same result is also obtained by keeping very thin leaves of gutta-percha, prepared by different methods, immersed for a month in water deprived of air: their pores becoming gradually filled with the liquid, they became heavier than the water, and then ceased to float. Gutta-percha is also heavier in proportion to the length of time it has been exposed to the air, particularly in thin leaves.

The porous structure of gutta-percha becomes changed into a fibrous texture when it is drawn out so as to double its length: then retaining but little extensibility, it supports, without breaking, the action of a force equal to double that required for its elongation in the first instance.

Common gutta-percha resists cold water, damp, and also the various influences which excite fermentation; but it can be softened, and it experiences a sort of superficial doughy fusion by the action of the solar rays in summer.

It is not attacked by alkaline solutions, even when caustic and concentrated; ammonia, saline solutions, water containing carbonic acid, the various vegetable and mineral acids, do not act upon it; the weaker alcoholic liquors (wines, beer, &c.) do not touch it; and even brandy scarcely dissolves a trace of it. Olive-oil does not appear to attack gutta-percha when cold; when hot, it dissolves a small portion of it, which is again precipitated on cooling.

Sulphuric acid with one equiv. of water colours it brown, and disintegrates it with a sensible evolution of sulphurous acid.

Muriatic acid, in its saturated solution in water at a temperature of 68° F., attacks gutta-percha slowly, and gives it a more or less deep brown colour, at length rendering it brittle.

Monohydrated nitric acid attacks it rapidly, with effervescence and an abundant evolution of fumes of hyponitrous acid; the substance is decomposed, and coloured of a brownish orange-red: it becomes doughy, and afterwards solidifies by degrees and remains friable.

In the cold, and even by heat, only a part of the gutta-percha (0·15 to 0·22) is dissolved by anhydrous alcohol or ether. Benzine and spirits of turpentine dissolve it partially when cold, but nearly completely if aided by heat. Sulphide of carbon and chloroform dissolve gutta-percha when cold; the solutions may be filtered beneath a bell-glass to prevent evaporation; the filter retains the foreign matters of a reddish brown colour, whilst the solution passes perfectly clear, and almost colourless. The filtered liquid, exposed to the air in a saucer, allows the solvent to escape, and deposits the white gutta-percha in a plate of greater or less thickness, which shrinks gradually in proportion to the evaporation of the liquid.

Except the colour, which has disappeared, the gutta-percha then offers the characters and properties mentioned above as belonging to the commercial substance. Submitted to a gradually-raised temperature, it softens and melts, and may be made to boil without acquiring a sensible colour; the transparent fluid gives off abundant vapours, which are condensible into a nearly colourless oily liquid. The portions last distilled have a brownish orange colour, and a thin layer of carbonaceous deposit remains adherent to the sides of the vessel.

Analysis.—We have said above that alcohol and ether can dissolve only a portion of gutta-percha; this is because that substance consists, in fact, of three proximate principles, the separation of which has required very delicate observation, although they are very clearly distinguished by several of their properties.

When gutta-percha in thin leaves is brought into contact, in a close vessel, with 15 to 20 vols. of cold anhydrous alcohol, and the temperature raised slowly by means of the water-bath to the point of ebullition (172° F.), and kept at this point during several hours, the liquid, if filtered whilst boiling and left in a closed flask, will, at the end of from 12 to 36 hours, begin to deposit on the sides of the vessel and on the surface of the solution white opaline granules, distant from one another, but some of them in groups; their size will gradually increase for some days. These granules, carefully examined under the microscope, will be found to have the form of spherules truncated by the sides of the vessel. Their surface is either smooth, or bristling with very small transparent, elongated, lamellar crystals. Some superficial fissures appear to indicate that these spherules are formed of a sort of transparent yellow kernel covered with a white pellicle.

Perhaps no other example is known of this singular crystalline structure. In fact, cold anhydrous alcohol dissolves the whole of the yellow spheroidal substance, whilst the superficial pellicle, in the interior of which the alcohol has substituted itself for the solid globule, appears whiter and less transparent.

The alcoholic solution, which has been for some days depositing this complex spheroidal crystallisation, can again take up by heat a portion of the two proximate principles remaining in the substance, allowing a fresh quantity to crystallise on cooling. The extraction is completed by returning the boiling alcohol several times upon the gutta-percha until it no longer dissolves anything.

The solid substance which has resisted the action of the solvent, possesses, with some modifications, the principal properties of crude gutta-percha; we shall here call it *pure gutta.* As to the two other organic principles, one is a *yellow resin*, which is much more soluble in cold alcohol than the other, the *white crystalline resin.*

By taking advantage of these different degrees of solubility, we are enabled with time and patience to effect the complete purification of these three principles. The separation may also be effected by treating finely-divided gutta-percha with cold ether, which dissolves the mixture of the two resins more abundantly than alcohol; they are afterwards separated from one another by the same treatment already described for alcohol.

The tendency of the white resin to form itself into radiated groups is manifested in a rather remarkable circumstance, which it is easy to reproduce. Narrow ribands cut from a thin leaf of ordinary gutta-percha are to be placed in a tube, and immersed in anhydrous alcohol. The tube is then closed, and left for twenty or thirty days, when a few whitish points appear here and there on the ribands, and afterwards on the sides of the tube. These points, which become gradually larger, are formed of crystalline tufts of the white resin. Thus this proximate principle is separated directly, and in the cold, even when the atmospheric temperature is gradually rising, for instance during the spring or early summer.

The crystalline white resin, when completely purified by washings with alcohol, and then redissolved in anhydrous alcohol, is deposited by slow spontaneous evaporation in the air, in radiated crystals, forming sometimes symmetrical tufts arranged in stars, and then presenting the appearance of a sort of efflorescence.

Distinctive characters and properties of the three proximate principles which constitute common Gutta-percha.—The most abundant of these three principles, forming at least from 75 to 82 per cent. of the whole mass, is the pure gutta-percha, which presents the principal properties of the commercial substance; it is white, transparent at a temperature of 212° F., when all its parts are melted together; opaque or semi-transparent when cold, from its then acquiring a structure which causes the interposition of air, or of a liquid possessing a different refraction from its own. This structure appears still more distinct than in the natural substance containing all three principles.

In thin sheets, and at a temperature of 50° to 68° F., it is supple, tough, extensible, but not very elastic. At 112° F., it softens and turns back upon itself, and becomes more and more adhesive and translucent in proportion to the elevation of temperature, undergoing a sort of doughy fusion, which becomes more distinct towards 212° to 230°. Heated beyond this point, it melts, boils, and distils, furnishing a pyrogenous oil and carburetted gases.

Soubeiran believes the composition of perfectly pure gutta-percha to be $C^{12}H^{10}$, corresponding to 87·8 carbon and 12·2 hydrogen. Faraday found caoutchouc to contain 87·2 carbon, 12·8 hydrogen; hence their chemical composition is identical.

Pure gutta-percha, like the other two proximate principles, is quickly rendered electrical by friction, and is a bad conductor of heat; it generally floats on water, but sinks to the bottom as soon as its pores are filled with this liquid. It is insoluble in alcohol and ether, almost completely insoluble in benzine at 32° F.; it is soluble at 77°, and becomes more and more so in proportion as the temperature is raised. The saturated solution at 86° forms itself into a semi-transparent mass when cooled below 32°; alcohol precipitates the pure gutta-percha from its solution in benzine.

At 82°, spirits of turpentine dissolves very little gutta-percha, whilst it disintegrates and dissolves it readily when hot.

Chloroform and sulphide of carbon dissolve gutta-percha in the cold.

After the extraction by means of ether of the two resins interposed in the thin leaves of the white gutta-percha, leaving the last portion of ether with which they were impregnated to evaporate in the open air, these leaves, enclosed in a flask, experienced, after remaining there for two months at a temperature of from 68° to 82° F., an alteration which appeared to depend on their porosity, the action of the air, and perhaps the ether retained in their pores. However it be, these leaves had then acquired new properties; they were brittle; exhaled a very distinct sharp odour; brought into contact with an excess of anhydrous ether, they were partially dissolved; the soluble portion, obtained by the evaporation of the ether and dessication at 194° F., was glutinous and translucent; it became opaque and hard by cooling down to 14° F.

Sulphide of carbon, renewed three times in six days, and evaporated each time after two days' contact, left as residue a white flexible leaf. The portion not dissolved, swelled and transparent, did not appear to undergo any change when left in sulphide of carbon for ten days.

This kind of spontaneous transformation would perhaps become complete if more prolonged; its study will require much time; it will perhaps put us in the way of ascertaining the causes of certain changes observed in some small objects formed of gutta-percha. It has already been ascertained, that thin leaves, exposed for eight consecutive days to the action of the sun in moist air, were discoloured, and that their substance had become in great part soluble in ether.

Monohydrated sulphuric acid disintegrates, and communicates a brown colour to the pure gutta, with evolution of sulphurous acid; after eight days' contact, the deep brown liquid, on dilution with water, becomes turbid, and furnishes a brown flocculent precipitate. Nitric acid, with a single equivalent of water, attacks the pure gutta with a lively effervescence, and the evolution of orange-vapours of hyponitrous acid. Muriatic acid, in its saturated solution, slowly attacks the thin leaves of gutta, giving them a deep brown colour; at the end of eight days it becomes friable. The reaction of muriatic acid establishes an additional distinctive character between this proximate principle and the two others.

M. Payen has carefully examined the chemical and physical peculiarities of the three principles which he has discovered in gutta-percha. These have, however, no interest for the manufacturer, and we refer the chemical student to M. Payen's Memoir.

The juice of Muddar has been proposed as a substitute for gutta-percha, but we are not aware that it has in any manufacture taken its place. Dr. Falconer describes a new kind of gutta-percha, which grows in the most southern British possession of the Merguin Islands, Indian Ocean.

If a solution of gutta-percha in chloroform be mixed with 3 parts of ether, and exposed for some time to a temperature below 15°, the gutta-percha is precipitated as a white powder, forming when washed and dried a soft white mass. On spreading this solution on a plate of glass, a skin is formed, resembling kid-glove leather, which becomes transparent on the application of heat. These films are beautifully white, if carefully prepared, and they have been employed in the manufacture of the finest kinds of artificial flowers.

In 1848, Dr. Faraday drew the attention of experimentalists to the highly insulating power of gutta-percha, which not only possesses this property under ordinary circumstances, but likewise retains it under atmospheric conditions which would make the surface of glass a good conductor. This has led to its almost universal adoption as the insulator for the wires of the electrical telegraph. When buried in the earth, unless it is attacked by insects, or by a fungus, it retains its highly insulatory power, and we have every reason for believing that gutta-percha does not undergo a change when immersed in sea-water. It has, however, been found, that when it has been exposed to the intense sunshine of India, it undergoes a remarkable change; oxygen is absorbed, the gutta-percha loses its coherence, and at the same time its powers of insulation.

Some idea of the progress made in the applications of gutta-percha will be found by the following Table of Imports. The demand for this substance is still increasing, and it is to be feared that a destructive process is adopted in collecting the juice from the trees to meet the demand:—

	cwts.		cwts.
1850	11,130	1858	19,641
1851	10,778	1859	18,593

Substitutes for Gutta-percha.—Sir William Holmes forwarded to the Council of the Society of Arts from Demerara, some other specimens of a gum termed 'Balata,' the produce of the bullet-tree (*Sapota Mulleri*) which grows in that colony, and which, he states, possesses the properties of gutta-percha, and may be used as a substitute for it. Sir William Holmes says in his communication: 'I was Commissioner, representing the colony of British Guiana, at the International Exhibition of 1862. Among the varied contributions from the colony was a specimen of the dried milk of the bullet-tree; it weighed perhaps half a pound. Amongst the numerous individuals who visited the Guiana department was Mr. Charles Hancock, who is well known in the gutta-percha trade. This gentleman was struck with the appearance of the specimen, and obtained a portion for experiment. He reported most favourably as to its utility and value, a result most gratifying to me, as I had received adverse opinions from less experienced persons. This happened, I think, in July 1862: from that time to the present, I have been engaged in investigations how to produce the material cheaply, and how to dry or coagulate it rapidly. In both particulars I believe I have succeeded so far as to warrant the importation of steam-machinery to be applied to its extraction; and by a fortunate accident I have discovered how to dry or coagulate it, preserving the characteristic of elasticity, at a single operation, by the addition of a simple ingredient not very costly. . . . .

'Amongst the useful properties of the *Balata*, I believe the fresh milk of the bullet-tree to be the best waterproofing material yet discovered. The bullet-tree is a magnificent timber-tree, often squaring 30 to 40 inches, and is much used, especially in Berbice, for building purposes. The milk, when quite fresh, is so bland that it is sometimes used as a substitute for cows' milk, and the fruit is delicious.'

Mr. Ondaatjie, surgeon, forwarded to the same Society, from Ceylon, a specimen of the *Alstonia scholaris*, which he supposes may be used as a substitute for gutta-percha. The tree abounds with milky juice like the gutta-percha, has a fleshy bark and porous wood, and belongs to the natural order *Apocyneæ*. The natives believe that the tree is poisonous, but Mr. Ondaatjie has proved it not to be so.

GYLE. A brewer's vat or utensil. The vinegar-maker's fermented wort.

GYPSUM. This natural production, which in its varieties is known as *alabaster*, *selenite*, and *satin spar*, is a sulphate of lime, containing sulphuric acid, 46·51; lime, 32·56; water, 20·93.

The *anhydrite* from Derby is a mineral like gypsum, but, as its name indicates, containing no water; its composition being, lime, 41·2; sulphuric acid, 58·8; this is also called *muriacite* and *tripe-stone*. It absorbs moisture and changes to gypsum. When gypsum is carefully burnt, it loses its water of composition, and forms the well-known *plaster-of-Paris*.

The transparent varieties of gypsum are called *selenite;* its fine massive varieties are *alabaster*, and its fibrous kinds *satin spar*. There is another variety in small scales of a pearly lustre, known as *Schaumkalk*.

The fibrous forms of gypsum are cut and polished for small ornamented objects, and are sometimes known as *satin spar*.

The gypsum of our own country is found, in apparently inexhaustive quantities, in the Red Marl formation in the neighbourhood of Derby, and has been worked for many centuries. The great bulk of it is used for making plaster-of-Paris, and as a manure; and it is the basis of many kinds of patented cements, as Keene's, Martin's, and others.

To get it for these purposes, it is worked by mining underground, and the stone is blasted by gunpowder; but this shakes it so much as to render it unfit for working into ornaments, &c.; to procure blocks for which it is necessary to have an open quarry. By removing the superincumbent marl, and laying bare a large surface of the rock, the alabaster being very irregular in form, and jutting out in several parts, allows of its being *sawn* out in blocks of considerable size, and comparatively sound (as is illustrated by the large tazza in the Museum of Practical Geology). This stone, when protected from the action of water, is extremely durable, as may be seen in churches all over the country, where monumental effigies, many centuries old, are now as perfect as the day they were made, excepting of course wilful injuries; but exposure to rain soon decomposes the stone, and it must be borne in mind that it is perfectly unsuited for garden vases or other out-door work in this country.

In working, it can be sawn up into slabs with toothed saws, and for working mouldings and sculptures, fine chisels, rasps, and files are the implements used; the polishing is performed by rubbing it with pieces of sandstone, of various degrees of fineness, and water until it is quite free from scratches, and then giving a gloss by means of polishing powder (oxide of tin) applied on a piece of cloth, and rubbed with a considerable degree of friction on the stone. This material gives employment in Derby to a good many hands in forming it into useful and ornamental articles, and is commonly called Derbyshire Spar; most of the articles are turned in the lathe, and it works something like very hard wood.

Another kind of gypsum also found in Derbyshire is the fibrous or silky kind; it occurs in thin beds, from one to six inches in depth, and is crystallised in long needle-like fibres; being easily worked, susceptible of a high polish, and quite lustrous, it is used for making necklaces, bracelets, brooches, and such like small articles.

Gypsum is commonly found in this country, in irregular deposits, in the New Red Marls, especially at Chellaston in Derbyshire, Fauld in Staffordshire, and Newark in Nottinghamshire. A deposit of white crystalline gypsum has been recently discovered in the prosecution of the experimental boring at Netherfield, near Battle in Sussex, undertaken by the Sub-Wealden Exploration Committee. The gypseous deposits are upwards of fifty feet in thickness, and occur in beds, which are probably of Purbeck age. No gypseous deposits of equal extent, on this geological horizon, had been previously known in this country. The great deposits of gypsum worked at Montmartre and elsewhere in the neighbourhood of Paris—from which 'Plaster-of-Paris' borrows its name—occur in the Eocene beds of the Paris basin, equivalent to certain strata represented in this country in the Isle of Wight. See ALABASTER; PLASTER-OF-PARIS.

H

HABANA BROWN. This name has been given to aniline-brown. See ANILINE-BROWN.

HACKLE. A flax comb. See FLAX.

HADDOCK. The *Morrhua æglefinus*, one of the *Gadidæ*, or cod tribe.

HADE. A miner's term, used in Derbyshire and some of the northern counties, signifying the inclination or deviation from the vertical of any mineral vein or lode. *Hadings* signify that some parts of the veins incline, while others are vertical.

HÆMATIN. A product of the decomposition of *hæmoglobin*, or the red-colouring matter of the blood. The name *hæmatin* was also given by Chevreul to a crystalline substance, of a pale pink colour, and brilliant lustre when viewed in a lens, which he extracted from logwood. See HÆMATOXYLIN.

Scientific terms with prefixes similar to that of *hæmatin* are derived from the Greek *αἷμα*, *blood.*

HÆMATINONE. A kind of glass used by the ancients for making ornamental vessels, mosaics, &c. It is described by Pliny, and has been found pretty abundantly in the excavations of Pompeii. This glass is of a beautiful red colour, but the colour disappears on melting. Von Pettenkofer obtained a similar glass, which he has called *astralite*, by melting a mixture of silica, lime, calcined magnesia, litharge, soda, copper-hammerings, and smithy-scales. See ASTRALITE.

HÆMATITE. Native peroxide of iron. In true hæmatite, sometimes called for distinction's sake *red hæmatite*, the oxide is anhydrous, whilst in the so-called *brown hæmatite* it is hydrated.

The hæmatite proper occurs in a remarkable manner in irregular deposits in carboniferous limestone, at Whitehaven in Cumberland, and at Ulverstone in Lancashire. The following analysis of the Whitehaven ore of Cleator Moor by Mr. A. Dick, shows its peculiar character:—

Peroxide of iron	95·16
Protoxide of manganese	0·24
Lime	0·07
Phosphoric acid	trace
Sulphuric acid	trace
Bisulphide of iron	trace
Insoluble residue	5·68
	101·15
Iron, total amount	66·60

The following analysis of the Ulverstone ore is by the same chemist:—

Gillbrow Ore.

Peroxide of iron	86·50
Protoxide of manganese	0·21
Lime	2·77
Magnesia	1·46
Carbonic acid	2·96
Phosphoric acid	trace
Sulphuric acid	0·11
Insoluble residue	6·55
	100·56
Iron, total amount	60·55

Another ore, that of Lindale Moor, near Ulverstone, was analysed by Mr. J. Spiller, with the following results:—

Peroxide of iron	94·23
Protoxide of manganese	0·23
Alumina	0·51
Lime	0·05
Magnesia	trace
Phosphoric acid	minute trace
Sulphuric acid	0·09
Bisulphide of iron	0·03
Water, hygroscopic	0·39
,, combined	0·17
Insoluble residue	5·18
	100·88
Iron, total amount	65·98

The production of the red hæmatite in Cumberland and Lancashire has been during the last few years as follows:—

	1868 Tons	1869 Tons	1870 Tons	1871 Tons	1872 Tons
Whitehaven ore	725,248	848,974	1,014,143	976,874	954,505
Furness ore	767,625	784,507	871,938	931,048	909,077

Some of the Furness ore is smelted with charcoal at furnaces in the district, and in 1872 about 600,000 tons were used at the Barrow Hæmatite Works.

The Cleator Moor, Workington, and other Cumberland furnaces, in 1872, used 572,329 tons of the Whitehaven iron-ore.

All the remainder was sent into the other great iron-making districts for mixing with the argillaceous carbonates, and other ores of iron. Hæmatite is highly valued for making pig-iron well adapted for conversion into steel by the Bessemer process. See IRON.

HÆMATOGLOBULIN. Synonym of HÆMOGLOBIN.

HÆMATOSIN. A substance at one time regarded as the red-colouring matter of the blood.

HÆMATOXYLIN. The colouring matter of logwood, the *Hæmatoxylon Campechianum* of botanists. It is, in fact, the characteristic principle of this dye-wood. To procure hæmatoxylin, digest, during a few hours, ground logwood in water heated to a temperature of about 130° Fahr.; filter the liquor, evaporate it to dryness by a steam-bath, and put the extract in alcohol of 0·835 for a day. Then filter anew, and after having inspissated the alcoholic solution by evaporation, pour into it a little water, evaporate gently again, and then leave it to itself in a cool place. In this way numerous crystals of hæmatoxylin will be obtained, which may be purified by washing with alcohol and drying.

When subjected to dry distillation in a retort, hæmatoxylin affords all the usual products of vegetable bodies, along with a little ammonia; which proves the presence of azote. Boiling water dissolves it abundantly, and assumes an orange-red colour, which passes into yellow by cooling, but becomes red again with heat. Sulphurous acid destroys the colour of solution of hæmatoxylin. Potash and ammonia convert into a dark purple tint the pale solution of hæmatoxylin; when these alkalis are added in large quantity, they make the colour violet-blue, then brown-red, and lastly, brown-yellow. By this time the hæmatoxylin has become decomposed, and cannot be restored to its pristine state by neutralising the alkalis with acids.

The waters of baryta, strontia, and lime exercise an analogous power of decomposition; but they eventually precipitate the changed colouring matter.

A red solution of hæmatoxylin subjected to a current of sulphuretted hydrogen becomes yellow; but it resumes its original hue when the sulphuretted hydrogen is removed by a little potash.

The protoxide of lead, the protoxide of tin, the hydrate of peroxide of iron, the hydrate of oxides of copper and nickel, and oxide of bismuth, combine with hæmatoxylin and colour it blue with more or less of a violet cast.

Hæmatoxylin precipitates glue from its solution in reddish flocks. This substance has not hitherto been employed in its pure state; but as it constitutes the active principle of logwood, it enters as an ingredient into all the colours made with that dye-stuff.

These colours are principally violet and black. See LOGWOOD.

HÆMOGLOBIN. The red-colouring matter of the blood. See Blood.

HAIDINGERITE. A hydrated arsenate of lime, named after the late Von Haidinger, of Vienna.

HAIR (*Cheveu*, *Crin*, Fr.; *Haar*, Ger.) is of all animal products the one least liable to spontaneous change. It can be dissolved in water only at a temperature somewhat above 230° F., in a Papin's digester; but it appears to be partially decomposed by this heat, since some sulphuretted hydrogen is disengaged. By dry distillation, hair gives off sulphuretted gases, while the residuum contains sulphate of lime, common salt, much silica, with some oxide of iron and manganese. It is a remarkable fact that fair hair affords magnesia, instead of these latter two oxides. Horse-hair yields about 12 per cent. of phosphate of lime.

We have no recent analysis of hair. Vauquelin found nine different substances in black hair; in red hair, a red oil instead of a greenish black one.

Hairs are tubular, their cavities being filled with a fat oil, having the same colour with themselves. Hair plunged in chlorine gas is immediately decomposed and converted into a viscid mass; but when immersed weak in aqueous chlorine, it undergoes no change, except a little bleaching.

Living hairs are rendered black by applying to them for a short time a paste made by mixing litharge, slaked lime, and bicarbonate of potash, in various proportions, according to the shade of colour desired. The ordinary mode of dyeing human hair is first to saturate the hair with the sulphide of potassium in solution; then, when this has been well absorbed and is partially dry, a solution of nitrate of silver is to be applied. By varying the proportions of the sulphide, and the strength of the silver solution, almost any tone of colour, from a brown to a black, can be produced.

The salts of silver, mercury, lead, bismuth, as well as their oxides, blacken hair, or make it of a dark violet, by the formation, most probably, of metallic sulphurets (sulphides).

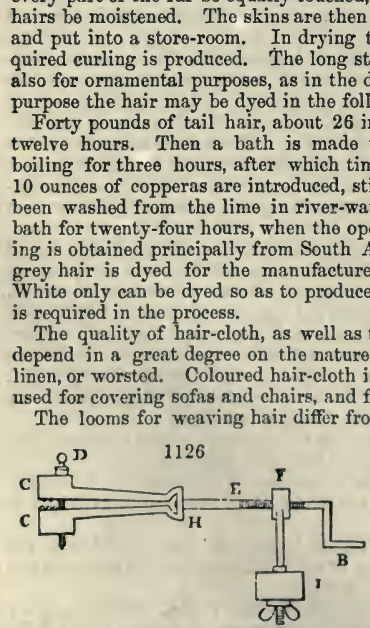
Hair as an object of manufacture is of two kinds, the *curly* and the *straight*. The former, which is short, is spun into a cord, and boiled in this state, to give it the tortuous springy form. The hairs of rabbits and hares are prepared for the hatmaker by a process called *sécrétage*, so as to render them fit for felting. The skins with the hair still upon them are laid upon a table, and with a brush, made from the bristle of the wild boar, a solution of nitrate of mercury is applied many times in succession, till every part of the fur be equally touched, and till about two-thirds of the length of the hairs be moistened. The skins are then placed together to complete the impregnation, and put into a store-room. In drying there is a retraction of the hairs, and the required curling is produced. The long straight hair is woven into cloth for sieves, and also for ornamental purposes, as in the damask hair-cloth of chair-bottoms. For this purpose the hair may be dyed in the following way:—

Forty pounds of tail hair, about 26 inches long, are steeped in lime-water during twelve hours. Then a bath is made with a decoction of 20 lbs. of logwood, kept boiling for three hours, after which time the fire is withdrawn from the boiler, and 10 ounces of copperas are introduced, stirred about, and the hair is immersed, having been washed from the lime in river-water. The hair should remain in this cooling bath for twenty-four hours, when the operation will be finished. Hair used for weaving is obtained principally from South America and from Russia. All the black and grey hair is dyed for the manufacture of black hair-cloth for covering furniture. White only can be dyed so as to produce what are called fancy colours, and great care is required in the process.

The quality of hair-cloth, as well as the brilliancy and permanency of the colours, depend in a great degree on the nature of the warp, which may be either of cotton, linen, or worsted. Coloured hair-cloth is made at Worcester, Sheffield, and Paris, and used for covering sofas and chairs, and for railway carriages.

The looms for weaving hair differ from the common ones, only in the templet and the shuttle. Two templets of iron must be used to keep the stuff equably but lightly stretched. These templets, of which one is represented in *fig.* 1126, are constructed in the shape of flat pincers; the jaws, C C, being furnished with teeth inside. A screw, D, binds the jaws together, and hinders the selvage from going inwards. Upon the side cross-beam of the loom, seen in section at I, a bolt is fixed which carries a nut F at its end, into which a screwed iron rod E enters, on one of whose ends is the handle B. The other extremity of the screw E is adapted by a washer and pin to the back of the pincers at the point H, so that by turning the handle to the right or the left, we

1126



draw onwards or push backwards the pincers and the stuff at pleasure. The warp of the web is made of black linen yarn. The weft is of hair, and it is thrown with a long hooked shuttle, or a long rod, having a catch hook at its end. The length of this shuttle is about three feet; its breadth half an inch, and its thickness one sixth. It is made of boxwood. The reed is of polished steel; the thread warps are conducted through it in the usual way. The workman passes this shuttle between the hairs of the warp with one hand, when the shed or shuttle way is opened by the treddles; a child placed on one side of the loom presents a hair to the weaver near the selvage, who catches it with the hook of his shuttle, and by drawing it out passes it through the warp. The hairs are placed in a bundle on the side where the child stands, in a chest filled with water to keep them moist, for otherwise they would not have the suppleness requisite to form a web. Each time that a hair is thrown across, the batten is driven home twice. The warp is dressed with paste in the usual way. The hair-cloth, after it is woven, is hot calendered to give it lustre. In the Great Exhibition of 1851, J. Bardoffsky (Russia) exhibited a collection of bowls, dishes, plates, &c., formed of the hair of the rabbit, hare, and other animals, which were felted and afterwards varnished. They had the appearance of papier-maché, and were very light.

The chief kinds of hair used in the arts are *horse-hair*, used for stuffing seats and for hair-seating; *cow-hair*, for making felt and for mixing with mortar; *goats'-hair*, *mohair*, &c., for weaving into textile fabrics; *camels'-hair*, *mohair*, &c., for artists' pencils; *hog-hair* and other coarse kinds for common brushes; and *human hair* for wigs, chignons, and other articles of head-dress.

Hair *imported* in the years 1871 and 1872:—

HAIR BRUSHES. The *hair brushes* are manufactured with coarse hair, as that of the swine, the wild boar, the dog, &c., and these are usually attached, by binding with cord or by securing them with a piece of tin plate, to a wooden handle. The manufacture of hair brushes, clothes brushes, tooth and nail brushes, is necessarily very large, and of considerable importance. The technical details of this manufacture would occupy space to the exclusion of more important matter.

HAIR PENCILS, for artists. *Hair pencils* are composed of very fine hairs, as those of the sable, the miniver, the marten, the badger, and the polecat. These are usually mounted in a quill, but sometimes they are secured as in the former case with tinned iron.

The most essential quality of a good pencil is to form a fine point, so that all the hairs without exception may be united when they are moistened by laying them upon the tongue, or drawing them through the lips. When hairs present the form of an elongated cone in a pencil, their point only can be used. The whole difficulty consists, after the hairs are cleansed, in arranging them together so that all their points may lie in the same horizontal plane. We must wash the tails of the animals whose hairs are to be used, by scouring them in a solution of alum till they be quite free from grease, and then steeping them for twenty-four hours in lukewarm water. We next squeeze out the water by pressing them strongly from the root to the tip, in order to lay the hairs as smooth as possible. They are to be combed in the longitudinal direction, with a very fine-toothed comb, and finally wrapped up in fine linen, and dried. When perfectly dry, the hairs are seized with pincers, cut across close to the skin, and arranged in separate heaps, according to their respective lengths.

Each of these little heaps is placed separately, one after the other, in small tin pans with flat bottoms, with the tips of the hair upwards. On striking the bottom of the pan slightly upon a table, the hairs get arranged parallel to each other, and their delicate points rise more or less according to their lengths. The longer ones are to be picked out and made into so many separate parcels, whereby each parcel may be composed of equally long hairs. The perfection of the pencil depends upon this equality; the tapering point being produced simply by the attenuation of the tips.

A pinch of one of these parcels is then taken, of a thickness corresponding to the intended size of the pencil; it is set in a little tin pan, with its tips undermost, and is shaken by striking the pan on the table as before. The root end of the hairs being tied by the fisherman's or seaman's knot, with a fine thread, it is taken out of the pan, and then hooped with stronger thread or twine; the knots being drawn very tight by means of two little sticks. The distance from the tips at which these ligatures are placed is of course relative to the nature of the hair, and the desired length of the pencil. The base of the pencil must be trimmed flat with a pair of scissors.

Nothing now remains to be done but to mount the pencils in quill or tin-plate tubes, as above described. The quills are those of swans, geese, ducks, lapwings, pigeons, or larks, according to the size of the pencil. They are steeped during twenty-four hours in water, to swell and soften them, and to prevent the chance of their splitting when the hair-brush is pressed into them. The brush of hair is introduced by its tips into the large end of the cut quill, having previously drawn them to a point with the lips, when it is pushed forwards with a wire of the same diameter, till it comes out at the other and narrower end of the quill.

The smaller the pencils, the finer ought the hairs to be. In this respect the manufacture requires much delicacy of tact and experience.

HALIOTIS. *The sea ear-shell.* A genus of molluscous animals belonging to the class *Gasteropoda.* These shells, possessing a fine nacre, are extensively used in the ornamentation of papier-maché articles, and mother-of-pearl ornaments.

HALITE. A mineralogical name for rock-salt.

HÄLLEFLINTA. An old Swedish name still retained for certain felstones. See Felspathic Rocks.

HALLOYSITE. An earthy hydrated silicate of alumina, closely related to clay.

HALOGEN, is a term employed by Berzelius to designate those substances which form compounds of a saline nature by their union with metals; such are chlorine, iodine, bromine, fluorine, and cyanogen; the salts thus formed being called *haloïd salts,* from their resemblance to common salt ($NaCl$), (ἅλς, sea salt, and εἶδος, form). Since the discovery of the compound halogen, *Cyanogen,* some chemists have been led to view all salts as under the type of haloïd salts; assuming in the different acids certain compound halogens, as in sulphuric acid the halogen (SO^4), in nitric acid the halogen (NO^6), &c.; which in combination with hydrogen form the acids; the different salts being formed by the displacement of the hydrogen by the metal, as follows: sulphuric acid (HSO^4), sulphate of potash (KSO^4); nitric acid (HNO^6), nitrate of soda ($NaNO^6$), &c.—H.K.B.

HALOÏDS. Salts formed by combination of a metal with a radical, or halogen. Modern ideas on the constitution of salts have greatly tended to weaken the old distinction between haloïd salts and oxysalts.

HALOTRICHITE. A hydrous sulphate of alumina and sesquioxide of iron. See Alum, Feather.

HANDSPIKE. A strong wooden bar, used as a lever to move the windlass and capstan in heaving the anchor, or raising any heavy weights aboard ship. The handle is round, smooth, and somewhat taper. The other end is squared to fit the holes in the head of the capstan or the barrel of the windlass.

HANGING-WALL. In *mining,* the upper wall of an inclined vein; the rock which hangs over the lode.

HARDENING. The processes by which metals are rendered harder than they are when they first leave the hands of the workman.

Some metals are hardened by hammering or rolling; but care is required not to carry this too far, as brittleness may be induced. Sudden cooling is had recourse to with some metals. Pure hammered iron appears after annealing to be equally soft, whether suddenly or slowly cooled; some of the impure kinds of malleable iron harden by immersion. Steel, however receives by sudden cooling that extreme degree of hardness combined with tenacity, which places it so incalculably beyond every other material for the manufacture of cutting-tools.

In hardening and tempering steel there are three things to be considered, namely, the means of heating the objects to redness, the means of cooling the same, and the means of applying the heat for *tempering,* or 'letting them down.'

Steel pens are hardened by being heated in large quantities in iron trays within a furnace, and then plunged into a oily mixture; generally they are likewise tempered in oil, or a composition, the boiling-point of which is the same as the temperature suited to 'letting them down.'

Saws and springs are hardened in various compositions of oil, suet, wax, and other ingredients, 'which however lose their hardening property after a few weeks' constant use.' Steel plates are hardened occasionally by allowing water to fall on them when hot.

Case-hardening is the process by which wrought iron is first converted exteriorly into steel, and is subsequently hardened to that particular depth, leaving the central parts in their original condition of soft and fibrous iron. The principal agents used for case-hardening are animal matters, as the hoofs, horns, bones, and skins of animals. The prussiate of potash, which contains a compound of carbon and nitrogen, is also employed for case-hardening. In principle its action is the same as that of the animal substances. The iron is heated in the open fire to a dull red, and the prussiate is either sprinkled upon it or rubbed on in the lump; it is returned to the fire for a few minutes, and immersed in water. In the volume of Lardner's 'Cyclopædia,' on *Iron and Steel*, edited by Robert Hunt, the subjects of hardening and tempering are treated in a practical manner. See Iron.

HARDNESS. (*Dureté*, Fr.; *Härte*, *Festigkeit*, Ger.) A hard body will *scratch* one that is softer than itself. This method of determining the hardness of minerals is employed by mineralogists. A good steel file is commonly used for trying the respective hardness of minerals.

Mohs introduced a scale of hardness which shows the gradual increase in hardness through 10 minerals:—

1. *Talc*; common laminated light green variety.
2. *Gypsum*; crystallised variety.
3. *Calcite*; transparent variety.
4. *Fluor spar*; crystalline variety.
5. *Apatite*; transparent variety.
6. *Feldspar* (orthoclase; white cleavable variety).
7. *Quartz*; transparent.
8. *Topaz*; ditto.
9. *Sapphire*; cleavable varieties.
10. *Diamond.*

The following table, compiled by Dr. Ure for the early editions of his Dictionary, will still be found very useful as representing, relatively, the hardness of the mineral named, although the numbers which express the degree of hardness do not agree with the scale of Mohs:—

Substances	Hardness	Sp. grav.	Substances	Hardness	Sp. grav.
Diamond, from Ormus	20	3·7	Sardonyx . . .	12	2·6
Pink diamond . .	19	3·4	Occidental amethyst .	11	2·7
Bluish diamond . .	19	3·3	Crystal . . .	11	2·6
Yellowish diamond .	19	3·3	Carnelian . . .	11	2·7
Cubic diamond . .	18	3·2	Green jasper . .	11	2·7
Ruby.	17	4·2	Reddish-yellow ditto.	9	2·6
Pale ruby, from Brazil	16	3·5	Schorl . . .	10	3·6
Deep blue sapphire .	16	3·8	Tourmaline . .	10	3·0
Ditto, paler . .	17	3·8	Quartz . . .	10	2·7
Topaz . . .	15	4·2	Opal. . . .	10	2·6
Whitish topaz . .	14	3·5	Chrysolite. . .	10	3·7
Ruby spinel . .	13	3·4	Zeolite . . .	8	2·1
Bohemian topaz . .	11	2·8	Fluor . . .	7	3·5
Emerald . . .	12	2·8	Calcareous spar. .	6	2·7
Garnet . . .	12	4·4	Gypsum . . .	5	2·3
Agate . . .	12	2·6	Chalk . . .	3	2·7
Onyx. . . .	12	2·6			

One of the most ready means of discriminating between different kinds of precious stones is to be found in their different degrees of hardness, coupled with their specific gravities. These are given in the article on Gems. In many of the mineralogical articles in this Dictionary, the letter H is used as an abbreviation of 'hardness.'

HARDWARE. Under this term are comprehended the articles manufactured of any of the baser metals. See these respectively.

HARE. The common hare (*Lepus timidus*) not only furnishes an article of food, but the skin is used as a fur, and was formerly employed to a large extent in making the felt bodies of hats.

HARE WOOD. See Sycamore.

HARICOTS. The seeds of certain species of *Phaseolus*, or beans.

HARMALA RED. A red-colouring matter, obtained from the seeds of *Peganum Harmala*, a plant found in the Crimea. It is obtained by digesting the seed in alcohol for some days. This colouring matter unites with acids, forming red-salts, and dyes wool or silk mordanted with the salts of alumina a light rose-red or a deep scarlet. The colours are said to be fugitive.

HARMALINE. An organic alkaloïd extracted from the seeds of the *Peganum Harmala.* A base obtained by the oxidation of harmaline has been called *harmine.*

HARMOTOME. A hydrous silicate of alumina and baryta. This zeolite crystallises in the rhombic system, often in twins crossing each other, whence the common name 'Cross-stone.'

It accompanies lead-ore at Strontian in Argyleshire, and at Andreasberg in the Hartz. It is also found, with other zeolites, in cavities in amygdaloidal rocks.

HARRISITE. A variety of copper-glance, with cubic cleavage; supposed to be a pseudomorph after galena.

HARTITE. A hydrocarbon, found in brown-coal near Vienna.

HARTSHORN, SPIRIT OF, is the old name for the solution of ammonia in water, the weak Liquor ammonia of the London Pharmacopœia.

HASSOCK. A term given to a kind of sandstone occurring in the quarries of Kentish Ragstone in Kent. When of good quality, it is employed in building the interior walls of churches. The following is an analysis of hassock, by Dr. Plomby, of Maidstone: carbonate of lime, 53; alumina, 4; oxide of iron, 8; silica, 32; small quantities of phosphate of lime, soda, magnesia, chlorine and sulphuric acid, 3: =100.

HATCHETTINE. One of the native hydrocarbons. It occurs in the crevices of septaria of clay-ironstone from the coal-measures at Ebbw Vale, in masses resembling wax. It is also found in Argyleshire. According to Johnston its composition is: carbon, 85·91; hydrogen, 14·62: =100·53. It is also known as *mineral tallow.*

HAT MANUFACTURE. (*L'art de chapelier*, Fr.; *Hutmacherkunst*, Ger.) Hat is the name of a covering for the head worn by both sexes, but principally by men.

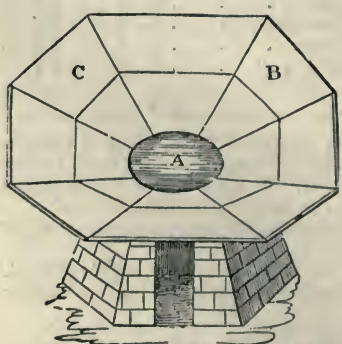
As the art of making hats does not involve the description of any curious machinery, or any interesting processes, we shall not enter into minute details upon the subject. It will be sufficient to convey to the reader a general idea of the methods employed in the manufacture of beaver and silk hats.

The materials used in making stuff hats are the furs of hares and rabbits freed from the long hair, together with wool and beaver. The beaver is reserved for the finer hats.

The fur is first laid upon a hurdle made of wood or wire, with longitudinal openings; and the operator, by means of an instrument called the bow (which is a piece of elastic ash, six or seven feet long, with a catgut stretched between its two extremities, and made to vibrate by a bowstick), causes the vibrating string to strike and play upon the fur, so as to scatter the fibres in all directions, while the dust and filth descend through the grids of the hurdle.

After the fur is thus driven by the bow from one end of the hurdle to the other, it forms a mass called a *bat*, which is only half the quantity sufficient for a hat. The bat or *capade* thus formed is rendered compact by pressing it down with the *hardening skin* (a piece of half-tanned leather), and the union of the fibres is increased by covering them with a cloth, while the workman presses them together repeatedly with his hands. The cloth being taken off, a piece of paper, with its corners doubled in, so as to give it a triangular outline, is laid above the bat. The opposite edges of the bat are then folded over the paper, and, being brought together and pressed again with the hands, they form a conical cap. This cap is next laid upon another bat, ready hardened, so that the joined eges of the first bat rest upon the new one. This new bat is folded over the other, and its edges joined by pressure as before; so that the joining of the first conical cap is opposite to that of the second. This compound bat is now wrought with the hands for a considerable time upon the hurdle between folds of linen cloth, being occasionally sprinkled with clear water, till the hat is *basoned*, or rendered tolerably firm.

1127



The cap is now taken to a wooden receiver, like a very flat mill-hopper, consisting of eight wooden planes, sloping gently to the centre, which contains a kettle filled with water acidulated with sulphuric acid. The technical name of this vessel is the *battery*. It consists of a kettle A, *fig.* 1127; and of the planks, B, C, which are sloping planes, usually eight in number, one being allotted to each workman. The half of each plank next the kettle is made of lead, the upper half of mahogany. In this liquor the hat is occasionally dipped, and wrought by the hands, or sometimes with a roller, upon the sloping planks. It is thus fulled or thickened during four or five hours; the knots or hard substances are picked out by the workman, and fresh felt is added by means of a wet brush to those parts that require it. The beaver is applied at the end of this operation. In the manufacture of beaver hats, the grounds of beer are added to the liquor in the kettle.

Stopping, or thickening the thin spots, seen by looking through the body, is performed by daubing on additional stuff with successive applications of the hot acidulous liquor from a brush dipped into the kettle, until the body be sufficiently shrunk and made uniform. After drying, it is stiffened with varnish composition rubbed in with a brush; the inside surface being more copiously imbued with it than the outer; while the brim is peculiarly charged with the stiffening.

When once more dried, the body is ready to be *covered*, which is done at the *battery*. The first cover of beaver or napping, which has been previously *bowed*, is strewed equably over the body, and patted on with a brush moistened with the hot liquor, until it gets incorporated; the cut ends towards the root being the points which spontaneously intrude. The body is now put into a coarse hair-cloth, then dipped and rolled in the hot liquor, until the root ends of the beaver are thoroughly worked in. This is technically called rolling off, or *roughing*. A strip for the brim, round the edge of the inside, is treated in the same way; whereby everything is ready for the second cover (of beaver), which is incorporated in like manner; the rolling, &c., being continued till a uniform, close, and well-felted hood is formed.

The hat is now ready to receive its proper shape. For this purpose the workman turns up the edge or brim to the depth of about 1½ inch, and then returns the point of the cone back again through the axis of the cap, so as to introduce another inner fold of the same depth. A third fold is produced by returning the point of the cone, and so on till the point resembles a flat circular piece having a number of concentric folds. In this state it is laid upon the plank, and wetted with the liquor. The workman pulls out the point with his fingers, and presses it down with his hand, turning it at the same time round on its centre upon the plank, till a flat portion, equal to the crown of the hat, is rubbed out. This flat crown is now placed upon a block, and, by pressing a string called a *commander*, down the sides of the block, he forces the parts adjacent to the crown, to assume a cylindrical figure. The brim now appears like a puckered appendage round the cylindrical cone; but the proper figure is next given to it, by working and rubbing it. The body is rendered waterproof and stiff by being imbued with a varnish composed of shellac, sandarach, mastic, and other resins dissolved in alcohol or naphtha.

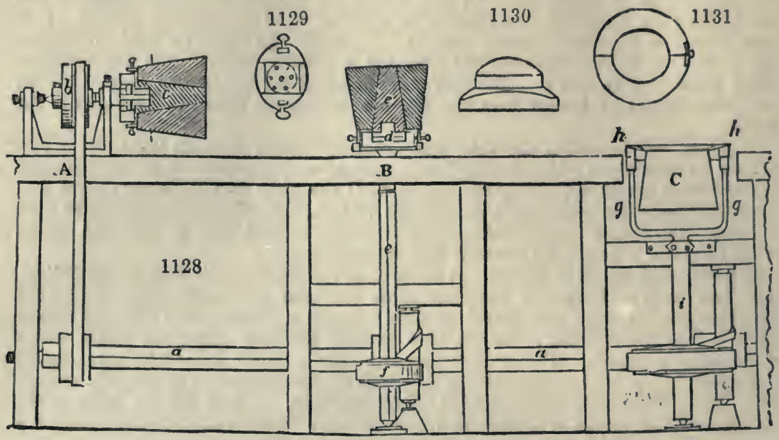
The hat being dried, its nap is raised or loosened with a wire brush or card, and sometimes it is previously pounced or rubbed with pumice, to take off the coarser parts, and afterwards rubbed over with seal-skin. The hat is now tied with pack-thread upon its block, and is afterwards dyed.

The dyed hats are now removed to the stiffening shop. Beer-grounds are next applied on the inside of the crown, for the purpose of preventing the glue from coming through; and when the beer-grounds are dried, glue (gum Senegal is sometimes used), a little thinner than that used by carpenters, is laid with a brush on the inside of the crown, and the lower surface of the brim.

The hat is then softened by exposure to steam, on the steaming-basin, and is brushed and ironed till it receives the proper gloss. It is lastly cut round at the brim by a knife fixed at the end of a gauge, which rests against the crown. The brim, however, is not cut entirely through, but is torn off so as to leave an edging of beaver round the external rim of the hat. The crown being tied up in a gauze paper, which is neatly ironed down, is then ready for the last operations of lining and binding.

The furs and wools of which hats are manufactured contain in their early stage of preparation, *hemps* and *hairs*, which must be removed in order to produce a material for the better description of hats. This separation is effected by a sort of winnowing machine, which wafts away the finer and lighter parts of the furs and wools from the coarser.

The annexed figures represent Mr. Ollerenshaw's machine, generally employed for ironing hats. *Fig.* 1128 is the framework or standard upon which three of these lathes are mounted, as A, B, C. The lathe A is intended to be employed when the crown of the hat is to be ironed. The lathe B, when the flat top, and the upper side of the brim is ironed, and lathe C, when its under side is ironed; motion being given to the whole by means of a band passing from any first mover (as a steam-engine, water-wheel, &c.) to the drum on the main-shaft *a a*. From this drum a strap passes over the rigger *b*, which actuates the axle of the lathe A. On to this lathe a sort of chuck is screwed, and to the chuck the block *c* is made fast by screws, bolts, or pins. This block is represented in section, in order to show the manner in which it is made, of several pieces held fast by the centre wedge-piece, as seen at *fig.* 1129.



1129 1130 1131 1128

The hat-block being made to turn round with the chuck, at the rate of about twenty turns per minute, but in the opposite direction to the revolution of an ordinary turning lathe, the workman applies his hot iron to the surface of the hat, and thereby smooths it, giving a beautiful glossy appearance to the beaver; he then applies a plush cushion, and rubs round the surface of the hat while it is still revolving. The hat, with its block, is now removed to the lathe B, where it is placed upon the chuck *d*, and made to turn in a horizontal direction, at the rate of about twenty revolutions per minute, for the purpose of ironing the flat top of the crown. This lathe B moves upon an upright shaft *e*, and is actuated by a twisted band passing from the main-shaft round the rigger *f*. In order to iron the upper surface of the brim, the block *c* is removed from the lathe, and taken out of the hat, when the block, *fig.* 1130, is mounted upon the chuck *d*, and made to turn under the hand of the workman, as before.

The hat is now to be removed to the lathe C, where it is introduced in an inverted position, between the arms *g g* supporting the rim *h h*, the top surface of which is shown at *fig.* 1131. The spindle *i* of the lathe turns by similar means to the last, but slower: only ten turns per minute will be sufficient. The workman now smooths the under side of the brim, by drawing the iron across it, that is, from the centre outwards. The hat is then carefully examined, and all the burs and coarse hairs picked out, after which the smoothing process is performed as before, and the dressing of the hat is complete. This description of the manufacture of the beaver hat has been retained, though it is now but little practised, the silk hat having taken its place.

Silk hats, for several years after they were manufactured, were liable to two objections: first, the body or shell over which the silk covering is laid, was, from its hardness, apt to hurt the head; second, the edge of the crown being much exposed to blows, the silk nap soon got abraded, so as to lay bare the cotton foundation, which is not capable of taking so fine a black dye as the silk; whence the hat assumed a shabby appearance. Messrs. Mayhew & White, of London, proposed to remedy these defects, by making the hat-body of stuff or wool, and relieving the stiffness of the inner part round the brim, by attaching a coating of beaver upon the under side of the brim, so as to render the hat pliable. Round the edge of the tip or crown, a quantity of what is called stop-wool is to be attached by the ordinary operation of bowing, which will render the edge soft and elastic. The hat is to be afterwards dyed of a good black colour, both outside and inside; and being then properly stiffened and blocked, is ready for the covering of silk.

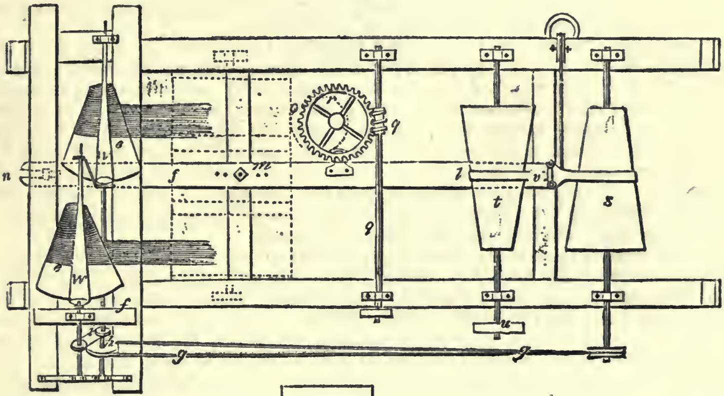
The plush employed for covering silk hats is a raised nap or pile woven usually upon a cotton foundation; and the cotton, being incapable of receiving the same brilliant black dye as the silk, renders the hat apt to turn brown whenever the silk nap is partially worn off. To counteract this evil, the foundation of the plush is now frequently made entirely of silk. To these two improvements, now pretty generally introduced, the present excellence of the silk hats may be ascribed.

Fig. 1132 is a side view of the carding-engine, employed in preparing the silk for hats, with a horizontal plan or view of the lower part of the carding-machine, showing the operative parts of the winding-apparatus, as connected to the carding-engine. The doffer-cylinder is covered with fillets of wire-cards, such as are usually employed in carding-engines, and these fillets are divided into two, three, or more spaces, extending round the periphery of the cylinder, the object of which division is to separate the sliver into two, three, or more breadths, which are to be conducted to and wound upon distinct blocks, for making so many separate hats or caps.

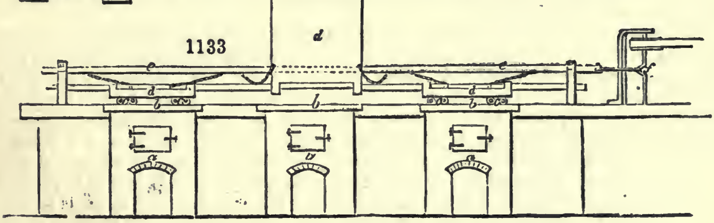
The principal cylinder of the carding-engine is made to revolve by a rigger upon its axle, actuated by a band from any first mover as usual, and the subordinate rollers or cylinders belonging to the carding-engine, are all turned by pulleys, and bands, and gear, as in the ordinary construction.

The wool or other material is supplied to the feeding-cloth, and carried through the engine to the doffer-cylinder, as in other carding-engines; the doffer-comb is actuated by a revolving crank in the common way, and by means of it the slivers are taken from the doffer-cylinder, and thence received on to the surfaces of the blocks *e e*. These blocks, of which two only are shown to prevent confusion, are mounted upon axles, supported by suitable bearings, in a carriage *f f*, and are made to revolve by means of a band *g g*, leading from a pulley on the axle of a conical drum beneath. The band *g* passes over a pulley *h*, affixed to the axle of one of the blocks, while another pulley *i*, upon the same axle, gives motion, by means of a band, to as many other blocks as are adapted to the machine.

1132



1133



As it is necessary in winding the slivers on to the blocks, to cross them in different directions, and also to pass the sliver over the hemispherical ends of the blocks, in order that the wool or other material may be uniformly spread over the surface in forming the cap or hood for the shell or foundation of the intended hat, the carriage *f*, with the blocks, is made to traverse to and fro in lateral directions upon rollers at each end.

This alternating motion of the carriage is caused by a horizontal lever *l l* (seen in the horizontal view *fig.* 1132), moving upon a fulcrum-pin at *m*, which lever is attached to the carriage at one extremity *n*, and at the other end has a weighted cord which draws the side of this lever against a cam-wheel *o*. This cam is made to revolve by means of a band and pulley, which turns the shaft and endless screw *q*, and this endless screw, taking into a toothed wheel *r*, on the axle of the cam *o*, causes the cam to revolve, the periphery of which cam running against a friction-roller on the side of the lever *l*, causes the lever to vibrate, and the carriage *f f*, attached to it, to traverse to and fro upon the supporting-rollers, as described. By these means the slivers are laid in oblique directions (varying as the carriage traverses) over the surface of the blocks.

The blocks being conically formed, or of other irregular figures, it is necessary in order to wind the slivers with uniform tension to vary their speed according to the diameter of that part of the block which is receiving the sliver. This is effected by giving different velocities to the pulley on the axle of the conical drum *s*, corresponding with *c*. There is a similar conical drum *t*, placed in a reverse position in the lower part of the frame, which is actuated by a band from any convenient part of the machine passing over a pulley *u*, upon the axle of *t*. From the drum *t*, to the drum *s*, there is a band *v*, which is made to slide along the drums by the guidance of two rollers at the end of the lever *l*.

It will now be seen that when the larger diameter of the cam-wheel *o* forces the lever outwards, the band *v* will be guided on the smaller part of the conical drum *t*, and the larger part of *s*, consequently the drum *s* will at this time receive its slowest motion, and the band *g* will turn the blocks slower also; the reverse end of the lever *l*, having by the same movement slidden the carriage into that position which causes the slivers to wind upon the large diameter of the blocks.

When the smaller diameter of the cam is acting against the side of the lever, the weighted cord draws the end of the lever to the opposite side, and the band *v* will be guided on to the larger part of the cone *t*, and the smaller part of the cone *s*; consequently, the quicker movement of the band *g*, will now cause the blocks *e e* to revolve with a corresponding speed. The carriage *f* will also be moved upon its rollers to the reverse side, and the sliver of wool or other material be now wound upon the smaller parts and ends of the blocks, at which time the quicker rotation of the blocks is required. It may be here observed, that the cam-wheel *o* should be differently formed according to the different shaped blocks employed, so as to produce the requisite movements of the lever and carriage suited thereto.

It only remains to state that there are two heavy conical rollers, *w w*, bearing upon the peripheries of the blocks *e e*, which turn loosely upon their axles by the friction of contact, for the purpose of pressing the slivers of wool or other material on the blocks as it comes from the doffer-cylinder of the carding-engine, and when the blocks have been coated with a sufficient quantity of the sliver, the smaller end of the pressing-rollers is to be raised, while the cap is withdrawn from the block. The process being continued as before, the formations of other bodies or caps is effected in the manner above described.

After the caps or bodies of hats, &c., are formed in the above described machine, they are folded in wet cloths, and placed upon heated plates, where they are rolled under pressure, for the purpose of being hardened. *Fig.* 1133 represents the front of three furnaces *a a a*, the tops of which are covered with iron plates *b b b*. Upon these plates, which are heated by the furnace below, or by steam, the bodies wrapped in the wet cloths *c c c*, are placed, and pressed upon by the flaps or covers *d d d*, sliding upon guide-rods, to which flaps a traversing motion is given, by means of chains attached to an alternating bar *e e*. This bar is moved by a rotary crank *f*, which has its motion by pulleys from any actuating power. When any one of the flaps is turned up to remove the bodies from beneath, the chains hang loosely, and the flap remains stationary.

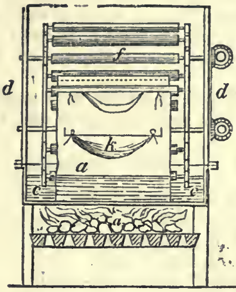
These caps or hat-bodies, after having been hardened in the manner above described, may be felted in the usual way by hand, or they are felted in a fulling-mill by the usual process employed for milling cloths, except that the hat-bodies are occasionally taken out of the fulling-mill, and passed between rollers, for the purpose of rendering the felt more perfect.

Mr. Carey, of Basford, obtained a patent in October 1834 for an invention of certain machinery to be employed in the manufacture of hats, which is ingenious, and seems to be worthy of notice in this place. It consists in the adaptation of a system of rollers, forming a machine, by means of which the operation of roughing or plaiting of hats, may be performed; that is, the beaver or other fur may be made to attach itself, and work into the felt or hat-body, without the necessity of the ordinary manual operations.

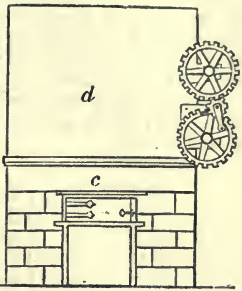
The accompanying drawings represent the machine in several views, for the purpose of showing the construction of all its parts. *Fig.* 1134 is a front elevation of the machine; *fig.* 1135 is a side elevation of the same; *fig.* 1136 is a longitudinal section of the machine; and *fig.* 1137 is a transverse section: the similar letters indicating the same parts in all the figures.

Upon a brick or other suitable base, a furnace or fireplace *a*, is made, having a descending flue *b*, for the purpose of carrying away the smoke. A pan or shallow vessel *c c*, formed of lead, is placed over the furnace; which vessel is intended to contain a sour liquor, as a solution of vitriolic acid and water. On the edge of this pan is erected a wooden casing *d d d*, which encloses three sides, leaving the fourth open for the purpose of obtaining access to the working apparatus within. A series of what may be termed lantern-rollers, *e e e*, is mounted on axles turning in the side casings; and another series of similar lantern-rollers, *f f f*, is in like manner mounted above. These lantern-rollers are made to revolve by means of bevel pinions, fixed on the ends of their axles, which are turned by similar bevel-wheels on the lateral shafts, *g* and *h*, driven by a winch, *i*, and gear, as shown in *figs.* 1135 and 1136.

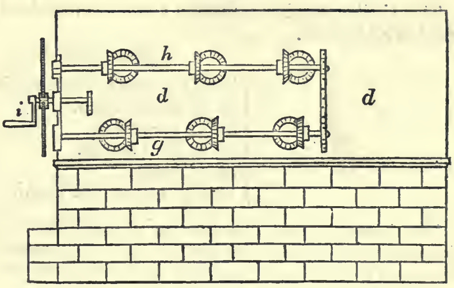
1134



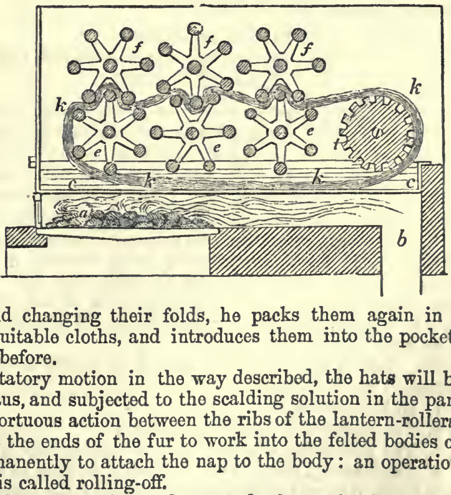
1135



1136



1137



Having prepared the bodies of the hats, and laid upon their surfaces the usual coatings of beaver, or other fur, when so prepared they are to be placed between hair-cloths, and these hair-cloths folded within a canvas or other suitable wrapper. Three or more hats being thus enclosed in each wrapper, the packages are severally put into bags or pockets in an endless band of sackcloth, or other suitable material; which endless band is extended over the lantern-rollers in the machine.

In the first instance, for the purpose of merely attaching the furs to the felts (which is called slicking, when performed by hand), Mr. Carey prefers to pass the endless band *k k k*, with the covered hat-bodies, over the upper series *f f f*, of the lantern-rollers, in order to avoid the inconvenience of disturbing the fur, which might occur from subjecting them to immersion in the solution contained in the pan, before the fur had become attached to the bodies.

After this operation of slicking has been effected, he distends the endless band, *k k k*, over the lower series of lantern-rollers *e e e*, and round a carrier-roller *l*, as shown in *fig.* 1137; and, having withdrawn the hat-bodies for the purpose of examining them, and changing their folds, he packs them again in a similar way in flannel, or other suitable cloths, and introduces them into the pockets or bags of the endless bands, as before.

On putting the machine in rotatory motion in the way described, the hats will be carried along through the apparatus, and subjected to the scalding solution in the pan, as also to the pressure, and to a tortuous action between the ribs of the lantern-rollers, as they revolve, which will cause the ends of the fur to work into the felted bodies of the hats, and by that means permanently to attach the nap to the body: an operation which when performed by hand, is called rolling-off.

A varnish made by dissolving shellac, mastic, sandarac, and other resins in alcohol, or the naphtha of wood-vinegar, is generally employed as the stiffening and waterproof ingredient of hat-bodies. A solution of caoutchouc is often applied to whalebone and horsehair hat-bodies.

The following recipe has been prescribed as a good composition for stiffening hats: 4 parts of shellac; 1 part of mastic; ½ part of turpentine; dissolved in 5 parts of alcohol, by agitation and subsequent repose, without the aid of heat. This stiffening-varnish should be applied quickly to the body or foundation with a soft oblong brush, in a dry and rather warm workshop; the hat being previously fitted with its inside turned outwards upon a block. The body must be immediately afterwards taken off, to prevent adhesion.

Another method of proceeding is, first to dissolve the gums by agitation in twice the due quantity of spirits, whether of wood or wine, and then, after complete solution, draw off one half the spirit in a still, so as to bring the stiffening to a proper consistency. No sediment subsequently appears on diluting this solution, however much it may be done.

Both the spirit and alkali stiffenings for hats made by the following two recipes, have been tried by some of the first houses in the trade, and have been much approved of:—

Spirit-Stiffening.

7 lbs. of orange shellac.
2 lbs. of gum sandarac.
4 oz. of gum mastic.
½ lb. of amber resin.
1 pint of solution of copal.
1 gallon of spirit of wine or wood-naphtha.

The shellac, sandarac, mastic, resin, are dissolved in the spirit, and the solution of copal is added last.

Alkali-Stiffening.

7 lbs. of common block shellac.
1 lb. of amber resin.
4 oz. of gum thus.
4 oz. of gum mastic.
6 oz. of borax.
½ pint of solution of copal.

The borax is first dissolved in a little warm water (say 1 gallon); this alkaline liquor is now put into a copper pan (heated by steam), together with the shellac, resin, thus, and mastic, and allowed to boil for some time, more warm water being added occasionally until it is of a proper consistence.

Hat-Dyeing.—The ordinary bath for dyeing hats employed by the London manufacturers consists, for 12 dozen, of—

144 lbs. of logwood.
12 lbs. of green sulphate of iron, or copperas.
7½ lbs. of verdigris.

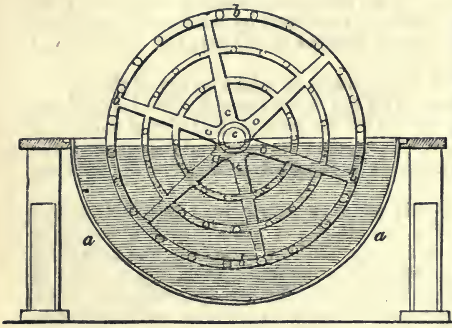
The copper is usually made of a semi-cylindrical shape, and should be surrounded with an iron jacket or case, into which steam may be admitted, so as to raise the temperature of the interior bath to 190° F., but no higher, otherwise the heat is apt to affect the stiffening varnish, called the gum, with which the body of the hat has been imbued. The logwood having been introduced and digested for some time, the copperas and verdigris are added in successive quantities, and the above proportions, along with every successive two or three dozens of hats, suspended upon the dipping-machine. Each set of hats, after being exposed to the bath with occasional airings during 40 minutes, is taken off the pegs, and laid out upon the ground to be more completely blackened by the peroxidation of the iron with the atmospheric oxygen. In 3 or 4 hours the dyeing is completed. When fully dyed, the hats are well washed in running water.

Mr. Buffum states that there are four principal objects accomplished by his patent invention for dyeing hats:—

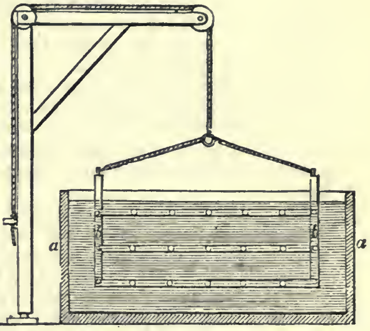
1. In the operation;
2. The production of a better colour;
3. The prevention of any of the damages to which hats are liable in the dyeing;
4. The accomplishment of the dyeing process in a much shorter time than by the usual methods, and consequently lessening the injurious effects of the dye-bath upon the texture of the hat.

Fig. 1138 shows one method of constructing the apparatus. *a a* is a semi-cylindrical shaped copper vessel, with flat ends, in which the dyeing process is carried on. *b b b* is a wheel with several circular rims mounted upon arms, which revolve upon an axle *c*. In the face of these rims a number of pegs or blocks are set at nearly equal distances apart, upon each of which pegs or blocks it is intended to place a hat, and as the wheel revolves, to pass it into and out of the dyeing liquor in the vat or copper. This wheel may be kept revolving with a very slow motion, either by gear connecting its axle, *c*, with any moving power, or it may be turned round by hand, at intervals of ten minutes; whereby the hats hung upon the pegs will be alternately immersed for the space of ten minutes in the dyeing liquor, and then for the same space exposed to the atmospheric air. In this way, the process of dyeing, it is supposed, may be greatly facilitated and improved, as the occasional transition from the dye-vat into the air, and from the air again into the bath, will enable the oxygen of the atmosphere to strike the dye more perfectly and expeditiously into the materials of which the hat is composed, than by a continued immersion in the bath for a much longer time.

1138

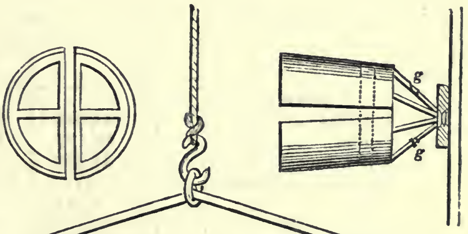


1139



A variation in the mode of performing this process is suggested, and the apparatus *fig.* 1139 is proposed to be employed. *a a* is a square vat or vessel containing the dyeing liquor; *b b* is a frame or rack having a number of pegs placed in it for hanging the hats upon which are about to be dyed, in a manner similar to the wheel above described. This frame or rack is suspended by cords from a crane, and may in that way be lowered down with the hats into the vat, or drawn up and exposed in the air; changes which may be made every 10 or 20 minutes.

1142 1140 1141



Mr. William Hodge's patent improvements in hat-dyeing, partly founded upon an invention of Mr. Bowler, consist, first, in causing every alternate frame to which the suspenders or blocks are to be attached, to slide in and out of grooves, for the purpose of more easily removing the said suspenders when required. *Fig.* 1140 represents the improved dyeing frame, consisting of two circular rims, *a a*, which are connected together at top and bottom, by three fixed perpendicular bars on the frame-work *b b b*. Two other perpendicular frames, *c c*, similar to the former, slide in grooves, *d d d d*, fixed to the upper and lower rims. These grooves have anti-friction rollers in them for the purpose of making the frames *c c*, to slide in and out more freely. The suspenders or substitutes for blocks, by these means, may be more easily got at by drawing out the frames *c c*, about half way, when the suspenders, which are attached to the frames with the hats upon them, may be easily reached, and either removed or altered in position; and when it is done on one side, the sliding-frame may be brought out on the other, and the remaining quantity of 'suspenders' undergo the same operation.

The patentee remarks, that it is well known to all hat dyers, that after the hats have been in the dyeing liquor some time, they ought to be taken out and exposed to the action of the atmospheric air, when they are again immersed in the copper, that part of the hat which was uppermost in the first immersion being placed downwards in the second. This is done for the purpose of obtaining an uniform and regular dye. The patentee's mode of carrying this operation into effect is shown in the figure: *e e* are pivots for the dyeing-frame to turn upon, which is supported by the arms *f*, from a crane above. The whole apparatus may be raised up or lowered into the copper by means of the crane or other mechanism. When the dyeing-frame is raised out of the copper, the whole of the suspenders or blocks are reversed, by turning the apparatus over upon the pivots *e e*, and thus the whole surfaces of the hats are equally acted upon by the dyeing material.

It should be observed, that when the dyeing-frame is raised up out of the copper, it should be tilted on one side, so as to make all the liquor run out of the hats, as also to cause the rims of the hats to hang down, and not stick to the body of the hat, or leave a bad place or uneven dye upon it. The second improvement described by the patentee, is the construction of 'suspenders,' to be substituted instead of the ordinary blocks.

These 'suspenders' are composed of thin plates of copper, bent into the required form, that is, nearly resembling that of a hat-block, and made in such a manner as to be capable of contraction and expansion to suit different sized hats, and keep them distended, which may be altered by the workman at pleasure, when it is required to place the hats upon them, or remove them therefrom. The dyeing-frame at *fig.* 1140, is shown with only two of these 'suspenders,' in order to prevent confusion. One of these suspenders is represented detached at *fig.* 1141, which exhibits a side view; and *fig.* 1142, a front view of the same. It will be seen by reference to the figure, that the suspenders consist of two distinct parts, which may be enlarged or collapsed by a variety of means, and which means may be suggested by any competent mechanic. The two parts of the suspenders are proposed to be connected together by arms *g g*, and at the junction of these arms a key is connected for turning them round when required. It will be seen on reference to the front view, *fig.* 1142, that the 'suspenders' or substitutes for blocks are open at the top or crown-part of the hat; this is for the purpose of allowing the dyeing liquor to penetrate.

Hats or Bonnets imported.

From the mixture of copperas and verdigris employed in the hat-dye, a vast quantity of an ochreous muddy precipitate results, amounting to no less than 25 per cent. of the weight of the copperas. This iron mud forms a deposit upon the hats, which not only corrodes the fine filaments of the beaver, bu causes both them and the felt-stuff to turn speedily of a rusty brown. There is no process in the whole circle of our manufactures so barbarous as that of dyeing stuff hats. No ray of chemical science seems hitherto to have penetrated the dark recesses of their dye-shops. Some hatters have tried to remove this corrosive brown ochre by a bath of dilute sulphuric acid, and then counteract the evil effect of the acid upon the black dye by an alkaline bath; but with a most unhappy effect. Hats so treated are most deceptive and unprofitable; as they turn of a dirty brown hue when exposed for a few weeks to sunshine and air.

HAUERITE. A bisulphide of manganese, occurring at Kalinka in Hungary. It is named after the eminent Austrian geologist, Von Hauer.

HAUSMANNITE. Native proto-peroxide of manganese. See MANGANESE.

HAÜYNE. A mineral occurring in blue or green crystals and crystalline masses, belonging to the cubic system, and presenting a complex constitution; they consist of a silicate of alumina, lime, soda, and potash, with sulphate of lime.

HAWTHORN. (*Épine blanche*, Fr.; *Weissdorn*, Ger.) *Cratægus Oxycantha*, Linn. This shrub has a hard whitish wood, but as it is small and difficult to work, it is not much used.

HAYESINE. A borate of lime, which is found abundantly on the western coast of South America, so called from its discoverer. It has been introduced for use in our glass manufacture, and is used by our potters. See BORACIC ACID.

HAYTORITE. A pseudomorph of quartz after datholite, found at Hay Tor in Devonshire.

HAZEL. (*Noisetier*, Fr.; *Haselstaude*, Ger.) The *Corylus Avellana*, a small underwood, used a little in turnery and for the manufacture of toys. The nuts are eaten.

HAZEL. A North of England term for a hard grit.

HAZEL MOULD. The name given in Hampshire to a light loamy soil.

HEARTH (*Foyer*, Fr.; *Heerde*, Ger.) is the flat or hollow space in a smelting furnace upon which the ore and fluxes are subjected to the influence of flame.

HEARTHSTONE. A soft stone employed for whitening door-steps, &c. A large quantity of hearthstones are brought to London from the quarries in the Upper Greensand at Godstone in Surrey. See GREENSAND.

HEAT. The Force or Principle upon which the conditions, relatively, of solid, fluid, and aeriform states depend. That which produces the sensation of warmth.

The discussion of the habitudes of heat with the different kinds of matter belongs to physico-chemical science, and is treated of in Watts's 'Dictionary of Chemistry.' It will suffice, in this place, to state succinctly those laws which have, more directly, a bearing on any of our manufacturing processes.

Heat and motive power are mutually convertible, and heat requires for its production, and produces by its disappearance, motive power in the proportion of 772 *foot-pounds for each Fahrenheit unit of heat.—Rankine.*

This unit of heat has been established by Dr. Joule to be the amount of heat required to raise the temperature of one pound of liquid water by one degree of Fahrenheit. A falling weight, or any other mode of motion, produces a definite quantity of heat according to this law.

If the total actual heat of a homogeneous and uniformly hot substance be conceived to be divided into any numbers of equal parts, the effect of those parts in causing work to be performed will be equal.—Rankine.

Or, in other words, of a given equivalent of heat, from whatever source produced, the work which it can effect is always an equal and constant quantity.

Heat may be produced by friction, as we see in the development of it powerfully, in the axles of railway carriages insufficiently lubricated. By the attrition of two pieces of wood ignition can be obtained.

Heat is developed in the mixture of bodies of different densities, such as spirits of wine and water, or sulphuric acid and water, there being a diminution of volume in each case.

Heat is produced by many conditions of chemical combination, in numerous cases so energetically as to produce intense combustion and even explosion.

Heat is obtained by combustion for our ordinary manufacturing processes, and domestic uses. This is a chemical union of one body with another, as carbon with oxygen; but to effect this, an excitant appears necessary or a continually increasing excitement of the energy upon which heat depends, as, the application of flame in one case and the phenomena of spontaneous combustion in another.

Electricity by its disturbing power, developes heat, and this all-important force is also rendered manifest by the processes of vitality (vital or nervous force).

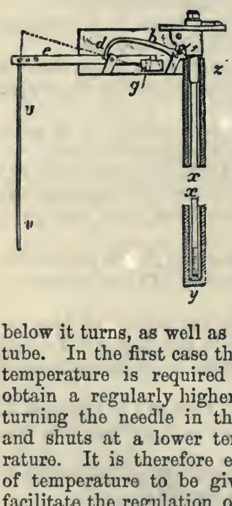
Dr. Joule has clearly shown, that whatever may be the source of heat, a certain fixed elevation of temperature is produced by a given amount of mechanical, chemical, electrical, or vital disturbance, and that the mechanical value of the *cause* producing the heat is exactly represented by the mechanical *effect* obtained.

For a full discussion of this important point, see the Memoirs of Joule, of Thomson, and of Rankine, in the 'Philosophical Transactions' of London and Edinburgh. The applications of heat will be found under the proper heads. The reader should also consult the article Heat in Watts's 'Dictionary of Chemistry.' See also Spheroidal State.

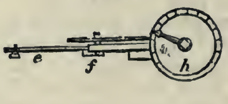
HEAT-REGULATOR, or Thermostat. The name given by M. Bonnemain to an ingenious apparatus for regulating the temperature of his incubating stove-rooms. See Incubation, Artificial, for the manner of applying the Heat-Regulator.

The construction of the regulator is founded upon the unequal distillation of different metals by the same degree of heat. A rod of iron *x*, *fig.* 1143, is tapped at its lower end into a brass nut *y*, enclosed in a leaded box or tube, terminated above by a brass collet *z*. This tube is plunged into the water of the boiler, alongside of the smoke-pipe. *Fig.* 1144, is a bird's-eye view of the dial, &c. The expansion of the lead being more than the iron for a like degree of temperature, and the rod enclosed within the tube being less easily warmed, whenever the heat rises to the desired pitch, the elongation of the tube puts the collet *z* in contact with the heel, *a*, of the bent lever *a*, *b*, *d*; thence the slightest increase of heat lengthens the tube anew, and the collet lifting the heel of the lever, depresses the other end *d* through a much greater space, on account of the relative lengths of its legs. This movement operates near the axis of a balance-bar *e*, sinks one end of this, and thereby increases the extent of the movement, which is transmitted directly to the iron skewer *v*. This, pushing down a swing-register, diminishes or cuts off the access of air to the fire-place. The combustion is thereby obstructed, and the temperature falling by degrees, the tube shrinks and disengages the heel of the lever. The counterpoise *g*, fixed to the balance-beam *e*, raises the other extremity of this beam by raising the end, *d*, of the lever as much as is necessary to make the heel bear upon the collet of the tube. The swing-register acted upon by this means presents a greater section to the passage of the air; whence the combustion is increased. To counterbalance the effect of atmospheric changes, the iron stem which supports the regulator is terminated by a dial disc, round the shaft of the needle above *h*, *fig.* 1144; on turning this needle, the stem below it turns, as well as a screw at its under end, which raises or lowers the leaden tube. In the first case the heel falls, and opens the swing-register, whence a higher temperature is required to shut it, by the expansion of the tube. We may thus obtain a regularly higher temperature. If, on the contrary, we raise the tube by turning the needle in the other direction, the register presents a smaller opening, and shuts at a lower temperature; in this case we obtain a regularly lower temperature. It is therefore easy, says M. Bonnemain, to determine *à priori* the degree of temperature to be given to the water circulating in the stove-pipes. In order to facilitate the regulation of the apparatus, he graduated the disc dial, and inscribed upon its top and bottom the words Strong and Weak heat.

1143



1144

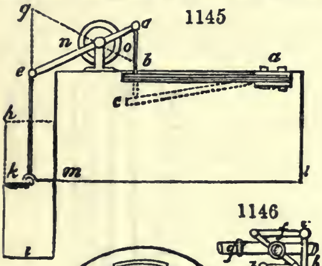


Thermostat, is the name of an apparatus for regulating temperature, in vaporisation, distillations, heating baths or hothouses, and ventilating apartments, &c.; for which I obtained a patent in the year 1831. It operates upon the physical principle, that when two thin metallic bars of different expansibilities are riveted or soldered facewise together, any change of temperature in them will cause a sensible movement of flexure in the compound bar, to one side or other; which movement may be made to operate, by the intervention of levers, &c., in any desired degree, upon valves, stopcocks, stove-registers, air-ventilators, &c.; so as to regulate the temperature of the media in which the said compound bars are placed. Two long rulers, one of steel, and one of hard hammered brass, riveted together, answer very well; the object being, not simply to *indicate*, but to *control* or *modify* temperature. The following diagrams will illustrate a few out of the numerous applications of this instrument:—

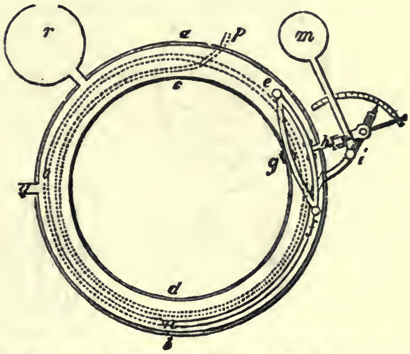
Fig. 1145, *a*, *b*, is a single thermostatic bar, consisting of two or more bars or rulers of differently expansible solids (of which, in certain cases, wood may be one): these bars or rulers are firmly riveted or soldered together, face to face. One end of the compound bar is fixed by bolts at *a*, to the interior of the containing cistern, boiler, or apartment, *a l m b*, whereof the temperature has to be regulated, and the other end of the compound bar at *b* is left free to move down towards *c*, by the flexure which will take place when its temperature is raised.

The end *b*, is connected by a link, *b d*, with a lever *d e*, which is moved by the flexure into the dotted position *b g*, causing the turning-valve, air-ventilator, or register, *o n*, to revolve with a corresponding angular motion, whereby the lever will raise the equipoised slide-damper *k i*, which is suspended by a link from the end, *e*, of the lever, *e d*, into the position *k h*. Thus a hothouse or a water-bath may have its temperature regulated by the contemporaneous admission of warm, and discharge of cold air, or water.

Fig. 1146, *a b c* is a thermostatic hoop, immersed horizontally beneath the surface of the water-bath of a still. The hoop is fixed at *a*, and the two ends *b c*, are connected by two links *b d*, *c d*, with a straight sliding rod *d h*, to which the hoop will give an endwise motion, when its temperature is altered; *e*, is an adjusting screw-nut on the rod *d h*, for setting the lever *f g*, which is fixed on the axis of the turning-valve or cock, *f* at any desired position, so that the valve may be opened or shut at any desired temperature, corresponding to the widening of the points *b*, *c*, and the consentaneous retraction of the point *d* towards the circumference *a b c* of the hoop. *g h*, is an arc graduated by a thermometer, after the screw-piece *e* has been adjusted. Through a hole at *h*, the guide-rod passes; *i*, is the cold-water cistern; *i f k*, the pipe to admit cold water; *l*, the overflow pipe, at which the excess of hot water runs off.

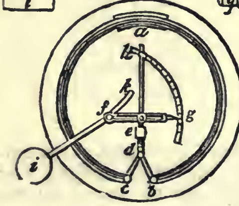


1145



1148

1146



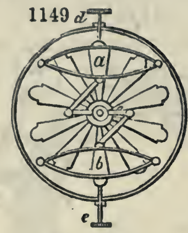
1147

Fig. 1147 shows a pair of thermostatic bars, bolted fast together at the ends *a*. The free ends *b*, *c*, are of unequal length, so as to act by the cross links *d*, *f*, on the stopcock *e*. The links are jointed to the handle of the turning plug of the cock, on opposite sides of its centre; whereby the plug will be turned round in proportion to the widening of the points *b*, *c*. *h g* is the pipe communicating with the stopcock.

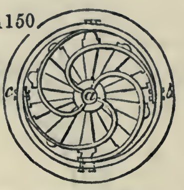
Suppose that for certain purposes in pharmacy, dyeing, or any other chemical art, a water-bath is required to be maintained steadily at a temperature of 150° F.: let the combined thermostatic bars, hinged together at *e*, *f*, *fig.* 1148, be placed in the bath between the outer and inner vessels *a*, *b*, *c*, *d*, being bolted fast to the inner vessel at *g*; and have their sliding rod *k*, connected by a link with a lever fixed upon the turning plug of the stopcock *i*, which introduces cold water from a cistern *m*, through a pipe *m*, *i*, *n*, into the bottom part of the bath. The length of the link must be so adjusted that the flexure of the bars, when they are at a temperature of 150°, will open the said stopcock, and admit cold water to pass into the bottom of the bath through the pipe *i n*, whereby hot water will be displaced at the top of the bath through an open overflow-pipe at *q*. An oil-bath may be regulated on the same plan; the hot oil overflowing from *q*, into a refrigeratory worm, from which it may be restored to the cistern *m*. When a water-bath is heated by the distribution of a tortuous steam-pipe through it, as *i n o p*, it will be necessary to connect the link of the thermostatic bars with the lever of the turning plug of the steam-cock, or of the throttle valve *i*, in order that the bars, by their flexure, may shut or open the steam passage more or less, according as the temperature of the water in the bath shall tend more or less to deviate from the pitch to which the apparatus has been adjusted. The water of the condensed steam will pass off from the sloping winding-pipe *i n o p*, through the sloping orifice *p*. A saline, acid, or alkaline bath has a boiling temperature proportional to its degree of concentration, and may therefore have its heat regulated by immersing a thermostat in it and connecting the working-part of the instrument with a stopcock *i*, which will admit water to dilute the bath whenever by evaporation it has become concentrated, and has acquired a higher boiling point. The space for the bath, between the outer and inner pans, should communicate by one pipe with the water-cistern *m*, and by another pipe with a safety cistern *r*, into which the bath may be allowed to overflow during any sudden excess of ebullition.

Fig. 1151 is a thermostatic apparatus, composed of three pairs of bars *d d d*, which are represented in a state of flexure by heat; but they become nearly straight and parallel when cold. *a b c* is a guide rod, fixed at one end by an adjusting screw *e*, in the strong frame *f e*, having deep guide grooves at the sides. *f g*, is the working-rod which moves endways when the bars *d d d*, operate by heat or cold. A square register-plate *h g*, may be affixed to the rod *f g*, so as to be moved backwards and forwards thereby, according to the variations of temperature; or the rod *f g*, may cause the circular turning air-register, *i*, to revolve by rack and wheel work, or by a chain and pulley. The register-plate *h g*, or turning register *i*, is situated at the ceiling or upper part of the chamber, and serves to let out hot air. *k*, is a pulley, over which a cord runs to raise or lower a hot-air register *l*, which may be situated near the floor of the apartment or hot-house, to admit hot air into the room. *c* is a milled head, for adjusting the thermostat, by means of the screw at *e*, in order that it may regulate the temperature to any degree.

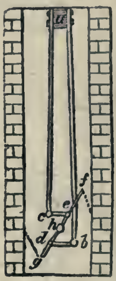
1149

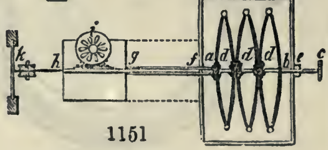


1150



1152





1151

Fig. 1152 represents a chimney, furnished with a *pyrostat*, *a b c*, acting by the links *b*, *d*, *e*, *c*, on a damper *f h g*. The more expansible metal is in the present example supposed to be on the outside. The plane of the damper-plate will, in this case, be turned more directly into the passage of the draught through the chimney by increase of temperature.

Fig. 1150 represents a circular turning register, such as is used for a stove, or stove-grate, or for ventilating apartments; it is furnished with a series of spiral thermostatic bars, each bar being fixed fast at the circumference of the circle *b*, *c*, of the fixed plate of the air-register; and all the bars act in concert at the centre *a* of the turning part of the register; by their ends being inserted between the teeth of a small pinion, or by being jointed to the central part of the turning plate by small pins.

Fig. 1149 represents another arrangement of the thermostatic apparatus applied to a circular turning register, like the preceding, for ventilating apartments. Two pairs of compound bars are applied so as to act in concert, by means of the links *a c*, *b c*, on the opposite ends of a short lever which is fixed on the central part of the turning plate of the air-register. The two pairs of compound bars *a b*, are fastened to the circumference of the fixed plate of the turning register, by two sliding rods *a d*, *b e*, which are furnished with adjusting screws. Their motion of flexure is transmitted by the links *a c* and *b c*, to the turning plate, about its centre, for the purpose of shutting or opening the ventilating sectorial apertures, more or less, according to the temperature of the air which surrounds the thermostatic turning register. By adjusting the screws *a d*, and *b c*, the turning register is made to close all its apertures at any desired degree of temperature; but whenever the air is above that temperature, the flexure of the compound bars will open the apertures.

HEAVE, *a miner's term,* expressing the dislocation of a lode. See FAULT.

HEAVY-SPAR (*Spath pesant*, Fr.; *Schwerspath*, Ger.), is an abundant mineral, which accompanies veins of lead, silver, mercury, &c., but is often found, also, in large masses. Its colour is usually white, or flesh coloured. It varies from translucent to opaque. It belongs to the trimetric system, but occurs in many crystalline forms, of which the cleavage is a right rhomboidal prism. It is met with also of a fibrous, radiated, and granular structure. Its sp. gr. varies from 4·1 to 4·7; H=2·5 to 3·5. It has a strong lustre, between the fatty and the vitreous, sometimes pearly. It melts at 35° Wedgw. into a white opaque enamel. It is a sulphate of baryta; its constituents being 65·67 baryta, and 34·33 sulphuric acid; but it is sometimes rendered impure by oxide of iron, silica, carbonate of lime, and alumina, and commonly by sulphate of strontia. It is not acted upon by acids; decrepitates before the blowpipe; and is difficultly fusible, or only on the edges. In the inner flame it is reduced to a sulphuret, and the globule when moistened smells slightly hepatic. It is decomposed by calcination in contact with charcoal at a white heat, into sulphide of barium; from which all the baryta-salts may be readily formed. Its chief employment in commerce is for adulterating white-lead; a purpose which it readily serves on account of its density. Its presence here is easily detected by dilute nitric acid, which dissolves the carbonate of lead, and leaves the heavy-spar. It is also a useful ingredient in some kinds of pottery, and glass.

The following were the quantities of barytes, both carbonate and sulphate, returned to the Mining Record Office, from the mines of Great Britain, and reported in Hunt's 'Mineral Statistics' for 1872:—

Derbyshire, the Isle of Arran, and Ireland produced some sulphate of baryta which has not been given in the above return.

The term *Cawk* has been applied to the opaque massive variety, of an earthy appearance, and dirty-white colour, which is found in Derbyshire and Staffordshire.

HECKLE (*Séran*, Fr.; *Hechel*, Ger.) is an implement for dissevering the filaments of flax, and laying them in parallel stricks or tresses. See FLAX.

HELICIN. A crystalline alkaloïd produced by the oxidation of *salicin*, the bitter principle of the poplar and willow.

HELIOGRAPHY was the name given by M. Niepce to his process for obtaining, through the agency of the solar rays upon plates of metal or glass covered with resins, the impression of external objects. The process has been employed of late years in preparing lithographic stones, and steel or copper plates, for receiving photographic impressions, which might be subsequently printed from. The name Heliography is a far more appropriate one than Photography; but the latter has become too permanently fixed in our language to leave any hope of our returning to the former. See PHOTOGRAPHY.

HELIOTROPE is a variety of green jasper, marked with blood-red points; whence its vulgar name of *blood-stone*. See Blood-Stone.

HELLEBORE. Several species of *Helleborus*, a genus of plants belonging to the natural order *Ranunculaceæ*, were formerly used as drastic purgatives. The *Veratrum album*, a widely different plant, is known as 'White Hellebore.'

HELVINE. A silicate of the protoxides of manganese, iron, and glucinum, with sulphide of manganese. It is commonly found in tetrahedral crystals, whence its name *Tetrahedral Garnet*. The best examples come from Saxony.

HEMATIN. See Hæmatin.

HEMATITE. See Hæmatite.

HEMATOGLOBULIN. See Hæmatoglobulin.

HEMATOSIN. See Hæmatosin.

HEMATOXYLIN. See Hæmatoxylin.

HEMIMORPHITE. A name for silicate of zinc, or smithsonite. See Calamine, Electric.

HEMLOCK. The *Conium maculatum*, a highly poisonous umbelliferous plant used in medicine. Its properties are mainly due to the presence of an oily liquid called *conia*.

HEMLOCK SPRUCE. The *Abies Canadensis*, the wood of which has been used for railway sleepers, and is employed for baths.

HEMP. (*Chanvre*, Fr.; *Hanf*, Ger.) A plant (*Cannabis sativa*), a native of India, but has been long introduced into Europe, and cultivated extensively in Italy, and in Russia and Poland; a small quantity has been cultivated in Suffolk, in Lincolnshire, and in Ireland.

Hemp is assorted into *clean hemp*, *out-shot hemp*, *half-clean hemp*, and *hemp codilla*. According to M'Culloch, a bundle of clean hemp from Russia weighs from 55 to 65 poods; of out-shot, from 48 to 55 poods; of half-clean, 40 to 45 poods—the pood being equal to 36 lbs. avoirdupois.

Hemp imported in 1871 and 1872.

Manilla hemp is the produce of the wild banana, *Musa textilis*. 'It is known,' says Mr. Craufurd, in his 'History of the Eastern Archipelago,' 'to our traders and navigators under the name of Manilla rope, and is equally applicable to cables and to standing or running rigging.'

Sunn and Jute are two varieties of hemp. Hemp is used in the manufacture of *huckaback* for towels and common tablecloths, and of the low-priced cloth worn by agricultural labourers. The largest consumption of this material is in the manufacture of sail-cloth and cordage.

From Mexico, British India, Ceylon, and other countries, we imported of *vegetable substances applicable to the same uses as hemp and flax*: in 1871, 23,106 cwts., value 26,040*l.*; in 1872, 64,880 cwts., value 94,564*l.*

HEMP SEED. (*Chènevis*, Fr.; *Hanfsaat*, Ger.) The seed of the hemp; it is used for crushing for its oil, or as food for birds.

HENBANE. The *Hyoscyamus niger.* Henbane is a plant used in medicine, from which modern chemistry has extracted a crystalline vegetable principle called *hyoscyamine*, which is very poisonous, and when applied in solution to the eye, determines a remarkable dilatation of the pupil, as *belladonna* also does. See Hyoscyamine.

HENNA. The herb used for dyeing the nails in the East. See Alkenna.

HEPAR, which signifies *liver* in Latin, was a name given by the older chemists to some of the compounds of sulphur.

HEPATIC AIR. Sulphuretted hydrogen gas.

HERMETICAL SEAL is an expression derived from Hermes, who was said to be the parent of Egyptian chemistry. It is used to designate the perfect closure of a hollow vessel, by the cementing or melting of the lips of its orifice; as in the case of a glass thermometer.

HERNANDIA OVIGERA. Hernant seeds, some of which are imported from India for tanning.

HERRINGS. The herring-family belongs to the order *Malacopterygii*, characterised by having a scaly body like the salmon, and no adipose dorsal fin. The herrings, *Clupea Harengus*, are a well-known fish inhabiting the deep water all round the British Isles. They approach the shores in the months of August and September, for the purpose of depositing their spawn, which takes place in October or November. At this period they are caught in immense numbers; upwards of 20,000,000 fish have, it is said, been taken off Lowestoft alone. By thus destroying the gravid fish, we wantonly destroy one of our most important fisheries. The quantity of herrings which appear on our coasts is becoming less and less each year; and unless some system is adopted, this fish will, in a comparatively short time become extinct, and a most important industry be destroyed.

HERSCHELITE. A hydrated silicate of alumina, soda, and potash, crystallizing in the rhombic system. It is found in lava in Sicily, and splendid examples have been recently obtained from the basalt quarries at Richmond in Victoria.

HESPERIDEÆ or *Aurantiaceæ.* A family of dicotyledonous plants. They are trees or shrubs. The leaves are dark green, glabrous, of a coriaceous texture, and dotted with numerous transparent points, caused by the presence of receptacles filled with a volatile oil which communicates the odour peculiar to the family. The species are numerous, the greater number originally natives of the tropical regions of Asia, though now cultivation has spread them over the larger portion of the globe. The flowers are usually octoriferous; the fruit has a more or less acid pulp; and the wood is generally compact and valuable. The genus *Citrus* contains the best known species of the family. Under Citrus, most of the fruits are referred to. The fruits, however, of several other genera belonging to the family are greatly esteemed in the countries which produce them. The *Wampa*, highly relished in China and the Indian Archipelago, is the fruit of *Cookea punctata*, and considered excellent. The *Oegle marmelas* is used in medicine, and a perfume is prepared from the rind of the fruit, which is itself delicious, and acts as a laxative.

HESSONITE. See Essonite.

HEULANDITE. A hydrous silicate of alumina and lime, occurring in oblique crystals in cavities in amygdaloidal rocks.

HICKORY. The *Juglans alba*; white walnut, a native of America. There are several species, all natives of North America, and growing into stately trees. The wood of the hickory, and some others of the *Juglandaceæ*, is tough and strong; therefore it is used for making shafts and springs for carriages, such screws as are employed in bookbinders' presses, for cogged wheels, and many other purposes where toughness is a desideratum. The hickory nuts are much esteemed, and form an article of trade. The heart of the wood is often red, and the bark has been recommended by Dr. Bancroft, as a yellow die.

HIDE. (*Peau*, Fr.; *Haut*, Ger.) The strong skin of an ox, horse, or other large animal. The lists of *imports* below will show to what an extent a trade in the skins of animals is carried on with this country. We receive hides largely from Russia and the north of Europe. From America there are also large quantities brought to this country.

The following Table shows the number of hides which were imported in 1871 and 1872:—

	1871		1872	
		£		£
Tanned, tawed, curried, or in any way dressed: dry . . . . .cwts.	604,302	2,083,466	808,420	3,003,920

Varnished, japanned, or enamelled ,,	218,664	895,895	479,658	123,098

HIGHGATE RESIN. A fossil copal occurring in the London clay of Highgate, near London.

HIPPOCASTANUM. The common horse-chestnut (*Æsculus Hippocastanum*). The seeds contain much starchy matter, and have of late years been used on the Continent for the preparation of starch. When roasted they are said to form a fair substitute for coffee. In Switzerland they are used as food for sheep. It is said that the young leaves of the horse-chestnut have been used instead of hops. The American Horse-chestnut or Buck-eye (another species of *Æsculus*) is reputed to be poisonous.

HIPPOPOTAMUS TEETH. See Ivory.

HISINGERITE. A hydrous silicate of peroxide of iron, magnesia, &c.; from Sweden.

HISLOPITE. A green calc-spar coloured with glauconite; from India.

HOG-GUM. The hog-gum of Jamaica, which is used locally as a medicine, is the produce of *Rhus metopium*.

HOG-NUT. The edible fruit of *Carya porcina*.

HOG'S LARD, or *Axungi*; the latter name derived from the use to which it was put by the ancients, *i.e.* to grease the axle of a wheel. It is obtained from the hog (*Sus scrofa*) and other members of the hog tribe. Hog's lard is largely used in the manufacture of ointments, pomatum, &c. Its proximate analysis gives, according to Braconnot: stearine and margarine, 38; elaine, 62. The stearine is separated and used in the manufacture of candles, and the elaine sold under the name of Lard Oil.

HOLING. The act of cutting away the under part of a coal-seam, so as to bring down the overlying mass of coral. See Mining.

HOLLAND. A linen fabric, which is sold when unbleached as *brown holland*, and which is used when bleached for finer purposes. See Linen.

HOLLANDS. A grain spirit manufactured in Holland.

HOLLY. (*Le Houx*, Fr.; *Stechpalme*, Ger.) The *Ilex aquifolium* of Linnæus, a British plant. Its leaves yield a yellow colouring matter similar to that obtained from buckwheat. The wood is as white as ivory, very hard and fine grained, and susceptible of a high polish; it is employed for many purposes.

HOMBERG'S PHOSPHORUS. Sulphide of calcium, which after exposure to sunlight appears luminous in the dark.

HOMOGENEOUS. A uniformity of structure as applied to metals. Steel is said to be homogeneous when the particles constituting the mass are of the same size and structure throughout.

HOMOLOGOUS. A term used in organic chemistry to denote that substances differ by the constant increment C^2H^2 ($\mathbf{CH^2}$). Thus, in the great series of acids commencing with the formic and extending up to the fatty acids, each *homologue* contains C^2H^2 more than the one before, and C^2H^2 less than the one following, thus:—

Formic acid . .	$C^2H^2O^4$ ($\mathbf{CH^2O^2}$)
Acetic acid . .	$C^4H^4O^4$ ($\mathbf{C^2H^4O^2}$)
Propionic acid . .	$C^6H^6O^4$ ($\mathbf{C^3H^6O^2}$)
Butyric acid . .	$C^8H^8O^4$ ($\mathbf{C^4H^8O^2}$) &c.—C.G.W.

HONDURAS MAHOGANY. See Mahogany.

HONES AND HONE SLATES. These are slaty stones which are used in straight pieces for sharpening tools after they have been ground on revolving grindstones. The more important varieties are the following:—

The *Norway Ragstone* which is the coarsest variety of the hone slates, is imported in large quantities from Norway. In Charnwood Forest, near Mount Sorrel, in Leicestershire, particularly from the Whittle Hill quarry, is obtained the *Charnley Forest Stone*, said to be one of the best substitutes for the Turkey oilstone, and it is much in request by joiners and others. *Ayr stone*, *Snake stone*, and *Scotch stone*, are used especially for polishing copper plates. The *Welsh oilstone* is almost in equal repute with the Charnley Forest stone; it is obtained from the vicinity of Llyn Idwall, near Snowdon, and hence it is sometimes called *Idwall stone*. From Snowdon is also obtained the *cutler's green stone*. The *Devonshire oilstones*, obtained near Tavistock, which were introduced by Mr. John Taylor, are of excellent quality; but the supply of them being irregular, they have fallen into disuse.

The *German razor-hone* has been long celebrated. It is obtained from the slate mountains in the neighbourhood of Ratisbon, where it occurs in the form of a yellow vein running through the blue slate, varying in thickness from 1 to 18 inches. When quarried it is sawn into thin slabs, and these are generally cemented to slices of slate which serve as a support. Sometimes, however, the yellow and the blue slate are cut out naturally combined. There are several other hone stones, which, however, require no particular notice.

The *Turkey oilstone* is said to surpass in its way every other known substance, and it possesses in an eminent degree the property of abrading the hardest steel; it is, at the same time, of so compact and close a nature as to resist the pressure necessary for sharpening a graver, or any instrument of that description. There are white and black varieties of the Turkey oilstone, the black being the hardest, and it is imported in somewhat larger pieces than the white; they are found in the interior of Asia Minor, and are brought down to Smyrna for sale.

HONEY (*Mel*, Fr.; *Honig*, Ger.) is a sweet viscid liquor, secreted in the nectaries of flowers, collected by the working bees, and deposited by them in the waxen cells of their combs. Virgin honey is that which is collected from a hive, the bees of which have never swarmed; the common honey is obtained from the older hives. The former, which is considered the best, is whitish or pale yellow, of a granular texture, a fragrant smell, and a sweet slightly pungent taste; the latter is darker coloured, thicker, and not so agreeable either in taste or smell. Honey would seem to be simply collected by the bees, for it consists of merely the vegetable products, such as the sugars of grape, gum, and manna, along with mucilage, extractive matter, a little wax, and acid.

Narbonne honey, the flavour of which is so much admired, owes its peculiarity to the flowers on which the bees feed.

Trebizond honey has been long celebrated for its intoxicating qualities. The description given in Xenophon's 'Retreat of the Ten Thousand' is well known. Many examples of poisonous honey are on record.

Honey is collected and sold to a considerable extent in Britain, particularly in the north-western counties of Wales. At Wrexham in Denbighshire there is an annual fair, called the 'Honey Fair.' Many ale breweries employ a portion of honey to add strength and flavour to their brewings.

HONEY-COMB. The waxen cells of the bee. See WAX.

HONEY-DEW. A viscid saccharine substance, resembling manna, and occurring on the leaves of the lime, black alder, maple, rose, oak, and other trees. Its secretion appears to be due to certain abnormal conditions of the plant. Boussingault analysed the honey-dew collected in July and August 1869, from the leaves of a lime at Liebfrauenberg in the Vosges. It contained a sugar analogous to cane-sugar, together with levulose or fruit-sugar and dextrine. The proportions of these substances, as determined by optical examination with polarised light, were as follow:—

Cane-sugar	48·86	55·44
Inverted sugar	28·59	24·75
Dextrine	22·55	19·81
	100·00	100·00

The second analysis is almost identical with that of the manna of Mount Sinai, as determined by Berthelot. It has been calculated that in one day a single lime-tree may yield from 4 to 7 lbs. of honey-dew, reckoned in a dry state.

HONEY-STONE. (*Mellite*, Fr.; *Honigstein*, Ger.) A mineral of a yellowish or reddish colour, and a resinous aspect, crystallising in octahedrons with a square base; specific gravity 1·58. It is harder than gypsum, but not so hard as calc-spar; it is deeply scratched by a steel point; very brittle; affords water by calcination; blackens, then burns at the flame of the blowpipe, and leaves a white residuum which becomes blue when it is calcined, after having been moistened with a drop of nitrate of cobalt. It is a hydrous mellate of alumina, and consists of:—

	Klaproth	Wöhler	V. Iljenkoff
Mellitic acid . . .	46	44·4	42·36
Alumina	16	14·5	14·20
Water	38	41·1	44·16
	100	100·0	100·72

The honey-stone, like amber, belongs to the geological formation of lignite. It has been hitherto found only at Artern in Thuringia.; at Luschitz, near Bilin in Bohemia; and near Walchow in Moravia.

HOP (*Houblon*, Fr.; *Hopfen*, Ger.) is the name of a well-known plant of the natural family of *Urticaceæ*, and of the *Diœcia pentandria* of Linnæus. The female flowers, placed upon different plants from the male, grow in ovoid cones formed of oval leafy scales, concave, imbricated, containing each at the base an ovary furnished with two tubular open styles, and sharp-pointed stigmata. The fruit of the hop is a small rounded seed, slightly compressed, brownish coloured, enveloped in a scaly calyx, thin, but solid, which contains, spread at its base, a granular yellow substance, appearing to the eye like a fine dust, but in the microscope they seem to be round, yellow, transparent, grains; deeper coloured, the older the fruit. This secretion which constitutes the useful portion of the hop, has been examined in succession by Ives, Planche, Payen, and Chevallier. A pretty full account of the results of their researches in treating of the hop is given in the article Beer.

Number of Acres under the Cultivation of Hops in England.

The preceding Tables are retained, as showing the history of our hop cultivation in a way which cannot be continued. The duty on hops was repealed from September 16, 1862, so that since that period we have no means of obtaining, except through indirect channels, any accurate statements as to production.

The following is the last official return published of hops imported:—

HORDEINE is the name given by Proust to the peculiar starchy matter of barley. It seems to be a mixture of the starch, lignine, and husks, which constitute barley-meal. See Beer.

HORDEUM VULGARE. See Barley.

HOREHOUND. The *Marrubium vulgare*, used in England as a simple domestic remedy for coughs.

HORIZONTAL WELLS. Having given an article on Artesian Wells (which see) it appears necessary that something should be said respecting the system proposed by Mr. Lucas, in his work on 'Horizontal Wells, a new application of Geological Principles to effect the Solution of the problem of Supplying London with Pure Water,' 1874.

In recapitulating the geological principles on which his scheme is based, Mr. Lucas refers to the obvious tendency of water absorbed by the edges of permeable sedimentary rocks to sink through these until it reaches an impervious stratum, when it flows down the dip of the beds. This is illustrated by the fact that springs which break out at the surface mostly do so from the line of junction of a porous and an impervious bed, and, of course, from the base of the former, especially where the dip is considerable. In most cases, the drainage of several porous strata is collected at one general point, and to tap this is to obtain, very much more effectually filtered than it can be by any artificial appliances, the water of a large area of natural drainage.

Extensive data on this point are given by Mr. Lucas from the experience of miners, to whom these natural incidents are the occasion of great inconvenience and cost. Some of the collieries in the Durham coal-field, sunk through the magnesian limestone, are troubled with as much as 5,000 gallons a minute. So great, however, is the imperviousness of shale, that five feet of it at the bottom of a shaft forty or fifty fathoms deep through the limestone will turn back that amount of water, allowing none of it to pass through. Mr. Lucas thus concisely indicates the principle of his plan:—'The shaft is sunk to procure a certain stratum; but were water the object, in this as in all other cases, it would certainly be followed along its bed, at the junction of the sandstones with the shales, by levels in a manner similar to that in which the ordinary water-levels of a mine are carried along the bed mined for. Nothing could exceed the purity of water that has been filtered through hundreds of feet of pure quartzose sandstone. The springs of clear water that break from the base of sandstones at their outcrop, in all formations, give striking proofs of the truth of this statement. The waters drawn from wells sunk in such beds also corroborate it. If, then, a large town requires water-supplies, and at no great distance from it there lies a formation containing alternations of porous and impervious beds, which rise above the level of the town, then there should be no difficulty in supplying water at high pressure on the constant system. Such formations occur within easy reach of London.'

The particular sources from which it is proposed to supply the metropolis are the Lower Greensands of Surrey and the underlying chalk, chiefly the former. The first-named form hills from 800 to 967 feet in height, as at Leith Hill, and Hind Head, and consist of a series of highly porous sands, sandstones, and limestones, 400 feet thick, resting upon a bed of absolutely impervious clay, upon the top of which all the water that sinks through the greensands flows down. The upper part of this latter bed is also sandy, and contains a vast amount of water. This was proved in the construction of the Sevenoaks Tunnel, when the water from the latter beds proved a source of much difficulty to the excavators, and now pours in a fully-formed stream from the tunnel's mouth. 'A tunnel driven along the strike of the beds, or water-level, must of necessity arrest all the water that is flowing down it as far as the gallery is carried.' Again, Mr. Lucas argues, 'We have, in fact, in the Lower Greensands of Surrey, a combination of the circumstances most favourable for gathering and storing water. The height of the range attracts a high rainfall, the breadth of the absorbing surface causes much of it to be absorbed. The thickness of the porous beds affords a large reservoir for water absorbed. The complete imperviousness of the retaining clays, Atherfield and Gault, prevents the escape of these waters, which are thus held in a subterraneous reservoir, whose lowest rim is at the deepest valley cutting through the Gault clays.'

Mr. Lucas proposes to collect the supply of water for London from the Leith Hill range 'by means of horizontal galleries driven along the strike of the beds on the Atherfield clay, as by that means very large quantities of water may be gained. The height of the range, and the breadth of the absorbing surface presented by it, together with the great thickness of the porous beds, all point to the suitability of the area from a geological point of view. The great natural reservoir of the chalk of the North Downs of Surrey may also be tapped in a similar manner. The galleries will be placed in a different position, as the water-bearing part of the chalk is near the top of that formation. As regards actual experience of the Lower Greensands, the case of the Sevenoaks Tunnel has already been mentioned. That tunnel was driven at right angles to the strike of the beds, and therefore cannot be viewed as a criterion of the quantity of water to be gained by a gallery of equal length carried along the strike, on the Atherfield clay. This quantity would of course be enormously larger.' See Artesian Wells.

HORN (Eng. and Ger.; *Bois*, *Corne*, Fr.), particularly of oxen, cows, goats, and sheep, is a substance soft, tough, semi-transparent, and susceptible of being cut and pressed into a variety of forms; it is this property that distinguishes it from bone. Turtle or tortoise-shell seems to be of a nature similar to horn, but instead of being of a uniform colour, it is variegated with spots. See Tortoise Shell.

Mr. Aikin ('Trans. Soc. of Arts') remarks, 'In the English language we have only one word to express two quite different substances; namely, the branched bony horns of the stag genus, and the simple laminated horns of the ox genus and other kindred genera. The bony horns are called in the French *bois*, from their likeness to the branch of a tree; they are annually renewed. The other horn, to which the French appropriate the term *corne*, is found on the ox, the antelope, the goat, and sheep kinds.'

The valuable properties of horn render it susceptible of being employed in a variety of works fit for the turner, snuff-box, and comb maker. The means of softening the horn need not be described, as it is well known to be by heat; but those of cutting, polishing, and soldering it, so as to make plates of large dimensions, suitable to form a variety of articles, may be detailed. The kind of horn to be preferred is that of goats and sheep, from its being whiter and more transparent than the horn of any other animals. When horn is wanted in sheets or plates, it must be steeped in water, in order to separate the pith from the kernel, for about fifteen days in summer, and a month in winter; and after it is soaked, it must be taken out by one end, well shaken and rubbed in order to get off the pith; after which it must be put for half an hour into boiling water, then taken out, and the surface sawed even lengthways; it must again be put into the boiling water to soften it, so as to render it capable of separating; then, with the help of a small iron chisel, it can be divided into sheets or leaves. The thick pieces will form three leaves, those which are thin will form only two, whilst young horn, which is only one quarter of an inch thick, will form only one. These plates or leaves must again be put into boiling water, and when they are sufficiently soft, they must be scraped with a sharp cutting instrument, to render those parts that are thick even and uniform; they must be put once more into the boiling water, and finally carried to the press.

At the bottom of the press employed, there must be a strong block, in which is formed a cavity, of nine inches square, and of a proportionate depth; the sheets of horn are to be laid within this cavity, in the following manner: at the bottom, first a sheet of hot iron, upon this a sheet of horn, next again a sheet of hot iron, and so on, taking care to place at the top a plate of iron even with the last. The press must then be screwed down tight.

There is a more expeditious process, at least in part, for reducing the horn into sheets, when it is wanted very even. After having sawed it with a very fine and sharp saw, the pieces must be put into a copper made on purpose, and there boiled until sufficiently soft, so as to be able to be split with pincers; the sheets of horn must then be put in the press where they are to be placed in a strong vice, the chaps of which are of iron and larger than the sheets of horn, and the vice must be screwed as quick and tight as possible; let them cool in the press or vice, or it is as well to plunge the whole into cold water. The last mode is preferable, because the horn does not shrink in cooling. Now draw out the leaves of horn, and introduce other horn to undergo the same process. The horn so enlarged in pressing, is to be submitted to the action of the saw, which ought to be set in an iron frame, if the horn is wanted to be cut with advantage, in sheets of any desired thickness, which cannot be done without adopting this mode. The thin sheets thus produced must be kept constantly very warm between plates of hot iron to preserve their softness; every leaf being loaded with a weight heavy enough to prevent its warping. To join the edges of these pieces of horn together, it is necessary to provide strong iron moulds suited to the shape of the article wanted, and to place the pieces in contact with copper-plates or with polished metal surfaces against them; when this is done, the whole is to be put into a vice and screwed up tight, then plunged into boiling water, and after some time it is to be removed from thence and immersed in cold water. The edges of the horn will be thus made to cement together and become perfectly united.

To complete the polish of the horn, the surface must be rubbed with the subnitrate of bismuth by the palm of the hand. The process is short, and has this advantage, that it makes the horn dry promptly.

When it is wished to spot the horn in imitation of tortoise-shell, metallic solutions must be employed as follows:—To spot it red, a solution of gold in aqua regia must be employed; to spot it black, a solution of silver in nitric acid must be used; and for brown, a hot solution of mercury in nitric acid. The right side of the horn must be impregnated with these solutions, and they will assume the colours intended. The brown spots can be produced on the horn by means of a paste made of red lead, with a solution of potash, which must be put in patches on the horn, and subjected some time to the action of heat. The deepness of the brown shades depends upon the quantity of potash used in the paste, and the length of time the mixture lies on the horn. A decoction of Brazil wood, or a solution of indigo, in sulphuric acid, or a decoction of saffron and Barbary wood may also be used. After having employed these materials, the horn may be left for half a day in a strong solution of vinegar and alum.

In France, Holland, and Austria, the comb-maker and horn-turners use the clippings of horn—which are of a whitish yellow—and tortoise-shell skins, out of which they make snuff-boxes, powder-horns, and many curious and handsome things. They first soften the horn and shell in boiling water, so as to be able to submit them to the press in iron moulds, and by means of heat they form them into one mass. The degree of heat necessary to join the horn clippings must be stronger than that for shell skins, and it can only be found out by experience. The heat must not, however, be too great, for fear of scorching the horn or shell. Considerable care is required in these operations, not to touch the horn with the fingers, or with any greasy body, because the grease will prevent the perfect joining. Wooden instruments should be used to move them, while they are at the fire, and for carrying them to the moulds.

In making a ring of horn for bell-pulls, &c., the required piece is to be first cut out in the flat of its proper dimensions, and nearly in the shape of a horse-shoe; it is then pressed in a pair of dies to give its surface the desired pattern; but previous to the pressure, both the piece of horn and the dies are to be heated; the piece of horn is to be introduced between the dies, squeezed in a vice, and when cold, the impression or pattern will be fixed upon the horn. One particular condition, however, is to be observed in the construction of the dies, for forming a ring. They are to be so made that the open ends of the horse-shoe piece of horn, after being pressed, shall have at one end a nib, and at the other a recess of a dovetailed form, corresponding to each other; and the second operation in forming this ring of horn is to heat it, and place it in another pair of dies, which shall bring its open ends together, and cause the dovetailed joints to be locked fast into each other, which completes the ring, and leaves no appearance of the junction.

In forming the handles of table knives and forks, or other things which require to be made of two pieces, each of the two pieces or sides of the handle is formed in a separate pair of dies; the one piece is made with a counter-sunk groove along each side, and the other piece with corresponding leaves or projecting edges. When these two pieces are formed, by first being cut out of the flat horn, then pressed in the dies in a heated state, for the purpose of giving the pattern, the two pieces are again heated and put together, the leaves or edges of the one piece dropping into the counter-sunk grooves of the other piece, and being introduced between another pair of heated dies, the joints are pressed together and the two pieces formed into one handle.

In making the knobs for drawers which have metal stems or pins to fasten them into the furniture, the face of the knob is to be first made in a die, as above described, and then the back part of the knob with a hole in it; a metal disc plate of iron is next provided, in which the metal stem or screw pin is fixed, and the stem being passed through the aperture in the back piece, and the two, that is, the back and front pieces of horn put together, they are then heated and pressed in dies as above described; the edge of the back piece falling into the counter-sunk groove of the front piece, while by the heat they are perfectly cemented together.

Mr. J. James has contrived a method of opening up the horns of cattle, by which he avoids the risk of scorching or frizzling, which is apt to happen in heating them over an open fire. He takes a solid block of iron, pierced with a conical hole, which is fitted with a conical iron plug, heats them in a stove to the temperature of melting lead, and, having previously cut up the horn lengthwise on one side with a saw, he inserts its narrow end into the hole, and drives the plug into it with a mallet. By the heat of the irons the horn gets so softened, in the course of about a minute, as to bear flatting out in the usual way.

Importation of Horns.

	1871.		1872.	
	Tons	£	Tons	£
Tips and pieces of horn and hoofs . . .	5,700	110,466	6,362	160,490

The largest quantities being from British India, the United States of America, and Australia.

HORNBEAM. The *Carpinus betulus*, sometimes called the yoke-elm. It is a stringy and tough wood, which grows in some parts of Europe, and which is imported from America. It is used by millwrights for the cogs of wheels, also for skittles, and for mallets.

HORNBLENDE. (*Amphibole*, Fr.; *Hornblende*, Ger.) The term *hornblende*, restricted originally to certain dark-coloured lamellar minerals occurring chiefly in syenite and diorite, was afterwards considerably extended in its application, and at present includes a large number of minerals allied to the original hornblendes in crystalline form, and, to a certain extent, in chemical composition; but nevertheless differing widely from the typical hornblendes, not only in colour, density, and other physical characters, but also in their mode of occurrence. The necessity for grouping these minerals together was first recognised by the French crystallographer Haüy, who proposed to name the whole species *amphibole*, and to retain Werner's term *hornblende* only for the common varieties; a nomenclature still frequently adhered to in France.

The typical hornblendes crystallize in forms belonging to the oblique system, and present a perfect prismatic cleavage; whilst other varieties occur in a columnar, fibrous, lamellar, or granular condition. The hardness is tolerably constant, being slightly below that of felspar; but the specific gravity varies with the chemical composition. All the hornblendes are anhydrous silicates of various protoxide-bases, usually lime, magnesia, and protoxide of iron; these bases being capable of replacing one another in chemical combination, without affecting the crystalline form of the compound. Many of the ferruginous varieties contain alumina, the amount of which may rise to upwards of 15 per cent.: the condition in which this compound exists in hornblende is by no means well ascertained, but it is usually supposed to replace the silica, the compounds being thus regarded as silico-aluminates. In many varieties, fluorine occurs to the extent of 2 or 3 per cent., and exists probably as a silico-fluoride of calcium and magnesium. It is interesting to note that certain hornblendes also contain titanic acid.

On the chemical composition of the hornblende depends to a great extent the general character of the mineral; thus, those varieties which contain only lime and magnesia have always a white or very pale colour and a low specific gravity, sometimes not higher than 2·9; while before the blowpipe they fuse to a nearly colourless glass. On the other hand, the ferruginous hornblendes have a dark green or black colour; a much higher density, often reaching 3·4; and are fusible with greater facility, producing a glass more or less deeply coloured. The iron-hornblendes, again, are partially decomposed by hydrochloric acid, which has scarcely any effect on the other varieties. When exceedingly rich in iron, the mineral affects the magnetic needle.

These differences of composition, and the corresponding diversity of physical characters, have given rise to numerous varieties, of which the following are the most important:—

Tremolite, so named from the Swiss valley of Tremola, is a silicate of magnesia and lime, containing silica, 58·87; magnesia, 28·19; lime, 11·00; and alumina, 1·77 = 99·83 (*Rammelsberg*). It occurs usually in slender-columnar or flat-bladed crystals of a white, grey, or pale green colour; and of specific gravity 2·93. The crystals are commonly imbedded in dolomite or granular limestone, as at St. Gothard in Switzerland, and Glen Tilt in Scotland. Other localities are the Tyrol, the Bannat, Wermland in Sweden, New England, Maine, Massachusetts, and other of the United States. Tremolite forms the *Amphibole blanche* of French mineralogists. *Grammatite* and *Calamite* are Swedish varieties, whilst *Raphilite* is a Canadian tremolite, presenting an asbestiform structure. Many of the fibrous hornblendes separate on decomposition into fibres more or less delicate, and thus form varieties of asbestus.

The occasional presence of protoxide of iron in certain tremolites furnishes a passage to the variety of hornblende called *actinolite*—the *actinote* or *Amphibole verte* of the French, the *Strahlstein* (*ray-stone*) of the Germans. It occurs in slender-columnar crystals, often disposed in radiated groups, presenting a high lustre and leek-green or black-green colour. Its specific gravity is about 3. A typical actinolite from the Zillerthal yielded to Rammelsberg's analysis: silica, 55·50; magnesia, 22·56; lime, 13·46; and protoxide of iron, 6·25 = 97·77. Actinolite is found chiefly in talcose schist, serpentine, and other magnesian rocks: in Cornwall it occurs at the Lizard, and at Botallack and other western mines. Among foreign localities may be mentioned Greiner in the Zillerthal, St. Gothard, Salzburg, Sweden, Norway, &c.

Anthophyllite is a grey or clove-brown fibrous or lamellar hornblende, occurring in Norway, Greenland, and the United States. Its composition is silica, 56·74; magnesia, 24·35; protoxide of iron, 14·40; protoxide of manganese, 2·38; and water, 1·67 = 99·54 (*Vopelius*).

Hornblende proper, the *Amphibole noire* of the French, includes the dark-coloured iron-bearing varieties to which the name was originally applied. *Common hornblende* occurs in dark green or black crystals, usually imperfectly formed, and readily distinguished by the silky lustre of its cleavage planes. It forms an essential constituent of syenite, diorite, and hornblende-rock; and occurs as an accessory mineral in many trachytes. The *basaltic hornblende* of Werner includes the black crystallised specimens usually associated with lavas and other volcanic rocks. *Noble hornblende*, or *pargasite*, is a dark green, somewhat translucent mineral, occurring in thick, stout crystals, or in granular masses, embedded in calcareous spar, at Ersby, near Pargas, in Finland. The following is Rammelsberg's analysis of a Pargas hornblende: silica, 41·26; magnesia, 13·49; lime, 11·95; protoxide of iron, 9·92; peroxide of iron, 4·83; alumina, 11·92; potash, 2·70; soda, 1·44; and water, 0·52 = 99·73.

In the hornblende called *arfvedsonite*, soda occurs in considerable quantity, as shown by the following analysis: silica, 51·22; soda, 10·58; protoxide of iron, 7·80; peroxide of iron, 23·75; lime, 2·08; magnesia, 0·90; and potash, 0·68 = 98·13 (*Rammelsberg*). Arfvedsonite is an exceedingly fusible black mineral found in Greenland; and often separated as a distinct species.

The mineral called *uralite*, discovered by the late G. Rose in the greenstones of the Ural range, is commonly regarded as a pseudomorph, since it presents the external form of augite with the cleavage and chemical composition of hornblende; thus establishing a relation between the two minerals. This relation is indeed so intimate that it has been proposed to unite them in one species. Hornblende differs, however, from augite in the angle of the prism obtained by cleavage being much more obtuse; but it has been shown that the two forms are easily derivable the one from the other. Hornblende, again, is more fusible than augite; it has a somewhat lower range in specific gravity; it often contains fluorine, an element which has never been found in augite. Hornblende, moreover, occurs in granitic and other highly-silicated rocks; whilst augite is confined to the more basic rocks, such as basalt; occasionally, however, the two minerals occur together. Experiments on the artificial formation of these minerals have rendered it probable that the same chemical compound may form augite when rapidly cooled from a state of fusion, and hornblende when slowly cooled; indeed, hornblende has been converted into augite by fusion and rapid solidification.

It has been shown by Tschermak, and independently by Mr. Allport, that hornblende may be distinguished from augite in sections of rock examined under the microscope, by the fact that hornblende is dichroic, whilst augite is not: the intensity of the dichroism varies, however, to a great extent in different hornblendes.

The hornblendic minerals, although highly important in a geological point of view, have little or no economic value. Certain Swedish hornblendes have been employed in smelting magnetic ores: and the fibrous varieties known as asbestus have received various applications. See ASBESTUS.—F.W.R.

HORNBLENDE-ROCK. (*Amphibole*, Fr.; *Hornblendfels*, Ger.) A rock, consisting chiefly of crystalline-granular, dark green, or black hornblende, associated commonly, but by no means necessarily, with felspar, quartz, and mica in small quantity. The rock often assumes a schistose structure, and then passes into *Hornblende slate* (*Schiste amphibolithique*, Fr.; *Hornblendschiefer*, Ger.). This slate usually occurs in connection with mica-schist, gneiss, and other metamorphic rocks. When the hornblende belongs to the bright green variety called actinolite, the rock becomes an *actinolite schist*, or *Strahlsteinschiefer* of the Germans. Hornblende also occurs, although to a less extent, in other rocks; such as *syenite* (a granite in which hornblende replaces mica), and *greenstone* and *diorite* (rocks consisting of hornblende and felspar). The *timazite* of Hungary and Transylvania is a trachytic greenstone, containing the peculiar hornblende called *gamisgradite*.

On exposure to atmospheric influences, hornblendic rocks easily decompose; the protoxide of iron passing into the condition of peroxide. Soils resting on such rocks are frequently remarkable for their fertility.

HORN-LEAD, or *Phosgenite*. Native chlorocarbonate of lead. See LEAD.

HORN-QUICKSILVER. Native subchloride of mercury. See CALOMEL.

HORN-SILVER, or *Luna Cornea*. Both these names were given by the alchemists to fused chloride of silver. Horn-silver is found native as kerargyrite. See SILVER.

HORNSTONE. A variety of quartz, resembling flint, but more brittle, and breaking with a more splintery fracture. It sometimes occurs imbedded in limestone. See CHERT.

HORSE. In *mining*, any large isolated mass of rock occurring in a vein, or splitting a vein or seam into two or more parts.

HORSE CHESTNUT. (*Marronnier d'Inde*, Fr.; *Gemeine Rosskastanie*, Ger.) The wood of this well-known tree is used by the Tunbridge turner; otherwise it is only employed for some large varnished works. See HIPPOCASTANUM.

HORSE-FLESH ORE. A Cornish name for purple copper-ore. See COPPER.

HORSE-POWER, in steam-engines, was estimated by Watt at 32,000 lbs. avoirdupois lifted one foot high per minute, for one horse. M. D'Aubuisson, from an examination of the work done by horses in the whims, or gigs (*machines à molettes*) for raising ore from the mines at Freiberg, the horses being of average size and strength, has concluded that the useful effect of a horse yoked during eight hours, by two relays of four hours each, in a manège or mill-course, may be estimated at 40 kilogrammes raised 1 meter per second; which is nearly 16,440 lbs. raised one foot per minute; being very nearly one half of Mr. Watt's liberal estimates for the horse-power of his steam-engines.

Frederick William Simms, M.Inst.C.E., adopted some peculiar conditions of work on which he was engaged to determine the value of *horse*-power. He had to make a tunnel for the South-Eastern Railway. This tunnel was driven in the middle bed of the Lower Greensand, between which and the surface of the ground is interposed only the upper bed of the same stratum; but in sinking the eleven shafts for the work, it was found that at the level of the top of the tunnel, the ground assumed the character of a quicksand, saturated with water, in such quantity that it could not be reduced by manual labour. Under these circumstances horse-gins were erected for drawing the water by barrels, containing 100 gallons each, weighing when full about 1,310 lbs.

The engineer's intention was, to drive simultaneously from these shafts, in the direction of the tunnel, an adit or heading to carry off the water; but the earth, which was sand mixed with fine particles of blue clay, was so filled with water as to become a mass of semifluid mud; great exertions were therefore necessary to overcome the water, without erecting pumps. At first this was accomplished by making each horse work for 12 hours and then for 8 hours per day, allowing 1 hour for food and rest: as the water increased it became necessary to work night and day, and the time of each horse's working was reduced generally to 6 hours, and sometimes to 3 hours. As all the horses were hired at the rate of seven shillings per day, the engineer, who had charge of the works, ordered a daily register to be kept of the actual work done by each horse, for the double purpose of ascertaining whether they all performed their duty, and also hoping to collect a body of facts relative to horse-power which might be useful hereafter.

Mr. Simms gives as a proposition, 'That the proper estimate of horse-power would be that which measures the weight that a horse would draw up out of a well; the animal acting by a horizontal line of traction turned into the vertical direction by a simple pulley, whose friction should be reduced as much as possible.' He states that the manner in which the work was performed, necessarily approached very nearly to these conditions; and after giving the principal dimensions of the horse-gins, he analyses each set of experiments, and by taking the mean of those against which no objections could be urged, he arrives at the following results:—

The power of a horse for 8 hours = 23,412 lbs. raised 1 foot high in one minute.
Do. 6 „ = 24,360 „ „
Do. 4½ „ = 27,056 „ „
Do. 3 „ = 32,943 „ „

Of these results he thinks the experiments for 6 hours and for 3 hours alone should be adopted as practical guides, all the others being in some degree objectionable.

As a means of comparison, the following table of estimates of horse-power is given:—

Name	Pounds raised 1 foot high in a minute	Hours of work	Authority
Boulton and Watt . .	32,000	8	Robinson's Mech. Phil., ii. 145.
Tredgold. . . .	27,500	8	Tredgold on Railroads, p. 69.
Desaguliers . . .	44,000	8	Dr. Gregory's Mathematics for Practical Men, p. 183.
„ . . .	27,500	Not stated	
Saussure	34,020	8	
More, for Society of Arts.	21,120	Not stated	
Smeaton	22,000	„	

These are much higher results than the average of his experiments, and would more nearly accord with the extremes obtained by him; but under such excessive fatigue, the horses were speedily exhausted, and died rapidly. Nearly one hundred horses were employed: they were of good quality; their average height was 15 hands ¼ inch, and their weight about 10½ cwts., and they cost from 20*l.* to 40*l.* each. They had as much corn as they could eat, and were well attended to.

The total quantity of work done by the horses, and its cost, was as under:—

	tons
Registered quantity of water drawn 104 feet, the average height, 28,220,800 gallons	128,535
Do. earth, 3,500 yds. 1 ton 6 cwts. per yard	4,550
Total weight drawn to the surface	133,085

Total cost of horse-labour, including a boy to drive each horse, 1,585*l.* 15*s.* 3*d.*, or 2·86*d.* per ton the average height of 104 ft.

Mr. Palmer made some experiments on the amount of work performed by horses tracking boats on canals. On the upper end of the mast of the boat a pulley was hung; over this the towing rope was passed, with the means of suspending to its extremity given weights, so as exactly to balance the power exerted by the horse.

The results arrived at by these means were so various, that he could not deduce any average conclusions, as the power exerted varied between 30 lbs. and 120 lbs., the power diminishing as the speed was increased. He thought that 2½ miles was too high an average estimate, and that it should not exceed 2 miles per hour, although in all estimates of horse-power, the speed was considered to be at an average of 2½ miles per hour, and all experiments were reduced to that standard.

Mr. Hawkins, some years since, had made numerous inquiries respecting the work done by horses in drawing upon common turnpike-roads, and found that four good horses could draw an ordinary stage-coach, with its complement of passengers, at the rate of 10 miles an hour; that if they ran stages 10 miles in the hour, the horses must rest one day in each week; that good horses, so worked, would last only five years, each horse drawing about half a ton. He had been informed by waggoners, that good horses would walk at the rate of 2½ miles per hour, for 12 hours out of 24, making 30 miles a day; and that they would continue to do such work day by day, each horse drawing 1 ton, for many years, provided they had not been worked hard when young.

It is desirable to know the average speed at which the different rates of work had been performed; this was essential in order to found any calculation upon the results given. Coach proprietors calculated that at a speed of 10 miles per hour, a horse was required for every mile going and returning, so that one horse was kept for every mile of road. Now supposing a four-horse coach, with an average load, to weigh 2 tons, the load for each horse was 10 cwts.; whereas in the case of a horse drawing a cart, the gross load frequently amounted to 2 tons, but the speed was reduced to 2½ miles per hour, at which pace he conceived that 16 miles per day might be considered a fair day's work; this therefore was double the distance with four times the load, or eight times the coach-work, but with a heavier horse.

The law that the quantity of work done was as the square root of the velocity,—or as the cube root of the velocity, in equal times,—is confined to work upon canals, or bodies moving through the water.

Mr. Rennie had tried some experiments on the force of traction of the boats on the Grand Junction Canal. The towing rope was attached to a dynamometer, which had previously been tested by weights.

The horse, although urged at first starting, was afterwards allowed to fall into his natural speed, which was 2½ miles per hour on the average of 20 miles. The maximum speed was 4 miles, and the minimum 2 miles, per hour. The dynamometer indicated an average of 108 lbs., which was capable of overcoming the resistance of the loaded barge of 25 tons, being in the ratio of 15·00. The weight of the horse was about 11 cwts.

He also tried many experiments upon a fast boat, lent to him in 1833 by the late Colonel Page. These experiments were principally made in order to ascertain the comparative resistance of vessels moving through water at different velocities, and the Grand Junction Canal afforded a convenient opportunity of undertaking them.

The boat was 70 feet in length, 4 feet in breadth, and drew 9 inches in water.

The traction indicated by the dynamometer the following resistance:—

Miles per hour		lbs.
At 2½	the resistance was	20
3	„	27
3½	„	30
4	„	50
4½	„	60
5	„	70 to 75

One horse was employed in these experiments.

Miles per hour		lbs.
At 6	the resistance was	97 to 214
7	„	250
8	„	336
9·69	„	411
10	„	375
11¼	„	392
	Average	336

Two horses were employed in these experiments.

Stakes were fixed near the margin of the canal, so as to ascertain the rise and fall of the wave caused by the boat in passing; and it was observed that when a boat passed with a velocity of from 4 to 6 miles per hour, the rise of the wave was 5 inches and the fall 5 inches, making a wave of 10 inches in depth; and when the velocity was 11¼ miles, the rise was reduced to 2½ inches and the fall to 2½ inches.

Great difference existed in the power of horses, their weights and structure; and the large dray-horses used by Messrs. Barclay, Perkins, and Co. did a full average duty as assumed by Boulton and Watt; but considering the average power of strong and weak animals, he had adopted 22,000 lbs. raised 1 foot high as the standard: much, however, depended on the nature of the work performed.

Mr. Davidson has given the following statement of the work performed by a London brewer's horse per day; the cost of feed and of wear and tear per horse per annum being derived from actual experience among a large number of horses at Messrs. Truman, Hanbury, and Co.'s brewery. The feed, &c., is supposed to have cost the same per quarter, per truss, &c., each year:—

Years	Pounds weight drawn 6½ miles per horse per day	Pounds weight drawn 6½ miles per horse returning per day	Average pounds weight drawn 13 miles per horse per day	Cost of feed and straw per horse per annum			Difference per horse of horses bought and sold per annum

Mr. Beardmore mentions a case which occurred in a work near Plymouth, which he believed would give the fair value of the work actually performed daily by a horse for a considerable period.

A quarry-waggon, weighing 2½ tons, carrying an average load of stone of 5¾ tons, was drawn by one horse along a railway 960 feet in length, 260 of it being level, and the remaining 700 feet having an inclination of 1 in 138. During 48 working days the number of trips was 1,302, or an average of 27·1 trips each day; the time of performing each trip was 4 minutes, or at a speed of 2·72 miles per hour; and the total weight drawn, including that of the waggons, was 23,959,600 lbs.

Repeated experiments proved, that upon the incline of 1 in 138 the waggons in their ordinary working state would just remain stationary; the friction was therefore assumed to be 16·2 lbs. per ton; by calculation it was found that the horse raised 39,320 lbs. 1 foot high per minute during the 8 working hours each day: the useful effect, or net amount of stone carried, being 21,738 lbs. raised 1 foot high per minute. This difference between the work done and the useful effect arose from the necessary strength and weight of the waggons.

The animal employed was a common Devonshire cart-horse, 8 years old, 15 hands high, and weighed 10¾ cwts.; he continued doing the same work throughout a whole summer, remaining in good condition; but a lighter horse was found unequal to it.

Prof. Rankine defined horse-power in a somewhat different form. 'The *power* of a machine is the energy exerted, and the *effect* the useful work performed in some interval of time of definite length, such as a second, a minute, an hour, or a day.' There is a peculiar unit of power appropriated to its expression, called a HORSE-POWER, which is in Britain—

550 foot-pounds per second,
or 33,000 foot-pounds per minute,
or 1,980,000 foot-pounds per hour.

In France the terms *Force de Cheval* or *Cheval-Vapeur* is applied to the following rate of work:—

Foot-pounds
73 kilogrammètres per second = $542\frac{1}{2}$
or 4,500 kilogrammètres per minute = 32,549
or 270,000 kilogrammètres per hour = 1,952,948,

being about one-seventieth part less than the British horse-power.

This is also called an *actual* or *real* horse-power, to distinguish it from a *nominal* horse-power.

Nominal Horse-power is a conventional mode of describing the dimensions of a steam-engine, for the convenience of makers and purchasers of engines, and bears no fixed relation to *indicated* or to *effective* horse-power. The mode of computing nominal horse-power, established amongst Civil manufacturers of steam-engines by the practice of Boulton and Watt, is as follows:—

Assume the velocity of the piston to be 128 feet per minute × cube root of length of stroke in feet. Assume the mean effective pressure to be seven pounds on the square inch.

Then compute the horse-power from these fictitious data, and the area of the piston; that is to say,

$$\text{Nominal H. P.} = 7 \times 128 \times \sqrt[3]{\text{stroke in feet}}$$

$$\times \text{ area of piston in square inches} \div 33{,}000$$

$$= \frac{\sqrt[3]{\text{stroke in feet}} \times \text{area of piston in inches}}{47 \text{ nearly}}$$

$$= \frac{\sqrt[3]{\text{stroke in feet}} \times \text{diam.}^2 \text{ in inches}}{60}$$

The indicated power of different engines usually exceeds the nominal power as computed by the above rule in proportions ranging from $1\frac{1}{2}$ to 5.

In the rule established by the *Admiralty* for computing nominal horse-power, the *real velocity of the piston* is taken into account; but the *fictitious effective power* of seven pounds on the square inch is assumed consequently by the Admiralty rules.

$$\text{Nominal H. P.} = \text{velocity of piston in feet per minute}$$

$$\times \text{ area of piston in inches} \times 7 \div 33{,}000$$

$$= \frac{\text{velocity in feet per min.} \times \text{diam.}^2 \text{ in inches}}{6{,}000}$$

The indicated power of marine engines ranges from *once* to *three times*, and is on an average about *twice* the nominal power as computed by the Admiralty rule.

Both the Civil rule and the Admiralty rule for computing the power of engines are applicable to low-pressure engines alone. For high-pressure engines there is a customary rule proposed by Mr. Bourne, which consists in assuming the effective pressure to be 21 pounds per square inch, the other data being the same as in the rule for low-pressure engines. See Rankine's 'Manual of the Steam Engine and other Prime Movers.'

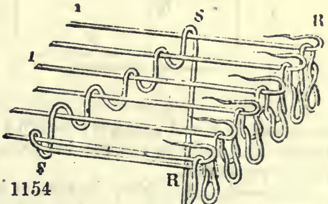
HORSE-RADISH. The root of *Cochlearia Armoracia*, eaten as a condiment. For the distinctions between the roots of horse-radish and monkshood, see Aconite.

HORSESHOES. The ordinary method of making these is well known. There has, however, been introduced with much success a machine for making horseshoes; and one of these machines has been erected at Chillington Ironworks, Wolverhampton, by the inventor, Mr. Henry Burden, of Troy, New York. As early as 1835 he took out a patent for a machine for making horseshoes, which he improved upon in 1843, and this was turned to practical account by the production of a considerable number of horseshoes. The present machine, however, which was patented in 1857, is entirely different from the former ones, and is a very remarkable piece of mechanism. In the previous machines the piece of iron bar of which the shoe was to be made was rolled into shape before being bent, and the pressure of the rollers being in the direction of its length, the bar, when it was pressed, was naturally rather extended in length than width, and the widening which is required at the crown of the shoe was not properly effected. By the present plan the bar, after being heated, enters the machine by a feeding apparatus, a piece of the required length is cut off, and, by a stroke from a piece of steel, shaped like the inside of a horseshoe, is bent, and falls upon a die on a wheel beneath, corresponding to one on a cylinder above, and thus acquires by pressure the desired shape, two lateral strikers at the same moment hitting the extremities, or heels, of the shoe, and driving them inwards into the required shape. Thence it passes between another pair of dies, where it is stamped, and by an ingenious arrangement is flattened from the curled shape which the wheel gives it as it falls at the mouth of the machine. The shoes thus made are remarkable for their exactness in shape and in the position of the holes—a most important point with regard to the safety of horses' feet; and they can be produced, when the machine is in proper order, at the rate of 60 per minute, which is more than two men can forge in a day; their superiority over shoes forged by hand is very striking. As the bar is bent before being pressed in the die, the pressure at the crown is in the direction of the width, and hence the widening is readily effected.

HOSIERY. (*Bonneterie*, Fr.; *Strumpfweberei*, Ger.) The *stocking-frame*, which is the great implement of this business, though it appears at first sight to be a complicated machine, consists merely of a repetition of parts easily understood, with a moderate degree of attention, provided an accurate conception is first formed of the nature of the hosiery fabric. This texture is totally different from the rectangular decussation which constitutes cloth, as the slightest inspection of a stocking will show; for this, instead of having two distinct systems of thread, like the warp and the weft, which are woven together by crossing each other at right angles, the whole piece is composed of a single thread united or looped together in a peculiar manner, which is called stocking-stitch, and sometimes chain-work.

This is best explained by the view in *fig.* 1153. A single thread is formed into a number of loops or waves, by arranging it over a number of parallel needles, as shown at R; these are retained or kept in the form of loops or waves, by being drawn or looped through similar loops or waves formed by the thread of the preceding course of the work, S. The fabric thus formed by the union of a number of loops is easily unravelled, because the stability of the whole piece depends upon the ultimate fastening of the first end of the thread; and if this is undone, the loops formed by that end will open, and release the subsequent loops one at a time, until the whole is unravelled, and drawn out into the single thread from which it was made. In the same manner, if a thread in a stocking-piece fails, or breaks at any part, or drops a stitch, as it is called, it immediately produces a hole, and the extension of the rest can only be prevented by fastening the end. It should be observed that there are many different fabrics of stocking-stitch for various kinds of ornamental hosiery, and as each requires a different kind of frame or machine to produce it, we should greatly exceed our limits to enter into a detailed description of them all. That species which we have represented in *fig.* 1154 is the common stocking-stitch used for plain hosiery, and is formed by the machine called the common stocking-frame, which is the groundwork of all the others. The operation, as we see, consists in drawing the loop of a thread successively through a series of other loops, so long as the work is continued, as is very plainly shown for one stitch in *fig.* 1155.

1153

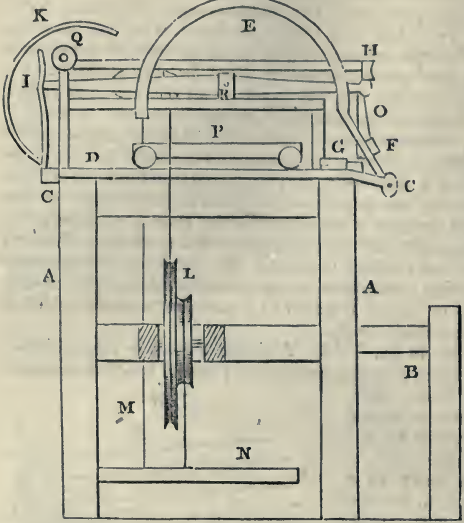


1154

The first kind of frame, which forms the foundation of all the others, is that for knitting plain hosiery, or the common stocking-frame.

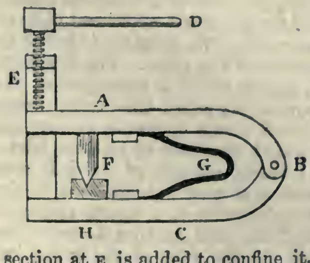
Of this valuable machine, the invention of Mr. Lee of Cambridge, a side elevation is given in *fig.* 1155, with the essential parts. The framing is supported by four upright posts, generally of oak, ash, or other hard wood. Two of these posts appear at A A, and the connecting cross rails are at C C. At B is a small additional piece of framing, which supports the hosier's seat. The iron-work of the machine is bolted or screwed to the upper rails of the framework, and consists of two parts. The first rests upon a sole of polished iron, which appears at D, and to which a great part of the machinery is attached. The upper part, which is generally called the carriage, runs upon the iron sole at D, and is supported by four small wheels or trucks, as they are called by the workmen. At the upper part of the back standard of iron are joints, one of which appears at Q; and to these is fitted a frame, one side of which is seen extending to H. By means of these joints the end at H may be depressed by the hosier's hand, and it returns, when relieved, by the operation of a strong spring of tempered steel, acting between a cross bar in the frame, and another below. The action of this spring is very apparent in *fig.* 1156. In the front of the frame, immediately opposite to where the hosier sits, are placed the needles which form the loops. These needles, or rather hooks, are more or less numerous, according to the coarseness or fineness of the stocking; and this, although unavoidable, proves a very considerable abatement of the value of a stocking-frame. In almost every other machine (for example, those employed in spinning or weaving), it is easy to adapt any one either to work coarser or finer work, as it may be wanted. But in the manufacture of hosiery, a frame once finished, is limited for ever in its operation to the same quality of work, with this exception, that by changing the stuff, the work may be made a little more dense or flimsy; but no alteration in the size or quantity of loops can take place. Hence where the manufacture is extensively prosecuted, many frames may be thrown idle by every vicissitude of demand; and where a poor mechanic does purchase his own frame he is for ever limited to the same kind of work. The gauge, as it is called, of a stocking-frame is regulated by the number of loops contained in three inches of breadth, and varies very much; the coarsest frames in common use being about what are termed Fourteens, and the finest employed in great extent about Forties. The needles are of iron wire, the manufacture of which is very simple; but long practice in the art is found necessary before a needle-maker acquires the dexterity which will enable him both to execute his work well, and in sufficient quantity to render his labour productive.

1155



The process of making the needles is as follows:—Good sound iron wire, of a proper fineness, is to be selected; that which is liable to split or splinter, either in filing, punching, or bending, being totally unfit for the purpose. The wire is first to be cut into proper lengths, according to the fineness of the frame for which the needles are designed, coarse needles being considerably longer than fine ones. When a sufficient number (generally some thousands) have been cut, the wire must be softened as much as possible. This is done by laying them in rows in a flat iron box, about an inch deep, with a close cover; the box being filled with charcoal between the strata of wires. This box, being placed upon a moderate fire, is gradually heated until both the wires and charcoal have received a moderate red heat, because, were the heat increased to what smiths term the white heat, the wire would be rendered totally unfit for the subsequent processes which it has to undergo, both in finishing and working. When the box has been sufficiently heated, it may be taken from the fire, and placed among hot ashes until both ashes and box have gradually cooled; for the slower the wires cool, the softer and easier wrought they will be. When perfectly cool, the next process is to punch a longitudinal groove in the stem of every needle, which receives the point or barb, when depressed. This is done by means of a small engine worked by the power of a screw and lever. The construction of these engines is various; but a profile elevation of one of the most simple and commonly used will be found in *fig.* 1156. It consists of two very strong pieces of malleable iron, represented at A and C, and these two pieces are connected by a strong well-fitted joint at B. The lower piece, or sole of the engine at C, is screwed down by bolts to a strong board or table, and the upper piece A will then rise or sink at pleasure, upon the joint B. In order that A may be very steady in rising and sinking, which is indispensable to its correct operation, a strong bridle of iron, which is shown in section at E, is added to confine it, and direct its motion. In the upper part of this bridle is a female screw, through which the forcing screw passes, which is turned by the handle or lever D. To the sole of the engine C is fixed a bolster of tempered steel, with a small groove to receive the wire which is to be punched; and in the upper or moving part A, is a sharp chisel, which descends exactly into the groove, when A is depressed by the screw. These are represented at F, and above H. At G is a strong

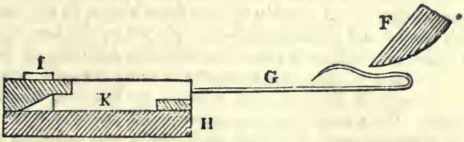
1156



spring, which forces up the chisel when the pressure of the screw is removed. The appearance of the groove, when the punching is finished, will be rendered familiar by inspecting *fig.* 1162, p. 817. When the punching is finished, the wires are to be brought to a fine smooth point by filing and burnishing, the latter of which should be very completely done, as, besides polishing the wire, it tends greatly to restore that spring and elasticity which has been removed by the previous operation of softening. The wire is next to be bent, in order to form the hook or barb; and this is done with a small piece of tin plate bent double, which receives the point of the wire, and by its breadth regulates the length of the barb. The stem of the needle is now flattened with a small hammer, to prevent it from turning in the tin socket in which it is afterwards to be cast; and the point of the barb being a little curved by a pair of small plyers, the needle is completed.

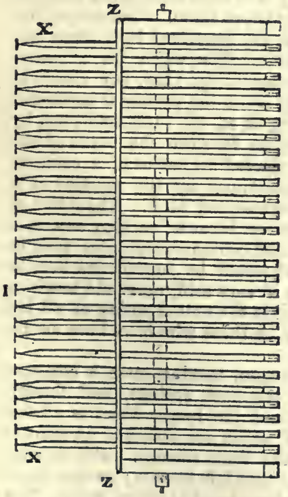
In order to fit the needles for the frame, they are now cast into the tin sockets or leads as they are called by the workman; and this is done by placing the needles in an iron mould, which opens and shuts by means of a joint, and pouring in the tin while in a state of fusion. In common operations, two needles are cast into the same socket. The form of the needle, when complete and fitted to its place in the frame, will be seen in *fig.* 1157, which is a profile section of the needle-bar exhibiting one needle. In this figure a section of the pressure is represented at F; the needle appears at G, and the socket or level at K. At H, is a section of the needle-bar, on the fore part of which is a small plate of iron called a verge, to regulate the position of the needles. When placed upon the bar resting against the verge, another plate of iron, generally lined with soft leather, is screwed down upon the sockets or leads, in order to keep them all fast. This plate and the screw appear at I. When the presser at F is forced down upon the barb, this sinks into the groove of the stem, and the needle is shut; when the presser rises, the barb opens again by its own elasticity.

1157

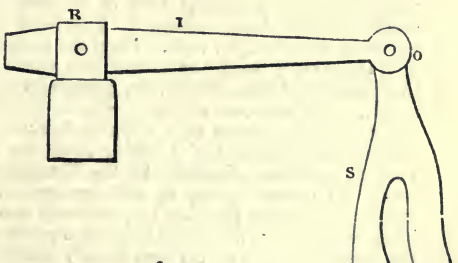


The needles or hooks being all properly fitted, the next part of the stocking-frame to which attention ought to be paid, is the machinery for forming the loops; and this consists of two parts. The first of these, which sinks between every second or alternate needle, is represented at O, *fig.* 1155, and is one of the most important parts of the whole machine. It consists of two moving parts; the first being a succession of horizontal levers moving upon a common centre, and called jacks, a term applied to vibrating levers in various kinds of machinery as well as the stocking-frame. One

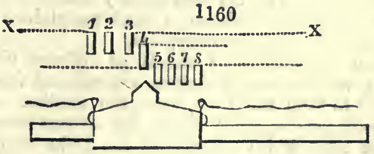
1158



1159



1160

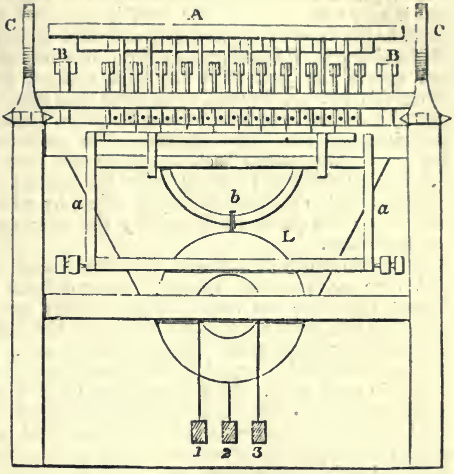


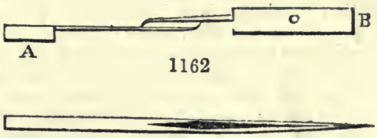
only of these jacks can be represented in the profile *fig.* 1155; but the whole are distinctly shown in a horizontal position in *fig.* 1158; and a profile upon a very enlarged scale is given in *fig.* 1159. The jack shown in *fig.* 1155, extends horizontally from O to I, and the centre of motion is at R. On the front, or right hand of the jack at O, is a joint suspending a very thin plate of polished iron, which is termed a sinker. One of these jacks and sinkers is allotted for every second or alternate needle. The form of the sinker will appear at S, *fig.* 1159; and in order that all may be exactly uniform in shape, they are cut out and finished between two stout pieces of iron, which serve as moulds or gauges to direct the frame-smith. The other end of the jack at I, is tapered to a point; and when the jacks are in their horizontal position, they are secured by small iron springs, one of which is represented at I, *fig.* 1155, each spring having a small obtuse-angled notch to receive the point of the jack, against which it presses by its own elasticity. In *fig.* 1159, the centre is at R, the pointed tail is omitted for want of room, the joint is at O, and the throat of the sinker, which forms the loop, is at S. The standards at R, upon which the jack moves, are called combs, and consist of pieces of flat smooth brass, parallel to, and equidistant from each other. The cross bar R, which contains the whole, is of iron, with a perpendicular edge or rim on each side, leaving a vacancy between them, or a space to receive the bottom part or tails of the combs. The combs are then placed in the bar, with a flat piece of brass called a countercomb, between each, to ascertain and preserve their distances from each other. These countercombs are exactly of the same shape as the combs, but have no tails. When both combs and countercombs are placed in the bar, it is luted with clay so as to form a mould, into which is poured a sufficient quantity of melted tin. When the tin has had time to cool, the countercombs having no tails are easily taken out, and the combs remain well fastened and secured by the tin, which has been fused entirely round them. Thus they form a succession of standards for the jacks; and a hole being drilled through each jack and each comb, one polished wire put through serves as a common centre for the whole.

The jack sinkers being only used for every alternate or second needle, in order to complete this part of the apparatus, a second set of sinkers is employed. These are, in form and shape, every way the same as the jack sinkers, but they are jointed at the top into pieces of tin, all of which are screwed to the sinker bar, H, *fig.* 1155; and thus a sinker of each kind descends between the needles alternately. By these sinkers the loops are formed upon all the needles, and the reason of two sets different in operation being employed, will be assigned in describing the mode of working the frame. The presser of the operation, of which something has already been said, appears at F; and of the two arms which support and give motion to it, one appears very plainly at E, its centre of motion being at C. The circular bend given to these arms, besides having an ornamental effect, is very useful, in order to prevent any part from interfering with the other parts which are behind, by elevating them entirely above them. The extremities of these arms at the termination of the bends behind, are connected by a cross bar, which has also a circular bend in the middle, projecting downwards for a reason similar to that already assigned. This bend is concealed in *fig.* 1155, but visible in the front elevation, *fig.* 1161. From the middle of the bend, the presser is connected with the middle treadle by a depending wire, appearing at M, *fig.* 1155, and thus, by the pressure of that treadle, the presser is forced down to close the barbs of the needle. The re-ascent of the presser is sometimes effected by means of a counterpoising weight passing over a pulley behind; and sometimes by the reaction of a wooden spring, formed of a strong hoop like that represented at K. The latter of these is preferred, especially by the Nottingham hosiers, because, as they assert, it makes the presser spring up with greater rapidity, and consequently saves time in working. How far this may be practically the case, it would be superfluous here to investigate; but it is obvious that the wooden spring, if very stiff, must add much to the hosier's exertion of his foot, already exercised against the united spring of all his barbs; and this inconvenience is much complained of by those who have been accustomed to work with the counterpoise.

At L are two pulleys or wheels, of different diameters, moving upon a common centre, by which the jack-sinkers are relieved from the back springs, and thrown downwards to form the loops upon the needles. About the larger wheel is a band of whipcord, passing twice round, the extremities of which are attached to what is called the slur, which disengages the jacks from the back springs. The smaller pulley, by another band, communicates with the right and left treadle; so that these treadles, when pressed alternately, turn the pulleys about in an inverted order. The directions of these bands also appear more plainly in the front elevation, *fig.* 1161. The construction of the slur, and its effect upon the jacks, will also be rendered apparent by *fig.* 1160. In this figure, eight jacks are represented in section, the tail part of three of which, 1, 2, 3, are thrown up by the slur in its progress from left to right; the fourth is in the act of rising, and the remaining four, 5, 6, 7, and 8, are still unacted upon, the slur not yet having reached them. As the slur acts in the direction of the dotted line x x, *fig.* 1160, behind the centres of the jacks, it is hardly necessary to remark, that this forcing-up of the tails must of course depress the joints by which the sinkers in front are suspended; the jack sinkers falling successively from the loops on every alternate needle, in the way represented at *fig.* 1163, where both kinds of sinkers appear in section, the light part expressing what is above the point at which the throat of the sinker operates upon the thread, and the dark part what is below. The second set, or, as they are called, the lead sinkers, from the manner of joining them, and suspending them from the bar above, appear still elevated; the position of the bar being represented by the line, A B. But when these are pulled down to the level of the former by the operator's hands, the whole looping will be completed, and the thread C D, which is still slack, will be brought to its full and proper degree of tension, which is regulated by top screws, so as to be tempered or altered at pleasure. The sinking of this second set of sinkers may be easily explained by *fig.* 1164. The direction of the sinkers is expressed by the line E; the bar from which they are suspended will be at A; the top frame is in the direction from A to B; the back standards at D; and the joint at B, is the centre of motion. If E is pulled perpendicularly downwards, the spring C will be contracted, and its upper extreme point, G, will be brought nearer to its lower extreme point F, which is fixed. Again, when the force which has depressed E is removed, the spring C will revert to its former state, and the sinkers will rise. The raising of the jack sinkers and jacks takes place at the same time, by the hosier raising his hands; and for the cause of this we must revert to *fig.* 1158. The lead sinkers in rising lay hold of notches, which raise the extreme parts of the set of jacks z, z, which are called half-jacks. Between the extremities of these at z z, is a cross bar, which, in descending, presses all the intermediate jacks behind the common centre, and restores them to their original posture, where they are secured by the back springs, until they are again relieved by the operation of the slur recrossing at the next course.

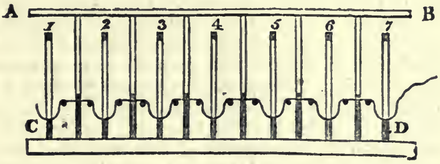
1161



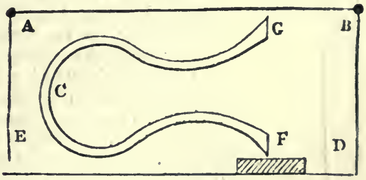


1162

1163



1164



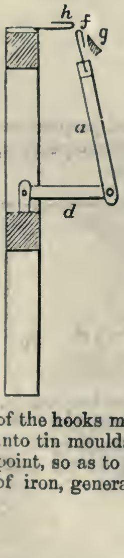
Working of the Frame.—In order to work a frame, the whole apparatus being previously put into complete order, the hosier places himself on the seat B in front, and provides himself with a bobbin of yarn or stuff. This bobbin he places loosely on a vertical pin of wire, driven into one side of the frame contiguous to the needles, so that it may turn freely as the stuff is unwound from it. Taking the thread in his hand, he draws it loosely along the needles, behind the barbs, and under the throats of the sinkers. He then presses down one of the treadles to pass the slur along, and unlock the jack from the back springs, that they may fall in succession. When this is done, the number of loops thus formed is doubled by bringing down the lead sinkers, and the new formed loops are lodged under the barbs of the needles by bringing forward the sinkers. The preceding course, and former fabric, being then again pushed back, the barbs are shut by depressing the middle treadle, and forcing down the presser upon the needles. The former work is now easily brought over the shut needles, after which, by raising the hands, both sets of sinkers are raised; the jacks are locked by the back springs, and the hosier goes on to another course.

From this it will be apparent, that the remark made in the outset is well founded, that there are in reality no complicated or difficult movements in the stocking-frame. Almost the whole are merely those of levers moving upon their respective fulcra, excepting that of the carriage which gives the horizontal motion to the sinkers, and that is merely an alternate motion on four wheels. Yet the frame is a machine which requires considerable experience and care, both to work it to advantage, and also to keep it in good order. This circumstance arises greatly from the small compass in which a number of moving parts must be included. Owing to this, the needles, unless cautiously and delicately handled, are easily bent or injured. The same circumstance applies with equal or greater force to the sinkers, which must be so very thin as to be easily injured. But as these must work freely, both in a perpendicular and horizontal direction between the needles, in a very confined and limited space, the slightest variation in either, from being truly and squarely placed, unavoidably injures the others. When a hosier, either ignorant of the mechanical laws of their relation to each other, or too impatient to wait for the assistance of another, attempts to rectify defects, he in most cases increases them tenfold, and renders the machine incapable of working at all, until repaired by some more experienced person. This circumstance has given rise to a set of men employed in this trade, and distinguished by the name of upsetters; and these people, besides setting new frames to work, have frequently more employment in repairing old ones injured by want of care or skill.

It seems unnecessary to go further into detail respecting a machine so well known, and which requires practical attention even more than most others. It may, therefore, be sufficient to describe shortly some of its varieties, the most simple and common of which is the rib stocking-frame.

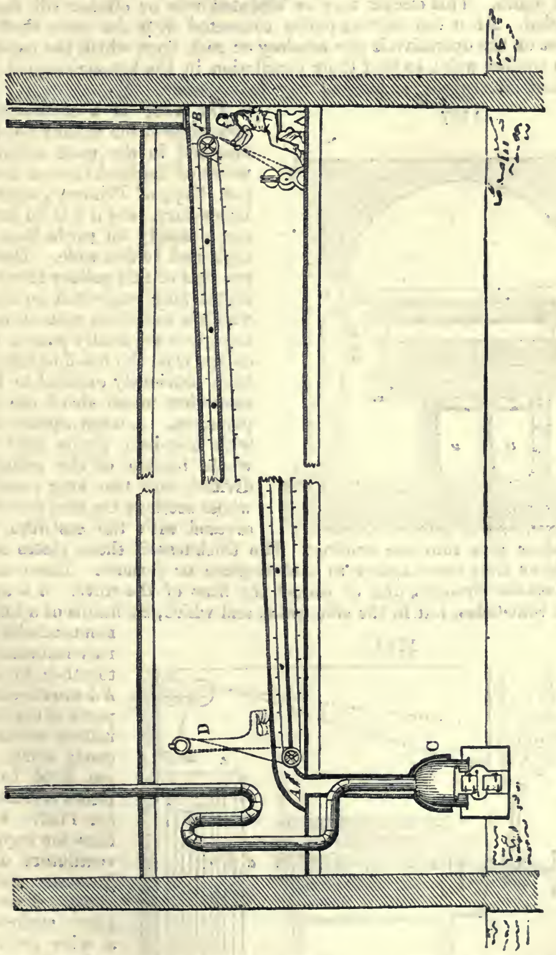
Rib stocking-frame.—This frame, which, next to the common frame, is most extensively in use, is employed for working those striped or ribbed stockings, which are very common in all the different materials of which hosiery is formed. In principle it does not differ from the common frame, and not greatly in construction. The preceding general description will nearly apply to this machine with equal propriety as to the former; that part, however, by which the ribs or stripes are formed is entirely an addition, and to the application of this additional machinery it may be proper to pay the chief attention, referring chiefly to *fig.* 1161, which is a front elevation. This figure has been already referred to for the illustration of those parts of the machinery which are common to both, and those parts therefore require no recapitulation. The principle of weaving ribbed hosiery has considerable affinity to that of weaving that kind of cloth which is distinguished by the name of tweeling, for the formation of stripes, with some variation arising merely from the different nature of the fabric. In cloth-weaving, two different kinds of yarn intersecting each other at right angles, are employed; in hosiery only one is used. In the tweeling of cloth, striped as dimity, in the cotton or kerseymere, and in the woollen manufacture, the stripes are produced by reversing these yarns. In hosiery, where only one kind of yarn is used, a similar effect is produced by reversing the loops. To effect this reversing of the loops, a second set of needles is placed upon a vertical frame, so that the bends of the hooks may be nearly under those of the common needles. These needles are cast into tin moulds, pretty similar to the former, but more oblique or bevelled towards the point, so as to prevent obstructions in working them. They are also screwed to a bar of iron, generally lighter than the other, and secured by means of plates: this bar is

1165



not fixed, but has a pivot in each end, by means of which the bar may have a kind of oscillatory motion on these pivots. Two frames of iron support this bar; that in which it oscillates being nearly vertical, but inclined a little towards the other needles. *Fig.* 1165, which is a profile elevation, will serve to illustrate the relative position of each bar to the other. The lower or horizontal frame, the ends only of which can be seen in *fig.* 1161, under *a a*, appears in profile in *fig.* 1165, where it is distinguished by *d*. The vertical frame at *a* is attached to this by two centre-screws, which serve as joints for it to move in. On the top of this frame is the rib-needle bar at *f*, in *figs.* 1155 and 1165, and one needle is represented in *fig.* 1165 at *f*. At *g* is a small presser, to shut the barbs of the rib-needles, in the same manner as the large one does those of the frame. At *h* is one of the frame needles, to show the relative position of the one set to the other. The whole of the rib-bar is not fitted with needles like the other; for here needles are only placed where ribs or stripes are to be formed, the intervals being filled up with blank leads, that is to say, with sockets of the same shape as the others, but without needles; being merely designed to fill the bar and preserve the intervals. Two small handles depend from the needle bar, by which the oscillatory motion upon the upper centres is given. The rising and sinking motion is communicated to this machine by chains which are attached to iron sliders below, and which are wrought by the hosier's heel when necessary. The pressure takes place partly by

1166



the action of the small presser, and partly by the motion of the needles in descending. A small iron slider is placed behind the rib-needles, which rises as they descend, and serves to free the loops perfectly from each other.

In the weaving of ribbed hosiery, the plain and ribbed courses are wrought alternately. When the plain are finished, the rib-needles are raised between the others, but no additional stuff is supplied. The rib-needles intersecting the plain ones, merely lay hold of the last thread, and, by again bringing it through that which was on the rib-needle before, give it an additional looping, which reverses the line of chaining, and raises the rib above the plain intervals, which have only received a single knitting.

HOT BLAST. See Iron.

HOT-FLUE is the name given in England to an apartment heated by stoves or steam-pipes, in which padded and printed calicoes are dried hard. *Fig.* 1166 represents the simplest form of such a flue, heated by the vertical round iron stove c, from whose top a wide square pipe proceeds upwards in a slightly-inclined direction, which receives the current of air heated by the body and capital of the stove. In this wide channel there are pulleys, with cords or bands which suspend by hooks and conduct the web of calico from the entrance at B, where the operative sits, to near the point A, and back again. This circuit may be repeated once or oftener till the goods are perfectly dried. At D the driving-pulley connected with the main shaft is shown. Near the feet of the operative is the *candroy* or reel, upon which the moist goods are rolled in an endless web; so that their circulation in the hot-air channel can be continued without interruption as long as may be necessary.

1167

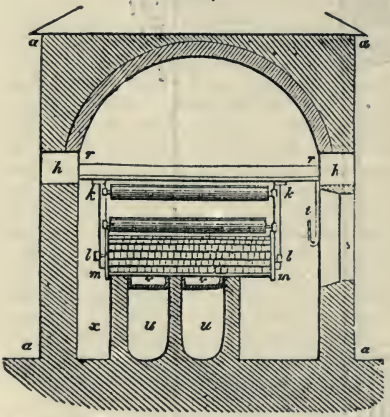


Fig. 1167 is a cross-section of the apparatus of the regular hot-flue, as it is mounted in the most scientific calico-works of England, those of James Thomson, Esq., of Primrose, near Clitheroe, Lancashire, *a a a a* is an arched apartment, nearly 30 yards long, by 13 feet high, and 10 feet wide. Through about one half of this gallery there is a horizontal floor supported on arches, above which is the driest space, through which the goods are finally passed before they escape from the hot-flue, after they have been previously exposed to the hot but somewhat moist air of the lower compartment. A large square flue covered with cast-iron plates runs along the whole bottom of the gallery. It is divided into two long parallel vaults, whose sections are seen at *u u*, *fig.* 1167, covered with the cast-iron plates *v v*, grooved at their ends into one another. The thickness of these plates is increased progressively as they come nearer to the fireplace or furnace. There are dampers which regulate the draught, and of course the heat of the stove. *h h* are the air-passages or vent-holes, left in the side walls, and which, by means of a long iron rod mounted with iron plates, may be opened or closed together to any degree. *k k* are the cast-iron supports of the tinned brass rollers which guide the goods along, and which are fixed to the cross pieces represented by *r r*, *fig.* 1167. *l l* are iron bars for supporting the ventilators or fans (see Foundry and Ventilation). These fans are here enclosed within a wire grating. They make about 300 turns per minute, and expel the moist air with perfect effect. *s* indicates the position of the windows, which extend throughout the length of the building. *t* is a

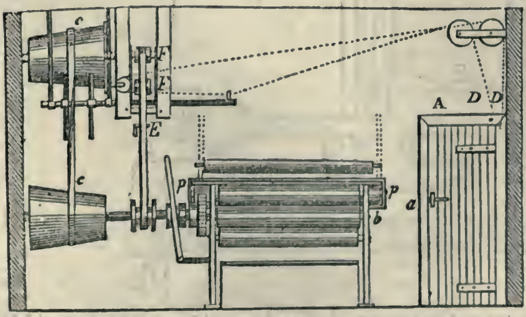
1168



gas-light jet, placed at the side of each window to supply illumination for night-work.

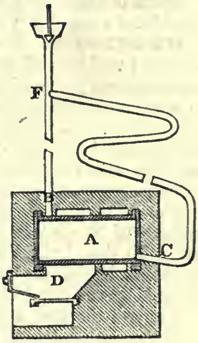
The piece is stretched along the whole extent of the gallery, and runs through it in the course of one minute and a half; being exposed during its passage to the heat of 212° Fahr.

In *fig.* 1168, A is the iron door of entrance to the hot-flue gallery; at *b* is the padding-machine, where the goods are imbued with the general mordant. The speed of this machine may be varied by means of the two conical drums *c c*, which drive it; since when the band *c c* is brought by its forks and adjusting screws nearer to the narrow end of the lower drum, the cylinder upon the main shaft with the latter is driven quicker; and *vice versâ.* Over D D the cords are shown for drawing the drum mechanism into gear with the main-shaft band, F, F, E; or for throwing it out of gear. The pulleys F F carry the bands which transmit the motion to the padding machine. A cylindrical drum exterior to the hot-flue, covered with flannel, serves to receive the end of the series of pieces, and to draw them through the apartment. This mode of drying the padded calicoes requires for each piece of 28 yards three pounds of coal for the furnace when a fan is employed, and four pounds without it. See CALICO-PRINTING.

HOT-WATER APPARATUS. (*Calorifère d'eau*, Fr.; *Wasser-Heitzung*, Ger.) In the *Dictionnaire Technologique*, vol. iv. we find a description of an apparatus of late years much employed for heating conservatories, &c., by hot water circulating in pipes:—

This mode of heating is analogous to that by stove-pipes; it is effected by the circulation of water, which, like air, is a bad conductor, but may serve as a carrier of caloric by its mobility. We may readily form an idea of the apparatus which has been employed for that purpose. We adapt to the upper part of either a close kettle, or of an ordinary cylindric boiler A, *fig.* 1169, a tube B, which rises to a certain height, and descends, making several sinuosities with a gentle slope till it reaches the level of the bottom of the boiler, to whose lowest part, as that which is least heated, it is fitted at C. At the highest point of the tube F we adapt a vertical pipe, destined to serve as an outlet to the steam which may be formed if the temperature be too much raised; it serves also for the escape of the air expelled from the water by the heat; and it permits the boiler to be replenished from time to time as the water is dissipated by evaporation; lastly, it is a tube of safety.

1169



The apparatus being thus arranged, and all the tubes as well as the boiler filled with water, if we kindle fire in the grate D, the first portions of water heated, having become specifically lighter, will tend to rise: they will actually mount into the upper part of the boiler, and, of course, enter the tube B F: at the same time an equivalent quantity of water will re-enter the boiler by the other extremity C of the tube. We perceive that these simultaneous movements will determine a circulation in the whole mass of the liquid, which will continue as long as heat is generated in the fire-place; and if we suppose that the tubes, throughout their different windings, are applied against the walls of a chamber, or a stove-room, the air will get warmed by contact with the hot surfaces; and we may accelerate the warming by multiplying these contacts in the mode indicated.

This *calorifère* can be employed with equal advantage and with more safety than those with heated air, when it is wished to heat large apartments. In the present case, the temperature of the water, without pressure, in the tubes, must be always under 100° C. (212° F.), even in those points where it is most heated, and less still in all the other points, while the temperature of the flues in *air stoves*, heated directly by the products of combustion, may be greatly higher. In air stoves, however, the pipes may without inconvenience have a large diameter, and present, consequently, a large heating surface; whereas, with the water *calorifère*, the pressure exercised by liquid upon the sides of the tubes being in the ratio of the surfaces, we are obliged, in order to avoid too great pressure, to employ a multitude of small tubes, which is expensive. Lastly, if the hot-water circulation is to be carried high, as may be often necessary in lofty buildings, the pressure resulting from the great elevation would call for proportional thickness in the tubes and the boiler; for these reasons it appears that water cannot in all cases be advantageously substituted for air or steam in the applications above stated: yet this mode of heating presents very decided advantages where it is needed to raise the temperature a small number of degrees in a uniform manner.

M. Bonnemain applied, with much success, these ingenious processes of heating by the circulation of water to maintain a very equal temperature in hothouses (*serres-chaudes*), in stoves adapted to artificial incubation, and in preserving or quickening vegetation within hothouses, or outside of their walls, during seasons unpropitious to horticulture.

Since the capacity of water for heat is very great, if the mass of it in a circulation-apparatus be very considerable, and the circulation be accelerated by proper arrangements, as by cooling the descending-tube exterior to the stove-room, we may easily obtain by such means a moderately high and uniform temperature, provided the heat generated in the fire-place be tolerably regular. We may easily secure this essential point by the aid of the *fire-regulator*, an instrument invented by M. Bonnemain.

It should be clearly understood that wood will become charred and eventually take fire if kept in contact with iron pipes through which hot water circulates. This may appear contrary to ordinary experience. There are, however, numerous evidences which prove distinctly that it is dangerous to have wood in contact with even hot-water pipes, and that it is infinitely more so to have it near to pipes through which the circulation of heated air is carried on.

There are several arrangements for carrying out this system of warming; but the principle is the same in all of them. Heated water ascends from the boiler, circulates through the pipes, giving warmth to the building in its passage, and it returns cool to the boiler, to be again circulated.

HOWLITE. A hydrous borate of lime. See Boracic Acid.

HUANO. See Guano.

HUMBOLDTILITE. A silicate of alumina, lime, magnesia, soda, &c. It occurs in crystals belonging to the pyramidal system, in the ejected limestones of Monte Somma. A substance identical in chemical composition and crystalline form has been found in slags from some of the Staffordshire blast-furnaces.

HUMITE. A silicate of magnesia from Vesuvius; known also as *Chondrodite.*

HUMUS. The vegetable matter of the soil, called also *Ulmin.* By action of alkalis it yields *humic* or *ulmic acid.*

HUNGARY WATER. Supposed to be named after a queen of Hungary, who used it as a cosmetic: it is prepared by distilling rosemary. See Eau de Cologne.

HYACINTH. The name under which are included the transparent, bright-coloured varieties of zircon. Hyacinth differs from jargoon merely in colour, which is orange-red passing into poppy-red. Though not much worn at the present time, it is a valuable gem, and makes a very superb ring-stone when of a bright tint and free from flaws. The larger species are sometimes made into seals. Hyacinths occur in the sand and alluvial deposits of certain rivers in Ceylon, also in the state of sand, mingled with various other substances, in the bed of a stream at Expailly (Haute-Loire) in France, as well as in basalt near the same place. It is also found in volcanic tuff in Auvergne, in Bohemia, Saxony, the Tyrol, Transylvania, Greenland, in the zircon-syenite of Fredericksvärn, in Norway, and in the iron mines of Arendal; also at Miask in the Urals, Vesuvius, at Santa Rosa in New Grenada, at Scalpay in Harris, Scotland, Egypt, the East Indies, and elsewhere. The hyacinth-red varieties of zircon are sold by the inhabitants of Ceylon as inferior rubies.—H. W. B.

Many of the stones used in jewellery under the name of hyacinth are nothing more than hyacinth-coloured garnets, belonging to the variety known as *cinnamon-stone* or *essonite.* This false hyacinth may be readily distinguished from the true gem by difference of specific gravity; that of the cinnamon-stone being only about 3·6, whilst the specific gravity of the true hyacinth rises as high as 4·7. Moreover, zircon is a doubly-refracting mineral, and garnet singly-refracting: a distinction which may sometimes be of value in the discrimination of cut stones. Both substances have about the same degree of hardness. The red zircon loses its colour on ignition, and increases in density. Some finely-coloured hyacinths have recently been found in the form of rolled pebbles at Mudgee, in New South Wales.

HYALOGRAPHY. The art of etching on glass. The process may be effected either chemically, by the action of hydrofluoric acid; or mechanically, by means of the sand-blast. See Glass.

HYDRACIDS. A term sometimes applied to those acids which obviously contain hydrogen as an essential constituent, such as hydrochloric acid. The term was formerly used to distinguish these acids from another class called *oxyacids,* such as sulphuric acid; but as these also are now known to contain hydrogen, the old distinction has lost its significance. All acids, indeed, are hydracids.

HYDRATES are compounds of the oxides, salts, &c., with water in definite or equivalent proportions. Thus slaked lime consists of one atom of quicklime = 28, + one atom of water = 9, of which the sum is 37 on the hydrogen scale. 'The very different functions performed by water in the various modes of combination it affects render it necessary to adopt a definite principle of nomenclature in this respect. . . . I shall employ the word *hydrate* only where the water is combined with a base, such as a metallic oxide, thus, hydrate of lime, hydrate of potash, hydrated oxide of lead.' —*Kane.*

HYDRAULIC LIME. The poorer sorts of limestone, such as contain from 8 to 25 per cent. of foreign matter, in silica, alumina, magnesia, &c., form the best hydraulic limes. All the water limestones are of a bluish-grey or brown colour, which is communicated to them by the oxide of iron. They are usually termed *stone-lime* by the builders of the metropolis, to distinguish them from common chalk-lime, but so far improperly, that the Dorking limestone is not much harder than chalk, and the Halling limestone is actually a chalk, and not harder than the pure chalk of the same neighbourhood, from which it is only distinguished in appearance by being a little darker. These, though calcined, do not slake when moistened; but if pulverised they absorb water without swelling up or heating, like *fat* lime, and afford a paste which hardens in a few days under water, but in the air they never acquire much solidity.

The following analyses of different hydraulic limestones are by Berthier:—

	No. 1	No. 2	No. 3	No. 4	No. 5
A. *Analyses of limestones.*					
Carbonate of lime . . .	97·0	98·5	74·5	76·5	80·0
„ magnesia . .	2·0	...	23·0	3·0	1·5
„ protoxide of iron .	...	...	...	3·0	...

Silica and alumina . . .	...	...	...	15·2	18·0
Oxide of iron	1·0	1·5	1·2		
	100·0	100·0	98·7	99·2	99·5
B. *Analyses of the burnt lime.*					
Lime	96·4	97·2	78·0	68·3	70·0
Magnesia	1·8	...	20·0	2·0	1·0
Alumina	1·8	2·8	2·0	24·0	29·0
Oxide of iron	...	...	...	5·7	...
	100·0	100·0	100·0	100·0	100·0

No. 1 is from the fresh-water lime formation of Château-Landon, near Nemours; No. 2, the large-grained limestone of Paris; both of these afford a fat lime when burnt. Dolomite affords a pretty fat lime, though it contains 42 per cent. of carbonate of magnesia. No. 3 is a limestone from the neighbourhood of Paris, which yields a poor lime, possessing no hydraulic property; No. 4 is the secondary limestone of Metz; No. 5 is the lime-marl of Senonches, near Dreux; both the latter have the property of hardening under water, particularly the last, which is much used at Paris on this account.

All good hydraulic mortars must contain alumina and silica; the oxides of iron and manganese, at one time considered essential, are rather prejudicial ingredients. By adding silica and alumina, or merely the former, in certain circumstances, to fat lime, a water-cement may be artificially formed; as also by adding to lime any of the following native productions, which contain silicates; puzzolana, trass or tarras, pumice-stone, basalt-tuff, or slate-clay. Puzzolana is a volcanic product, which forms hills of considerable extent to the south-west of the Apennines, in the district of Rome, the Pontine marshes, Viterbo, Bolsena, and in the Neapolitan region of Puzzuolo, whence the name. A similar volcanic tufa is found in many other parts of the world. According to Berthier, the Italian puzzolana consists of 44·5 silica; 15·0 alumina; 8·8 lime; 4·7 magnesia; 1·4 potash; 4·1 soda; 12 oxides of iron and titanium; 9·2 water; in 100 parts.

The *tufa* stone, which when ground forms *trass*, is composed of 57·0 silica, 16·0 clay, 2·6 lime, 1·0 magnesia, 7·0 potash, 1·0 soda, 5 oxides of iron and titanium, 9·6 water. This tuff is found abundantly, filling up valleys in beds of 10 or 20 feet deep, in the north of Ireland, among the schistose formations upon the banks of the Rhine, and at Monheim in Bavaria.

The fatter the lime the less of it must be added to the ground puzzolana, or trass, to form a hydraulic mortar; the mixture should be made extemporaneously, and must at any rate be kept dry till about to be applied. Sometimes a proportion of common sand-mortar instead of lime is mixed with the trass. When the hydraulic cement hardens too soon, as in 12 hours, it is apt to crack; it is better when it takes 8 days to concrete. Through the agency of the water, silicates of lime, alumina (magnesia), and oxide of iron are formed, which assume a stony hardness.

Besides the above two volcanic products, other native earthy compounds are used in making water-cements. To this head belong all limestones which contain from 20 to 30 per cent. of clay and silica. By gentle calcination, a portion of the carbonic acid is expelled, and a little lime is combined with the clay, while a silicate of clay and lime results, associated with lime in a subcarbonated state. A lime-marl containing less clay will bear a stronger calcining heat without prejudice to its qualities as a hydraulic cement: but much also depends upon the proportion of silica present, and the physical structure of all the constituents.

The mineral substance most used in England for making such mortar is vulgarly called *cement-stone.* It is a reniform limestone, which occurs distributed in single nodules, or rather lenticular cakes, in beds of clay. They are mostly found in those argillaceous strata which alternate with the limestone beds of the Oolite formation, as also in the clay strata above the chalk, and sometimes in the London clay. On the coasts of Kent, in the isles of Sheppey and Thanet, on the coasts of Yorkshire, Somersetshire, and the Isle of Wight, &c., these nodular concretions are found in considerable quantities, having been laid bare by the action of the sea and weather. They were called by the older mineralogists *Septaria* and *Ludus Helmontii* (Van Helmont's coits). When sawn across, they show veins of calc-spar traversing the siliceous clay, and are then sometimes placed in the cabinets of *virtuosi.* They are found also in several places on the Continent, as at Neustadt-Eberswalde, near Antwerp, near Altdorf in Bavaria; as also at Boulogne-sur-mer, where they are called Boulogne pebbles (*galets*). These nodules vary in size from that of a fist to a man's head; they are of a yellow-grey or brown colour, interspersed with veins of calc-spar, and sometimes contain cavities bestudded with crystals. Their specific gravity is 2·59.

The Blue Lias cement-stones are considered the strongest water-limes of this country, and are found on opposite sides of the Bristol Channel, near Watchet in Somersetshire, and Aberthaw in Glamorganshire, and also in North Wales and at Lyme Regis in Dorsetshire. The Dorking or Merstham lime and the Halling lime, so termed from a village on the left bank of the Medway above Rochester, but which is also found near Burnham on the opposite side of the river, though not possessing such strong hydraulic properties as the lias, are also much esteemed.

Analyses of several cement-stones, and of the cement made with them:—

	No. 1	No. 2	No. 3	No. 4	No. 5

Oxide of iron	8·6	15·0	13·0	...	13·7

No. 1, English cement-stone analysed by Berthier; No. 2, Boulogne stone, by Drapiez; No. 3, English ditto, by Davy; No. 4, reniform limestone-nodules from Arkona, by Hühnefeld; No. 5, cement-stone of Avallon, by Dumas.

In England the stones are calcined in shaft-kilns, or sometimes in mound-kilns, then ground, sifted, and packed in casks. The colour of the powder is usually dark brown-red. When made into a thick paste with water it absorbs little of it, evolves hardly any heat, and soon indurates. It is mixed with a sharp sand in various proportions, immediately before using it; and is employed in all marine and river embankments, for securing the seams of stone or brick floors or arches from the percolation of moisture, and also for facing walls to protect them from damp.

HYDRAULIC CEMENT. This is a kind of mortar used for building piers or walls under, or exposed to, water, such as those of harbours, docks, &c. The cement of Pouilly is prepared from a Jurassic (secondary) limestone, which contains 39 per cent. of silica, with alumina, magnesia, and iron oxide. Vicat forms a factitious Roman cement by making bricks with a pasty mixture of 4 parts of chalk and 1 part of dry clay, drying, burning, and grinding them. River-sand must be added to this powder; and even with this addition, its efficacy is somewhat doubtful; though it has, for want of a better substitute, been much employed at Paris.

Prof. Kuhlmann, of Lisle, has made certain improvements in the manufacture of lime-cement, and he has prepared artificial stone possessed of a hardness and solidity fit for the sculptor. See STONE, ARTIFICIAL.

In operating by the dry method, instead of calcining the limestone with sand and clay alone, as has been hitherto commonly practised, this inventor introduces a small quantity of soda, or preferably, potash, in the state of sulphate, carbonate, or muriate —salts susceptible of forming silicates—when the earthy mixture is calcined. The alkaline salt, equal in weight to about one-fifth that of the lime, is introduced in solution among the earths.

All sorts of lime are made hydraulic in the humid way, by mixing slaked lime with solutions of common alum or sulphate of alumina; but the best method consists in employing a solution of the silicate of potash, called liquor of flints, or soluble glass, to mix in with the lime, or lime and clay. An hydraulic cement may also be made which will serve for the manufacture of architectural ornaments, by making a paste of pulverised chalk, with a solution of the silicate of potash; the said liquor of flints likewise gives chalk and plaster a stony hardness, by merely soaking them in it after they are cut or moulded to a proper shape. On exposure to the air they get progressively indurated. Superficial hardness may be readily procured by washing over the surface of chalk, &c., with liquor of flints, by means of a brush. This method affords an easy and elegant method of giving a stony crust to plastered walls and ceilings of apartments; as also to statues and busts, cast in gypsum, mixed with chalk.

The essential constituents of every good hydraulic mortar are caustic lime and silica; and the hardening of this compound under water consists mainly in a chemical combination of these two constituents through the agency of the water, producing a hydrated silicate of lime. But such mortars may contain other bases besides lime, as, for example, alumina and magnesia, whence double silicates of great solidity are formed; on which account dolomite is a good ingredient of these mortars. But the silica must be in a peculiar state for these purposes; namely, capable of affording a gelatinous paste with acids; and if not so already, it must be brought into this condition, by calcining it, along with an alkali or an alkaline earth, at a bright red heat, when it will dissolve, and gelatinise in acids. Quartzose sand, however fine its powder may be, will form no water-mortar or lime; but if the powder be ignited with the lime, it then becomes fit for hydraulic work. Ground felspar or clay forms with slaked lime no water-cement; but when they are previously calcined along with the lime, the mixture becomes capable of hardening under water.

Hamelin's Cement is composed of ground Portland stone (roe-stone), sand and litharge, in the proportion of 62 of the first, 35 of the second, and 3 of the third, in 100 parts; but other proportions will also answer the purpose. Considerable dexterity is required to make good work with it.

Limestone, which contains as much as 10 per cent. of clay, comports itself after calcination, if all the carbonic acid be expelled, just as pure limestone would do. When it is less strongly burned, it affords, however, a mass which hardens pretty speedily in water. If the argillaceous proportion of a marl amounts to 18 or 20 per cent., it still will slake with water, but it will absorb less of it, and forms a tolerably good hydraulic mortar, especially if a little good Roman Cement be added to it. When the proportion of clay is 25 to 30 per cent. after burning, it heats but little with water, nor does it slake well, and must therefore be ground by stampers or an edge millstone, when it is to be used as a mortar. This kind of marl yields commonly the best water-cement without other addition. Should the quantity of clay be increased farther, as up to 40 per cent., the compound will not bear a high or long-continued heat without being spoiled for making hydraulic mortar after grinding to powder. When more strongly calcined, it forms a vitriform substance, and should, after being pulverised, be mixed up with good lime, to make a water-mortar. If the marls in any locality differ much in their relative proportions of lime and alumina, then the several kinds should be mixed in such due proportions as to produce the most speedily-setting, and most highly-indurating hydraulic cement.

Hydraulic limes or cements require the presence of carbonate of lime with silica, or silicate of alumina, or magnesia. It is stated that dolomite calcined at a moderate heat exhibits the property of a hydraulic lime. See DOLOMITE.

If carbonate of lime be mixed with gelatinous silica, it forms a good hydraulic cement. See SILICA; and STONE, ARTIFICIAL.

If a hydraulic lime be calcined at too high a temperature, the silicate undergoes partial fusion, and will not set afterwards under water. The heat, therefore, employed for burning the hydraulic limestones should only be just high enough to expel the water from the clay and the greater part of the carbonic acid from the carbonate of lime.

Neither clay (silicate of alumina) nor lime alone will set under water, but if we carefully mix chalk and clay together, and then calcine them at a moderate heat, a good hydraulic cement is obtained.

Hydraulic limestones may be separated into two kinds, as indicated by their constituents. One set consists of the carbonates of the earths, these yield a fat lime; the other set is composed of silicates, or a mixture of silicates of alumina, lime, magnesia, or potash, although of the latter less frequently, with usually much free silica; consequently these are a kind of clay.

In burning hydraulic limestones, the silica and alumina, when the lime has once parted with its carbonic acid, react upon each other. The lime enters into feeble combination with the silica, producing a less stable compound than the original, and which is readily acted on by acids, which was not the case previous to burning.

Burnt hydraulic lime is, in nearly all cases, soluble in acids. The presence of a silicate that can be decomposed by acids is proved by the formation of a thick jelly of silica. The property of yielding gelatinous silica by solution in acids, may be regarded as one of the proofs that the limestone possesses the property of 'setting,'—becoming hard under water.

The degree of hardness acquired by hydraulic lime varies considerably. The time required for hardening differs still more widely; some hydraulic cements will set in a few minutes, others will require weeks and months. The more of the aluminous constituents which the limestone contains the more quickly will the cement prepared from it solidify.

As already remarked, too much heat in the kiln, causing partial fusion of the silica, destroys the hydraulic property of the lime. In technical phrase it renders the lime much weaker, and at last completely destroys its power as a water-cement.

Hydraulic lime should acquire a certain consistence before it is immersed in water. If this is not attended to, the hydraulic lime never hardens, the particles form a porous mass, there is no kind of agglutination; consequently, considerable care is required in every stage of the process of making and using hydraulic cements.

It is impossible in this work to do full justice to this very important subject; we must therefore refer our readers to General Pasley's works on *Limes and Cements*, to the papers of Mr. Timperly in the *Transactions of the Institution of Civil Engineers*, and to the works especially of MM. Vicat and Belidor. See PUZZOLANA; ROMAN CEMENT.

Scott's Cement.—The following remarks on hydraulic cements, and on the preparation of a new and valuable kind of these cements, are abstracted from some memoirs by Major-General Scott in the *Papers on Subjects connected with the Duties of the Corps of Royal Engineers.* General Scott's hydraulic cement has been used in the construction of the Royal Albert Hall and many other buildings, and we are given to understand, generally with satisfactory results.

The superiority of hydraulic mortars over pure lime-mortars consists very much in the former containing within themselves the property of solidifying without the assistance of the atmosphere; while the pure lime-mortars do not possess such a property, and in the absence of carbonic acid in the atmosphere, no solidification will ensue.

Many impure limestones contain a proportion of clay (silicate of alumina and iron) intimately mingled with the carbonate of lime. By burning, the carbonic acid gas is expelled from them as in the case of the pure limestones, the clay assisting in its expulsion through the affinity of its silicic acid for the lime, and also parting with its own combined water. A further action then takes place: the silicic acid of the clay and the lime, at the high temperature of the kiln, react on one another, and either form a silicate of lime, or approximate to its formation so far that on the addition of water it is formed with more or less rapidity. As, however, this action is more perfect in the water-cements, and there is much in common between them and the hydraulic limes, it will be better here to explain in what their difference consists, and then to speak of them together.

The difference between them cannot be precisely defined with reference to chemical composition, for there are some limestones which will yield cement or lime according to the temperature at which they are burned. It must rather be referred to the manner in which they behave when moistened with water. If a piece of cement be dipped in water for a few seconds until it ceases to hiss from the escape of air from its pores, it may become harder, or it may after a time partially break up, with or without sensible warmth. If a piece of fresh pure lime be similarly treated, in a few minutes it begins to heat and swell, and the violence of the action is such as to throw it abroad in a bulky impalpable powder. In the latter case one affinity only comes into play, that of the lime for the water; but with the cement, a second affinity is in operation. By the action of the heat in the process of burning, the affinity of the lime for the silicic acid of the clay is brought into play, and modifies the violence of its affinity for water, and when the temperature is sufficiently high, the lime and the silicic acid enter into chemical combination, and the compounds so formed, on being moistened with water, pass into hydrates in a gradual and quiet manner, without any of the tumultuous action which is so remarkable in the combination of pure lime with water.

The hydrated silicates resulting are not afterwards appreciably affected by water, and so much of the lime as the silicic acid can take up passes from a soluble to an insoluble condition, thus affording a cementing material suitable for hydraulic purposes. When the heat of the kiln is too far urged, vitrification ensues from the complete formation of an anhydrous silicate, and a comparatively inert substance is produced, which undergoes no change on being mixed with water, or will only unite with it after considerable periods of time.

The hydraulic limes are intermediate between the cements and the pure limes, and partake of the character and mode of action of each class of substances. The proportion of clay in them is generally smaller than in the cements, and the lime sufficiently predominates to produce by its violent affinity for water the degree of heat, expansion, and amount of vapour requisite to throw them into powder. When the quantity of clay, as compared with the lime, is small, the violence of the slaking is scarcely less than that of the pure limes, but in proportion as the clay is relatively larger in amount, the heat generated in combining with the water is less, and the lime slakes to a powder more imperfectly and with less increase of volume; until at last, on reaching the boundary of the cements, the slaking must be urged on by confining the heat generated, and the lime allowed to lie longer to ensure the completion of the action before it is mixed with sand and made into mortar.

In the ordinary kiln-burning, some portions of the hydraulic limes, by too great heat of the charge, are brought into that condition when the silicates formed combine very slowly with water. The silicic acid having undergone a great modification, the powders of such limes can unite and form new hydrated compounds, but by a process so slow that it may be measured by weeks, months, or years, instead of minutes, hours, and days, thereby, in badly-mixed mortar, doing great injury; expansion taking place after the mortar has been laid in the work, it has been known to throw down arches, and lift heavy masses of masonry.

If hydraulic limes be allowed to dry too rapidly, they will not properly harden.

With regard to cements, some portions of a charge are often spoiled by lowness of temperature in burning, and thus prevent the desired rapidity of forming silicates, and retard the solidification of the mortar without the assistance of water.

Besides the proportion of clay and lime, and the temperature of burning, the composition of the clay has much to do with the rapid setting of hydraulic limes and cements. The larger the amount of iron and alumina present, the more readily will the lime and clay pass through the different stages to the formation of a perfect cement, though temperature in burning has much to do with its character, for from the same bed of chalk-marl have been made a hydraulic lime, a quick setting cement, and a cement resembling the Portland cement. See LIME.

As the cements may, and practically always do, partake of the slow solidifying action of the hydraulic limes, so the hydraulic limes partake, when exposed to the air, of the hardening action of the carbonic acid gas of the atmosphere, to which the pure limes owe the external hard crust.

The addition of puzzolana, trass, &c., often improves the hydraulic limes. The action of these substances is similar to that of clay found naturally mingled with the carbonate of lime in hydraulic limestones. These have been calcined by volcanic heat, and though burnt clay may produce a similar effect, it is rarely so perfect.

Preparation of this Cement.—The limestone to be employed in the manufacture of the cement is burnt to quick-lime by any of the ordinary processes, avoiding over-burning, as usual. Limes burned until they assume a blue or greenish tinge require peculiar and very careful treatment to fit them for the purpose.

The quick-lime is either wheeled in barrows or carried in baskets into an oven, and is laid on the perforated arches forming the floor, to the depth of 1 foot 6 inches on the crown, and 2 feet over the haunches. With a large-sized lime this depth may increase a few inches, and when the lime is very small it must be somewhat decreased; or, in other words, the lime must not be so closely and deeply packed as to impede the draught too much. The lime-dust produced in burning the lime becomes useful in making the hatches of the oven air-tight, and if there is any excess, it may be ground down with the cement without sensibly deteriorating its strength.

When the oven is loaded, the charging hatch is closed with a double 4-inch dry brick wall, the included space being filled in with lime-dust. The whole may be made air-tight at top by means of an opening through the crown of the arch. An iron door can be employed, and with saving of labour, but a brick wall will generally be found more convenient.

The small hatch intended to assist in cooling the oven, in order to draw the charge, is better closed with an iron door on hinges, the whole being made tight with a mixture of moistened clay and sand, technically termed 'pug.'

If the lime employed is pure or feebly-hydraulic lime, it is advisable to allow it to remain, with a current of air passing through it for a period which will vary, generally, with the temperature of the air, and the draught through the oven. The object of this is that the moisture carried through by the air may open or split the lime a little, and otherwise facilitate the combination of the sulphurous acid during the subsequent process, without, however, causing it to fall abroad. Whatever the nature of the lime operated upon, such exposure renders the process more certain, and should be employed whenever the tendency to slake with heat is not readily destroyed without it. The period of exposure will vary from twelve to forty-eight hours. After this exposure, a fire of coke or coal is kindled by means of a faggot or brushwood on the fire-bars, and a slow fire is kept up until the lime immediately over the arches shows a dull glow, such as is barely visible when viewed in the dark through the pipes in the sides of the oven. The firing is then raked out, and after the lapse of a quarter or half an hour, according to the size of the oven, the ash-pit is closed, and the chimney-top covered with a slate-stone, or plate of iron, until it is judged that the heat throughout the mass of lime is pretty well equalised. When coal is used, there is sometimes a little difficulty in preventing the smoke escaping through the fire-doors after each fresh feeding of the fire, but this may be obviated with a little care and more frequent feeding. The flame of coal heats the charge more equally. A mixture of coal and coke may also be employed.

The time required for heating the lime depends on so many circumstances that no definite rule can be laid down; the dullest possible glow will sufficiently indicate when the first point is attained, that a burner acquainted with the action of his oven will not require the use of the viewing pipe at all.

When the heat in the oven is judged sufficient, and to be sufficiently equalised, the ash-pit and the chimney are opened, and iron pots containing coarse unpurified sulphur are pushed in on the fire-bars, and placed in such a manner as to distribute the fumes of the burning sulphur equally. The pots may be made of wrought iron, of sufficient capacity to hold about 25 lbs. of sulphur each, the allowance being 15 lbs. to each yard of lime. A few red-hot cinders are thrown into each pot as it is pushed in, to ignite the sulphur. In ten or fifteen minutes the sulphur will be fully ignited, and its fumes will begin to escape through the chimneys very freely; the chimneys should then be closed again perfectly, and a little clay or lime-dust used to make the cover tight. The fire-doors and ash-pits are also to be plastered at the crevices, with the exception of a small opening at the bottom of each of the latter, which opening is to be regulated by the amount of air which may be required to carry on the combustion of the sulphur, without allowing the sulphurous acid to escape, and such escape would be immediately detected by the smell.

When the sulphur is all consumed, which may be ascertained by looking from time to time, after the lapse of some hours, into the oven fire-door, the wall closing the hatch is thrown down, and all other openings made free to the passage of air, to cool the charge and oven sufficiently to allow the former to be removed.

The grinding is then commenced; a few trial samples are made up with water, and an examination made at the top, middle, and bottom of the charge, to obtain information as to temperature for future guidance. If the lime from the bottom of the charge, when moistened, remains quite dead on the outside of the lumps, a sort of crust being formed there, and at the heart the lumps retain its usual properties, this is a proof that the bottom portion, if not the whole charge, was too hot when the sulphur process was commenced; if the upper layers still retain the usual characteristics of the unprepared lime, no crust being visible on the bottom portions, this shows that the heat at the top was not great enough, and probably that the temperature throughout was too low. Some pieces will always be found insufficiently prepared, but their effect is lost in the mass, and the samples should be three or four in number from each part of the charge, top, bottom, and centre, avoiding a selection of pieces near the walls. If in any case the mass is found insufficiently prepared, and the lower layers are crusted, the upper half may be removed and employed as ordinary lime, and the lower half ground down as cement. If the process should be judged to have been quite ineffectual, the removed portion of the charge can be replaced with fresh lime, and the operations of heating the lime to a faint glow, and of burning sulphur under it, be repeated; with ordinary care a failure can hardly occur, and should the sample specimens set firmly 'in pats' six inches square and half an inch thick, but yet grow too hot in setting to be safely trusted in work, a few days' exposure on the floor of the shed will render the cement fit for use. It is better, however, that 'in pats' of the above size, made up with water to a stiff consistency and without admixture of sand, the warmth in the setting—even when the cement is quite fresh from the oven—should be barely perceptible.

The grinding of the cement is the most serious part of the manufacture. Should the extent of the works justify a considerable outlay in grinding apparatus, the flour-mill construction is to be preferred, horizontal crushing rollers being used to reduce the lumps of cement to a size which the eye of the runner mill-stone can readily take. It is better also to sift it through a sieve, the coarse particles being again passed through the stones. For grinding, on the small scale, a pair of vertical wheels of iron or stone, turning on a pivot between them by horse-power, must be resorted to, the sifting apparatus being attached by suitable machinery to the gearing of the wheel, or worked by manual labour. The wire-gauze used for the sieves should have thirty meshes to the inch. The construction of both descriptions of mills is well understood by mill-makers.

When the cement is prepared from the pure and feebly-hydraulic limes, and it becomes necessary to impart to them properties which will enable them to resist the action of water, artificial or natural puzzolanas must be restored to. If such substances are ground down with the cement to a fine powder, and intimately mixed with the cement, one part of puzzolana will give to two parts of pure lime-cement, by weight, the necessary degree of resistance; but if mixture by hand-labour be alone available, and the puzzolana be not in a fine state of division, its quantity in proportion to the cement should be increased, the amount of sand used for mortar being correspondingly diminished.

The clays best adapted for the manufacture of artificial puzzolana are such as are greasy to the touch. The temperature at which they ought to be calcined depends upon their chemical composition, but the action of the constituents is complicated, and actual trial must be resorted to for the determination of the most efficient degree of calcination. To make the trial, a portion of the clay under examination may be moulded into a cylinder five or six inches long, and one and a half inch diameter; this cylinder when dried is to be exposed, the one end in a violent fire, the other on or near the outside of it. When the more highly-heated end begins to vitrify, the cylinder is withdrawn from the fire and divided into three or four portions, according to the general appearance and colour of the different parts.

By pulverising each part, and mixing this puzzolana with the cement in the proportion of one part of burnt clay to two or three parts of cement, by measure, it is easy to determine by actual trials in water what degree of calcination gives the best results. To prevent the cylinder from breaking in the fire, it is moulded round a wire. As a general rule, it will be found that clays containing lime and other metallic oxides, especially alkalis, become energetic at low temperatures, though they may also succeed when burned at a violent heat. The poorer clays will only give good results when calcined at a very high temperature, and they have the further disadvantage of being difficult to reduce to powder.

Clay should be made ready for burning by moulding it into rounded balls of the size of an apple, and leaving it in the air to dry. A thick layer of coals is placed on the bars at the bottom, then layers of the clay balls and coal alternately; when the kiln is about two-thirds full, faggots should be placed under the bars and ignited, and as the combustible is consumed, more coals and clay should be added; the appearance of the clay will at once show whether a proper quantity of fuel has been used.

Concrete.—The following is an account, by a thoroughly practical man, of the use of hydraulic limes in the formation of concrete. It is from a paper read by George Robertson, C.E. before the Scottish Society of Arts, 'On the Concrete used in the late Extension of the London Docks.'

The great mass of the concrete was made with naturally hydraulic lime, blue lias from Lyme Regis in Dorsetshire. which requires no artificial mixture with puzzolana or minion to render it capable of setting *permanently* under water. The word 'concrete' in this paper implies, therefore, that made with blue-lias lime, unless otherwise specified. The Dorsetshire lias was the only lime burned on the works; all lias from Warwickshire or Leicestershire was bought ready burned from the merchants. Lias requires much greater care in burning than richer limes, because any sudden or extra heat, which would do little harm to Dorking lime, greatly injures lias by forming a glass between the silica and the lime in the stone, instead of only driving off the water and carbonic acid. The combination between the silica and lime, to which lias owes its hydraulic properties, ought only to take place in the humid way —*i.e.* with the assistance of water, after the application of the lime as mortar or concrete. Lias comes from Lyme Regis in two different forms, the one with a clean conchoidal fracture, and the other of a shaley nature, approaching in appearance even to clay-state, but quite soft. The shaley lias, which contains so much clay as to have the properties of a cement, is not so desirable as the hard clean stone, because it carries less sand, and is therefore more expensive. The stone cost 4*s.* 3*d.* a ton when shipped at Lyme, but 10*s.* 9*d.* before it was stacked round the kiln at London, which is as much as the same stone cost delivered at the works of the New Graving Dock at Leith. Freight to London is always heavy, for there is no steady return freight, like coal, to be had. Notwithstanding the high price of the stone delivered at Shadwell, and having to pay freight on thousands of tons of water and carbonic acid, to be afterwards driven off by the heat of the kiln, the engineer-in-chief of the Dock Company, the late Mr. Rendel, determined to burn the limestone in London, as the extra cost would be a comparatively small item in such extensive works. It was very desirable to have the best possible lime where concrete was to play so important a part.

Two egg-shaped draw-kilns of brick were therefore erected, of a total height of 43 feet from the floor to the top of the dome, and an extreme internal diameter of 14 feet, contracting to 5 feet at the fire-bars, and 11′ 6″ at 32 feet above the floor. The practical objection to having a less diameter than this at the top, is the difficulty that would arise in charging the kiln with evenly-distributed layers of coal and stone tipped in from barrows at the top through the windows in the dome. It has likewise been objected that a contracted top to a kiln prevents the escape of carbonic acid, although it has a counterbalancing advantage in confining the heat, and throwing it down with a reverberatory effect on the charge. This theoretical objection appears to be fanciful. It was found necessary, after these kilns had been working for a short time, to dome the mouth over with a brick arch, to prevent stones from flying into the neighbouring streets. The chimney at the top of this was only three feet in diameter, and yet no difference was afterwards perceptible, either in the time required for burning, or in the percentage of imperfectly-burned stone. On the other hand, there is little doubt that the dome acted economically on the coal required, for the average of 7,000 tons of limestone was little more than one ton of coal to 11½ of stone, the limits being 1 to 10, and 1 to 13. Carbonic acid came away freely after the kiln had been lighted for three hours, and it appeared to have ample room for escape. An average of 11½ tons of stone burned by one ton of coal is very high; but the coal was Welsh, and cost 1*l.* 1*s.* a ton. Newcastle coal, or bituminous coal in general, was inadmissible; for it was essential to have little or no smoke from kilns in the heart of London. At Leith, one ton of the coal of the neighbourhood appears to burn only six or seven tons of lias, but the coal is only one-third of the price of Welsh coal. The barrows of coal and properly broken stone were lifted to the top of the kiln by a hoist worked by the mortar mill engine, and were tipped in through three openings in each dome, as evenly as possible. After the kiln was lighted, these windows were kept closed with boiler-plate shutters. The cost of charging, including breaking up the stone and coal, was 1*s.* 6*d.* per ton of the two when mixed in the kiln. Unless the demand for quick-lime was very irregular, the kilns were always kept lighted; but whenever they were allowed to go out, the charge of quick-lime was left in the kiln, as the place most free from moisture. Whenever the fire is let out in draw-kilns, the next charge is nearly sure to burn irregularly, and there is a considerable loss of heat in re-warming the kiln. Draw-kilns are liable to irregularity from apparently slight causes, such as the direction of the wind, &c.; and in the Shadwell kilns there was also a permanent tendency to burn quickest down the side warmed by the adjacent kiln, for they were both in one block of building. But draw kilns are better suited for burning lias than flare kilns, as the heat is more uniformly distributed through the charge; there is, therefore, less danger of over-burning the lower half and under-burning the upper.

Each kiln held 100 tons of stone, and burnt 21 tons per diem. The two together produced 25 tons of quick-lime every day, a quantity sufficient for about 97 cubic yards of mortar, or 170 cubic yards of concrete: 9 tons of coal will burn 100 tons of stone, which produce 59·37 tons of quick-lime, or 1,583 bushels of ground lime, enough for 400 cubic yards of concrete, when the ballast is moderately dry. Drawing the lime from the kiln cost 1¼*d.* per ton of quick-lime. The total cost of the burnt lime amounted to 24*s.* per ton. When quite hot from the kiln, 26½ bushels of ground lime went to the ton; but after keeping some time, a ton swelled to 30 bushels, which is what bought lias usually weighs. A bushel of lime, ground when fresh burnt, contains, therefore, one-seventh more lime than a bushel of stale lime; and a cubic yard of concrete, of specified proportions, is so much the better when made with fresh lime.

Coke was used in the kiln for a short time, but it was found to be 8 per cent. dearer than Welsh coal; and, moreover, the heat given out by it was too quick and strong, casing many of the stones over with a vitrified silicate, which hindered the free escape of carbonic acid. When coke was burnt, therefore, the percentage of unburnt stone was raised much above the usual average of 1½ or 2 per cent.

The equally burnt and softest lumps, usually of a buff colour, were picked out for grinding; and the remainder, more of a liver colour, slaked for mortar. The lumps were first broken tolerably small by hand, and then crushed still smaller between iron rollers revolving in the hopper of the grindstones. These rollers were at first made fluted, but it was found that strong projecting cogs did the work more effectually. The hopper was fed with lumps of lime by an endless chain of small wrought-iron buckets worked by the engine. It was intended that these should be self-acting, and dredge the lime up from a well; but it was found necessary to have a man constantly feeding them with a spade, or the supply was not regular.

The lime was ground to a fine powder between two pairs of horizontal French burr millstones; the upper one revolving at a speed of 90 revolutions per minute. Each pair of stones was able to grind 3 tons of quick-lime per hour, at a total cost for grinding of 1*d.* per bushel when the consumption was 360 bushels per diem; less, if more lime was used. This is made up as follows: feeding and attending to the hopper and lift, ½*d.*; engine power, ¼*d.*; measuring the lime into bags for the contractor, and recutting the stones as the furrows became worn, the remaining ¼*d.* A bushel of lime ground fresh from the kiln weighed 84 lbs.; and at this weight the total cost was 11¾*d.* In buying ground lime from a merchant, if the purchaser buys by weight, he pays for the water absorbed from the atmosphere; if he buys by measure, he pays for the expansion caused by that moisture: the fairest way for both parties would be to specify the bushel to be of a certain average weight, say for lias from Lyme Regis, 80 lbs. This would allow for the lime not being quite fresh, but would prevent it from being too stale.

The grindstones were composed of burrs from the fresh-water beds of the Paris basin, set in two radiated rings in cement, and backed up with plaster-of-Paris and mortar. The 'skirts' or outside burrs were five inches thick; the central or 'high burrs' somewhat thicker, to allow for the 'swallow,' which is a slight depression in the centre of the upper stone, about two feet in diameter, and at most 3″ deep. This acts as a kind of distributing reservoir for the lime as it falls from the hopper between the stones.

The face of the stones was divided into ten 'quarterings' by 'master furrows,' each of them being tangential to an imaginary circle concentric with the stone, and called its 'draft.' The size of this regulated the quantity of lime passing through the stones in a given time. A radius of five inches was found to grind ninety bushels per hour of a sufficiently fine quality. The particles of lime, whirling round near the centre of the stone, by their centrifugal velocity pass towards the outside along the master furrows, being ground finer as they recede from the central depression. Each master furrow had two other distributing furrows leading out of it, parallel to the former master furrow. The furrows are shallow grooves, or rather nicks about 1¼ inch wide, with the cutting edge sharp, and the other bevelled.

The hydraulic lime being thus prepared, it was employed in the formation of the required bed of concrete. This was formed by cementing a mixture of sand and gravel such as is found in the London basin,—called 'ballast,'—in the following manner:—

When the ballast was moderately dry, 12 cubic yards of gravel and 2 cubic yards of lime made 11 cubic yards of concrete, mixed and deposited. The shrinkage from the dry materials was then 22 per cent.; but if the ballast happened to be very dry, the shrinkage was more, and the same quantities made only 10 cubic yards.

A cubic yard of concrete requires about thirty-eight gallons of water to bring the dry materials to the requisite state of fluidity. Of this quantity nearly eight gallons enter into chemical combination with the oxide of calcium in the lias, and thirty gallons are either absorbed mechanically by the pores of the lime, retained by capillary attraction between the grains of sand, or lost by evaporation. After the concrete has been mixed and deposited, a gradual expansion takes place from the chemical action of the lime slaking; the less of this swelling, however, the better, as it disturbs the setting of the mortar round the pebbles, and causes friability in the concrete. Whenever concrete is made with quick-lime (as it usually is), there must be a certain amount of friability from this cause; and therefore, when it is important to have no swelling, as in blocks of concrete which have to be lifted, recourse must be had to slaked lime, or else to cement, which contracts rather than expands in setting. In the one case the concrete is long in hardening, having more moisture in it than the lime can absorb; and in the use of cement more expense is incurred. Portland cement is, however, not so expensive as might at first appear from the cement being double the price of lime, because the proportion to the ballast may be considerably reduced.

HYDRAULIC CRANES. The application of water-pressure to cranes is due to Sir Wm. Armstrong. These are now so generally applied, that although the subject belongs properly to Engineering, it is thought advisable to include some notice of these valuable and interesting machines in this work. A statement made, by the request of the British Association in 1854, by the inventor himself, so completely explains all the peculiarities of these cranes, that the paper is reproduced from the 'Proceedings' of the Association.

'The employment of water-pressure as a mechanical agent having recently undergone a great and rapid development, I may be permitted to make a few observations on the successive steps by which its present importance has been attained. In so doing I shall commence with the year 1846, in which, after many preliminary experiments, I succeeded in establishing, upon the public quay at Newcastle-on-Tyne the hydraulic crane which has formed the basis of what has since been effected.

'This crane both lifted the weight and swung round in either direction by the pressure of water, and was characterised, like all other hydraulic cranes since made, by remarkable precision and softness of movement, combined with great rapidity of action.

'The experiment thus made at Newcastle having proved satisfactory, I soon afterwards obtained authority, through the intervention of Mr. Harley, the Dock Surveyor of Liverpool, to construct several cranes and hoists upon the same principle at the Albert Dock in that town, where they were accordingly erected, and have ever since continued in operation.

'The next place at which these cranes were adopted was Grimsby New Dock, where an important step in the advancement of this kind of machinery was made on the suggestion of Mr. Rendel, who pointed out its applicability to the opening and closing of dock gates and sluices, and instructed me to extend its application to those objects. An extensive system of water-pressure machinery was accordingly carried out at that dock, and the result afforded the first practical demonstration that the pressure of a column of water could be advantageously applied as a substitute for manual labour, not merely for the cranage of goods, but also to give safe and rapid effect to those mechanical operations which are necessary for passing ships through the entrances of docks.

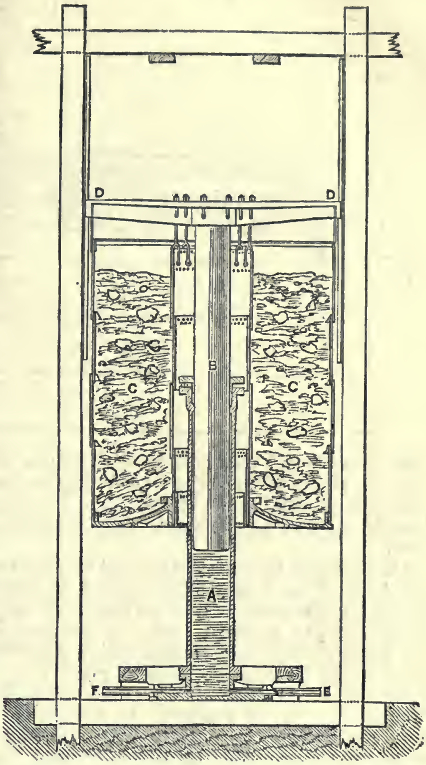
'In all these instances the moving column of water was about 200 feet in elevation. At Newcastle and Liverpool the supply was derived from the pipes communicating with the town reservoirs, but at Grimsby a tower was built for supporting a tank into which water was pumped by a steam-engine. In the former cases, the fluctuation of pressure, consequent upon the variable draught from the pipes for the ordinary purposes of consumption, proved a serious disadvantage; but this objection had no existence at Grimsby, where the tank upon the tower furnished a separate source of power, undisturbed by any interfering conditions. Nothing could be more effectual for its purpose than this tower; but, in the natural course of improvement, I was subseqently led to the adoption of another form of artificial head, which possessed the advantage of being applicable, at a comparatively small cost, in all situations, and of lessening the size of the pipes and hydraulic machinery, by affording a pressure of greatly-increased intensity.

'The apparatus thus substituted for a water tower I named "*the Accumulator*," from the circumstance of its accumulating the power exerted by the engine in charging it. The accumulator is, in fact, a reservoir giving pressure by *load* instead of by *elevation*, and its use, like that of every provision of this kind, is to equalise the strain upon the engine in cases where the quantity of power to be supplied is subject to great and sudden fluctuations.

'The construction of the accumulator is exhibited in *fig.* 1170, and needs but little explanation. A, cylinder; B, plunger; C C, loaded weight case; D, D, guides for ditto; E, pipe from pumping engine; F, pipe to hydraulic machine. It consists of a large cast-iron cylinder, fitted with a plunger, from which a loaded weight case is suspended, to give pressure to the water injected by the engine. The load upon the plunger is usually such as to produce a pressure in the cylinder equal to a column of 1,500 feet in elevation, and the apparatus is made sufficiently capacious to contain the largest quantity of water which can be drawn from it at once by the simultaneous action of all the hydraulic machines with which it is connected. Whenever the engine pumps more water into the accumulator than passes direct to the hydraulic machines, the loaded plunger rises and makes room in the cylinder for the surplus; but when, on the other hand, the supply from the engine is less, for the moment, than the quantity required, the plunger, with its load, descends and makes up the deficiency out of store.

'The accumulator also serves as a regulator to the engine; for when the loaded plunger rises to a certain height, it begins to close a throttle-valve in the steam-pipe, so as gradually to reduce the speed of the engine until the descent of the plunger again calls for an increased production of powder.

1170



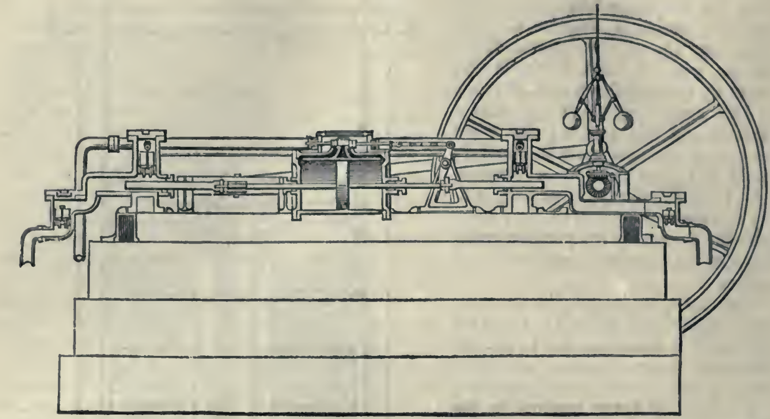
'The introduction of the accumulator, which took place in the year 1851, gave a great impulse to the extension of water-pressure machinery, which is now either already applied, or in course of being applied, to the purpose of cranage throughout all the great dock establishments in London, as also to a considerable extent in Liverpool and other places. I have also applied it extensively to railway purposes, chiefly under the direction or Mr. Brunel, who has found a multitude of cases, involving lifting or tractive power, in which it may be made available. Most of these applications are well exemplified at the new station of the Great Western Railway Company in London, where the loading and unloading of trucks, the hoisting into warehouses, the lifting of loaded trucks from one level to another, the moving of turn-tables, and the hauling of trucks and traversing machines are all performed, or about to be so, by means of hydraulic pressure supplied by one central steam-engine with connected accumulators. Mr. Rendel also, after having successfully adopted the low-pressure system to the working of the gates and shuttles at Grimsby, has since applied the high-pressure, or accumulator system, to the same purposes at other new docks, and a similar adaptation is being made by other eminent engineers at most of the new docks now in course of construction.

'I have also adapted hydraulic machinery to the opening and closing of swing-bridges and draw-bridges of large dimensions; and, in fact, there is scarcely any mechanical operation to which human labour has been hitherto applied as a mere moving power, which may not be efficiently performed by means of water-pressure emanating from a steam-engine and accumulator. Even if hand-labour be retained as the source of the power, the intervention of an accumulator will in many cases both economise labour and increase despatch. For example, a pair of heavy dock-gates requires the constant attendance of a considerable number of men, whose labour is only called into action occasionally, viz., when the gates are being opened or closed. Now, if an accumulator, charged by hand-pumps, were used, the labour employed would be constant, instead of occasional, and the power collected in the accumulator by the continuous process of pumping would be given out in a concentrated form, and thus the ultimate result would be effected with fewer hands and greater despatch than where manual labour is directly applied.

'The form of pumping-engine which I generally use for charging the accumulator is represented in *fig.* 1171. It consists of a horizontal steam-cylinder, with two force-pumps connected directly with the piston. These force-pumps are supplied with water from a cistern over the engine-room, into which the water discharged by the cranes is generally brought back by a return-pipe, so that the water is not wasted, but remains continuously in use.

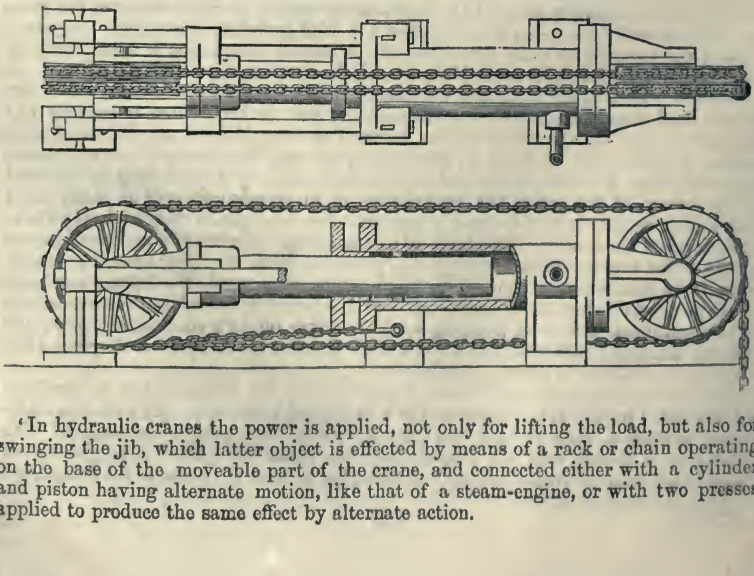
'With a pressure representing a column of 1,500 feet, the loss of head by friction in the pipes forms so small a deduction from the entire column as to be a matter of no consideration, and consequently the distance at which the engine may be situated from the points where the hydraulic machines may be placed is of little importance, except as regards the cost of the pipe. It is advisable, however, if the pipe be very long, to apply an accumulator at each extremity, so as to charge the pipe from both ends.

1171



'With regard to the mechanism of hydraulic cranes, the arrangement which I first adopted, and have ever since adhered to, consists of one or more hydraulic presses, with a set of sheaves, used in the inverted order of blocks and pulleys, for the purpose of obtaining an extended motion in the chain from a comparatively short stroke of the piston. This construction, which characterises nearly all the varieties of the hoisting and hauling machines to which I have applied hydraulic pressure is exhibited in *fig.* 1172, which represents one of these presses with sheaves attached, to multiply the motion fourfold. In cases where the resistance to be overcome varies very considerably, I generally employ three such cylinders, with rams or pistons acting either separately or conjointly upon the same set of multiplying sheaves, according to the amount of power required.

1172



'In hydraulic cranes the power is applied, not only for lifting the load, but also for swinging the jib, which latter object is effected by means of a rack or chain operating on the base of the moveable part of the crane, and connected either with a cylinder and piston having alternate motion, like that of a steam-engine, or with two presses applied to produce the same effect by alternate action.

'The absence of any sensible elasticity in water renders the motions resulting from its pressure capable of the most perfect control, by means of the valves which regulate the inlet and outlet passages of the machines; but this very property, which gives so much certainty of action, tends to cause shocks and strains to the machinery, by resisting the momentum acquired by the moving parts. Take, for example, the case of an hydraulic crane, swinging round with a load suspended on the jib, the motion being produced by the water entering on one side of a piston and escaping from the other. Under such circumstances, if the water-passages be suddenly closed by the regulating valve, it is obvious that the piston, impelled forward by the momentum of the loaded jib, but met by an unyielding body of water deprived of outlet, would be brought to rest so abruptly, as to cause, in all probability, the breakage of the machine. So also, in lowering a heavy weight with considerable velocity, if the escape-passage be too suddenly closed, a similar risk of injury would arise from the abrupt stoppage of the weight, if a remedy were not provided; but these liabilities are effectually removed by applying, in connection with the water-passages to the cylinder, a small clack-valve, opening upwards against the pressure into the supply-pipe, so as to permit the pent-up water in the cylinder to be pressed back into the pipe whenever it becomes exposed to a compressive force exceeding the pressure on the accumulator. By this means all jerks and concussions are avoided, and a perfect control over the movement of the machine is combined with great softness of action.

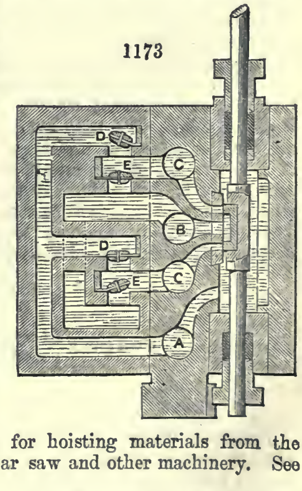
'With regard to the kind of valves used for water-pressure machines, I find that either lift-valves or slide-valves may be effectually applied, and kept tight under heavy pressures, provided that sand be excluded from the water, and the valves be made of proper material.

'In cases where a more prolonged movement is required than multiplying sheaves will conveniently afford, I employ rotative machines of various constructions. For heavy-pressures, such as an accumulator affords, an arrangement consisting of three plungers, connected with a triple crank, and bearing a general resemblance to a three-throw plunger pump, is well adapted for the purpose. The admission and exhaust valves are mitred spindles, pressed down by weights and levers, and lifted in proper rotation by cams fixed for that purpose upon a separate shaft; and these valves are associated with relief-clacks, to obviate the concussion which would otherwise be liable to take place at the turn of each stroke.

'The liability of water-pressure machinery to be deranged by frost has often been adduced as an objection to its use; and upon this point I may observe—first, that I have never experienced any interference from this cause when the machines were placed, as they generally are, beneath the surface of the ground, or within a building; and secondly, that when they are unavoidably exposed, all risk may be prevented by letting out the water in frosty weather whenever the machines cease working.

'When the moving power consists of a natural column of water, the pressure rarely exceeds 250 or 300 feet, and in such cases I have employed for rotative action a pair of cylinders and pistons, with slide-valves, resembling in some degree those of a high-pressure engine, but having relief-valves, to prevent shock at the turn of the stroke. *Fig.* 1173 shows a slide-valve adapted for the turning apparatus of a crane, but the relief-clacks of which are equally applicable to a water-pressure engine of the construction in question. Two of these clacks open against the pressure in the supply-pipe, so as to afford an escape for the water, which would otherwise be shut up in the cylinder when the exhaust port closes, and the other two communicate with the discharge-pipe, so as to draw in a portion of waste water to fill up the small vacancy which would otherwise be left in the cylinder on the closing of the admission port. A, supply pipe; B, exhaust pipe; C C, pipes to cylinder; D D, clacks opening against pressure; E E, clacks opening from exhaust. About four years ago I constructed four hydraulic engines upon this principle at Mr. Beaumont's lead mines in Northumberland, at the instance of Mr. Sopwith, Mr. Beaumont's well-known agent, and two more have recently been added at the same place. They are used for crushing ore, for hoisting materials from the mines, for pumping water, and for driving a circular saw and other machinery. See Hydraulic Machinery, for Mines.

1173



'If in progress of time railways should be generally extended into mountainous districts, so as to render them accessible for manufacturing purposes, the rapid streams which abound in such localities will probably become valuable sources of motive power, and a wider field may then be afforded for the application of water-pressure engines to natural falls.

'The object, however, which I have chiefly had in view since I first gave attention to this subject, has been to provide, in substitution of manual labour, a method of working a multiplicity of machines, intermittent in their action, and extending over a large area, by means of transmitted power produced by a steam-engine and accumulated at one central point. The common mode of communicating power by shafting could only be applied in cases where the machines were collected within a small compass, and where the accumulation of power necessary to meet varying resistance did not exceed that which a fly-wheel would afford. Compressed or exhausted air was almost equally inapplicable to the purposes I contemplated, in consequence of the many objections which its elasticity involves, as well as the liability to leakage, which, in an extended system of pipes and machines, requiring a multitude of joints, valves, and fitting surfaces, would form an insurmountable difficulty. But the use of water as a medium of transmission is free from all these objections, and its fitness for the purpose intended is now thoroughly established by the results which have been obtained.'

HYDRAULIC LIMESTONE. See Hydraulic Cement.

HYDRAULIC MACHINERY, FOR MINES. The application of a head of water to rotatory and reciprocatory engines, and the use of water in driving wheels, as well as in transmitting power from one point to another, are subjects of considerable importance in mining operations.

The power of water is derived either from its direct weight, as in the case of pressure-engines, or from its weight and impulse combined, as in overshot and breast-wheels.

In transmitting power for pumping purposes, advantage is taken of the non-compressibility of water, as well as of the facility with which water can be passed through straight or bent pipes.

Although the weight and incompressibility of water are in many ways advantageous for the purposes of the engineer, yet the use of water in pressure-engines necessitates peculiar mechanical contrivances. The valves have generally to be moved by an arrangement partially independent of the engine, whilst the shock consequent on instantly arresting the flow has to be mitigated by means of an air-vessel, momentum-plunger, or other suitable contrivance.

In Europe the rain-fall is from two to three feet per annum; about two-thirds of which is evaporated, the remainder finding its way to the sea. In Australia, where the atmosphere is exceedingly dry, and the rain-fall very much less, there are but few constant streams or rivers. The consideration which should therefore be given to the supply of water, and to the motors to be employed for mining purposes, must manifestly be governed by the hydrographic circumstances of different countries. But in lands where rain is tolerably frequent and abundant, the following remarks will admit of general application:—(1.) Mountainous countries, with a large extent of upper watershed, will furnish a tolerably constant volume of water, at a high fall, both for driving pressure-engines and turbines. (2.) Hilly localities much below the line of watershed will afford volume of water at a lesser fall, suitable for pressure-engines, turbines, and overshot wheels. (3.) A flat undulating country, with an extensive back-watershed, will frequently afford volume of water available as power through the medium of breast, undershot wheels, and low-fall turbines. (4.) Hilly localities near to the top of watersheds can only furnish an intermittent supply of water at comparatively low falls, and that to extend the use of water as power in such situations, store-dams will be requisite.

As the hydraulic engineer requires facts, data, and rules for his guidance, those deemed of practical importance will be given as concisely as possible.

Constitution of Water.

		By weight	By measure
Two gases	Oxygen	88·9	1
	Hydrogen	11·1	2
		100·0	3

Density of Water.—One cubic inch at 62°, the barometer being at 30 inches, weighs 252,458 grains, or water is 830 times heavier than atmospheric air. A cubic foot weighs 1,000 ounces, or 62½ lbs.

Expansion.—Water expands one-ninth of its bulk in freezing, and decreases in density. Under the influence of heat, from 40° to 212° Fahr., it increases in bulk to the extent of 1 cubic foot in every 23 feet.

Expansion at different Temperatures. 40° equal —·0000.

From 40° downwards	Expansion	From 40° upwards	Expansion
32°	·00022	64°	·00159
22°	.00090	102°	·00791
12°	·00236	212°	·04330

Gascous matter.—River or canal water contains $\frac{1}{20}$th of its volume.
Spring water „ $\frac{1}{14}$th „

Incompressibility.—Experiment has determined that water may be compressed about 1-46,500,000th part per atmosphere: a quantity so small that, practically speaking, water may be regarded as incompressible. The varying density and volume of water, although small, should be borne in mind by those entrusted with the construction of hydraulic apparatus. If it be allowed to freeze in cast-iron pipes, and no means be provided to allow for its free expansion, destruction of the arrangement is sure to follow, since a cubic inch of water exerts within the range of its expansion a force equal to 13⅓ tons.

Hydrostatics.—The *pressure*, weight, and equilibrium of water are included within this term.

The pressure of water at any depth is as the depth of the water; and the pressure upon the bottom of a pressure-column is as the base and perpendicular height.

Water contained within a cylinder or vessel presses equally in all directions.

To find the pressure of water upon a cylinder-piston at the bottom of a pressure-column:—

Rule.—Multiply the area of the piston in feet by the height of water in the pressure-column in feet, and their sum by the weight of a cubic foot of water, viz. 62·5 lbs.

Example.—What is the pressure upon the surface of a piston 2 feet diameter, the head of water in the pressure-column being 180 feet?

Piston, 2 feet diameter, area 3·1416. Then $3{\cdot}1416 \times 180 \times 62{\cdot}5 = 35{,}343$ lbs.

Or to find the pressure per square inch on the piston. Divide the product 35,343 lbs. by the number of square inches in the piston. Thus, area of piston 2 feet diameter is 452 square inches:

$$\frac{35{,}343}{452} = 78{\cdot}1 \text{ lbs.}$$

Thin Cylinders.—*To determine the thickness of thin hollow cylinders; the internal diameter, pressure, and tenacity of the material being given.*

Rule.—Multiply the internal diameter in inches by the pressure of water in pounds per square inch, and divide the product by the tenacity per square inch of the material.

Example.—The internal diameter of a cylinder being 30 inches, the water-pressure 250 lbs. to the square inch, and the tenacity of the material of the cylinder 12,000 lbs. per square inch, what must be the thickness of the cylinder?

$$\frac{250 \times 30}{12{,}000} = {\cdot}625, \text{ or } \tfrac{5}{8}\text{ths of an inch thick.}$$

To determine the pressure; the internal radius, thickness of cylinder, and tenacity of metal being given:—

Rule.—Divide the product of the thickness of the cylinder and tenacity of the material per square inch by the internal radius.

Example.—The thickness of the cylinder being ¼ of an inch, the tenacity 18,000, and the radius 6 inches, what pressure will the cylinder bear per square inch?

$$\frac{18{,}000 \times \frac{1}{4}}{6} = 750 \text{ lbs.}$$

Thick Cylinders.—*To determine the thickness of thick cylinders; the internal radius, the pressure, and the tenacity of the material of the cylinder being given:—*

Rule.—Subtract 1 from the square root of the quotient of the sum and difference of the tenacity per square inch of the material of the cylinder, and the pressure per square inch, and multiply this difference by the internal radius.

Example.—The internal radius of a thick hollow cylinder being 9 inches, the tenacity of the material of the cylinder 10,000, and the pressure 8,000 lbs. per square inch, what must be the thickness of the cylinder?

Sum of tenacity and fluid pressure	10,000 + 8,000 = 18,000
Difference of tenacity and fluid pressure	10,000 − 8,000 = 2,000
Quotient of sum and difference	18,000 ÷ 2,000 = 9·
Square root of quotient	$\sqrt{9\cdot}$ = 3·
Difference between root and 1	3· − 1· = 2·
Product of radius and difference	9· × 2· = 18 inches. *Ans.*

To determine the pressure per square inch which a thick hollow cylinder will withstand; the internal and external radii, and the tenacity of the material of the cylinder, being given:—

Rule.—Divide the difference of the square of the radii, and multiply the quotient by the tenacity per square inch of the material of the cylinder.

Example.—The internal and external radii of a thick hollow cylinder being respectively 9 and 27 inches, and the tenacity per square inch of the material of the cylinder 10,000 lbs., what pressure per square inch will the cylinder sustain?

Square of external radius	27 × 27 = 729
Square of internal radius	9 × 9 = 81
Difference of squares	729 − 81 = 648
Sum of squares	729 + 81 = 810

$$\text{Then } \frac{10{,}000 \times 648}{810} = 8{,}000 \text{ lbs. } \textit{Ans.}$$

Table I.—*Pressure of Water at different heads.*

Head in feet	Pressure in pounds per square inch	Head in feet	Pressure in pounds per square inch	Head in feet	Pressure in pounds per square inch	Head in feet	Pressure in pounds per square inch
1	·43	12	5·2	50	21·7	140	60·6
2	·87	15	6·5	60	26·	150	65·
3	1·3	18	7·8	70	30·3	160	69·3
4	1·73	20	8·7	80	34·7	175	76·
5	2·17	25	10·8	90	39·	180	77·9
6	2·6	30	13·	100	43·3	200	87·
8	3·47	35	15·1	120	51·9	250	108·
10	4·33	40	17·3	125	54·	300	130·

Rule.—Multiply head of water in feet by ·433 for pressure in pounds per square inch.

Example.—What pressure in pounds per square inch will be given by a head of 500 feet? 500 × ·433 = 216. *Ans.*

Table II.—*Weight of cylindrical columns of water, each one foot long, of various diameters, in pounds avoirdupois.*

Dia.	Weight	Dia.	Weight	Dia.	Weight	Dia.	Weight	Dia.	Weight	Dia.	Weight

¾	11·24	¾	26·02	¾	46·92	¾	73·95	¾	107·09	¾	146·35

Hydraulics treats of the *motion* of water, and Hydrodynamics of the *force* with which it acts.

Descending water is actuated by the same laws as falling bodies; and will fall through 1 foot in ¼ of a second, 4 feet in ½ of a second, and through 9 feet in ¾ of a second, and so on.

The velocity of a fluid spouting through an opening in the side of a vessel is the same that a body would acquire by falling through a perpendicular space equal to that *between the top of the water and the middle of the aperture.*

Rule.—Multiply the space in feet by 64·33, and the square root of the product will be the velocity acquired in feet per second.

Example.—What is the velocity of a stream per second, issuing from a head of 10 feet?

$$\sqrt{10 \times 64{\cdot}33} = 25{\cdot}36 \text{ feet.}$$

If the velocity be 70 feet per second, what is the head?

$$70^2 \div 64{\cdot}33 = 76\tfrac{1}{10} \text{ feet.}$$

The theoretical velocity with which a liquid issues from an orifice in the bottom or side of a vessel that is kept full, is eight times the square root of the head or distance fallen in feet. The practical velocity estimated for the entire opening is considerably less than the theoretical velocity, owing to oblique currents and to friction. These oblique currents produce a contraction in the vein or stream. The minimum transverse section of the contracted vein is the plane at which the velocity is nearly equal to the theoretical velocity. The quantity of water which will be discharged in a certain time depends upon the form of the opening, as well as upon the head. Thus, by means of a conical tube of the form of the contracted vein, the velocity at the opening, or smaller end of the tube, is nearly equal to the theoretical velocity. The actual velocity estimated for the entire opening, when constructed as ordinarily, and not large, is 5·4 times the square root of the head in feet.

Table III.—*Showing the relative velocities with which water, under a constant head, will flow through differently-formed apertures:—*

Theoretical velocity	8·
Velocity through a thin plate	5·
Velocity through a tube two or three diameters in length projecting outward	6·5
Velocity through a tube of the same length, projecting inward	5·45
Velocity through a conical tube of the form of the contracted vein	7·9

Table IV.—*Table for estimating the velocity with which water will flow under a given head.*

2	1	1·44339	4	4	2·08167	29	5·38516	400	20·00000
2	2	1·47196	4	5	2·10159	30	5·47723	500	22·36068
2	3	1·50000	4	6	2·12132	31	5·56776	600	24·49490

Sluices.—Rule. Multiply the square root of the depth of the water by 5·4; the product is the velocity in feet per second. This multiplied by the area of the orifice in feet, will give the number of cubic feet per second.

Example 1.—At what velocity in feet per second will water flow from a sluice under a head of 9 feet?

By Table IV., in the column 'square root of head,' opposite the head 9 feet, are the figures 3·00000.

Multiply this number by 5·4. 3·00000 × 5·4 = 16·200000 feet per second.

Note.—If the area of the opening is large compared with the head of water, take $\frac{2}{3}$rds of this velocity for the actual velocity.

Example 2.—What number of cubic feet and pounds of water will flow in one minute, under a 9-feet head, through an aperture, 2 inches wide by 84 inches long?

The velocity per second as given above is		16·2	feet.
The velocity per minute will be	16·2 × 60 =	972	feet.
The area of the opening is	84 × 2 =	168	square inches.
This area in square feet is	168 ÷ 144 =	1·16	square feet.
The velocity in feet per minute multiplied by the area of the aperture	972 × 1·16 =	1127·52	*cubic feet per minute.*
A cubic foot of water weighs 62·4 lbs., Hence	1127·52 × 62·4 =	70·357	lbs. per minute.

If it were required to determine the theoretical power which this water would exert on a water-wheel, it would only be necessary to multiply the number of pounds of water by the fall in feet. But to find the actual power, it would be requisite to multiply the theoretical power by the efficiency of the wheel; and if it were desired to express the power in units of horse-power, the number of effective pounds would have to be divided by 33,000.

As a practical illustration, take an overshot wheel, and let the fall be 40 feet. The efficiency of this wheel under the most favourable circumstances does not exceed ·68. Then 70·357 lbs. × 40 feet × ·68 = 1,913,574 foot-pounds.

1,913,574 ÷ 33,000 = 57·9 actual horse-power.

To determine how much more water will flow under one head than under another.

Rule.—Divide the square root of the greater head in feet by the square root of the less.

Example.—How much more water will flow under a 9-feet head than under a 3-feet head?

By Table IV. the square root of the 9-feet head is 3·00000, and the square root of the 3-feet head is 1·73205.

Hence 3·00000 ÷ 1·73205 = 1·15 times as much.

Vertical Apertures or Slits.—The quantity of water that will flow out of one that reaches as high as the surface, is $\frac{2}{3}$rds of that which would flow out of the same aperture if it were horizontal at the depth of the base.

$$\text{Or, } \frac{\text{velocity at bottom} \times \text{depth} \times 2}{3} \times \text{breadth of slit} = \text{number of cubic feet per second.}$$

Velocity of Streams.—In a stream the velocity is greatest at the surface and in the middle of the current.

To ascertain the velocity of water in streams.—First method. (1) Select a place where the run of water is tolerably straight. (2) Measure along the course one hundred or more feet. (3) At each end of the measurement at right angles to the flow set a straight cord. (4) Get hard wood floats or indicators not affected by the wind, and which will sail uniformly with the velocity of the stream. (5) Drop a float lightly into the stream just above the upper cord, and observe the exact time of passing from one cord to the other. (6) Repeat this experiment, starting a float both in the middle and near to the margin of the stream. (7) Take the mean of the several trials for the surface velocity, and four-fifths for the mean velocity of the water. (8) Multiply the latter velocity by the average breadth and depth of the channel, and the product will express the volume of water between the cords within the time of the observation.

Second Method. Take the number of inches that a floating body passes over in one second in the middle of the current, and extract its square root; double this root, subtract it from the velocity at top and add 1; the result will be the velocity of the stream at the bottom; and the mean velocity of the stream is equal to the velocity at the surface, less the square root of the velocity at the surface increased by $\frac{5}{10}$ths of 1.

Example.—If the velocity at the surface and in the middle of a stream be 36 inches, what is its velocity at the bottom, and what is its mean velocity?

Square root of 36 = 6.
Double this root, 6 × 2 = 12.
36 + 1 − 12 = 25 inches per second velocity at bottom. *Ans.*
Again, 36 + ·5 − 6 = 30·5 inches per second mean velocity. *Ans.*

Weirs and Rectangular Notches.—The following Table V. gives the number of cubic feet of water per minute that will pass over a weir for each inch in width, and from 1 to 19 inches in depth.

Depth of weir in inches	Depth of weir in parts of an inch							
	0	⅛	¼	⅜	½	⅝	¾	⅞
	Number of cubic feet per minute							
1	0·403	0·408	0·563	0·649	0·740	0·835	0·966	1·035
2	1·141	1·248	1·360	1·475	1·593	1·714	1·838	1·964
3	2·094	2·121	2·361	2·599	2·639	2·782	2·927	3·062
4	3·225	3·337	3·531	3·688	3·848	4·009	4·173	4·339
5	4·506	4·676	4·849	5·023	5·200	5·378	5·558	5·740
6	5·925	6·105	6·298	6·488	6·681	6·874	7·071	7·266

10	12·747	13·147	13·228	13·471	13·716	13·961	14·208	14·457
11	14·707	14·957	15·211	15·465	15·721	15·978	16·236	16·495
12	16·757	16·206	17·283	17·549	17·816	18·083	18·352	18·622
13	18·895	19·167	19·445	19·718	19·996	20·274	20·558	20·834
14	21·116	21·400	21·684	21·970	22·258	22·546	22·835	23·127
15	23·418	23·708	24·007	24·302	24·600	24·897	25·195	25·496
16	25·800	26·102	26·406	26·712	27·019	27·325	27·634	27·943
17	28·256	28·566	28·881	29·195	29·512	29·829	30·145	30·464
18	30·785	31·106	31·429	31·752	32·075	32·403	32·733	33·055

Let the weir be 10 inches in depth; opposite 10 inches the second column is 12·747, being the number of cubic feet discharged per minute 1 inch in width. Then again, suppose the weir 6⅜ inches deep. The figures answering to this number are 6·488, which is cubic feet discharged per minute for 1 inch in width. By multiplying the number of cubic feet discharged per inch in width by the width of the weir in inches, the total discharge per minute will be obtained. *Note.*—The water should be set back to a dead level before it passes over the weir-board, and the depth taken at a point before the curve commences.

Scour of Watercourse Beds.

Water running at a velocity of ¼ foot per second will scour *fine clay*
" " ½ " " " *fine sand*
" " ¾ " " " *coarse sand*
" " 1 " " " *fine gravel*

" " 5 " " " *conglomerate*

Discharge by Horizontal Pipes.—1st. The less the diameter of the pipe, the less is the proportionate discharge of water.

2nd. The greater the length of the discharging pipe, the greater the diminution of the discharge.

3rd. The friction of water is proportionally greater in small than in large pipes.

4th. The velocity of water flowing out of an aperture is as the square root of the height of the head of the water.

Discharge by Vertical Pipes.—The discharge of fluids by vertical pipes is augmented on the principle of the gravitation of falling bodies; consequently, the greater the length of the pipe, the greater the discharge of the fluid.

Inclined Pipes.—A pipe which is inclined will discharge in a given time a greater quantity of water than a horizontal pipe of the same dimensions.

FLOW OF WATER.—The time occupied by an equal quantity of water flowing through a pipe or gallery of equal lengths and equal falls is proportionally as follows: In a right line, as 90; in a true curve, as 100; and in passing a right angle, as 140.

WATER-WHEELS.—Water as a power or force is exerted on water-wheels both by its weight and impulse. Weight and impulse are combined together on the overshot and breast wheels.

The theoretical work accomplished by *weight* is the product of its force, and the vertical distance through which it is exerted; whilst the theoretical work realised by *impulse*, is the product of the force produced by the weight of the flow of water, and the vertical head necessary to produce the velocity with which the weight moves. The *available work* depends not only upon the magnitude of the force exerted, but upon the direction of that force in reference to the direction given to the resistance; also upon the form of the buckets of the wheel, friction, and losses by leakage.

The vertical height, from the centre of the opening in the sluice to the surface of the water in the head-race or reservoir, is termed the *head of discharge*. The distance in feet from the surface of the water until it meets the wheel is the *head of contact*. The perpendicular distance, from the surface of the water in the tail-race, at the time the wheel is working, to the point when the water meets the wheel, is termed the *fall*. Half the head of contact added to the fall will give the *effective fall*.

Water-wheels are of three kinds: the *Undershot*, *Breast*, and *Overshot*. The term undershot is applied to a wheel when the water strikes at, or below, the centre; the greatest effect being produced when the periphery of the wheel moves with a velocity of one-half that of the water. Breast wheels are those that have the water applied between the centre and the vertex. Overshot, when the water is brought over the wheel, and laid on the opposite side. In either case the maximum velocity is two-thirds that of the water.

The overshot wheel is the most advantageous, as it gives the greatest power with the least quantity of water. The next in order in point of efficacy is the breast wheel, which may be considered a mean between the overshot and undershot. For a small supply of water with a high fall, the first should be employed; when the quantity of water and height of fall are both moderate, the second form should be used. For a large supply of water with a low fall, the third form must be resorted to.

To find the maximum velocity of an undershot wheel:—

RULE.—Multiply the square root, or the perpendicular height of the fall, in feet by 8; the product is the velocity of the water in feet per second. Then multiply by ·57 for obtaining the velocity of the wheel in feet per second.

Example.—Required the maximum velocity of an undershot wheel when propelled by a fall of water 6 feet in height.

$8\sqrt{6} = 2{\cdot}45 \times 8 = 19{\cdot}6$ feet, velocity of water.

$19{\cdot}6 \times {\cdot}57 = 11{\cdot}17$ feet per second for the velocity of the wheel. *Ans.*

To find the head of water proper for breast and overshot wheels, at any velocity, the maximum velocity being two-thirds that of the water:—

RULE.—As the square of 16·095 or 259 is to 4, so is the square of the velocity of the water in feet per second to the head of water, or distance between the centre of the sluice aperture and the point where the water strikes upon the wheel.

Example.—Required the head of water necessary for a wheel 25 feet diameter, moving with a velocity of 5 feet per second.

$5 \div \frac{2}{3} = 5 \times \frac{3}{2} = 7{\cdot}5$, velocity of the water in feet.

$259 : 4 :: 7{\cdot}5^2 : {\cdot}87$, or head of water $10\frac{4}{10}$ inches. *Ans.*

For wheels of from 15 to 20 feet diameter, add $\frac{1}{10}$th of the diameter -1 foot. For wheels from 20 to 30 feet diameter add $\frac{1}{20}$th of the diameter. This additional head is intended to compensate for the friction of water in the aperture of the sluice to keep the velocity as 3 of water to 2 of the wheel; thus, in place of ·87 feet of head for a 25-feet wheel, it will be ${\cdot}87 = 10\frac{4}{10}$ inches $+ 25\frac{25}{20} = 10\frac{4}{10}$ inches $+ 1{\cdot}3 = 2$ feet $1\frac{4}{10}$ inch head of water.

Rule.—(1.) Find the velocity of the water per minute by extracting the square root of the height of the head of the water, viz. from the surface to the middle of the sluice-aperture, and multiply by 8, unless when the opening is small, and the head of water great, or proportionally so, when use from 5·5 to 8 for a multiplier.

(2.) Find the number of cubic feet and pounds delivered per minute; ascertaining the area of the sluice-aperture in feet, then multiply by the velocity of the water in feet per minute; divide the product by 1,728, and multiply the quotient by 62·5 lbs.

(3.) Multiply the number of pounds delivered per minute by ·35, and divide by 33,000; the quotient is the number of horse-power.

Example.—What is the power of an undershot wheel applied to a stream 2 feet × 80 inches from a head 25 feet?

(1.) $\sqrt{25} \times 6{\cdot}5 \times 60 = 1{,}950$ feet, velocity of water per minute.

(2.) $2 \times 80 \times 1{,}950 \times 12 \div 1{,}728 = 2166{\cdot}6$ cubic feet delivered per minute.

Then $2166{\cdot}6 \times 62{\cdot}5 = 135{,}412$ lbs. of water discharged in 1 minute.

(3.) $135{,}412 \times {\cdot}35 \div 33{,}000 = 1{\cdot}4$ effective horse-power. *Ans.*

To find the power of a breast wheel.—Rule. Find the effect of an undershot wheel, the head of water of which is the difference of level between the surface and where it strikes the wheel (breast), and add to it the effect of that of an overshot wheel, the height of the head of which is equal to the difference between where the water strikes the wheel and the tail-water; the sum is the effective horse-power.

Example.—What would be the power of a breast wheel applied to a stream 2 × 80 inches 14 feet from the surface, the rest of the fall being 13 feet?

$\sqrt{14} \times 6{\cdot}5 \times 60 = 1{,}458{\cdot}6$ feet, velocity of water per minute,

and $2 \times 80 \times 1{,}458 \times 12 \div 1{,}728 = 1{,}620$ cubic feet $\times 62{\cdot}5 = 101{,}250$ lbs. water discharged in 1 minute.

Then $101{,}250 \times {\cdot}35 = 1{\cdot}07$ horse-power as an undershot.

$\sqrt{11} \times 6{\cdot}5 \times 60 = 1{,}290$ feet, velocity of water per minute,

and $2 \times 80 \times 1{,}290 \times 12 \div 1{,}728 = 1{,}433$ cubic feet $\times 62{\cdot}5 = 89{,}562$ lbs. of water discharged in 1 minute.

× 11 height of fall $\times {\cdot}35 \div 33{,}000 = 20{\cdot}3$ horses, which added to the above $=$ 21·37. *Ans.*

To find the power of an overshot wheel.—Rule. Multiply the weight of water in pounds discharged upon the wheel in one minute by the height or distance in feet from the centre of the sluice-opening to the lower edge of the wheel, then multiply by ·68 and divide the product by 33,000, the quotient will be the number of horses'-power.

Example.—The weight of water discharged on a wheel per minute is 50,000 pounds, the height of fall is 26 feet, and diameter of wheel 25 feet, what is the power of the wheel?

Total height of fall from centre of sluice—opening to bottom of tail-race, 26 ft.; deduct clearance below, 8 in. Total, 25 ft. 4 in.

$50{,}000 \times 25{\cdot}4 \times {\cdot}68 \div 33{,}000 = 26\frac{1}{10}$ effective horses'-power. *Ans.*

Circle of gyration.—The centre or circle of gyration is that point or circle in a wheel into which, if the whole quantity of matter were collected, the same moving force would generate the same angular velocity. Motion ought always to be communicated from that centre whenever it is practible.

To find the circle of gyration.—Rule. Add together twice the weight of the shrouding, buckets, &c., $\frac{2}{3}$rds of the weight of the arms and the weight of the water; multiply the sum by the square of the radius; divide the product by twice the sum of the weight of the shrouding arms added to the weight of the water, and the square root of the quotient is the radius of the circle of gyration from the centre of suspension, nearly.

Example.—Required the distance of the centre of gyration from the centre of suspension in a water-wheel 22 feet diameter, shrouding, buckets, &c. = 18 tons, arms = 12 tons, and water 10 tons.

$$\text{Then } \sqrt{\{(2 \times 18 + \tfrac{2}{3} \times 12 + 10) \times 11^2 \div [(18 + 12) \times 2 + 10]\}}$$
$$= \sqrt{\{(36 + 8 + 10) \times 121 \div (30 \times 2 + 10)\}} = \sqrt{\{(54 \times 121) \div 70\}}$$
$$= \sqrt{(6{,}534 \div 70)} = \sqrt{93{\cdot}34} = 9{\cdot}7 \text{ feet from the centre of suspension.}$$

To find the horse-power of Water-wheels according to a method employed in various parts of America:

TABLE VIII.—*Coefficients.*

Head	Coefficient	Head	Coefficient	Head	Coefficient	Head	Coefficient
ft. in.		ft. in.		ft. in.		feet	
1	12	1 7	54	3 2	76	9	128
2	17	1 8	55	3 4	78	10	135
3	21	1 9	56	3 6	80	12	148
4	25	1 10	58	3 8	82	14	160
5	28	1 11	59	3 10	84	16	171
6	30	2 0	60	4 0	85	20	191
7	33	2 1	62	4 3	88	25	213
8	35	2 2	63	4 6	90	30	233
9	37	2 3	64	4 9	93	36	256
10	39	2 4	65	5 0	95	49	298
11	41	2 5	66	5 4	98	64	341
1 0	43	2 6	67	5 8	101	81	384
1 1	44	2 7	69	6 0	104	100	426
1 2	46	2 8	70	6 6	109	121	469
1 3	48	2 9	71	7 0	113	144	511
1 4	49	2 10	72	7 6	117	169	554
1 5	51	2 11	73	8 0	121	196	597
1 6	52	3 0	74	8 6	124	225	639

RULE.—Multiply the product of the coefficients—(see Table VIII.) opposite the given head, the area of the opening in the sluice in square inches, the entire head in feet (in case of the overshot or breast, the head by 40 and the fall by 78)—by the efficiency of the class of wheel, pointing off 6 figures as decimals.

Example 1.—The dimensions of a stream are 2 inches by 200 inches, the head 2 feet 3 inches and the fall 10 feet; what is its horse-power applied to a breast wheel?

2 inches × 200 = 400 square inches opening.
Coefficient by Table VIII. opposite 2 feet 3 inches = 64.
Efficiency by Table VII. arising from weight = 78.
Efficiency by Table VII. arising from impulse = 40.
Head 2·3 = 2·25 feet.
Product of efficiency and head 2·25 × 40 = 90.
Product of efficiency and fall 10 × 78 = 780.
Sum of products 780 + 90 = 870.
Then 870 × 400 × 64 = 22·27 horses'-power. *Ans.*

Example 2.—The dimensions of a stream are 10 inches square, the head 25 feet; what is its horse-power applied to a good turbine?

Square inches in opening 10 × 10 = 100.
Coefficient by Table VIII . opposite head (25 feet) = 213.
Efficiency by Table VII. of turbine = ·68
Then 100 × 213 × ·68 × 25 = 36·21 horses'-power. *Ans.*

To find the horse-power of a single or double direct-acting pressure-engine.—RULE. Multiply the net area of the piston in inches by the vertical pressure in pounds per square inch; then, for a single-acting engine, by one-half the journey made by the piston per minute; deduct $\frac{1}{4}$ for friction and absorption of power, divide by 33,000, and the quotient will be the effective horse-power. Should the engine be double-acting, double the figures of the quotient.

Example.—What load will a single-acting pressure-engine sustain, and what will be the horse-power, the diameter of the cylinder being 20 inches, effective journey of piston 60 feet per minute, height of pressure-column 200 feet?

Pressure-column Table I. 200 feet = 87 lbs. pressure per square inch.
Diameter of cylinder 20 inches = 314·16 square inches, and
Product of efficiency in Table VII. ·80
314·16 × 87 lbs. × ·80 = 21,865 lbs. actual load which piston will sustain.
Then 21,865 × 60 ÷ 33,000 = 49·7 effective horse-power.

Charging rams.—To find the area of a ram for charging an accumulator, to work under a given load when the effective sustaining power of the charging engine is known.

Rule.—Divide the effective sustaining power of the engine by the load per square inch to be imposed on the accumulator, the quotient will be the area of the charging ram.

Example.—The effective sustaining power of a pressure-engine is 21,865 lbs., and the accumulator is to carry a load of 800 lbs per square inch. What will be the area of the charging ram?

21,865 ÷ 800 = 27·2 inches area, or $5\frac{7}{8}$ inches diameter.

Accumulator.—To ascertain the weight required on an accumulator ram of a given diameter, the charging pressure being given.

Rule.—Multiply the area of the accumulator ram by the charging pressure in pounds, the product will be the weight required on the accumulator ram less the dead weight of the accumulator ram, cross-head and weight-box.

Example.—An accumulator ram is 10 inches diameter, the charging pressure is 800 lbs. per square inch, the weight of the ram, cross-head and weight-box is 6,000 lbs.: what extra weight must be added?

	lbs.
10 inches = 78·54 × 800 lbs.	62,832
Less weight of ram, cross-head and weight-box	6,000
Ans.	56,822

Useful Memoranda.

1 cubic foot of water weighs 1,000 ounces, or	62·5 lbs.
1 cubic inch ,,	·036 lb.
1 imperial gallon = 277·274 cubic inches	10 lbs.
1 ,,	0·16 cub. ft.
1 cubic foot of water = 6,238 gallons, or approximately	$6\frac{1}{4}$ gall.
1·8 cubic foot of water	1 cwt.
11·2 imperial gallons = 1 cwt. or 224 gall.	1 ton
35·84 cubic feet	1 ton
A column of water 12 inches high one inch square	·434 lbs.
,, ,, ,, diameter	·341 lbs.
One cylindrical foot of water	4,895 imp. gall.

Sea Water.

1 cubic foot = 64·11 lbs. or 1·027 times the weight of fresh water.

Rainfall.

Inches of rainfall × 2,323,200 = cubic feet per square mile.
,, × $14\frac{1}{2}$ = millions of gallons per square mile.
,, × 3,630 = cubic feet per acre.

Sundries.

A fall of $\frac{1}{10}$th of an inch in a mile will produce a current in rivers.
Melted snow produces about $\frac{1}{8}$th of its bulk in water.
Sound passes in water at a velocity of 4,708 feet per second.

Expansion of Water.

Volume of water at 32° = 1,000.
,, at 212° = 1,046; increase in 180° = ·046.

Construction of Water-wheels.—The application of vertical wheels to the purposes of mining is copiously illustrated in Agricola's work, 'De Re Metallica,' edition 1621, where overshot and undershot wheels are shown driving pumps direct, as well as through the medium of cranks and spur-gearing.

General Rules.—When iron is used for water-wheels, curved buckets and shroudings are preferable to deal float-boards and oak starts.

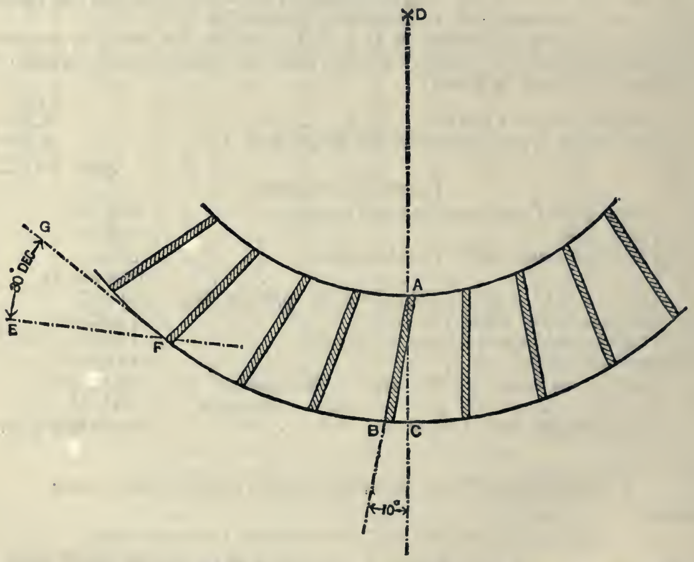
In designing iron wheels care should be taken that, while attempting to form a bucket which shall carry the water as long as it can act beneficially, the opening or mouth of the buckets shall not be so contracted as to prevent the free admission of water into them, or its free egress at the bottom of the periphery. Fairbairn's rule for bucket openings in wheels of high fall is nearly as 5 to 24, that is with a bucket holding 24 cubic feet, the area of the water entrance should be 5 square feet. In breast wheels the area should be increased to 8 square feet, or in the proportion of *one* to *three.* With these proportions the depth of shrouding is regarded as three times the distance from the tip to the back of the bucket.

In wheels receiving the water below the centre of the axis, a still larger opening for the entrance and exit of the water is required.

In each variety of wheel the maximum effect of the water can only be secured by making the bucket-openings sufficiently large to allow of the ready admission and escape of the water within the limits of the vertical centre.

Undershot water-wheels.—In localities where the supply of water is large, and the fall comparatively low, the undershot wheel offers an obvious and cheap medium for utilising the power of the current. In the year 1825 Poncelet, after an extensive series of experiments found that the floats, instead of presenting a plain radial surface to the impulse of the water, ought to consist of circular arcs of assignable radii of curvature. Following this discovery certain practicable rules have been established which may be abridged as follows: (1) Let the stream act on the buckets at from 7 to 26 inches from the point where the water leaves the wheel

1174

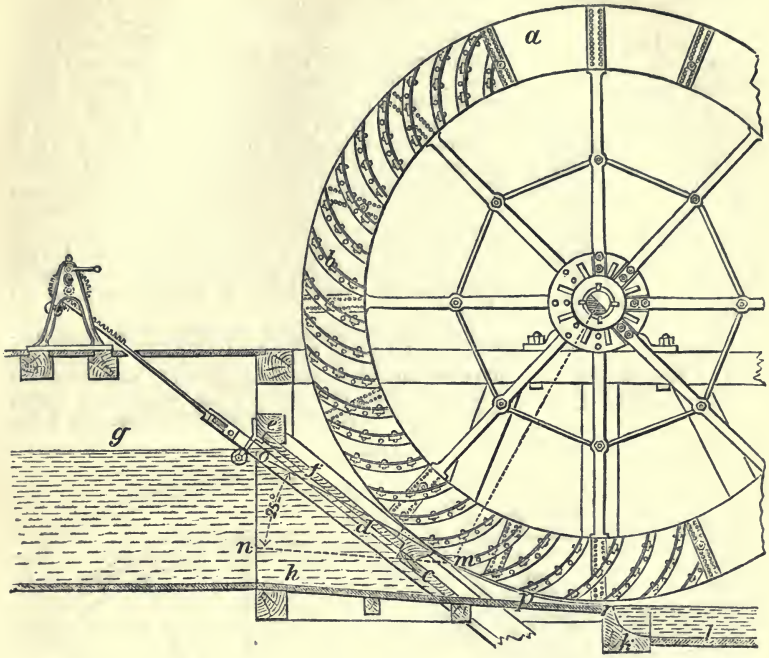


(2) The product of the square root of the perpendicular height in feet from the surface of the water in the head-race till it meets the buckets, multiplied by 4·2, will be the velocity of the skirt of the wheel in feet per second. (3) Set the sluice at the part where the water leaves it, as near the wheel as possible, with a backward inclination, and its under edge so formed as to run the water in the buckets at an angle of 30° from a tangent to the circumference. (4) Contract slightly the sides of the cistern next the sluice-frame conducting the water to the wheel. (5) Make the sluice-opening about 4 inches narrower than the wheel. (6) Make sluice and frame so that the impelling water may run freely and without obstruction to the buckets. (7) The width of wheel must not exceed width of passage for conveying the water.

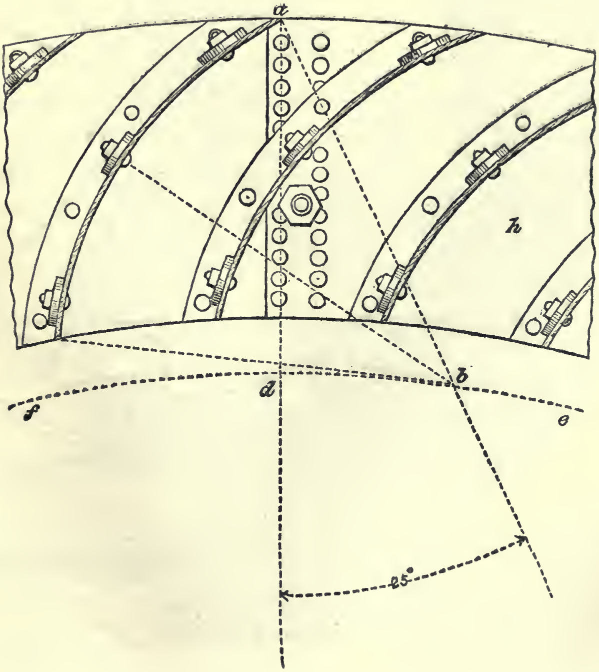
The method of setting out the buckets of an undershot wheel, as also the mean direction of the water entering the buckets, is shown in *fig.* 1174. A B line of buckets inclined at an angle of 10° from the radius line C D; F E mean direction of the water entering the buckets, the line being at an angle of 30° with the tangent line F G.

Poncelet's Undershot Water-wheel.—A part elevation of this wheel is shown in *fig.* 1175: *a*, shrouding; *b*, buckets; *c*, sluice-plate; *d*, grooves for sluice-plate; *e*, transverse beams; *f*, cross-binder and planking; *g*, reservoir; *h*, floor of water-course; *k*,

1175

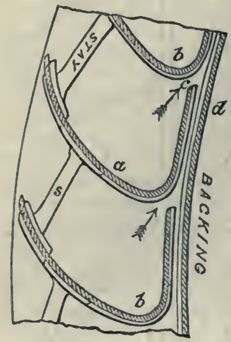


1176



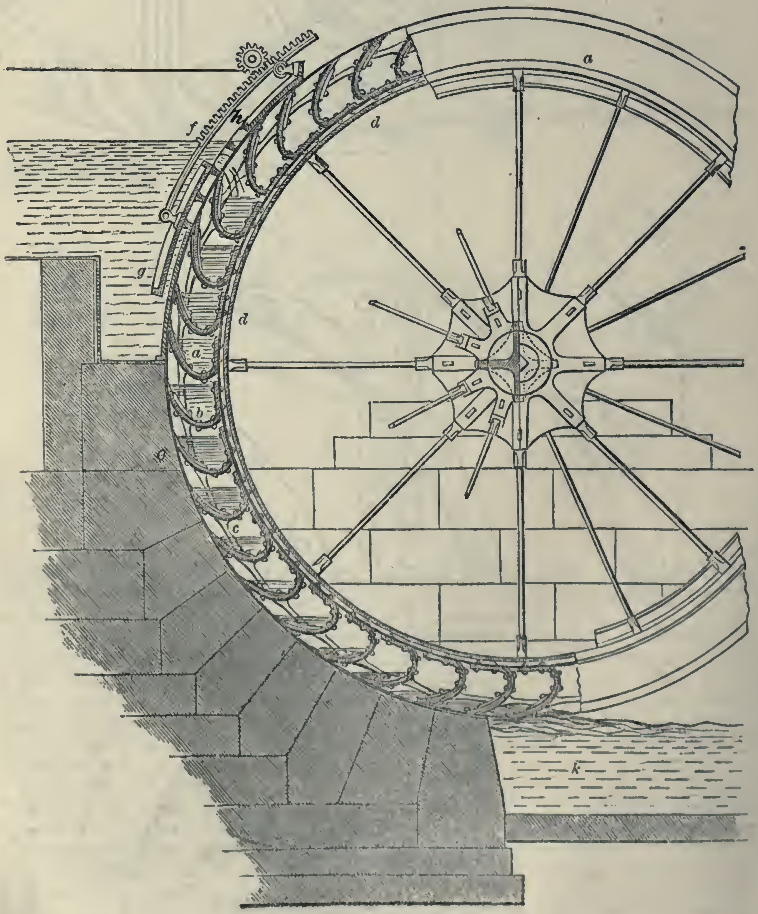
beam in which is formed an abrupt descent for the liberation of the water; *l p*, flanking of tail-race. In order that the water may impinge upon the buckets of the wheel with the least possible loss of effect, the bottom of the course, where it approaches the point of impulse, is made with a declination of from 3° to 4° from the horizontal direction. The line of direction *m n*, of that portion of the water flowing through the sluice opening *c*, ought therefore to make with the tangent line *m o*, to the circle of the wheel, an angle of 24° to 25°. The surface *p h* of the water-run is a tangent drawn to the small circular arc *p r*, which approaches close upon the circumference of the wheel at that part where it passes the vertical plane, and which should be as long as the distance between two contiguous buckets. At the point *r* the arc terminates abruptly for the width of the race, allowing a drop for the water equal to half the depth of the shrouding.

1177



Method of determining the curvature of the buckets.—From a point *a* (*fig.* 1176) in the extreme circumference draw the line *a b*, making an angle of 25° with the radius *a d*, drawn from the centre of the wheel to *a*. Then with a radius of $\frac{1}{6}$th of the depth of the shrouding *h*, less

1178



than the inner circumference; describe from the centre another circle, *e f*, cutting the line *a b* in *b*; this point *b* will be the centre from which the curve of the bucket should be drawn.

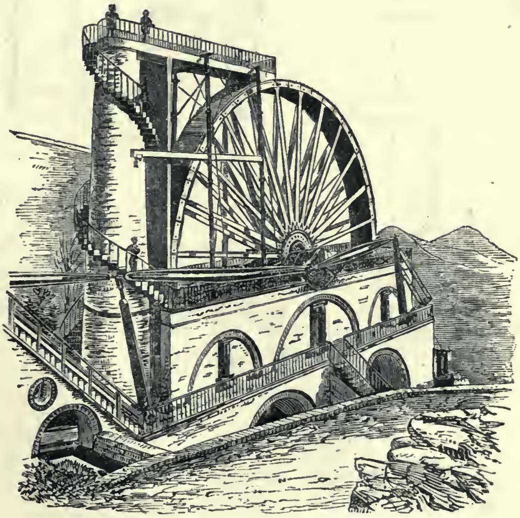
Breast Wheel.—The water acts on the periphery of this wheel both by its weight and impulse, one foot of fall affording as much power as two feet of head. The circumferential velocity is commonly about 4½ feet per second, and the speed of the water entering the buckets 6½ feet per second.

The slower the wheel revolves, and the higher it receives the water, the more the buckets may be sloped, so as to retain the water to the proper point of discharge.

For the purpose of expelling the air from the buckets, the stream should be of less width than that of the buckets, or otherwise openings should be formed in the backing ¾ of an inch wide, or the bucket constructed as shown in *fig.* 1177. A good example of the form of iron buckets employed in the breast wheel, as well as the arrangement for supplying and taking off the water, is shown in *fig.* 1178: *a*, shrouding; *b*, the buckets; *c*, stays between the buckets; *d*, sole plate or backing; *e*, breast work; *f*, cistern or mill-race; *g*, sluice-race; *h*, sluice-cover; *k*, tail-race. The distinguishing feature of the arrangement shown consists in the wheel working against a circular breast of masonry, fitted close to the outer circumference of the shrouding and ends of the buckets. The cistern leading into the wheel is likewise fitted close to its periphery. The loaded portion of the wheel is therefore enclosed, and hence, in forming the buckets, it is not absolutely necessary to contract the mouth for the purpose of retaining the water.

Overshot Wheel.—The overshot wheel receives its water a little distance to the right or left of the vertical centre line. Smeaton's experiments showed that the best effect was obtained when the circumferential speed was limited to 3½ feet per second, or 210 feet per minute. With, however, the increase of diameter in wheels, it is found that the speed may be advantageously augmented. A wheel 20 feet in diameter may move *six* feet per second, and where economy in the propelling power is not a special object, the circumference of the wheel may run at 8½ feet per second. This greater speed will be found in some cases desirable; the wheel may be lighter and cheaper than a slow-running wheel, and less gear will be required to bring the speed up to the required rate for driving machinery. In practice it is found that a fall of 7 inches will bring water upon a wheel full 3½ feet per second, and a fall of 19 inches will give a velocity to the stream of quite 6 feet per second. In reference to wheels of this class it may be observed: (1) when the volume of water is large and variable, and the fall of an intermediate height, it is found advantageous not to lay the water upon the top of the wheel, so that it may work overshot, but to make the diameter of the wheel greater than the mean height of the fall, and to lay on the water at about 45° from

1179

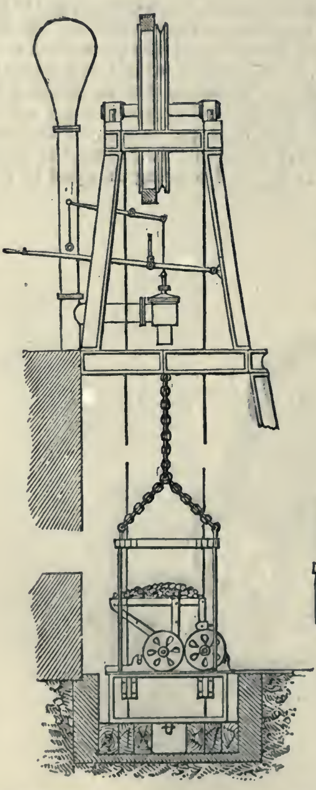


the perpendicular—or, as miners say, at *nine o'clock*; (2) when the fall exceeds 60 feet, a turbine, or water-pressure engine, will generally be found less costly and more effective; (3) wheels placed one over the other, and geared together, so as to employ a high fall of water, do not afford satisfactory results.

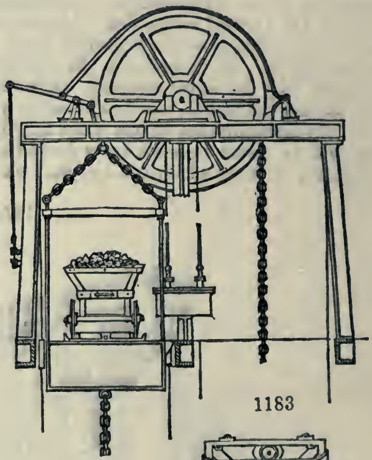
Fig. 1179 illustrates an overshot wheel employed in pumping at the Laxey Mines, Isle of Man. The diameter is 72 feet 6 inches; width between shroudings, 6 feet; length of shaft, 17 feet; diameter of shaft, 21 inches; length of crank, 5 feet; stroke, 10 feet; stroke in pump, 8 feet. The water is conveyed in pipes 2 feet diameter, and, after rising through the column, is carried to the top of the wheels by means of a launder. On one side of the crank a balance 'bob' is fixed; from the other is extended the sweep and 'flat rods,' reaching to the pump shaft, about 200 yards distant.

At Wheal Friendship, Tavistock, under the direction of the late Mr. Taylor, an aggregate fall of 526 feet was utilised through the medium of seventeen water-wheels, eight of which were employed in pumping. The largest wheel was 51 feet diameter, and 10 feet between the shrouding. The water ran into the buckets at the rate of 5,600 gallons per minute, consequently the horse-power expended was $\left(\frac{5,600 \times 10 \times 51}{33,000}\right)$ 86½. The wheel made 5 revolutions per minute; length of stroke in the pump, 6 feet; effective journey per minute, 30 feet; weight of water in the various lifts or columns of pumps, extending a depth of 188 fathoms, 66,415 lbs. The work performed by this wheel was therefore 69 per cent. of the power expended, or equal to 60 effective horse-power.

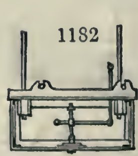
1180



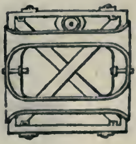
1181



1182



1183



Turbine.—The use of turbines in mining operations is somewhat limited by the high speed of the wheels, and the necessity of employing intermediate shafts and wheel-gear. Without reducing gear, the apparatus cannot be directly applied either to winding, dressing, or pumping purposes, but it might be advantageously employed to run a telo-dynamic cord across country, so as to give motion to various machines. See TURBINE.

Water-balance.—This apparatus is employed at various quarries in Wales, and at numerous places on the Continent. Its chief use is in lifting stuff vertically, but there are many cases where it is applied to incline hauling.

An endless chain is passed over a head-wheel; two wrought-iron boxes are attached to this chain, so that when one is at the top, the other is at the bottom of the shaft. Each water-box is covered by a strong platform, which carries a waggon, and each box is fitted with a valve. A pipe in connection with a cistern or reservoir, laid to the mouth of the shaft, is fitted with two valve-boxes.

The box being filled with water, overbalances the empty box, and raises it with its waggon of stuff to the top of the shaft. When the full box has descended to the bottom of the shaft, the valve is opened, and the water discharged into the adit or day level. The boxes run in rope guides, and the discharging valves may be opened by an attendant, or otherwise by striking a stud set for the purpose. Rails are laid so as to run the waggons off and on the platforms. *Fig.* 1180 is a cross elevation, showing the box and waggon at bottom of the shaft, also the charging-pipe and air-vessel at surface; *fig.* 1181 a side elevation of the box at surface, charging-pipe, brake-wheel, and lever; *fig.* 1182 section of box and discharge-valve; *fig.* 1183 plan of water-box.

Water-pressure Engines.—The power of these engines is derived from the weight of a column of water acting or pressing directly on rams or pistons.

To work these engines successfully, air-vessels, momentum-plungers, or other suitable contrivances, should be applied between the cylinder and the pressure-column.

For mining purposes pressure-engines ought to be of simple construction, all parts readily accessible, and the following suggestions more or less observed:—(1) Employ cotton-packing in gland-boxes instead of single or cup leathers for iron rods above 3 inches diameter; (2) if it is designed to work under very high pressures, use brass or brass-cased rams; (3) work with balanced valves; (4) in forcing water to an accumulator, set the pump-valves higher than the pump, or otherwise let the water gravitate to the bottom clack, so as to fill the ram cases, and prevent the ingress of air.

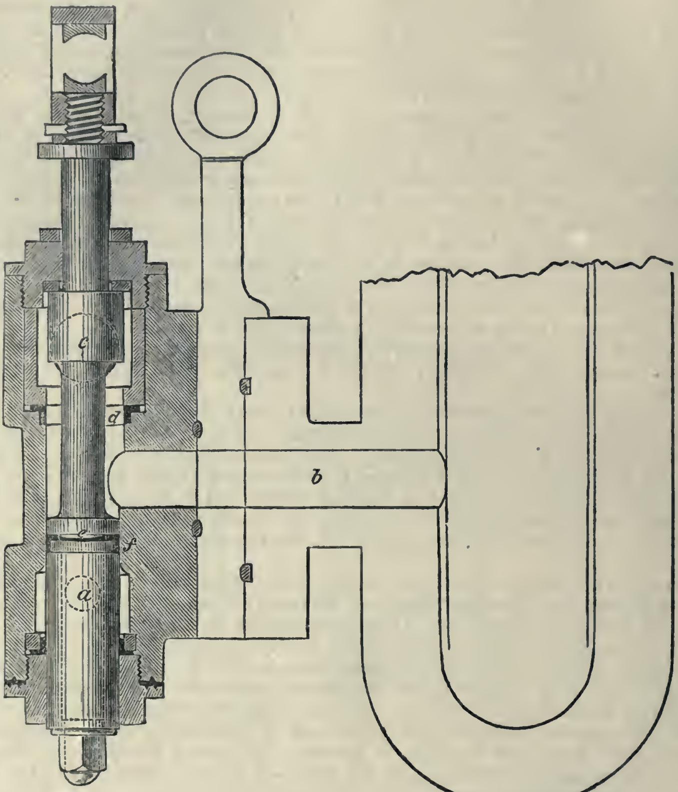
Owing to the shock communicated to the pressure pipes, as well as to other parts of the machinery, by the sudden stoppage of a flowing column of water, it is necessary to keep the piston speed very low. Long-stroke engines are also desirable.

It is exceedingly difficult to discover the original inventor of piston reciprocating water-engines, but machines of this class seem to have been first employed in Germany. In 1748 an engineer named Winderschmidt erected a water-pressure engine at the Grube Beständigkeit, Oberharz. Between 1759 and 1768 six additional engines were set to work at Schemnitz, in Hungary, and in 1767 other engines were placed at the Siegfried mine, near Freiberg, in Saxony. In Austria the first water-pressure machine was probably started about the middle of the last century. In 1765 Westgarth erected an engine at the Caldcleugh mine, Northumberland. Five years after Smeaton placed a water-pressure machine at Temple Newsam, Yorkshire. From 1798 to 1804 Trevithick erected engines at Huel Henry and Huel Druid, Cornwall, and one at the Alport mines, Youlgreave, Derbyshire. About 1835 Fairbairn constructed a water-pressure engine for the same mine. Between 1841 and 1848 Darlington designed and added three large pumping-engines, one of which, with a cylinder 50 inches diameter, was made at the Butterly Works, then under the management of the late Mr. Joseph Glynn. Subsequently Armstrong employed an accumulator and rotary engines at Allenheads. In 1833 Dean, of Hexham, and in 1862 Pattinson, Davison and Spencer, of the same town, built horizontal and vertical engines for the Leadhills Lead Mines, Lanarkshire. Darlington also designed and erected hydraulic pumping-engines at Lisburne, Cwmystwyth, Tarlargoch, and Minera, in North Wales, between the years 1843 and 1856.

Valves.—The slide-valve shown on page 863, *fig.* 1194, may be applied both to small pumping and winding engines intended to be worked under a heavy water pressure. It is an ordinary D-shaped slide made of 3½ parts of tin and 16 copper. The seating or face plate is also made of similar composite metal. The valve face is in some cases attached to the face holder in the following manner:—(1) Heat valve face holder, and wash face with a solution of chloride of zinc. (2) Re-heat valve face holder and valve face hot enough to melt tin. (3) Put melted tin on valve face and face holder, bring the two faces together and solder.

The balance valve shown in *fig.* 1184 is in use at the Wildberg mines, Prussia. The water under pressure flows through the opening *a*, then to the main cylinder through the port *b*. After having performed its work, it returns through the port *b* and passes away by the eduction opening *c*. The bar valve, as will be seen, moves into a single leather *d*, when the water flows to the cylinder, and on flowing from the cylinder the valve leather *e* passes into the cylindrical part *f* of the valve-box. Experience has shown that leathers worked in this way are thoroughly reliable, and that the valve itself is effective under very high pressures. Both valve bar and box are of gun-metal.

1184



Balance and Differential Pistons.—Under considerable pressures balance-valve pistons are necessary. Examples of their application is shown in Darlington's pressure-engine, N O, page 855 *fig.* 1187, and also in Trevithick's engine, B C, *fig.* 1188, page 856. Differential valve pistons, K I, are shown in *fig.* 1187, page 855.

Cup Leathers.—Cup leathers are either single or double, the former are partly clipped between two metallic surfaces, the latter are supported on a loose ring. For large plungers, leathers are costly, and apt to wear quickly. Iron surfaces are readily attacked by mineral waters which produce a saw-like roughness calculated to tear the edge and face of the leathers. For brass rams, leathers may be used with the greatest advantage, since in contact with that metal they will be very durable and cause but little friction. The table at the head of p. 853 gives the friction occasioned by the use of leathers on rams the surfaces of which are in good smooth working order.

Packing.—For cylinders of very large diameter under moderately low pressures, hemp rope, or gasket may be employed. Brass packing rings are also reliable. For valve pistons, passing ports, a close working fit between the piston and cylinder will prove satisfactory. Small pistons or rams travelling under high pressures should be fitted with single or double cup leathers. Iron rods above 3 inches diameter, if packed with lamp-wick, will give less trouble than if worked in contact with cup leathers.

Diameter of ram in inches	Friction per cent.	Diameter of ram in inches	Friction per cent.
2	2	11	·38

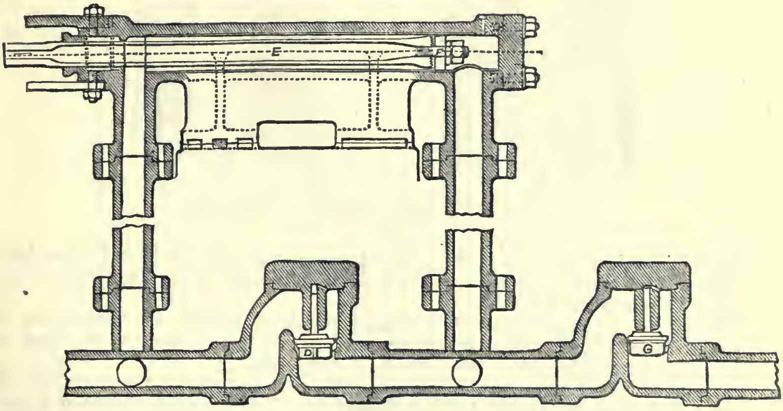
8	·50	17	·23
9	·44	18	·22
10	·40	19	·21

Charging Plungers and Pistons.—For charging accumulators or effecting the transfer of power, plungers are usually employed. The advantage which a plunger offers over a piston is that any leakage is instantly seen and can almost immediately be prevented. When it is required to force water under a high pressure the valves should not only be large, but set so that air cannot pass into the plunger case. A precautionary method is to gravitate the water to the bottom valve. In addition, it will in some cases be judicious to provide the ram cases with small pet valves for discharging any intrusion of air. Unless the air be entirely excluded from the plunger cases, the cubic inches of water delivered to the accumulator will by no means correspond to the cubic inches of the stroke. A simple and effective force pump is shown in *fig.* 1185. In this arrangement the outstroke of the pump causes the water contained in the annular space surrounding the rod E to be forced into the air vessel or accumulator whilst a further supply of water enters behind the piston through the inlet G. In the other half of the stroke the water behind the piston is discharged through the valve D and half of it into the annular space on the other side of the piston. In this pump the area of the rod E is exactly half that of the piston F. Both the inlet and delivery valves are of easy access.

1185



Accumulators and Air Vessels.—The accumulator is shown in *figs.* 1170 and 1189, and its use is fully explained at page 833. Air vessels may to some extent be used as a substitute for the accumulator, but this class of apparatus impose a varying resistance on the charging pumps, whilst the resistance offered by the accumulator is a constant one. Moreover, the air vessel has the serious defect of requiring frequent replenishing, owing to the absorption of air by the water. This especially occurs under high pressures, as will be gathered from the following particulars. (See Table, p. 854.)

The effective capacity of air vessels is governed by the pressure of water to which they are to be subjected. Long and capacious vessels will afford more satisfactory results than short and small ones. In most cases it will be desirable to fit the vessel with a pressure-gauge, and a gauge-glass. An example of an air vessel fitted in this way and applied for the purpose of relieving pressure and preventing shock is shown in *fig.* 1194, page 863, where D is the vessel.

	Oxygen	Nitrogen	Total
Composition of air	21 parts	79 parts	=100
Volume of air absorbed in water under a pressure of 15 lbs. per square inch . . .	·046 „	·025 „	= ·071
30 „ „ . . .	·092 „	·050 „	= ·142

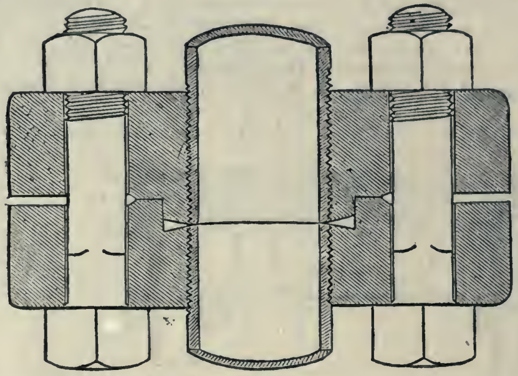
75 „ „ . . .	·230 „	·125 „	= ·355
90 „ „ . . .	·276 „	·150 „	= ·426

Pipes and Joints.—For underground mains wrought-iron pipes pitched inside will be found advantageous, since they will be found to resist the action of ordinary water, and can be bent cold to suit the course of a level. The ends should be fitted with thick cast-iron flanges, the latter faced and formed as shown in *fig.* 1186.

1186



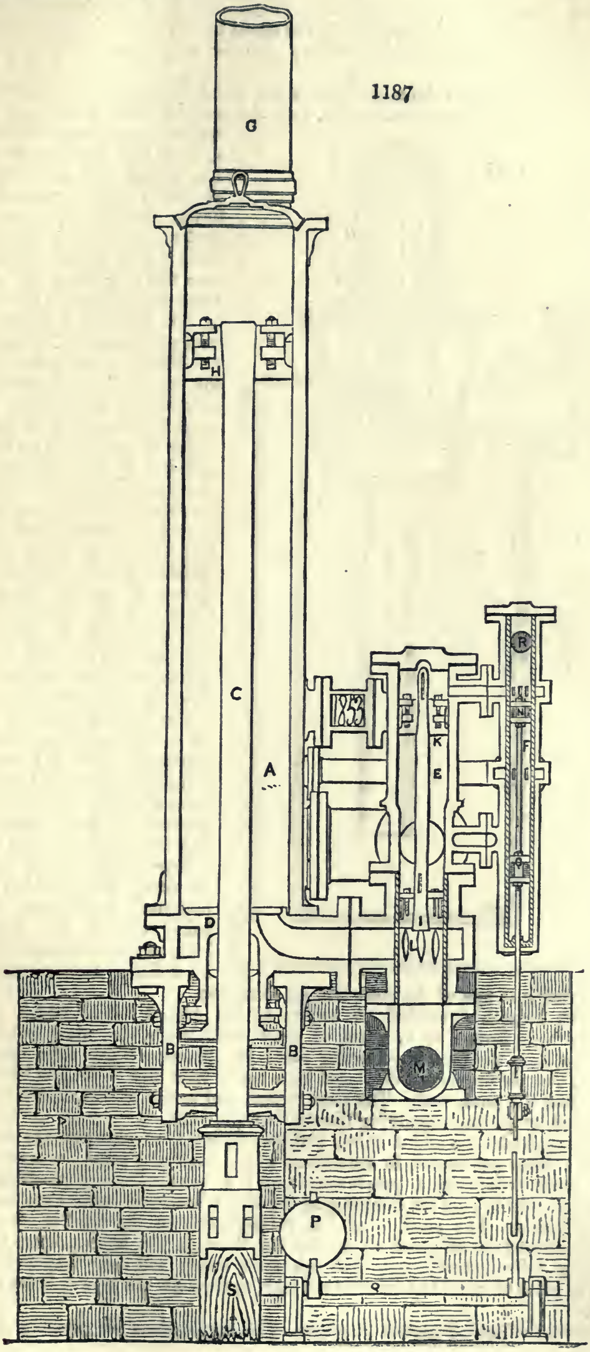
The joints should be made with a ring of gutta-percha from $\frac{3}{16}$ths to $\frac{1}{4}$ of an inch diameter, unless the main is to be charged with hot water, when it will be better to employ vulcanised rubber.

Pumping Engines.—Considerable attention has been given to the construction of pressure-engines by Mr. Darlington, who was actively engaged some years since in effecting the drainage of the Alport mines, in Derbyshire.

The first engine erected by him had a cylinder 50 inches diameter, and a stroke of 10 feet; the piston-rod passed through the bottom of the cylinder and formed a continuation with the pump-rod, whilst the valve and cataract gearing was worked by a rod connected with the top of the piston, which gave motion to a beam and plug-rod gearing. The column of water was 132 feet high, affording a pressure on the piston of about 58 pounds per square inch, or more than 50 tons on its area. The water was raised from a depth of 22 fathoms, by means of a plunger 42 inches diameter, and in very wet seasons it discharged into the adit nearly 5,000 gallons of water per minute. Water was admitted only on the under side of the piston, and in order to avoid violent concussion in working, two sets of valves were employed, the larger being cylindrically shaped, 22 inches diameter, and the smaller 5 inches diameter. In making the upstroke of the engine the cylindrical valves admitted a full flow of water for about $\frac{7}{8}$ths of the stroke, and then commenced closing, but at this stage the small valve opened, through which passed sufficient water to terminate the stroke. In this way the flow of water in the column was gradually slackened, and finally brought to a state of rest without imparting impact to the machinery. The speed of the engine was regulated by sluice-valves, one fixed between the engine and the pressure-column, and the other upon the discharge-pipe.

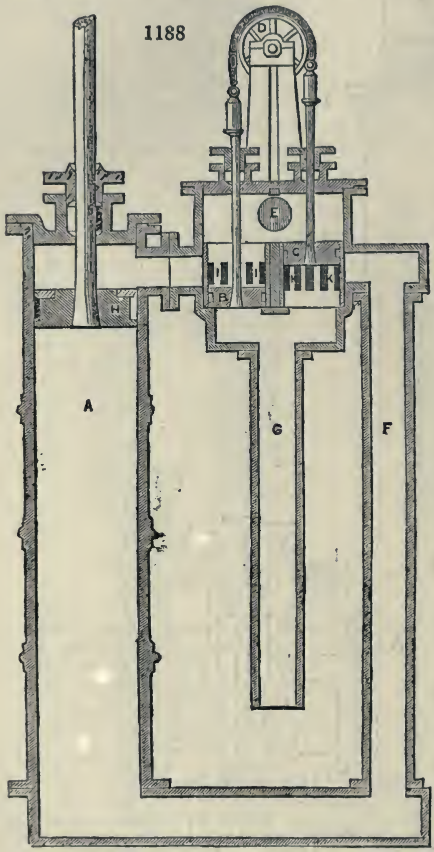
The cylindrical valves were made of brass with a thin feather-edged beat, and kept tight by a concentric boss, projecting from the nozzle, upon which hemp packing was laid. This was pressed down by a projection in the under surface of the valve bonnet. The water thus acted on the exterior of the valves between the zone of packing and the seatings, and when opened passed through the latter. Besides this engine, others of a different construction were designed and erected by Mr. Darlington, but the one to which he gave preference for simplicity, cheapness, and smoothness of action is illustrated in *fig.* 1187.

1187



This engine has one main cylinder A, resting on strong cast-iron bearers B B, fixed across the shaft. The piston-rod C is a continuation of the pump-rod S, and works through the cylinder bottom D. In front of the cylinder A is a smaller one E, with differential diameters for the admission and emission of water, and right and left are sluice valves not shown for regulating the speed of the engine. Connected with the second cylinder is a small 3-inch auxiliary cylinder F, provided with inlet and outlet regulating cocks.

1188



In starting this engine the sluice-valves and regulating cocks are opened, the water then flows from the pressure-column G, into the main cylinder A, through the nozzle cylinder E, and acts under the piston A, until the upstroke is completed. The piston I has a counter piston K, of larger diameter, and when relieved from pressure on its upper surface, the water acting between them forces it upwards, in which case the pressure is cut off from the main piston, and the water contained in the cylinder A is free to escape under the piston I, through the holes L. With the emission of water from the main cylinder through M, the downstroke is effected. The downward displacement of the pistons I and K is performed by the auxiliary cylinder F, and pistons N, O; the pressure-column is continually acting between these pistons, and by their alternate displacement by the fall-ball P, and canti-arbor Q. The water is either admitted or prevented from operating on the upper surface of the piston K. The water from the top of piston K escapes through the aperture R. The motion of the canti-arbor Q is effected by tappets fixed on the pump-rod S.

The largest cylinder erected was 35 inches diameter, stroke 10 feet, pressure-column 227 feet high. Its average speed was 80 feet, and maximum speed 140 feet per minute. The pressure of water under the piston was 98 lbs. per square inch, giving a total weight on its area of about 40 tons. The machine required no personal attendance, the motion being certain and continuous, as long as the working parts remained in order; consequently, the cost of maintaining it was of the most trifling character.

In 1803, Trevithick erected an engine at the Alport mines, which worked continuously for a period of 47 years, or until 1850, when the mines ceased working. The water from the pressure-columns acted on alternate sides of the main piston, by means of two piston valves, displaced by a heavy tumbling beam, and tilted by a projection from the pump-rod. The construction and action of this machine will be best understood by the accompanying illustration, *fig.* 1188.

A, main cylinder; B and C, valve pistons; D, chain wheel, upon the axis of which is fixed a lever not shown, in connection with a tumbling beam; E, aperture through which water enters from pressure-column; F, pipe in communication with main cylinder A; and G, pipe for discharging the water admitted both above and under the main piston H. The position of the valve-pistons in the woodcut shows that the pressure-column is supposed to be flowing through the holes I, upon the piston H, producing a down-stroke, and that the water which had been introduced under this piston in order to make the up-stroke is leaving through the pipe F, holes K, and outlet pipe G.

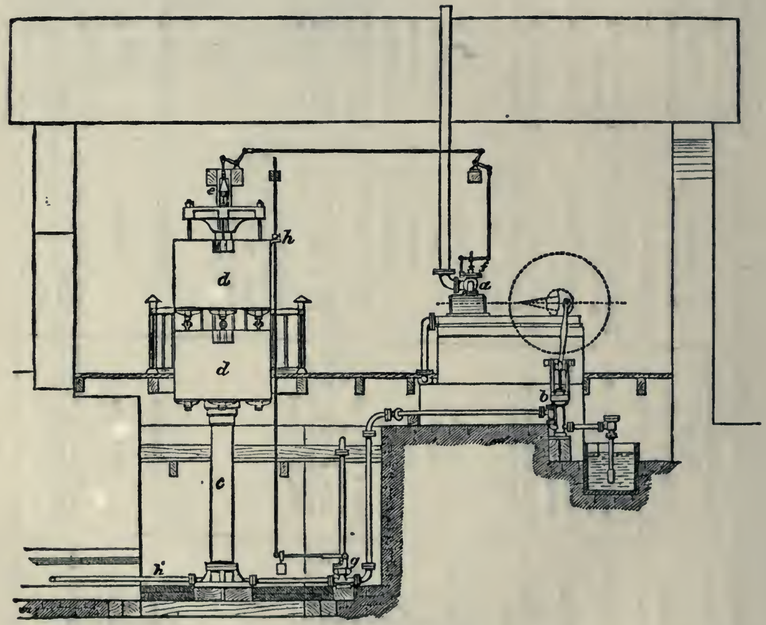
natural falls have been extended by Sir William Armstrong in the following manner:—

When the moving power consists of a natural column of water, the pressure rarely exceeds 250 or 300 feet; and in such cases he has employed, to produce rotary motion, a pair of cylinders and pistons, with slide-valves resembling in some degree those of a high-pressure engine, but having relief valves D to prevent shock at the return of the stroke, as shown in *fig.* 1173, page 835. Where the engine is single-acting, with plungers instead of pistons, the relief valves are greatly simplified, and, in fact, are reduced to a single clank in connection with each cylinder, opening against the pressure, which is the same as the relief valve in the valve chest of the hydraulic crane. The water-pressure engine erected at Mr. Beaumont's lead mines, at Allenheads in Northumberland, present examples of such engines applied to natural falls. They were there introduced under the advice of Mr. Sopwith, and are now used for the various purposes of crushing ore, raising materials from the mines, pumping water, giving motion to machinery for washing and separating ore, and driving a saw-mill and the machinery of a workshop. In all these cases nature, assisted by art, has provided the power. Small streams of water, which flowed down the steep slopes of the adjoining hills, have been collected into reservoirs at elevations of about 200 feet, and have been laid from these to the engines.

1189

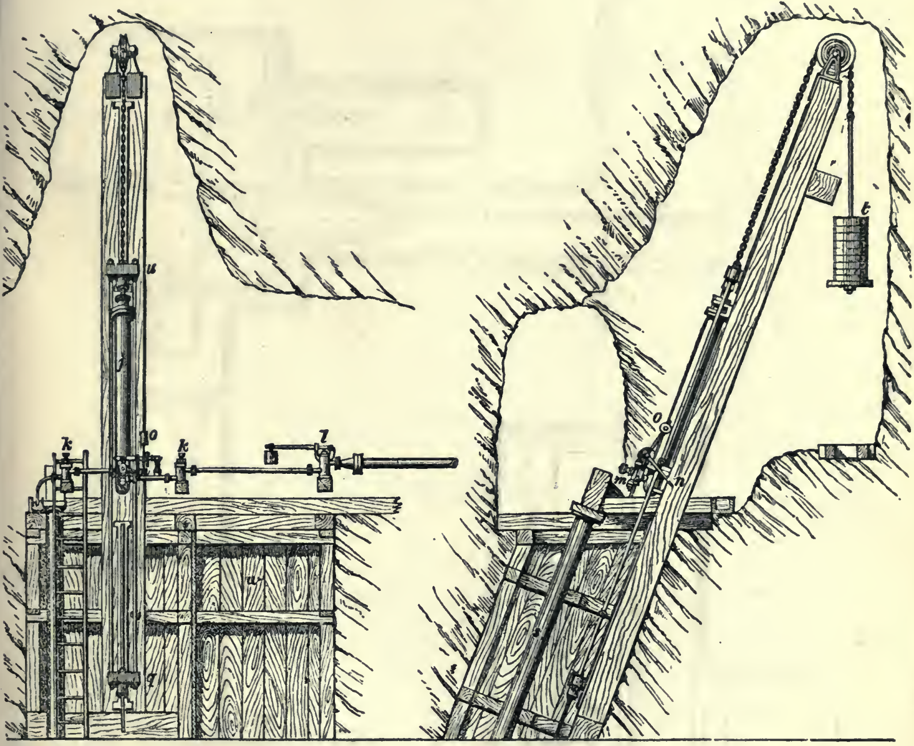


Another application of hydraulic machinery at the same mines has been made where falls of sufficient altitude for working such engines cannot be obtained. For the purpose of draining an extensive mining district and searching for new veins, a drift or level nearly six miles in length was executed. This drift runs beneath the valley of the Allen, nearly in the line of that river, and upon its course three mining establishments were formed. At each of these, power was required for the various purposes above mentioned, and it was desired to obtain this power without resorting to steam-engines. The river Allen was the only resource, but its descent was not sufficiently rapid to permit of its being advantageously applied to water-pressure engines. On the other hand, it abounded with falls suitable for overshot wheels, but these could not be applied to the purposes required without provision for conveying the power to many separate places. Under these circumstances, it was determined to employ the stream through the medium of overshot wheels in forcing water into accumulators, and thus generating a power capable of being transmitted by pipes to the numerous points where its agency was required.

A somewhat similar plan is also adopted at Portland Harbour, in connection with the coaling establishment there forming for the use of the navy. The object in that case is to provide power for working hydraulic cranes and hauling machines, and more particularly for giving motion to machinery for putting coal into war steamers. A reservoir on the adjoining height affords an available head of upwards of 300 feet; but in order to diminish the size of the pipes, cylinders, and valves connected with the hydraulic machinery, and also with a view of obtaining greater rapidity of action, a hydraulic pumping engine and accumulator are interposed for the purpose of intensifying the pressure and diminishing the volume of water acting as the medium of transmission.

Water-pressure engines erected at the Wildberg Mines, in Rhenish Prussia, are shown in *figs.* 1190 and 1191. They drain an isolated piece of ground distant from the main shaft 1,800 feet. A rotary horizontal high-pressure steam-engine is placed in connection with steam-boilers, *fig.* 1189. Two pumps, one of which is shown at *b*, force water into an accumulator, *c*. The accumulator-ram is mounted with two concentric boxes, *d*, *d*, one for affording the pumping, the other the winding, pressure.

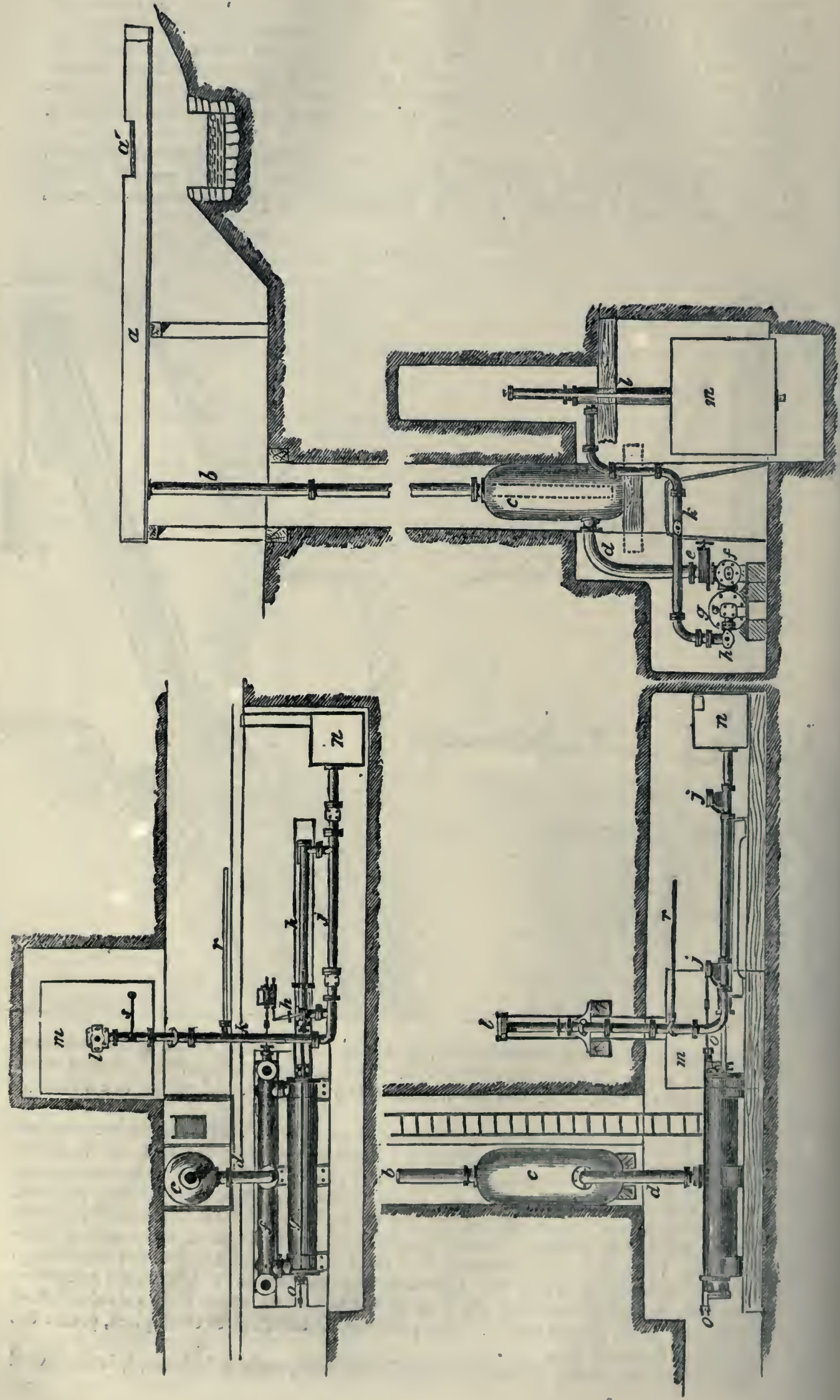
1190



As the power required is of an intermittent character, the steam-engine is controlled by the screw and weight, *e*, actuating the throttle-valve, *f*; and in order to guard against the possibility of the ram rising beyond prescribed limits, a waste-valve, *g*, is operated upon by the rod and stop, *h*. From the accumulator, wrought-iron pipes *h′*, fitted with cast-iron flanges, extend through an engine-shaft 60 fathoms in depth, and a level 1,500 feet in length. These pipes or main terminate in a reciprocating pole-engine, *fig.* 1190, *j*, having a stroke of 5 feet; *k*, *k*, are inlet and outlet regulating-valves; *l*, momentum valve, for obviating the concussion which would otherwise result from suddenly arresting the flow of the water; *m*, small slide valve, actuated by the canti-lever, *n*, and ball, *o*. The pump-rod is attached to cross-piece, *q*, and the pump itself is shown at *s*.

To compensate for any excess of weight in the pump-rods, a balance, *t*, is connected

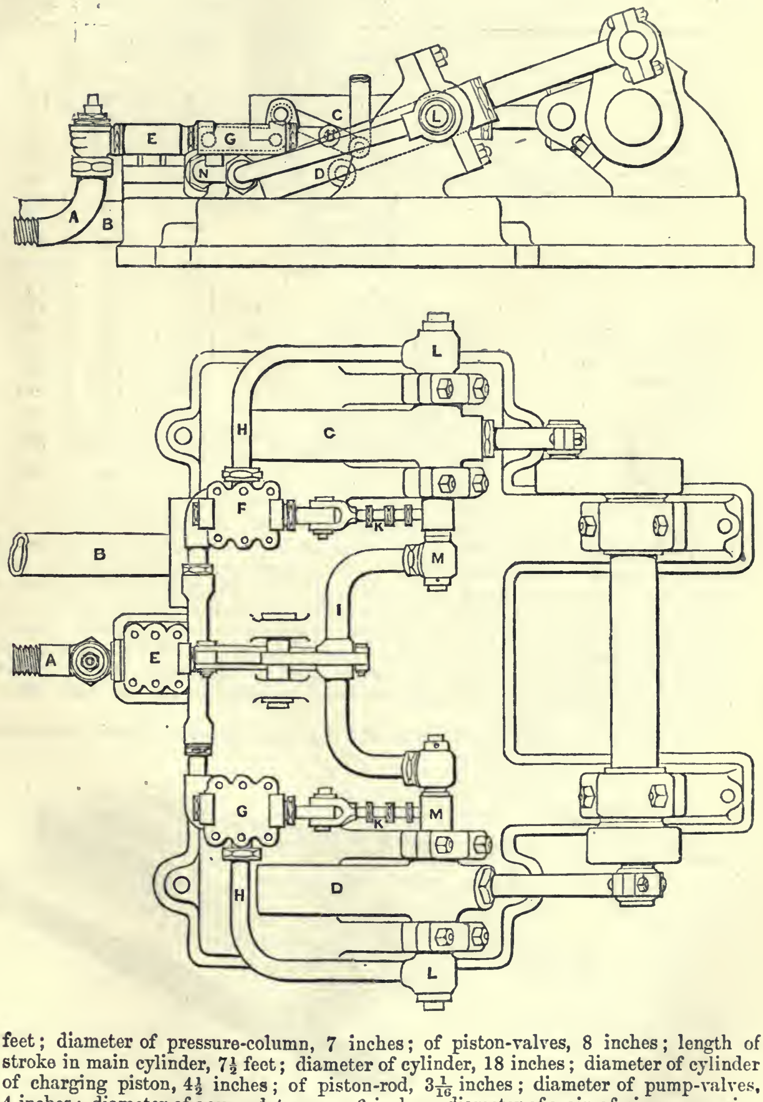
1191



by means of a chain with the cross-head, *u*. The detailed arrangement of the shaft, *w*, as well as the hydraulic winding-engine, is not shown, but this machine is also dependent on the accumulator for its power. The pressure applied is 750 lbs. per square inch. No leakage of water is experienced at the joints, and in every respect the performance of the apparatus is satisfactory.

Fig. 1191 represents one of the hydraulic engines employed at the same mines for charging an accumulator. The water for driving this engine is diverted from three different valleys into a common water-race, and passed through the pressure-column *b* into the engine, where, after having done its work, it is discharged into the day-level. The following are some particulars connected with this engine:—Available fall, 55 feet; diameter of pressure-column, 7 inches; of piston-valves, 8 inches; length of stroke in main cylinder, $7\frac{1}{2}$ feet; diameter of cylinder, 18 inches; diameter of cylinder of charging piston, $4\frac{1}{2}$ inches; of piston-rod, $3\frac{1}{16}$ inches; diameter of pump-valves, 4 inches; diameter of accumulator-ram, 6 inches; diameter of main of pipes conveying power from accumulator, 2 inches. *a*, water-launder with waste-gap a'; *b*, pressure-column; *c*, air-vessel; *d*, pipe from air-vessel to cylinder; *e*, sluice-valve; *f*, valve

1192



cylinder; *g*, main cylinder; *h*, charging-pump; *j*, valve-boxes; *k*, pipe from charging-pump to accumulator; *l*, accumulator; *m*, weight-box; *n*, water-cistern in connection with charging-pump; *o*, valve gear; *h*, small lever forming part of valve gear; *r*, pressure main, between accumulator and hydraulic engine; *s*, relief valve.

In these arrangements, intensity of pressure takes the place of magnitude of volume, and the power assumes a form susceptible of unlimited distribution and division, and is capable of being utilised by small and compact machines. The writer has recently applied engines fitted with two cylinders, each $1\frac{1}{4}$ inch diameter, and 7 inches stroke, to the winding of underground tackles or windlasses.

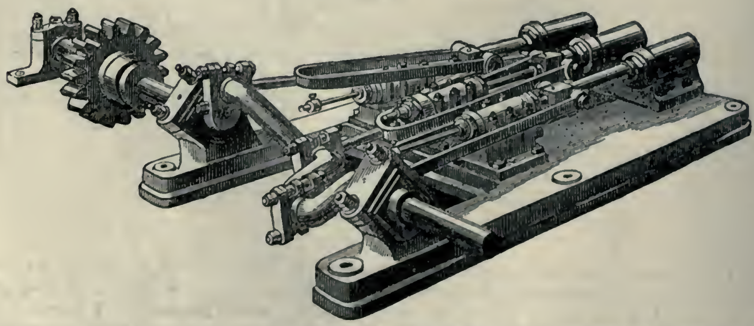
Rotary Engines.—*Fig.* 1192 shows Armstrong's rotary water-pressure engine. It is rendered double-acting by bringing the force to bear four times in the crank-circle. The cylinders are made to oscillate, and the plungers are attached directly to the crank-pin. A piston is formed at the inner end of the plunger, and water is admitted behind the piston, while the front is placed in communication with the pressure-pipe. A is the pressure-pipe; B, the exhaust-pipe; E, governor-valve; F, G, slide valves for producing admission and emission to and from the cylinder, C, D; I, pressure-pipe, communicating with the cylinders, C, D, in front of the piston. The slide-valves derive motion from the oscillatory movements of the cylinders, and are of the ordinary D-shape pattern.

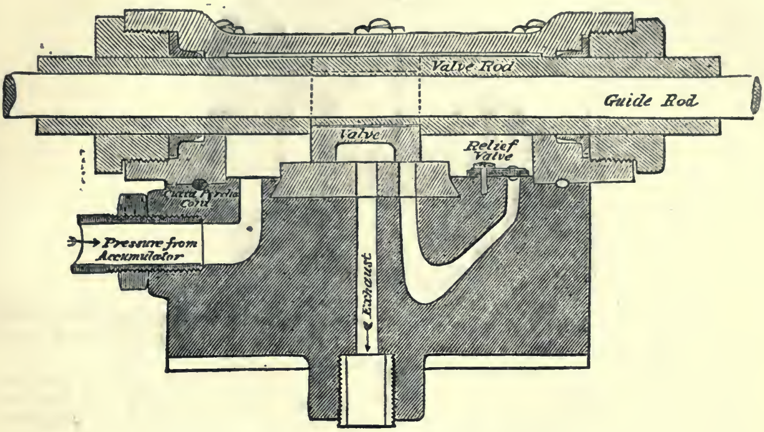
The engine, *fig.* 1193, is in use at the Wildberg Mines, in Prussia, for winding stuff from the 90 to the 50 fathom level. It consists of three rams, a three-throw crank, and three slide-valves.

1193

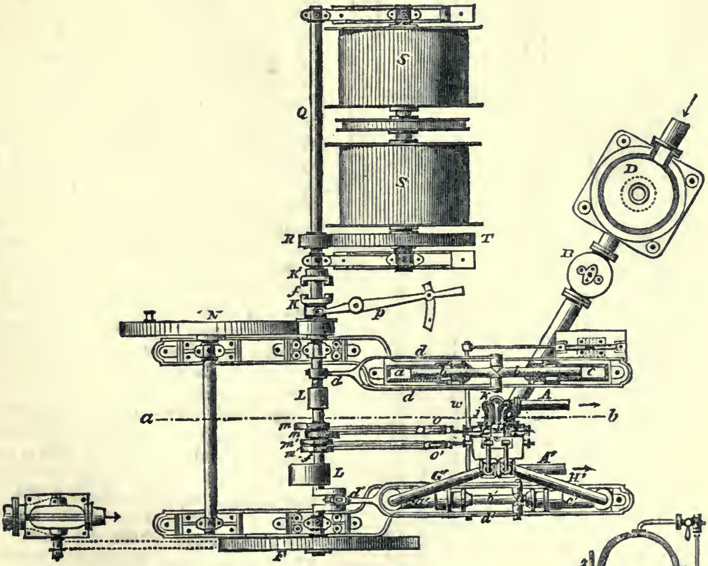


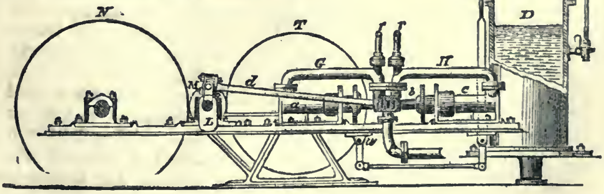
The rams are each 2½ inches diameter; length of stroke, 10 inches; speed, 60 strokes per minute. Each valve is worked direct from the rams by means of a rod ¾ inch diameter, fitted with adjustable stops. This rod passes through a tubular valve-rod moving in nut-boxes containing cup-leathers. This peculiar arrangement with the valve itself is shown distinctly in *fig.* 1194. The guide-rod is fitted with

1194



1195

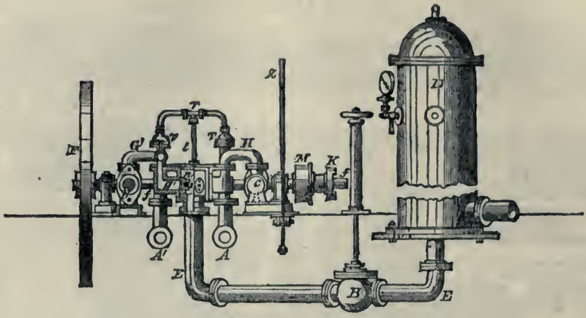




1196

the stops referred to, and passes through a tubular valve-rod; the valve is D-shaped; the pressure-port and exhaust-ports are shown; together with the relief-valve. The engine under its working pressure of about 500 lbs. per inch, runs with great regularity.

1197



1198

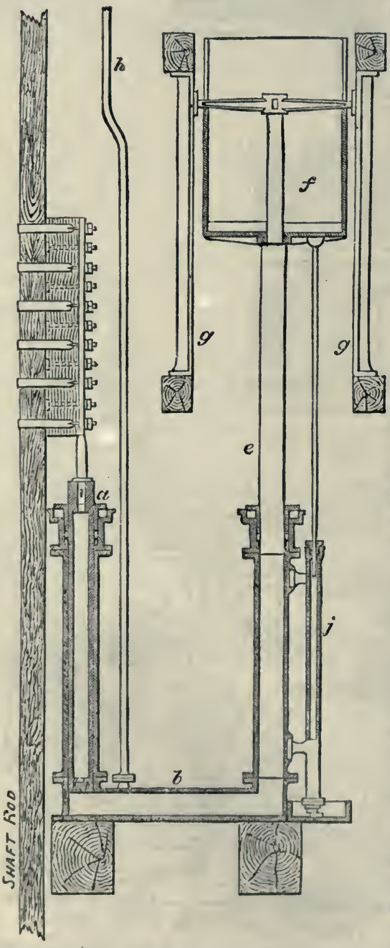


Fig. 1195 exhibits a rotary engine applied to winding, pumping, and ventilating purposes. In its general arrangement it includes an air-vessel, four ram-cases, and two winding-drums, a wheel fitted with crank-pin for pumping, and a fan. *Fig.* 1195, plan; *fig.* 1196, elevation on line *a*, *b*, of plan. *Fig.* 1197, cross-elevation of engine and air-vessel. A, A′, outlet-pipes from ram-cases; B, inlet-valve; D, air-vessel; E, inlet-pipe; F, fan driving-wheel, fitted on main shaft; G, H, outlet-pipes, connecting valve-boxes with ram-cases; K, K′, clutch-box; M, spur-pinion; N, N′, spur-wheel, with pin for attaching pump-rod; O, O′, excentric valve-rods; Q, shaft for driving winding-drum; R, spur-pinion; S, drum; I, spur-wheel on drum-shaft; *a*, *c*, ram-cases in section, *a*, *c*, in plan; *b*, rams; *d*, *d′*, fork crank-levers; *e*, slide-valves; *f*, pipes from cylinder; *g*, passage to cylinders; *m*, *m′*, excentrics; *p*, lever for shifting the clutch; *w*, brake-strap; *z*, brake-lever.

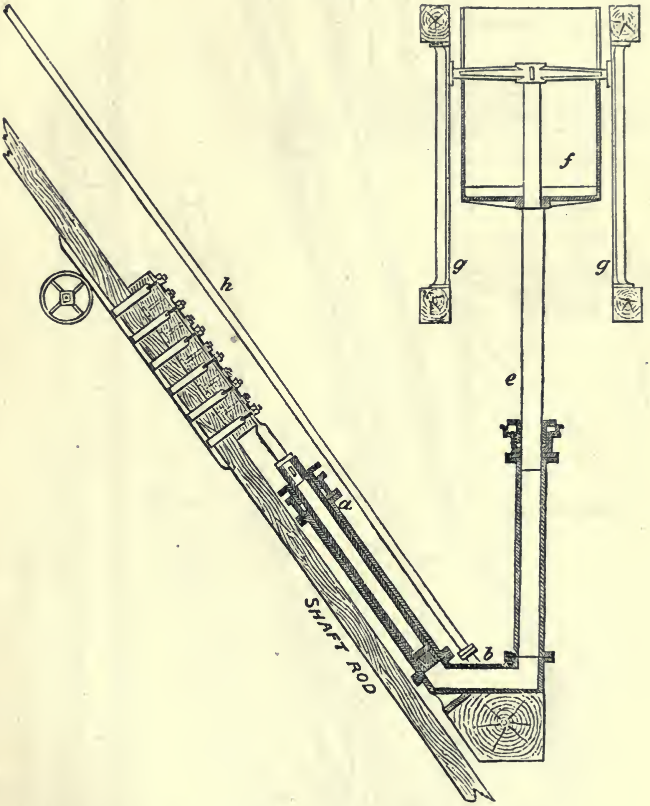
Hydraulic Bar.—In its simplest form the hydraulic bar consists of a main of pipes charged with water, with a plunger or piston at each end; the movement of one plunger equally affecting the movement of the other through the medium of the water stored within the main. Early in 1867 West and Darlington commenced to apply the hydraulic bar to the working of pumps and balancing of pump-rods. *Fig.* 1198 represents the counterbalancing apparatus in connection with a mining pump-rod when working in a vertical direction. *a*, plunger attached to main-rod; *b*, pipe connecting the second ram-case; *e*, plunger, with weight-box *f*; *g*, guides for weight-box; *h*, pipe communicating with cistern, for supplying such water as may be necessary to make up leakage; *j*, small supply-plunger, to be attached to the apparatus when the pipe, *h*, cannot be advantageously introduced.

The communication between the faces of the two plungers is entirely free; and hence, if the acting-ram, *a*, be raised, the balance-plunger, *e*, will fall and counterbalance the rods to the extent of its weight, less the trifling amount of friction incident to the movement.

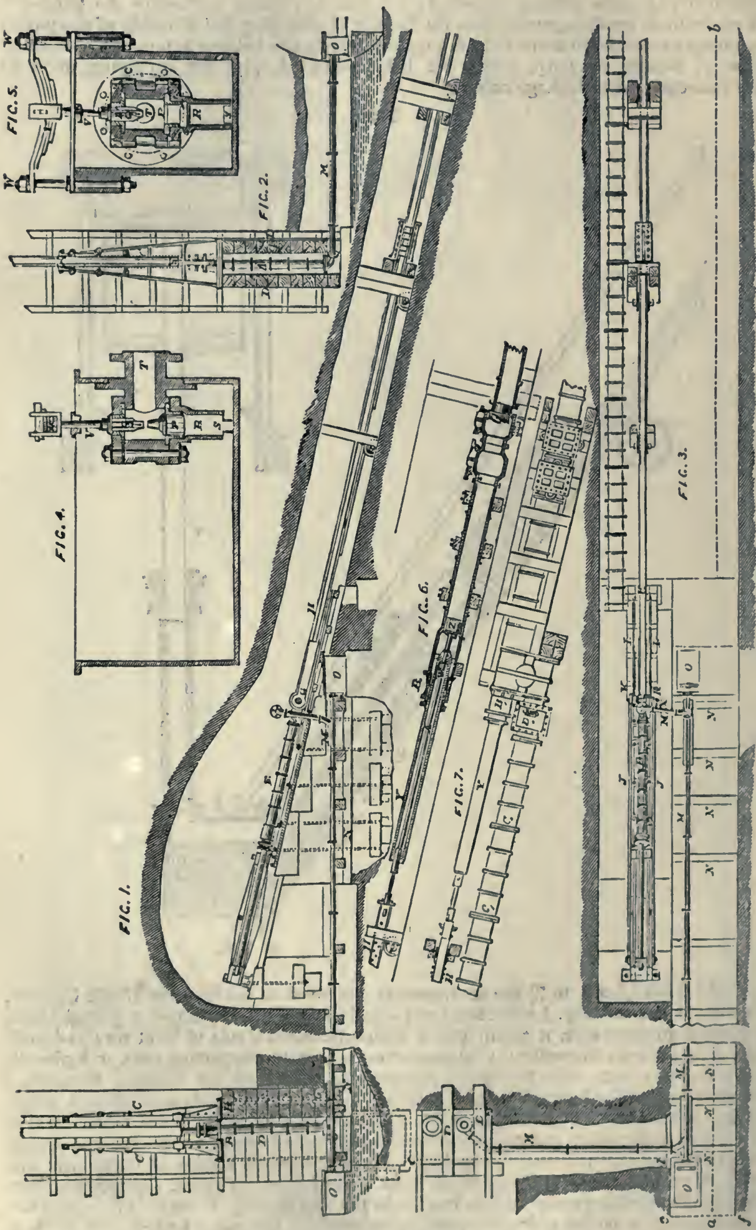
The details of this counterpoise arrangement (*fig.* 1199) are, in most respects, identical with those already described; but this *fig.*, which represents the pump-rod in an inclined position, exemplifies the facility of changing the direction of the power. *a*, plunger attached to main-rod; *b*, pipe connecting the balance ram-case; *e*, balance-ram; *f*, balance-box; *g g*, guides for balance-box: *h*, pipe for supplying water to the ram-cases when leakage occurs.

1199



In *fig.* 1200 (*figs.* 1 to 7) the arrangement employed at the Von der Heydt Colliery, Prussia, is shown. *Fig.* 1 side elevation: C guides for vertical plunger, D plunger-case, E inclined plunger-case, H pump rod, M hydraulic main, N sole of level, O valve-boxes. *Fig.* 2 transverse elevation: A plunger-case, D bearers supporting case, M hydraulic main, O valve-box. *Fig.* 3 plan: B plunger-case, D bearers for inclined plungers, J forming part of the hydraulic main, N bottom of level, O valve-boxes. *Fig.* 4 longitudinal section of valve-box: O.S. inlet, R pipe, P ordinary mitre valve for supplying main with water when necessary, *r* entrance to hydraulic main, G valve for discharging water from main, Y valve-stud, *i* spring. *Fig.* 5 transverse section of valve-box: S.R. inlet; P valve seating, T entrance to the main, G ejection valve, Y stud, *i* spring, W adjusting nuts for giving greater or less tension to the spring. *Fig.* 6 section of plunger and bucket pump: A bucket rod passing through plunger, Y plunger, Z bucket. *Fig.* 7 elevation of plunger pump valve-boxes and rising main: Y plunger-case, B stuffing box, C water main, D valve-box, H pump-rod. The motive plunger in this case is D, *fig.* 1. This plunger by means of the water contained within the main forces the plunger E upwards. This plunger in turn descends, or performs its downstroke in strict relation with the ascent of the forcing plunger. In these apparatus, *fig.* 1 to *fig.* 7, it is evi-

1200



dent that the reciprocating movements are unaffected by the position of the cylinders and that these may be placed either vertically or at any angle best suited to the special exigencies of the situation. The main of pipes may also run in an angular direction or through shafts and levels. In counterbalancing pump-rods the weight-box bears directly upon the line of pumping motion without occasioning any side strain. The transfer of power to any reasonable distance whether at surface, or underground, may also be effected at a loss in friction incomparably less than would arise from any other mode of transmission, whilst the pipes for the retention of the water may be carried into the remotest heading without causing any inconvenience. By one or other of the arrangements winzes may be drained below the deepest level, and the ground readily divided either for stopping or exploratory purposes.

The hydraulic bar apparatus for changing vertical into oblique motion consists, as heretofore, of two ram-cases coupled together; the motive ram alternating the pumping ram. In *fig.* 1201, *a* is the motive ram, fixed in vertical shaft; *b*, pumping ram, fixed in an inclined shaft; *c*, self-acting valve-arrangement for supplying water when necessary.

1201

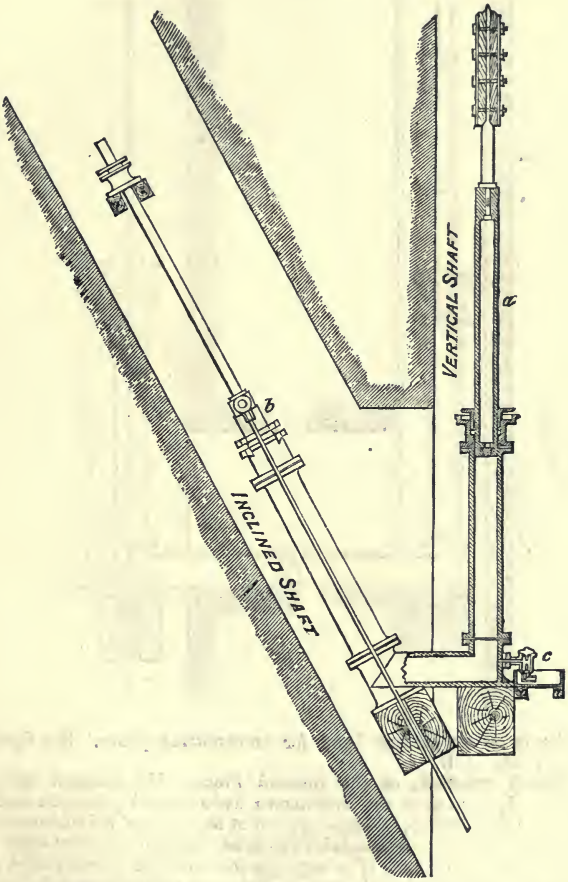


Fig. 1202, p. 868, shows a method in operation at Wheal Phœnix, in Cornwall, for transferring power from the main pump rod to a distant winze underground: *a*, main rod; *b*, supply pipe; *c*, water main; *d*, pumping rod fitted with side rods.

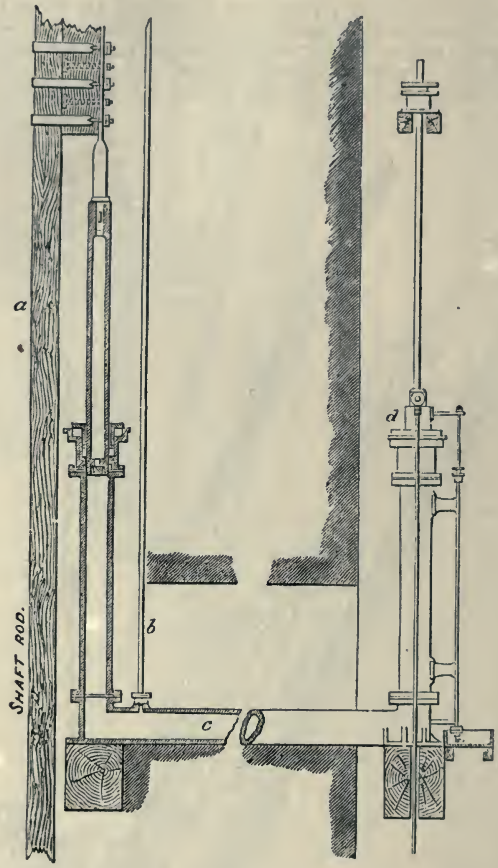
The Hydraulic Circuit.—In 1867, Jordan and Darlington designed an arrangement which they designated an hydraulic circuit. This apparatus consists of two or more force-pumps or plunger cases fitted with plungers. Motion is communicated to the force-pumps or plungers by any suitable machine fixed in a convenient situation. To each plunger-case is attached a small apparatus for drawing and discharging water under adjustable conditions. A main or run of pipes, the hydraulic circuit, commences from one of the plunger-cases; and when the power is to be transferred through drift-ways, the pipes are carried down the shaft through the levels to several points where power is required and returned by the same or a second shaft to the second ram-case,

1202



forming a circuit or an endless band for transmitting power. See Specification, A.D. 1867, No. 3386.—J. D.

HYDRAULIC PRESS, or the *Bramah Press.* Mr. Bramah took out his patent in 1796. It rests upon the well-known hydrostatical principle, that when a mass of fluid is in equilibrium, pressure applied at any part of it is transmitted over its whole mass, and each particle sustains the same pressure as every other particle. In its simplest form, it consists of a large piston moving in a water-tight cylinder, the bottom of which is filled with water, which also communicates by tubes filled with water, with the bottom of a cylinder of a small forcing pump. The water in this last is submitted to any pressure we may wish to apply, and that being transmitted to the large piston, lifts it up, moving along with it whatever may be connected with it. The apparent gain of power is just in proportion to the difference of areas of the sections of the pump, and of the cylinder. If the one, for example, have a radius of only one-fourth of an inch, and the others one of ten inches, the area, being in the proportion of the squares of the linear dimensions, will be as 1 to 1,600; and the apparent gain will be exactly proportional to this difference.

HYDRIODIC ACID (*Acide hydriodique,* Fr.; *Hydriodsäure,* Ger.) is an acid formed by the combination of 127 parts of iodine with 1 part of hydrogen by weight, and by measure equal volumes of iodine-vapour and hydrogen combined without condensation. It is obtained pure and in the gaseous state by introducing into a glass tube, closed at one end, a little iodine, then a small quantity of roughly-powdered glass moistened with water, upon this a few small fragments of phosphorus, and lastly more glass; this order, iodine, glass, phosphorus, glass, is repeated until the tube is two-thirds filled. A cork and narrow bent tube are then fitted and gentle heat applied, when the hydriodic acid is liberated, and may be collected in dry bottles by the displacement of air. Another process is to place in a small retort 10 parts of iodide of potassium with 5 of water, add 20 parts of iodine, then drop in cautiously 1 part of phosphorus cut into small pieces, and apply a gentle heat; hydriodic acid will be formed abundantly, and may be collected as before stated. The following equation expresses the reaction:—

$$2KI + 5I + P + 8HO \text{ yield } 2KO,HO,PO^5 + 7HI.$$

$$\mathbf{2KI + 5I^2 + 2P + 8H^2O = 2K^2HPO^4 + 14HI.}$$

Hydriodic acid greatly resembles hydrochloric acid; it is colourless, and highly acid, it fumes in the air, and is very soluble in water. Its density is 4·4, and under strong pressure it condenses to a yellowish liquid, which solidifies at 60° Fahr.

Hydriodic acid in solution is much more easily prepared by suspending iodine in water, and passing a stream of washed hydrosulphuric acid through it until the colour disappears; it is then heated to expel the hydrosulphuric acid, then allowed to rest, when it may be decanted from the precipitate of sulphur. The reaction consists simply in the displacement of the sulphur by the iodine, $HS + I = HI + S$.

This liquid may be evaporated until it acquires a density of 1·7, when it consists of $HI + 11HO$. It then distils at 262° Fahr. without decomposition. The solution cannot be long kept, it being decomposed by the oxygen of the air with the liberation of iodine, which imparts a dark colour to it. Chlorine decomposes it instantly, with liberation of the iodine.

The solution of hydriodic acid and of the iodides possess the power of dissolving a considerable quantity of iodine, forming a dark solution.—H.K.B.

HYDROBENZOIN. A compound produced by the action of nascent hydrogen on *benzoyl hydride—bitter almond oil.* See Benzole.

HYDROBROMIC ACID. See Bromine.

HYDRO-CARBONS. Compounds consisting of carbon and hydrogen only. See Carburetted Hydrogen: see also Watts's 'Dictionary of Chemistry.'

HYDROCHLORIC ACID, *Chlorhydric acid,* or *hydrogen chloride.* (*Acide chlorhydrique,* Fr.; *Salzsäure,* Ger.) *Sym.* HCl.; *at. weight,* 36·5. A compound of chlorine and hydrogen, which is a colourless gas, of a peculiar suffocating, pungent odour; it reddens vegetable blues, but possesses no bleaching properties. The solution of hydrochloric acid in water is the *muriatic acid* and *spirit of salt* of commerce; anciently *marine acid.*

Hydrochloric acid gas may be obtained by the direct union of its elements—hydrogen and chlorine. By exposure to sunlight, by passage of an electric spark, or by direct contact with flame, these two gases unite with explosive violence. 2 volumes of chlorine and 2 volumes of hydrogen combine to form 4 volumes of this acid. Its specific gravity is 1·247, air = 1·000.

By sealing up muriate of ammonia and sulphuric acid, apart, in a strong glass tube re-curved, and then causing them to act on each other, Sir H. Davy procured liquid muriatic acid. At 50° F. it condenses under a pressure of 40 atmospheres, to a liquid of spec. grav. 1·27.

Hydrochloric acid is best prepared by heating a mixture of 6 parts of chloride of sodium (*common salt*) and 10 parts of concentrated sulphuric acid previously diluted with 4 parts of water, in a capacious glass retort, connected with a set of Woolfe's bottles. This acid is extracted on a large scale from sea-salt, by the action of sulphuric acid at a moderate heat; but it was originally obtained from the salt by exposing a mixture of it and of common clay to ignition in an earthen retort. The acid gas which exhales is rapidly condensed by water. 100 cubic inches of water are capable of absorbing no less than 48,000 cubic inches of the acid gas, whereby the liquid acquires a specific gravity of 1·2109, and a volume of 142 cubic inches. This vast condensation of the gas is accompanied with a great production of heat; whence it becomes necessary to apply artificial refrigeration, especially if so strong an acid as the above is to be prepared. In general, the muriatic acid of commerce has a specific gravity varying from 1·15 to 1·20, and contains, for the most part, considerably less than 40 parts by weight of acid gas in the hundred. The above stronger acid contains 42·68 per cent. by weight; for since a cubic inch of water, which weighs 252·5 grains, has absorbed 480 cubic inches = 188 grains of gas; and 252·5 + 188 = 440·5; then 440·5 : 188 :: 100 : 42·68. In general a very good approximation may be found to the percentage of real muriatic acid, in any liquid sample, by multiplying the decimal figures of the specific gravity by 200. Thus, for example, at 1·162 we shall have by this rule, 0·162 × 200 = 32·4, for the quantity of gas in 100 parts of the liquid.

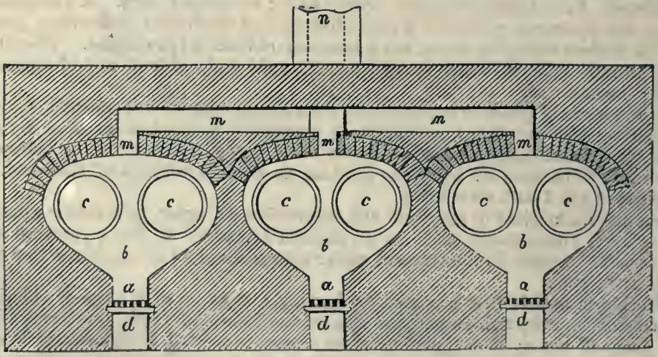
The preparation of this acid upon a commercial scale is frequently effected in this country by acting upon common salt in hemispherical iron pots, or in cast-iron cylinders, with concentrated sulphuric acid; taking 6 parts of the salt to 5 of the acid. The mouth of the pot may be covered with a slab of siliceous freestone, perforated with two holes of about two inches in diameter each, into the one of which the acid is poured by a funnel in successive portions, and into the other, a bent glass, or stoneware tube, is fixed, for conducting the disengaged muriatic gas into a series of large globes of bottle glass, one-third filled with water, and laid on a sloping sand-bed. A week is commonly employed for working off each pot; no heat being applied to it till the second day.

The decomposition of sea-salt by sulphuric acid was at one time carried on by some French manufacturers in large leaden pans, 10 feet long, 5 feet broad, and a foot deep, covered with sheets of lead, and luted. The disengaged acid gas was made to circulate in a conduit of glazed bricks, nearly 650 yards long, where it was condensed by a sheet of water exceedingly thin, which flowed slowly in the opposite direction of the gas down a slope of 1 in 200. At the end of this canal nearest the apparatus, the muriatic acid was as strong as possible, and pretty pure; but towards the other end, the water was hardly acidulous. The condensing part of this apparatus was therefore tolerably complete; but as the decomposition of the salt could not be finished in the leaden pans, the acid mixture had to be drawn out of them, in order to be completely decomposed in a reverberatory furnace; in this way nearly 50 per cent. of the muriatic acid was lost. And besides, the great quantity of gas given off during the emptying of the lead-chambers was apt to suffocate the workmen, or seriously injured their lungs, causing severe hæmoptysis.

The apparatus for condensing muriatic acid gas has been modified and changed, of late years, in many different ways.

The Bastringue Apparatus. At the end of a reverberatory furnace, a rectangular lead trough or pan, about 1 foot deep, of a width equal to that of the interior of the furnace, that is, about 5 feet wide and 6½ feet long, is encased in masonry, having its upper edges covered with cast-iron plates or fire tiles, and placed upon a level with the passage of the flame, as it escapes from the reverberatory. The arch which covers that pan forms a continuation of the roof of the reverberatory, and is of the same height. The flame which proceeds from the furnace containing the mixture of salt and sulphuric acid is made to escape between the vault and the surface of the iron plates or fire tiles, through a passage only 4 inches in height. When the burned air and vapours reach the extremity of the pan, they are reflected downwards, and made to return beneath the bottom of the pan, in a flue, which is afterwards divided so as to lead the smoke into two lateral flues, which terminate in the chimney. The pan is thus surrounded as it were with the heat and flame discharged from the reverberatory furnace. A door is opened near the end of the pan, for introducing the charge of sea-salt, amounting to 12 bags of 2 cwts. each, or 24 cwts. This door is then luted on as tightly as possible, and for every 100 parts of salt, 110 of sulphuric acid are poured in, of specific gravity 1·594, containing 57 per cent. of dry acid. This acid is introduced through a funnel inserted in the roof of the furnace. Decomposition ensues, muriatic acid gas mingled with steam is disengaged, and is conducted

1203

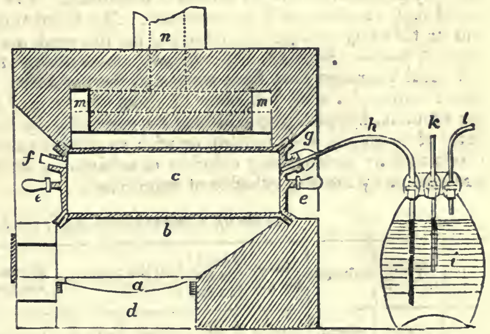


through 4 stone-ware tubes into the refrigerators, where it is finally condensed. These refrigerators consist of large stone-ware carboys, called *dame-jeannes* in France, to the number of 7 or 8 for each pipe, and arranged so that the neck of the one communicates with the body of the other; thus the gas must traverse the whole series, and gets in a good measure condensed by the water in them, before reaching the last.

When the operation is finished, the door opposite the pan is opened, and the residuum in it is discharged, in the form of a fluid magma, upon a square bed of bricks, exterior to the furnace. This paste speedily concretes on cooling, and is then broken into fragments and carried to the soda manufactory. The immense quantity of gas exhaled in discharging the pan, renders this part of the operation very painful to the workmen, and wasteful in reference to the production of muriatic acid. The difficulty of luting securely the cast-iron plates or fire tiles which cover the pan, the impossibility of completing the decomposition of the salt, since the residuum must be run off in a liquid state, finally, the damage sustained by the melting and corrosion of the lead, &c., are among the causes why no more than 80 or 90 parts of muriatic acid at 1·170 are collected, equivalent to 25 per cent. of real acid for every 100 of salt employed, instead of much more than double that quantity, which it may be made to yield by a well-conducted chemical process.

The *cylinder apparatus* is now much esteemed by many manufacturers. *Fig.* 1203 represents, in transverse section, a bench of iron cylinder retorts, as built up in a proper furnace for producing muriatic acid; and *fig.* 1204 a longitudinal section of one retort with one of its carboys of condensation. *a* is the grate; *b*, a fireplace, in which two iron cylinders, *c c*, are set alongside of each other. They are $5\frac{1}{2}$ feet long, 20 inches in diameter, about $\frac{1}{4}$ of an inch thick, and take 1·6 cwt. of salt for a charge; *d* is the ashpit; *e e* are cast-iron lids for closing both ends of the cylinders; *f* is a tube in the posterior lid, for pouring in the sulphuric acid; *g* is another tube, in the anterior lid, for the insertion of the bent pipe of hard glazed stone-ware *h*; *i* is a three-necked stone-ware carboy; *k* is a safety-tube; *l*, a tube of communication with the second carboy; *m m m m* are the flues leading to the chimney *n*.

1204



After the salt has been introduced, and the fire kindled, $83\frac{1}{4}$ per cent. of its weight of sulphuric acid, of sp. gr. 1·80, should be slowly poured into the cylinder through a lead funnel, with a siphon-formed pipe. The three-necked carboys may be either placed in a series for each retort, like a range of Woulfe's bottles, or all the carboys of the front range may be placed in communication with one another, while the last carboy at one end is joined to the first of the second range; and thus in succession. They must be half filled with cold water; and when convenient, those of the front row at least, should be plunged in an oblong trough of running water. The acid which condenses in the carboys of that row is apt to be somewhat contaminated with sulphuric acid, chloride of iron, or even sulphate of soda; but that in the second and third will be found to be pure. In this way 100 parts of sea-salt will yield 130 parts of muriatic acid, of sp. gr. 1·19; while the sulphate of soda in the retort will afford from 208 to 210 of that salt in crystals.

It is proper to heat all the parts of the cylinders equally, to insure the simultaneous decomposition of the salt, and to protect it from the acid; for the hotter the iron, and the stronger the acid, the less erosion ensues.

Some manufacturers, with the view of saving fuel by the construction of their furnaces, oppose to the flame as many obstacles as they can, and make it perform numerous circulations round the cylinders; but this system is bad, and does not even effect the desired economy, because the passages, being narrow, impair the draught, and become speedily choked up with the soot, which would be burned profitably in a freer space; the decomposition also, being unequally performed, is less perfect, and the cylinders are more injured. It is better to make the flame envelope at once the body of the cylinder; after which it may circulate beneath the vault, in order to give out a portion of its heat before it escapes at the chimney.

The fire should be briskly kindled, but lowered as soon as the distillation commences; and then continued moderate till the evolution of gas diminishes, when it must be heated somewhat strongly to finish the decomposition. The iron door is now removed, to extract the sulphate of soda, and to recommence another operation. This sulphate ought to be white and uniform, exhibiting in its fracture no undecomposed sea-salt.

In preparing hydrochloric acid from a mixture of common salt and sulphuric acid, the nature of the reaction varies with the proportions of raw materials employed. This is a point which demands the attention of the manufacturer. If two molecules of sulphuric acid be used with a single molecule of salt (or 98 parts by weight of acid to 78·5 of salt) the decomposition is completely at a moderate temperature, and bisulphate (acid sulphate) of soda is produced, whilst hydrochloric acid is evolved. But if *two* molecules of salt (or 117 parts by weight) be employed, with the same quantity of acid as before, the decomposition takes place in two stages, the final residue consisting wholly of neutral sulphate of soda; but in this case a much higher temperature is required to effect the decomposition. Hence the former method yields the hydrochloric acid with greater facility, and with less expenditure of fuel, whilst the latter process requires a higher temperature, but consumes only half the quantity of oil of vitriol.

Large quantities of hydrochloric acid are produced in the first stage of the manufacture of soda-ash. Formerly the acid-vapours were allowed to escape into the atmosphere, and caused great damage to the surrounding vegetation; but they are now carefully condensed in large towers or scrubbers. The weak solution of acid thus obtained may be afterwards concentrated. Mr. Clapham's process of obtaining a strong acid in this way consists in pumping up the weak acid into the condensing towers, where it becomes strengthened by fresh condensation of vapour.

Several processes have been suggested for obtaining hydrochloric acid without the use of sulphuric acid, but none of them can be said to be commercially successful. For example, hydrochloric acid may be generated by heating common salt with sulphate of magnesia, with pyrites, or with weathered sulphate of iron; the acid may also be obtained by decomposing chloride of calcium by the action of steam at a high temperature, or by heating chloride of magnesium.

Table of Hydrochloric Acid, by Dr. Ure.

Acid of 120 in 100	Specific gravity	Chlorine	Muriatic gas	Acid of 120 in 100	Specific gravity	Chlorine	Muriatic gas	Acid of 120 in 100	Specific gravity	Chlorine	Muriatic gas
100	1·2000	39·675	40·777	66	1·1328	26·186	26·913	32	1·0637	12·697	13·049

The muriatic acid of commerce has usually a yellowish tinge, due to the presence of chloride of iron; but when chemically pure, it is colourless. It fumes strongly in the air, emitting a corrosive vapour of a peculiar smell. The characteristic test of muriatic acid in the most dilute state, is nitrate of silver, which causes a curdy precipitate of chloride of silver.

Liquid muriatic acid has a very sour corrosive taste, a pungent suffocating smell, and acts very powerfully upon a vast number of mineral, vegetable, and animal substances. It is largely employed in the manufacture of chlorine for preparing bleaching powder and other purposes; it is also used in the preparation of chloride of zinc and other metallic chlorides used in the arts; it is employed in the generation of carbonic acid gas from carbonate of lime; and it is a constituent of certain freezing mixtures. In combination with nitric acid, it forms the *aqua regia* of the alchemists, so called from its property of dissolving gold. See SODA MANUFACTURE.

HYDROCYANIC ACID. Syn. *Cyanhydric acid, Prussic acid.* C^2NH (**CNH**). This highly important acid is regarded by all chemists as being formed on the exact type of the ordinary inorganic hydracids, such as the hydrochloric or hydriodic. The compound radical analogous to chlorine, which is contained in it, has received the name of *cyanogen*, and possesses the formula C^2N (**CN**). That this body is precisely analogous in its relations to the simple salt-radicals is rendered certain by numerous facts. It combines directly with metals to form compounds; it possesses the same vapour-volume, and unites with hydrogen to form a hydracid, which in its turn decomposes the metallic oxides with formation of water. Thus we have, with metallic oxides and hydrochloric acid (M standing for a metal), $MO + HCl = MCl + HO$, and with hydrocyanic and metallic oxides (Cy standing for cyanogen), $MO + HCy = MCy + HO$. Two volumes of chlorine and two of hydrogen yield four volumes of hydrochloric acid gas, and two volumes of cyanogen with two of hydrogen yield four volumes of hydrocyanic acid. The density of the vapour of hydrocyanic acid is consequently 0·9476, the theoretical number being 0·9342. Its density in the fluid state is 0·6967, at a temperature of 64°·4. It boils at 80° F. at ordinary pressures.

Hydrocyanic acid is never prepared in the anhydrous state, except as a curiosity or for the purpose of scientific investigation. In fact, it cannot be long preserved of great strength; a somewhat complex decomposition invariably takes place in it, with production of brown adhesive matters containing cyanide of ammonium, and also a substance by some considered to be an acid, and known as the azulmic. Paracyanogen is probably formed at the same time. The constitution of azulmic acid is by no means well known, and even its very existence, as a definite chemical substance, is doubtful. It is singular that the presence of a mineral acid greatly retards the decomposition of prussic acid, especially if it be dilute; the pharmacopœian acid conquently may be preserved of uniform strength, in well-filled and closely-stoppered bottles, for almost any length of time. The deadly nature of prussic acid unhappily causes it to be only too frequently resorted to by the despairing or the murderer. Fortunately, however, in spite of its volatility, the chemist possesses excellent means for its detection.

Preparation.—1. Hydrated acid. As prussic acid is largely employed in medicine, but in a very dilute form, it is usual to prepare it and dilute until of the proper degree of strength. The following process for preparing it will be found to give a satisfactory result, and, moreover, it may be performed on any quantity of materials. The apparatus for the purpose will vary with the scale on which the experiment is to be made. If on a few ounces, glass retorts and flasks answer well, if good condensation is ensured, by means of a Liebig's condenser well supplied with very cold water. If a large quantity of prussic acid is to be made, such as several gallons, the apparatus should consist of a stoneware still, with head adjusted by grinding. The head should be capable of adjustment with a stoneware adapter to a worm of the same material enclosed in a tub of water. The joints are to be luted with a mixture of one handfull of almond meal and five handfulls of linseed meal, worked with water to the consistence of putty. A solution of rough chloride of calcium in water is to be made and placed in a large iron pot, with a cover so contrived as to permit the still to drop in up to the flange. 10 parts of yellow prussiate of potash are then to be bruised in a mortar and mixed with dilute sulphuric acid prepared by adding 6 parts of sulphuric acid (density 1·850) to 42 of water. The head being luted on, a fire is to be kindled in the furnace under the iron pot, and the chloride of calcium bath is to be kept boiling constantly until 36 parts of acid have distilled over. The beak of the still should be placed in the funnel which conducts the acid to the Winchester quart bottles which are to contain the product, and a piece of wet bladder is to be stretched over the funnel to prevent evaporation of the acid into the laboratory. The worm used for the purpose must be ascertained to be perfectly clean, and, if prussic acid is to be frequently made, should be kept specially for that operation. To each Winchester quart of the acid distilling over, one drop of sulphuric acid may be added to insure its keeping. But the acid thus prepared generally keeps for a long time even without this precaution, owing probably to small traces of the sulphuric acid being carried over during the distillation.

It is quite impossible to conduct the operation so as to yield a product of uniform strength; it is absolutely necessary, therefore, to determine the percentage of real hydrocyanic acid, and dilute it to the required degree. It fortunately happens that 1 grain of hydrocyanic acid yields almost exactly 5 grains of cyanide of silver; for one equivalent of acid = 27 produces 1 equivalent of cyanide of silver = 134; so that 27 : 134 :: 1 : 4·96. The acid produced will have, probably, to be reduced to one of two standards; namely, the so-called Scheele's strength, containing 5 per cent. of acid, or the P.L., containing 2 per cent.; 100 grains of the former should, consequently, yield 25 grains, and 100 of the P.L. 10 grains of cyanide of silver. In either case the calculation becomes obvious.

2. The anhydrous acid. Several processes for conducting this dangerous operation are known; the following is, perhaps, the most generally convenient. A large glass retort is so arranged that its neck is directed upwards at an angle of about 45°; a cork fitted to the aperture in the neck connects a glass tube with a bottle containing a little chloride of calcium. From the latter vessel another tube proceeds to a U-tube containing fragments of chloride of calcium, and from the latter a third, conducting the dehydrated vapour of prussic acid to an upright glass tube contained in a mixture of ice and salt. Into the retort is placed a mixture of 10 parts of yellow prussiate of potash, 7 of oil of vitriol, and 14 of water. The retort is to be heated with a charcoal fire, and the temperature of the bottle and U-tube, containing the chloride of calcium, is not to be allowed to fall below 90°, in order to prevent condensation of the anhydrous prussic acid taking place anywhere except in the tube contained in the freezing mixture. The vapour of anhydrous prussic acid is so dangerous that the greatest precaution must be taken to prevent inhaling the smallest portion.

Detection of prussic acid.—When prussic acid exists in moderate quantity in a solution it may be detected by first adding a few drops of potash, then a mixture of protosulphate and persulphate of iron, and finally a little hydrochloric acid; a bright blue precipitate indicates the presence of the acid. A much more delicate test, and one that is applicable when, from the dilution of the solution, the salts of iron are no longer capable of acting, is by the conversion of the prussic acid into sulphocyanide of ammonium. For this purpose the prussic acid is to be warmed on a watch-glass with a drop of sulphide of ammonium, until the solution has become colourless. The addition of a trace of a solution of a persalt of iron will show, by the formation of a blood-red colour, the presence of the acid sought. A very neat mode of applying this test is to place one drop of sulphide of ammonium on a watch-glass inverted over another containing the suspected fluid. On leaving the apparatus in a warm place, arranged in this manner, for a short time, the upper glass will be found to contain sulphocyanide of ammonium, which, after drying, will be in a state well adapted for showing the reaction with a persalt of iron.—C.G.W.

HYDRODYNAMICS. The mechanical science which treats of the motion of fluids. This science has, of course, most important bearings on the pumping-engines, water-wheels, &c., employed to facilitate the operation of the miner. It is not, however, possible to embrace this, which belongs to mechanical engineering, in this work. See HYDRAULIC MACHINERY, FOR MINES.

HYDRO-EXTRACTOR. A name sometimes given to the machines employed for expelling the water from woven goods. See DESICCATION.

HYDROFLUORIC ACID. It was observed by Schwankhardt, in 1670, that fluor spar and oil of vitriol would eat into glass. Scheele, in 1771, determined that this peculiar property was due to the liberation of an acid from the fluor spar.

Hydrofluoric acid is best obtained by placing finely-powdered fluor spar in a leaden retort, and twice its weight of highly-concentrated oil of vitriol. By a gentle heat the gas is distilled over, which must be collected in a leaden tube, in which, by means of a freezing mixture, it may be condensed into a liquid. If a solution of this acid in water is required, the extremity of the tube from the retort is carried into water.

Hydrofluoric acid attacks glass with great readiness, by acting on its silica.

Glass upon which any design is to be etched, is covered with an etching-wax, and the design made in the usual manner; this is placed over a leaden vessel, in which is a mixture of fluor spar and oil of vitriol; a gentle heat being applied, hydrofluoric acid escapes, and immediately attacks the glass. See FLUORINE.

HYDROGEN. (*Hydrogène*, Fr.; *Wasserstoff*, Ger.) A permanently gaseous elementary body, the lightest of all known substances, its specific gravity being ·0693; 100 cubic inches weighing, under ordinary pressure and temperature, only 2·14 grains. It is therefore nearly 14·5 times lighter than atmospheric air.

From its extreme lightness it was formerly used for filling balloons, but it has been superseded for that purpose by ordinary coal-gas, which can be obtained at a much cheaper rate; the difference of buoyant power being compensated by increasing considerably the size of the balloon. It is itself inflammable, but will not support combustion. In burning it combines with oxygen, forming water, which contains $\frac{1}{9}$th of its weight of hydrogen.

It is generally prepared by the action of dilute sulphuric acid on zinc, although there are many other processes which furnish it; as the decomposition of steam by iron fillings with the aid of heat, the decomposition of water by electricity, &c.

In the act of combining with oxygen, as when burnt in the oxyhydrogen blowpipe, the greatest possible heat is obtained; a piece of stout platinum wire being fused when placed in the flame, which cannot be affected by the greatest heat of our furnaces.

Hydrogen is often used in the process of soldering metals; it which case it is requisite to bring the two surfaces of the metal together in a perfectly metallic state at a high temperature. Hydrogen effects this completely; by its combustion it supplies the heat, and by entering into combination with the oxygen of the air, prevents the formation of oxides, which are so easily formed at the temperature required for the melting of the metals, and which, when present, prevent the union of the surfaces. See Autogenous Soldering.

Hydrogen is often used also for the reduction of metals from their different combinations; the reduction is effected by passing a current of hydrogen over the compounds heated to redness.

HYDROGEN, PHOSPHORETTED, or *Phosphamine.* A compound of hydrogen and phosphorus, PH^3. It is spontaneously inflammable if it escapes into the air.

HYDROGEN, SULPHURETTED. See Sulphuretted Hydrogen.

HYDROMETER. An instrument for ascertaining the specific gravities of liquids. Baumé's hydrometer, which is much used in France, and other countries of the continent of Europe, when plunged in pure water at the temperature of 58° Fahr., marks 0 upon its scale; in a solution containing 15 per cent. of common salt (chloride of sodium), and 85 of water by weight, it marks 15°; so that each degree is meant to indicate a density corresponding to one per cent. of that salt. See Alcoholmeter.

HYDROPHANE. A variety of opal which readily imbibes water, and when immersed it becomes transparent, though opaque when dry. It is found in Hungary and in Ireland, near the Giant's Causeway, and at Crosreagh, Ballywillin.

HYDROSTATIC BALANCE. HYDROSTATIC PRESS. A balance or a press constructed in obedience to the law that *In a quantity of fluid submitted to compression, the whole mass is equally affected, and similarly in all directions.* The subject belongs to Practical Engineering.

HYDROSTATICS. The science which treats of the equilibrium of fluids, and of the pressure exerted by them.

In the engineering arrangements by which water is supplied to towns, hydrostatics becomes of the utmost importance. The highest possible level is obtained for the reservoir; and from this a series of pipes is arranged through all the streets and houses. The tendency of the water is to rise to its original level, and hence all the pipes are filled with water, and in all such as are below the level of the water in the reservoir a pressure upward is exerted equal to the height of the reservoir above that point; and if a hole is pierced in the pipe, the water jets out with a force equal to this pressure. In the highest houses, the water perhaps only finds its level, and flows out without pressure quickly. See Hydraulic Crane; Hydraulic Machinery, for Mines.

HYDROSULPHURETS or *Hydrosulphides.* Chemical compounds of bases with sulphuretted hydrogen, or hydrosulphuric acid.

HYDROXYL. A radical containing HO^2 ($\mathbf{HO}$). Great prominence has been given to it in recent chemical theories. *Peroxide of hydrogen*, or *oxygenated water*, may be regarded as free hydroxyl, since it contains the molecule, or two atoms, of hydroxyl $2HO^2$ ($\mathbf{H^2O^2}$).

HYGROMETER (*ὑγρός, moist, μέτρον, measure*), is an instrument which measures the amount or degree of moisture in the atmosphere.

Water, both liquid and solid, always tends to assume the gaseous form, and in so doing exerts an elastic force, increasing as the temperature rises, but in a higher ratio, and in order that such increasing force may be exerted when water is confined in a given space, it is necessary that a larger and larger quantity of water should become vapour; if the weight of water be not increased, its elastic force will rise with its temperature, but in a much less ratio. For aqueous vapour, like any other gas, tends to expand by $\frac{1}{491}$th part of its volume at 32° Fahr. for every degree of increased temperature. The terms *saturated* and of *maximum elastic force* are applied to aqueous vapour, when any reduction of temperature or increase of pressure causes some of the vapour to be condensed. The temperature of saturated vapour is said to be at the dew-point. Thus, aqueous vapour of 60° Fahr. and of an elastic force of 518 inches is saturated, and 60° is its dew-point. These remarks apply to aqueous vapour mixed with air; differing only in vapour spreading less rapidly in a space filled with air than in a vacuous space. Air is said to be saturated with moisture when the aqueous vapour it contains is of maximum elastic force, the temperature of the air is then called its dew-point.

Daniell's hygrometer was the first accurate instrument invented of the kind: it consists of a small glass siphon, at each end of which is a small glass bulb about 1½ inch in diameter, a small but delicate thermometer is placed in the longer leg, as much ether is poured into the lower bulb, which is of black glass, as will half cover the enclosed thermometer bulb; before sealing the tube the ether is boiled to drive out all the air; the instrument is completed by covering the upper bulb with muslin. It is placed on a small brass stand, on which is placed another thermometer, whose readings show the air-temperature, at the time the siphon shows the dew-point. To make an observation, all the ether in the tube is collected into the lower bulb, and from a tube or bottle a few drops of ether are poured on the muslin of the upper bulb, its evaporation condenses the vapour within, fresh vapour flows along the bent tube from the lower bulb, gradually the temperature is reduced, until the dew-point of the surrounding air is reached, immediately a film of condensed vapour from the air surrounds the black glass bulb like a ring, at the level of the ether within it, and if the thermometer be read directly, almost the true temperature of the dew-point can be obtained, while the exterior thermometer will be that of the surrounding air. The expenditure of ether is an objection to this instrument, while its portability is a great recommendation.

Subsequently, several other hygrometers were devised, but none that can compare with Regnault's Condenser Hygrometer, which is a perfect instrument of its kind. It consists of a very thin and brightly-polished silver thimble, 45 mm. high and 20 mm. in diameter, fitted to a glass tube, which is again fixed by a small lateral tube, and a metallic tube, to a stand; the upper end of the glass tube is closed by a cork bearing a thin glass tube descending nearly to the bottom of the silver thimble, and a very delicate thermometer, the pear-shaped bulb of which is in the centre of the thimble; an exactly similar thermometer, similarly placed within a glass tube and silver thimble, is mounted on the other side of the stand, but the cork is not penetrated by any glass tube. To make an observation, as much good ether as will more than a third fill the thimble is poured into the lesser tube of those first described; the cork is then fitted air-tight and the instrument is put in connection, by means of a caoutchouc tube, with a common aspirator. Water flowing from the aspirator, air is drawn through the tube, and bubbling up through the ether, causes a sufficiently rapid evaporation. After a minute or two dew will be formed on the polished surface of the thimble, the thermometer should be instantly read, and the stream from the aspirator stopped, another reading should be taken on the instant of the evaporation of the dew; within a few minutes the process of collecting and evaporating the dew may be repeated many times, and the mean of repeated readings will give a very exact point. The other thermometer will give the surrounding temperature. The costliness of this instrument has prevented the general use it deserves. Instrument-makers have rendered it less costly by omitting the second thermometer and its appendages, and substituting a tube of black glass for the silver thimble. For ordinary use a common test-tube, with about 1½ inch depth of ether, in which is inserted a delicate tube-thermometer, and a glass tube may be used successfully by blowing through the tube, which should be of considerable length to reduce the temperature. Professor Connell has invented an hygrometer, where an exhausting syringe is used to lower the temperature.

A more important instrument than either of the above mentioned is the psychrometer, or wet and dry bulb hygrometer. While with the others the constant repetition of an *experiment* is necessary, this reduces it simply to the reading of an *observation.* It consists of two delicate thermometers, one recording the ordinary temperature of the air, the bulb of the other is covered with muslin, round the neck a lampwick is twisted, conducting to a cistern of rain or distilled water, the best form of which is a short small-necked glass bottle. The thermometers should be exactly similar, and placed at about from 2 to 4 inches apart, and parallel with each other, mounted on metal scales.

When the air is completely saturated, or in that condition when it will take up no more moisture, the readings of the two will be the same, but as the atmosphere becomes drier, evaporation becomes more rapid and the mercury in the wet bulb will fall more or less degrees below the ordinary temperature. Evaporation will proceed from the wet bulb even below the freezing point, but the readings should then be taken with great care, as the differences will always be small. The reading of the wet bulb will give the temperature of evaporation, and from that and the temperature of the ordinary air has to be deduced the dew-point.

HYMENÆA COURBARIL. A tree growing in South America, from which the resin *anime* exudes. See ANIME.

HYOSCYAMINE. A crystalline alkaloïd obtained from the Henbane (*Hyoscyamus niger*). It is also found in the thorn-apple (*Datura Stramonium*), and is therefore sometimes called *Daturine.*

HYPERSTHENE. A foliated mineral resembling diallage, having a pearly or metallic lustre on the cleavage planes. It is a silicate of protoxide of iron and magnesia; found at St. Paul's Island, Labrador, and elsewhere.

HYPERSTHENITE, or *Hypersthene Rock.* A rock resembling gabbro, composed of labrador-felspar and hypersthene.

HYPOCHLORIC ACID. ClO^4 ($\mathbf{Cl^2O^4}$) *At. wt.* 67·5. When finely-powdered chlorate of potash is gradually mixed into a paste with strong sulphuric acid, and heated in a bath of alcohol and water, a yellow gas is disengaged, which is this hypochloric acid, or the *peroxide of chlorine.* Although of much interest as a chemical compound, it has no use in the arts. See Watts's 'Dictionary of Chemistry.'

HYPOCHLOROUS ACID. ClO ($\mathbf{Cl^2O}$) *At. wt.* 43·5. This acid is best obtained by diffusing red oxide of mercury finely divided through twelve times its weight of water, which is introduced into a bottle containing chlorine, and agitated until the gas is absorbed. An oxychloride of mercury is formed, which is removed by subsidence. The weak fluid obtained is put into a flask, and heated in a water-bath, when the evolved gas is collected in a smaller portion of water, which becomes a pure solution of hypochlorous acid.

The salts are termed hypochlorites. See CHLORINE and BLEACHING.

HYPOSULPHATES. Saline compounds formed by the union of hyposulphuric acid with bases.

HYPOSULPHITES. Saline compounds formed by the union of hyposulphurous acid with bases.

Hyposulphate of Soda. The salts of the hyposulphuric acid are obtained from the hyposulphate of manganese, which is itself thus prepared: finely-divided binoxide of manganese is suspended in water, artificially cooled, and a stream of sulphurous acid passed through it. The binoxide gives up half its oxygen, becoming protoxide, which unites with the hyposulphuric acid which is formed, producing the soluble hyposulphate of manganese, which is separated from the excess of binoxide by filtration.

The following equation represents the reaction:—

$$MnO^2 + 2SO^2 = MnO,S^2O^5.$$

If the temperature were allowed to rise, sulphuric acid would be formed, and not hyposulphuric:—

$$MnO^2 + SO^2 = MnO,SO^3.$$

The hyposulphuric acid, unlike the hyposulphurous acid, may be obtained in the free state, and its solution permits even of being evaporated *in vacuo*, until it acquires the density of 1·347; but if carried further, it is decomposed into sulphuric and sulphurous acids.

The acid is obtained in the free state by adding baryta water to the hyposulphate of manganese; the soluble hyposulphate of baryta, filtered from the oxide of manganese, and precipitated exactly by the cautious addition of sulphuric acid, and filtered from the precipitate of sulphate of baryta, yields the pure solution of the acid, which may be evaporated *in vacuo*, as above stated.

It has no odour, but a very sour taste.

The hyposulphate of soda may be made directly from the manganese salt or from the free acid.

All the hyposulphates are soluble; they have not as yet met with any commercial application.

Hyposulphite of Soda. This salt, now so extensively used for photographic purposes, was first introduced by Sir J. Herschel. It may easily be prepared by the following process: viz. by transmitting through a solution of sulphide of sodium (prepared by fusing together in a covered crucible equal weights of carbonate of soda, and flowers of sulphur), a stream of sulphurous acid until it ceases to be absorbed; the liquid is then filtered and evaporated, when the hyposulphite of soda, $NaO,S^2O^2 + 5HO$ ($\mathbf{Na^2O,S^2O^2 + 5H^2O}$) crystallises out.

Another and perhaps better process consists in digesting a solution of sulphite of soda on flowers of sulphur. The sulphur gradually dissolves, forming a colourless solution, which yields on evaporation crystals of hyposulphite of soda; the reaction being shown by the following equation:—

$$NaO,SO^2 + S = NaO,S^2O^2 \quad (\mathbf{Na^2O,SO^2 + S = Na^2O,S^2O^2}).$$

The baryta salt may be obtained in small brilliant crystals, by mixing dilute solutions of chloride of barium and hyposulphite of soda.

The hyposulphurous acid is incapable of existing in the free state, for almost immediately on the addition of an acid to the solution of its salts, it is decomposed into sulphurous acid, with liberation of sulphur. ($S^2O^2 = SO^2 + S$).

The soluble hyposulphites have the power, in a marked degree, of dissolving certain salts of silver, as the chloride, iodide, &c., which are insoluble in water; forming with them soluble salts, whose solutions possess an intensely sweet taste, although the solutions of the hyposulphites alone possess a disagreeable bitter taste.

From the above reaction arises the principal value of the hyposulphite of soda, which is used by the photographer to dissolve off from the photograph, after the action of the light on it, all the undecomposed silver salt, thus preventing the further action of the light on the picture.

A double hyposulphite of soda and gold is used for gilding the daguerreotype plate, and for colouring the positive proof obtained in photographic printing. This double salt may be obtained in a state of purity, by mixing concentrated solutions of 1 part of chloride of gold, and 3 parts of hyposulphite of soda; by the addition of alcohol it is precipitated; the precipitate must be re-dissolved in a small quantity of water, and again precipitated by alcohol.

HYSON. A green tea. See Tea.

HYSTATITE. A variety of titaniferous iron from Arendal in Norway.

I

IBEX. An animal of the goat-kind, the hair of which is esteemed for some kinds of manufacture. Two species occur in Europe: the common ibex (*Capra Ibex*), inhabiting the Alps, and *C. Pyrenaicus*, found in the Pyrenees: whilst other species are found in Asia and in Africa. The wool of the *skyn*, or ibex of Little Thibet, has been used in manufacturing certain fabrics.

ICE. Water begins to solidify or to become ice at 32° F. See Freezing.

ICE-HOUSE. (*Glacière*, Fr.; *Eishaus*, Ger.) For the uses of common life, in these climates, the most economical and convenient means of refrigeration in hot weather may be procured by laying up a store of ice in winter, in such circumstances as will preserve it solid during summer.

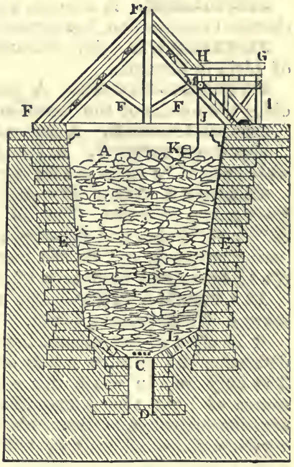
An ice-house should not be regarded as an object of mere luxury; in the southern countries of Europe it is considered among people in easy circumstances as an indispensable appendage to a country mansion. During the dog days, especially at those periods, and in those districts where the *sirocco* blows, a lassitude and torpor of mind and body supervene, with indigestion or total loss of appetite, and sometimes dysenteries, which are obviously occasioned by the excess of heat, and are to be prevented or counteracted chiefly by the use of cold beverages. By giving tone to the stomach, iced drinks immediately restore the functions of the nervous and muscular systems when they are languid; while they enable persons in health to endure without much inconvenience an atmosphere so close and sultry as would be intolerable without this remedy. Ice-houses, moreover, afford to country gentlemen a great advantage in enabling them to preserve their fish, butcher's meat, dead poultry, and game, which would otherwise, in particular states of the weather, immediately spoil. Considering at how little expense and trouble an ice-house can be constructed, it is surprising that any respectable habitation in the country should not have one attached to it. The simplest and most scientific form is a double cone, that is, two cones joined base to base; the one being of stones or brick-work, sunk under ground, with its apex at the bottom, into which the ice is rammed; the other being a conical roof of carpentry, covered with thatch, and pointed at top. The entrance should be placed always on the north side; it should consist of a corridor or porch with double doors, and be screened from the sunbeams by a small shrubbery. Such are the principles upon which an ice-house should be formed; but they will be better understood by the following explanation and figure.

A dry and sandy soil if possible should be selected; and here a cavity is to be dug, about 16 feet in diameter, terminating below like the point of a sugar-loaf. Its ordinary depth for a family may be about 24 feet; but the larger its dimensions are, the longer will it preserve the ice, provided it be filled. In digging, the workman should slope the ground progressively towards the axis of the cone, to prevent the earth falling in. This conical slope should be faced with brick or stone work about one foot thick, and jointed with Roman cement, so as to be air- and water-tight. A well is to be excavated, at the bottom 2 feet wide and 4 deep, covered at top with an iron grating for supporting the ice, and letting the water drain away.

The upper cone may likewise be built of brick-work, and covered with thatch; such a roof would prove the most durable. This is the construction shown in *fig.* 1205. Whatever kind of roof be preferred, there must be left in it an oblong passage into the interior. This porch should face the north, and be at least 8 feet long by 2½ feet wide; and perfectly closed by a well-fitted door at each end. All round the bottom of this conical cover, a gutter should be placed to carry off the rain to a distance from the ice-house, and prevent the circumjacent ground from getting soaked with moisture.

Fig. 1205 shows the section of a well-constructed ice-house, Under the ice-chamber A the ice is rammed into the space B. C is the grate of the drain-sink D. The portion E E is built in brick or stone; the base L of the ice-chamber slopes inwards towards the centre at C. The upper part of the brick-work E E is a little way below the level of the ground. The wooden framework, F F F F, forms the roof, and is covered with thick thatch. G H is the wooden work of the door I. At K the bucket is seen for lifting up a charge of ice, by means of the cord J passing over the pulley M, which enables the servant to raise it easily.

1205



The ice-house should have no window to admit light, but be, so to speak, hermetically sealed in every point, except at its cesspool, which may terminate in a water-trap to prevent circulation of air.

A clear day should be selected for charging the ice-house; but before beginning to fill, a quantity of long dry straw should be laid on the bottom crosswise; and as the ice is progressively introduced, straw is to be spread against the conical sides, to prevent the ice from coming into contact with the brick or stone-work. The more firmly compacted the ice is, the better does it keep; with which view it should be broken into pieces with mallets before being thrown in. No layers of straw should be stratified among the ice, for they would make its body porous. Some persons recommend to pour in a little water with the successive layers of ice, in order to fill up its small crevices and convert the whole into one mass.

Over the top layer a thick bed of straw should be spread, which is to be covered with boards surmounted with heavy stones, to close up the interstices in the straw. The inner and outer doors should never be opened at once; but the one should always be shut before the other is opened.

Dry snow well rammed keeps equally well with hard ice, if care be taken to leave no cavities in the mass, and to secure its compactness by sprinkling a little water upon the successive charges.

To facilitate the extraction of the ice, a ladder is set up against its sloping wall at one side of the door, and left there during the season.

Ice *imported* in 1871:—

	Tons	£	Tons	£

ICE-MANUFACTURE. Siebe's, Harrison's, and Carré's machines for making ice are described at page 488. See FREEZING.

ICE-PLANT. The *Mesembryanthemum crystallinum* is so called in allusion to the appearance of the surface of the leaves, which are studded with small watery vesicles. The ashes of the plant yield soda.

ICE-SPAR. A transparent glassy felspar, referred partly to sanidine and partly to anorthite.

ICELAND MOSS (*Lichen d'Islande*, Fr.; *Isländische Flechte*, Ger.) is a lichen, the *Cetraria Islandica*, which contains a substance soluble in hot water, but forming a jelly when it cools, styled *lichenine* by M. Guérin. This moss is called in the Pharmacopœia *Lichen Islandicus.* It appears to have derived its name from the circumstance that the Icelanders first discovered its medicinal qualities. Lichenine is prepared by extracting first of all from the plant a bitter colouring matter, by digesting 1 lb. of it in 16 lbs. of cold water containing 1 ounce of pearlash; then draining the lichen, edulcorating with cold water, and boiling it in 9 lbs. of boiling water, till 3 lbs. be evaporated. The jelly which forms, upon cooling the filtered solution, is dark coloured, but, being dried and redissolved in hot water, it becomes clear and colourless. Lichenine consists of 39·33 carbon, 7·24 hydrogen, and 55·43 oxygen. The mucilage of Iceland moss is preferred in Germany to common paste for dressing the warp of webs in the loom, because it remains soft, from its hygrometric quality. It is also mixed with the pulp, for sizing paper in the vat. For several curious compounds obtained from Iceland moss, see Watts's 'Dictionary of Chemistry.'

ICELAND SPAR. Crystallised carbonate of lime, of which the most beautiful specimens are brought from Iceland. These are remarkable for their double refraction; and hence this crystal is sometimes called *doubly-refracting spar.*

IDOCRASE. A mineral known also as *Vesuvian*, closely resembling garnet in chemical composition, but crystallising in the pyramidal system.

IDRIALINE. A hydrocarbon occurring with cinnabar in the quicksilver mines of Idria in Carniola.

IDWALE-STONE. A peculiar Welsh hone-stone. It is obtained from the older slate-rocks of the Snowdon district.

IGLESIASITE. A carbonate of lead and zinc, from Sardinia.

ILIXANTHINE. A substance derived from the leaves of the common holly, which might be employed for dyeing yellow.

ILLOOPA OIL. The produce of the *Bassia longifolia*, one of the most useful trees grown in India. The oil might be denominated a butter, as it is solid from 82° to 84° Fahr., and liquefies at 90° to 95° Fahr. It is used in India for illuminating purposes, and for the manufacture of soap. Samples of this oil were sent to the International Exhibition of 1862, by the Singapore Local Committee.

ILLUMINATION. The means of determining the relative values of various sources of illuminating power.

It is often of the utmost importance that we should be enabled, with facility, to determine the relative values of the light which we obtain from artificial sources. The only way in which this can be effected, is by comparing with some standard source of light the illuminating sources employed. Dr. Ure, who was on several occasions called on to direct his attention to inquiries of this nature, instituted many very ingenious and exact experiments; to some of these it appears important that we should direct especial attention. Of the original paper on the cost of illumination, many parts are now obsolete; but, as much of it is still of considerable practical value, the following selections have been made, all such being distinguished by Dr. Ure's name. After many experiments to determine a standard, Dr. Ure says:—

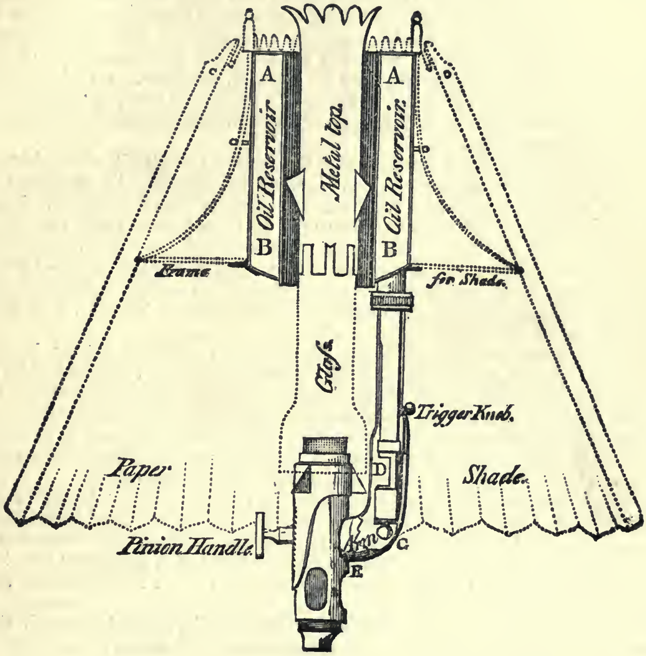
'After comparing lights of many kinds, I find every reason to conclude that a large wax candle, of three to the pound, either long or short, that is, either 12 or 15 inches in length, as manufactured by one of the great wax-chandlers in London, and furnished with a wick containing 27 or 28 threads of the best Turkey cotton, is capable of furnishing a most uniform, or nearly invariable standard of illumination. It affords one-tenth of the light emitted by one of the Argand lamps of the Trinity House, and one-eleventh of the light of my mechanical lamp, when each lamp is made to burn with its maximum flame, short of smoking.'

Dr. Ure, however, for many of his determinations employed the French mechanical lamp, known as Carcel's lamp; and in connection with this the following remarks occur:—

'Mr. Samuel Parker, long advantageously known to the public for his sinumbral and pneumatic fountain-lamps, as well as other inventions subservient to domestic comfort, having obtained a patent for a new lamp, in which the oil is heated by a very simple contrivance, in the cistern, to any desired degree, before arriving at the wick. I instituted an extensive series of experiments to determine its value in the production of light, and consumption of oil, compared to the value of other lamps, as well as candles in these respects.'

In *fig.* 1206, A, A, B, B, is a section of the cylinder which constitutes the cistern; the oil being contained between the inner and outer cylinders, and receiving heat from the flame of the lamp which passes up through the inner cylinder, and is reverberated more or less against its sides by the top of the metal chimney being notched and bent back. D is a slide-valve, which is opened to allow the oil to descend to the wick, and is shut when the cistern is to be separated from the pipe of supply, at E, for the purpose of recharging it with oil. The flame is modified, not by raising or lowering the wick, as in common lamps, but by raising or lowering the bell-mouthed glass chimney, which rests at its bottom on three points, and is moved by means of the rack-work mechanism F. The concentric cylindric space A, A, B, B, contains a pint imperial, and should be made entirely full before lighting the lamp; so as to leave no air in the cistern, which, by its expansion with the heat, would inevitably cause an overflow of the oil.

1206



The following arrangement was adopted in these experiments for determining the relative illumination of the different lights. Having trimmed, with every precaution, my French mechanical lamp, and charged it with pure sperm-oil, I placed it upon an oblong table, at a distance of 10 feet from a wall, on which a white sheet of paper was stuck. One of Mr. Parker's hot-oil lamps, charged with a quantity of the same oil, was placed upon the same table; and each being made to burn with its maximum brilliancy, short of smoking, the relative illumination of the two lamps was determined by the well-known method of the comparison of shadows; a wire a few inches long, and of the thickness of a crow-quill, being found suitable for enabling the eye to estimate very nicely the shade of the intercepted light. It was observed in numerous trials, both by my own eyes and those of others, that when one of the lamps was shifted half an inch nearer to or further from the paper screen, it caused a perceptible difference in the tint of the shadow. Professor Wheatstone kindly enabled me to verify the precision of the above method of shadows, by employing, in some of the experiments a photometer of his own invention, in which the relative brightness of the two lights was determined by the relative brightness of the opposite sides of a revolving silvered ball, illuminated by them.

1. The mechanical lamp was furnished with a glass chimney 1·5 inch in diameter at the base, and 1·2 at top; the wide bottom part was 1·8 inch long, and the narrow upper part 8 inches. When placed at a distance of 10 feet from the wall, its light there may be estimated as the square of this number, or 100. In the first series of experiments, when burning with its maximum flame, with occasional flickerings of smoke, it emitted a light equal to that of 11 wax candles, and consumed 912 grains of oil per hour. The sperm-oil was quite pure, having a specific gravity of 0·874

compared with water at 1000. In a subsequent series of experiments, when its light was less flickering, and equal only to that of 10 wax candles, it consumed only 815 grains, or 0·1164 of a pound per hour. If we multiply this number into the price of the oil (8*s.* per gallon) per pound, 11*d.*, the product 1·2084*d.* will represent the relative cost of this illumination, estimated at 100.

2. The hot-oil lamp burns with a much steadier flame than the mechanical, which must be ascribed in no small degree to the rounded slope of the bell-mouthed glass chimney, whereby the air is brought progressively closer and closer into contact with the outer surface of the flame, without being furiously dashed against it, as it is by the rectangular shoulder of the common contracted chimney. When charged with sperm-oil, and made to burn with its maximum flame, this lamp required to be placed one foot further from the screen than the mechanical lamp, in order that its shadow should have the same depth of tint. Hence, its relative illumination was, in that case, as the square of 11 to the square of 10; or as 121 to 100. Yet its consumption of oil was only 696 grains, or somewhat less than 0·1 of a lb. per hour. Had its light been reduced to 100, it would have consumed only 576 grains per hour, or ·082 of a lb. If we multiply this number by 11*d.*, the product 0·902*d.* will represent the relative cost of 100 of this illumination.

3. The hot-oil lamp being charged with the southern whale-oil, of specific gravity 0·926, at 2*s.* 6*d.* per gallon, or 3¾*d.* per lb., when burning with its maximum flame, required to be placed 9 feet and 1 inch from the screen to drop the same tint of shadow upon it as the flames of the other two lamps did at 10 and 11 feet with the sperm-oil. The square of 9 feet and 1 inch = 82 is the relative illumination of the hot-oil lamp with the southern whale-oil. It consumed 780 grains, or 0·111 of a pound per hour; but had it given 100 of light it would have consumed 911 grains, or 0·130 of a pound, which number being multiplied by its price 3¾*d.*, the product 0·4875*d.* will represent the relative cost of 100 of this light.

4. A hot-oil lamp charged with olive-oil of specific gravity 0·914, at 5*s.* 6*d.* per gallon, or 7½*d.* per lb. when burning with its maximum flame, required to be placed at 9 feet 6 inches, to obtain the standard tint of shadow upon the screen. It consumed 760 grains per hour. The square of 9½ feet is 90½, which is the relative intensity of the light of this lamp. Had it emitted a light = 100, it would have consumed 840 grains, or 0·12 of a pound per hour—which number multiplied by the price per pound, gives the produce 0·9*d.* as the relative cost of 100 of this light.

5. A hot-oil lamp charged with Price and Co.'s cocoa-nut oil (oleine), of specific gravity 0·925, at 4*s.* 6*d.* per gallon, or 5¾*d.* per lb. had to be placed 9 feet from the screen, and consumed 1,035 grains per hour. Had its light been 100 instead of 81 (9^2), the consumption would have been 1,277 grains, or 0·182 of a pound per hour! which number multiplied by its price per pound, the product 1·031*d.* will represent the cost of 100 of this illumination.

6. In comparing the common French annular lamp in general use with the mechanical lamp, it was found to give about one-half the light, and to consume two-thirds of the oil of the mechanical lamp.

7. Wax candles from some of the most eminent wax-chandlers of the metropolis were next subjected to experiment; and it is very remarkable that, whether they were threes, fours, or sixes in the pound, each afforded very nearly the same quantity of light, for each required to be placed at a distance of 3 feet from the screen to afford a shadow of the same tint as that dropped from the mechanical lamp, estimated at 100. The consumption of a genuine wax candle, in still air, is, upon an average of many experiments, 125 grains per hour, but as it affords only $\frac{1}{11}$th of the light of the mechanical lamp, 11 times 125 = 1,375 grains, or 0·1064 of a pound, is the quantity that would need to be consumed to produce a light equal to that of the said lamp. If we multiply that number by the price of the candles per lb. = 30*d.* the product = 5·892*d.* is the cost of 100 of illumination by wax. A wax candle, three in the pound (short), is one inch in diameter, 12 inches in length, and contains 27 or 28 threads, each about $\frac{1}{10}$th of an inch in diameter. But the quality of the wick depends upon the capillarity of the cotton fibrils, which is said to be the greatest in the Turkey cotton, and hence the wicks for the best wax candles are always made with cotton yarn imported from the Levant. A wax candle, three in the pound (long), is ⅞ths of an inch in diameter, 15 inches long, and has 26 threads in its wick. A wax candle, six to the pound, is 9 inches long, ⅘ths of an inch in diameter, and has 22 threads in its wick. The light of this candle may be reckoned to be, at most, about $\frac{1}{11}$th less than that of the threes in the pound. A well-made short three burns with surprising regularity in still air, being at the rate of an inch in an hour and a half, so that the whole candle will last 18 hours. A long three will last as long, and a six about 9½ hours. Sp. gr. of wax = 0·960.

8. A spermaceti candle, three in the pound, is $\frac{9}{10}$ths of an inch in diameter, 15 inches long, and has a plaited wick, instead of the parallel threads of a wax candle. The

same candles, four in the pound, are $\frac{8}{10}$ths of an inch in diameter, and 13½ inches long. Each gives very nearly the same quantity of light as the corresponding wax candles: viz. $\frac{1}{11}$th of the light of the above mechanical lamp, and consumes 142 grains per hour. Multiplying the last number by 11, the product, 1,562 grains = 0·223 of a pound, would be the consumption of spermaceti requisite to give 100 of illumination. Multiplying the last number by 24*d.*, the price of the candles per pound, the product, 5·352*d.* is the relative cost of 100 of this illumination.

9. *Stearic acid* candles, commonly called German wax, consume 168·5 grains, or 0·024 of a pound per hour, when emitting the same light as the standard wax candle. Multiplying the latter number by 11, and by 16*d.* (the price of the candles per lb.), the product 4·224*d.* will represent the relative cost of 100 of this illumination.

10. Tallow candles: moulds, short threes, 1 inch in diameter, and 12½ in length; ditto long threes, $\frac{9}{10}$ths of an inch in diameter, and 15 in length; ditto, long fours, $\frac{8}{10}$ths of an inch in diameter, and 13¾ in length. Each of these candles burns with a most uncertain light, which varies from $\frac{1}{12}$th to $\frac{1}{16}$th of the light of the mechanical lamp—the average may be taken at $\frac{1}{14}$th. The three consume each 144 grains, or 0·2 of a pound, per hour; which number, multiplied by 14, and by 9*d.* (the price per pound), gives the product 2·52*d.* for the relative cost of 100 of this illumination.

11. *Palmer's* spreading wick candles. Distance from the screen 3 feet 4 inches, with a shadow equal to the standard. Consumption of tallow per hour 232·5 grains, or 0·0332 of a pound. The square of 3 feet 4 inches = 11·09 is the relative illumination of this candle = 11·09 : 0·0332 :: 100 : 0·3 × 10*d.* = 3*d.* is the relative cost of this illumination.

12. Cocoa-nut stearine candles consumed each 168 grains per hour, and emitted a light equal to $\frac{1}{16}$th of the standard flame. Multiplying 168 by 16, the product 30·88 grains, or 0·441 of a lb., is the quantity which would be consumed per hour to afford a light equal to 100. And 0·441 multiplied by 10*d.*, the price per lb., gives the product 4·441*d.* as the cost of 100 of this illumination per hour.

13. A gas Argand London lamp, of 12 holes in a circle of ¾ of an inch in diameter, with a flame 3 inches long, afforded a light = 78½ compared to the mechanical lamp: and estimating the light of the said mechanical lamp as before at 100, that of the hot-oil lamp is 121, and that of the above gas-flame 78·57, or in round numbers 80, *and the common French lamp in general use* 50.

Collecting the preceding results, we shall have the following tabular view of the cost per hour of an illumination equal to that of the mechanical lamp, reckoned 100, or that of eleven wax candles, three to the pound.

Table of Cost per Hour of One Hundred of Illumination.

		Pence		Pence
1.	Parker's hot-oil lamp, with southern whale oil	0·4875	or about	½*d.*
2.	Mechanical or Carcel lamp, with sperm-oil	1·2804	„	1¼
3.	Parker's hot-oil lamp, with sperm-oil	0·902	„	1
4.	Ditto ditto common olive-oil	1·900	„	1
5.	Ditto ditto cocoa-nut oleine or oil	1·031	„	1
6.	French lamp in general use, with sperm-oil	1·7072	„	1¾
7.	Wax candles	5·822	„	6
8.	Spermaceti candles	5·352	„	5¼
9.	German wax (Stearic acid) ditto	4·224	„	4¼
10.	Palmer's spreading wick candles	2·800	„	2¾
11.	Tallow (mould) candles	2·520	„	2½
12.	Cocoa-nut stearine of Price and Co.	4·41	„	4½

The following Table contains, according to Péclet, the illuminating powers of different candles, and their consumption of material in an hour; the light emitted by a *Carcel* Argand lamp, consuming 42 grammes (= 42 × 15½ grains) in an hour, being called 100:—

	Intensity of light	Consumption per hour
Tallow candles, 6 in lb.	10·66	8·51
Stearine, or pressed tallow, 8 in lb.	8·74	7·51
„ „ 5 in lb.	7·50	7·42
Wax candles, 5 in lb.	13·61	8·71
Spermaceti, 5 in lb.	14·40	8·92
Stearic acid, commonly called stearine, 5 in lb.	14·40	9·33

The subjoined Table shows the economical ratios of the candles, where the second column gives the quantity of material in grammes which is requisite to produce as much light as the Carcel lamp:—

	Quality of material	Price per kilogramme	Cost of light per hour
Tallow candle, 6 per lb. . .	70·35	1 f. 40 c.	9·8 c.
,, ,, 8 per lb. . .	85·92	1 f. 40 c.	12·0 c.
Pressed tallow, 5 per lb. .	98·93	2 f. 40 c.	23·7 c.
Wax candle, 5 per lb. . .	64·04	7 f. 60 c.	48·6 c.
Spermaceti ditto, 5 per lb. .	61·94	7 f. 60 c.	47·8 c.
Stearine, 5 per lb. . . .	65·24	6 f.	37·1 c.

These results may be compared with mine given above. A kilogramme, or 1,000 grammes = 15,440 grains = 2¼ lbs. avoirdupois.'—*Ure.*

The rule observed in the determination of these questions of illuminating power, is, according to the laws of optics, that the sum of the impinging rays from any source, is inversely as the square of the distance from their source.

'The numerical estimation of the degrees of intensity of light constitutes that branch of Optics which is termed PHOTOMETRY.

'If light be a material emanation, a somewhat scattered in minute particles in all directions, it is obvious that the same quantity which is diffused over the surface of a sphere concentric with the luminous points, if it continue its course, will successively be diffused over larger and larger concentric spherical surfaces; and then its intensity, or the number of rays which fall on a given space, in each will be inversely as the whole surfaces over which it is diffused; that is, inversely as the square of their radii, or of their distances from the source of light. . . . . Let a candle be placed behind an opaque screen, full of small equal and similar holes; the light will shine through these, and be intercepted in all other parts, forming a pyramidical bundle of rays, having the candle in the common vertex. If a sheet of white paper be placed behind this, it will be seen dotted over with small luminous specks, disposed exactly as the holes in the screen. Suppose the holes so small, their number so great, and the eye so distant from the paper that it cannot distinguish the individual specks, it will still receive a general impression of brightness; the paper will appear illuminated, and present a mottled appearance, which, however, will grow more uniform as the holes are smaller and closer, and the eye more distant, and if extremely so, the paper will appear uniformly bright. Now if every alternate hole be stopped, the paper will manifestly receive only half the light, and will therefore be only half as much illuminated; and *cæteris paribus* the degree of illumination is proportional to the number of holes in the screen, or to the number of equally-illuminated specks on the surface; *i.e.* if the speck be infinitely diminished in size, and infinitely increased in number to the number of rays which fall on it from the original source of light.' (*Herschel.*) Reasoning thus, Sir John Herschel proceeds and establishes the following definitions:—

The real intrinsic brightness of a luminous object is the intensity of the light of each physical point in its surface.

The apparent intrinsic brightness of any object or luminary is the degree of illumination of its image or picture at the bottom of the eye.

The absolute light of a luminary is the sum of the areas of its elementary portions, each multiplied by its own intrinsic brightness.

The apparent light of an object is the total quantity of light which enters our eyes from it, however distributed on the retina.

Various instruments, called *photometers*, have been devised to measure the illuminating power of any body; these are, all of them, more or less defective, and the results which we obtain with the best of them are merely comparative with each other.

Bonguer's Photometer consists of two surfaces of white paper, of exactly equal size and reflective power, cut from the same piece in contact; these are illuminated, the one by the light whose illuminating power is to be measured; and the other by a light whose intensity can be varied at pleasure by an increase of distance, and can therefore be exactly estimated. The variable light is to be removed or approached, till the two surfaces are judged to be equally bright, when the distances of the luminaries being measured, or otherwise allowed for, the measure required is ascertained.

Rumford's Photometer.—Before a screen of white paper, in a darkened room, is placed a blackened cylindrical stick, and the two lights to be compared are so placed that two shadows are thrown upon the screen side by side, with an interval between them about equal in breadth to either shadow. The brighter flame must then be removed, or the feebler brought nearer to the screen, till the two shadows appear of equal intensity, when their distances from the lights must be measured, and their total illuminating powers will be in the direct ratio of the squares of the distances.

Ritchie's Photometer consists of a rectangular box, about an inch and a half or two inches square, open at two ends. It is blackened within to absorb the extraneous light. Within, inclined at angles of 45° to its axis, are placed two rectangular pieces of plain looking-glass, cut from one and the same rectangular strip; these are fastened so as to meet in the middle of a narrow slit, about an inch long, and an eighth of an inch broad, which is covered with a slip of fine tissue or oiled paper, and a blackened card prevents the reflected images from mingling. If we would compare two lights, they must be placed at such a distance from each other, and from the instrument between them, that the light from every part of each shall fall on the reflector next it, and be reflected to the corresponding portion of the paper. The instrument is then to be moved nearer to the one or the other, till the paper on either side of the division appears equally illuminated. When the lights are thus exactly equalised, it is clear that the total illuminating powers of the luminaries are directly as the squares of their distances from the middle of the instrument.

Wheatstone's Photometer is a small sphere with a reflecting surface, which being placed between the two lights, each light is seen on it by the spectator, the two being reflected from different points of the sphere's surface. By an ingenious but simple mechanical contrivance, a rapid looped motion is communicated to the ball, and by the principle of the *persistence of impressions*, the spectator immediately sees two looped curves of different brightnesses. The brighter light is removed until these curves seem of the same brightness, and the intensities of the luminous points are then as the squares of the distances.

Bunsen's Photometer consists of a sheet of cream-coloured letter-paper, rendered transparent over a portion of the surface by a mixture of spermaceti and rectified naphtha, which is solid at common temperatures, but becomes liquid on the application of a very gentle heat. The mixture is liquefied and painted over the paper with a brush, leaving a round disc of the size of half-a-crown in the centre uncovered. When a light is placed on one side of the paper a dark spot is observed on the uncovered portion. When another light is placed on the other side of the paper, the spot is still distinctly visible, if the distance of the light is such that the reflected portion from the paper be either of greater or of less intensity than that transmitted. When the paper is so situated between the two flames that the transmitted and reflected light are of the same intensity, the uncovered spot is no longer visible.

It will be evident from these descriptions that it is possible only, by any of these contrivances, to compare one light with another; there is not any arrangement by which we are enabled to express absolutely the illuminating power. Upon the principle of comparison, and comparison only, the following Tables have been constructed by the relative experimentalists. The observations of Péclet have been already given. The following comparative view of wax and stearine candles manufactured in Berlin, which have been deduced from the observations of Schubarth, is of much value:—

Kind of candles, and whence obtained		Relative intensity of light	Consumption in one hour, in grammes	Relative illuminating power
Common wax candles, of Tannhäuser	4's	103·5	7·877	85·20
	6's	91·0	7·176	83·20
	8's	100·0	6·562	100·0
Wax candles, of Walker . .	4's	132·7	9·398	92·66
	6's	120·3	8·082	97·69
	8's	113·1	7·132	104·1
Stearine candles, of Motard .	4's	117·4	9·427	81·74
	6's	111·8	9·383	78·23
	8's	121·0	7·877	100·7
Stearine candles, of Magnet and Oehmichen	4's	139·5	10·63	86·11
	6's	132·7	9·398	92·66
	8's	125·0	8·506	96·54
Stearine candles, from the same makers	6's	116·1	8·871	85·86
	8's	146·0	8·886	108·0
Candles made from palm-oil .	4's	124·5	9·880	82·67
	6's	115·3	9·178	82·56
	8's	167·5	8·813	113·70

These results show us that the mean illuminating power of wax and stearine candles is nearly the same.

The illuminating power of gases and of gas-burners will be found in the article Coal Gas.

ILMENITE. A variety of titaniferous iron ore, taking its name from one of its localities—the Ilmen Mountains in Siberia.

ILVAITE. A name frequently applied to the silicate of iron, known otherwise as *lievrite* and *yenite.* The term Ilvaite is derived from Ilva, the classical name of Elba—one of the localities of this mineral.

IMMORTELLES. Everlasting flowers, chiefly species of *Gnaphalium* and other Composite plants.

IMPERMEABLE is the epithet given to any kind of textile fabric rendered water-proof by one or other of the following substances:—

1. Linseed-oil, to which a drying quality has been communicated by boiling with litharge or sugar of lead, &c.

2. The same oil holding in solution a little caoutchouc.

3. A varnish made by dissolving caoutchouc in rectified petroleum or naphtha, applied between two surfaces of cloth, as described under Macintosh's patent. See Caoutchouc.

4. Vegetable or mineral pitch, applied hot with a brush, as in making tarpauling for covering goods in ships.

5. A solution of soap worked into cloth, and decomposed in it by the action of a solution of alum; whence results a mixture of acid, fats, and alumina, which insinuates itself among all the woolly filaments, fills their interstices, and prevents the passage of water.

6. A solution of glue or isinglass, introduced into a stuff, and then acted upon by a clear infusion of galls, whereby the fibres get impregnated with an insoluble, impermeable, pulverulent leather.

7. Plaster work is rendered impermeable by mixing artificial or natural asphaltum with it.

IMPORTS AND EXPORTS. Memorandum by the Inspector-General of Imports and Exports as to the method adopted for ascertaining the *real value* of the imports into the United Kingdom, issued by the Statistical Department of the Board of Trade in April 1864.

The *real value* of the imports into the United Kingdom—a term repeatedly employed in this work—as shown in the Statistical Accounts published under the authority of the Government, is ascertained as follows:—

1. In the case of certain articles—of those, namely, in regard to which the tariff prescribes that their value (either with or without a specification of quantity) shall be stated in the entry inwards at the Custom House—it rests on the declaration of the importers.

If the officer of Customs to whom such declaration of value is rendered should see reason to question its correctness, he is entitled to require further evidence on the point, or he may satisfy his doubts by an examination of the goods.

The articles of which the value is ascertained by this method, however, are but few compared with the whole number of those included in the Statistical Registry, and they are generally of minor importance.

2. In the case of the more numerous and more considerable articles which are entered at the Custom House by quantity alone, the value exhibited in the Statistical Record is obtained by means of a process of computation which combines the quantity with the average prices of the several commodities.

The average prices thus employed are supplied to the Inspector-General of Imports and Exports, in part by some of the leading merchants and brokers of the city of London, who willingly aid an operation so obviously serviceable to the public; in part by three gentlemen, who have special facilities for watching the course of the markets, and who receive a fixed remuneration from the Treasury for collecting such prices in the ports of London, Liverpool, and Hull, respectively.

In striking the average price for each article, regard is had to the specific distinctions under which it is exhibited in the tariff—these distinctions being of necessity observed also in the Statistical Registry—and not being in every instance identical with those which are commonly recognised in mercantile transactions.

As the same article, in many cases, varies widely in its market value, according to the country of which it is the produce, separate prices, applicable to the importations from the different countries, are in such cases required.

The rules which are required to be kept in view in fixing the average prices will appear more distinctly on reference to the annexed copy of an explanatory note which was addressed to the merchants and brokers from whom assistance was sought at the time when the registry of *real value* was first established.

When the prices obtained from different sources are found to disagree, such disagreement, unless it be referable to some known cause, is made the subject of a careful investigation before the average is finally adjusted.

The average price of an article being fixed for a particular month for the ports of London and Liverpool separately—and, in the case of certain descriptions of merchandise, for the port of Hull also—the quantity imported into each of the ports is computed at the price belonging to it, and the mean value thus ascertained of the importations into the two or the three ports, is adopted as the general rate of valuation for the importations into the kingdom at large.

The value attached to the importations of each article for the entire year is the sum of the values affixed to the importations of each successive month.

The following Table shows the manner in which the 'real value' of imports is computed in the office of the Inspector-General of Imports and Exports:—

Yellow Muscovado and Brown Clayed Sugar imported from Bengal in 1861.

[1] Quarters in Thousands.

IMPREST. A paper printed in the report on the public accounts, gives an authoritative definition of this technical term, so unintelligible to many persons. The word 'imprest' is generally used in opposition to the term 'final payment.' A final payment is a payment made in final discharge of an obligation of the government to the public creditor; as, for instance, the payment of a bill for stores supplied to the government, or the payment of a salary to a government clerk. An 'imprest' means an advance of public money, to enable the person to whom it may be made to carry on some public service; and the person to whom the advance is made is called the 'imprest accountant.'

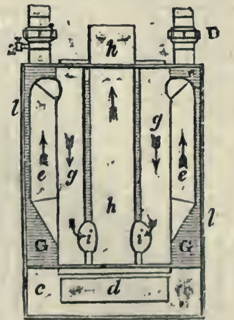
INCOMBUSTIBLE CLOTH is a tissue of the fibrous mineral called amianthus or asbestos. Cotton and linen cloth may be best rendered incapable of burning with flame by being imbued with a solution of sal-ammoniac or of alum.

INCUBATION, ARTIFICIAL. The Egyptians have from time immemorial been accustomed to hatch eggs by artificial warmth, without the aid of hens, in peculiar stoves, called *Mammals*. M. de Réaumur published in France, about a century ago, some ingenious observations upon this subject; but M. Bonnemain was the first person who studied with due attention all the circumstances of artificial incubation, and mounted the process successfully upon the commercial scale. So far back as 1777 he communicated to the Academy of Sciences an interesting fact, which he had noticed, upon the mechanism employed by chicks to break their shells; and for some time prior to the French Revolution he furnished the Parisian market with excellent poultry at a period of the year when the farmers had ceased to supply it. His establishment was ruined at that disastrous era, and no other has ever since been constructed or conducted with similar care. His apparatus derives peculiar interest from the fact that it was founded upon the principle of the circulation of hot water, by the intestine motions of its particles, in a returning series of connected pipes; a subject afterwards illustrated in the experimental researches of Count Rumford. It has of late years been introduced as a *novelty* into this country, and applied to warm the apartments of many public and private buildings. The following details will prove that the theory and practice of hot-water circulation were as perfectly understood by M. Bonnemain fifty years ago as they are at the present day. They were then publicly exhibited at his residence in Paris, and were afterwards communicated to the world at large in the interesting article of the *Encyclopédie Technologique*, intitled *Incubation Artificielle*, under the head of *Régulateur de Température*.

The apparatus of M. Bonnemain consisted: 1, of a boiler and pipes for the circulation of water; 2, of a regulator calculated to maintain an equable temperature; 3, of a stove-apartment, heated constantly to the degree best fitted for incubation, which he called the *hatching* pitch. He attached to one side a *poussinière* or chick-room, for cherishing the chickens during a few days after incubation.

The boiler is represented in vertical section and ground plan, in *figs.* 1207 and 1208. It is composed of a double cylinder of copper or cast iron *l*, *l*, having a grate *b* (see plan), an ashpit at *d* (section). The water occupies the shaded space c, c. *h*, *g*, *g*, *e*, *e*, are five vertical flues for conducting the burnt air and smoke, which first rise in the two exterior flues *e*, *e*, then descend in the two adjoining flues *g*, *g*, and finally remount through the passages *i*, *i*, in the central flue *h*. During this upward and downward circulation, as shown by the arrows in the section, the products of combustion are made to impart nearly the whole of their heat to the water by which they are surrounded. At the commencement, some burning paper or wood shavings are inserted at the orifice

1207



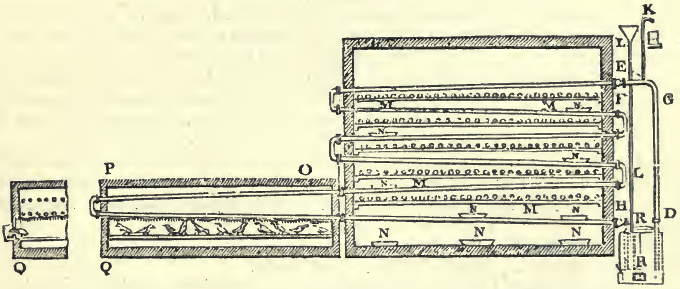
1208

m, to establish a draught in this circuitous chimney. The air is admitted into the ashpit at the side, in regulated quantities, through a small square door, moveable round a rod which runs horizontally along its middle line. This swing valve is acted upon by an expanding bar (see HEAT-REGULATOR), which opens it more or less, according to the temperature of the stove apartment in which the eggs are placed.

D is the upper orifice of the boiler, by which the hotter and consequently lighter particles of the water continually ascend, and are replaced by the cooled particles, which enter the boiler near its bottom, as shown in *fig.* 1209 at R. Into further details relative to the boiler it is needless to enter; for though its form, as designed by M. Bonnemain, is excellent and most economical of heat for a charcoal-fire, it would not suit one of pit-coal, on account of the obstruction to the pipes which would soon be caused by its soot.

In *fig.* 1209 the boiler is shown at R, with the rod which regulates the air-door of the ashpit. D is a stopcock for modifying the opening by which the hotter particles of water ascend; G is the water-pipe of communication, having the heating pipe of distribution attached between E F, which thence passes backwards and forwards with a very slight slope from the horizontal direction, till it reaches the *poussinière* O P Q. It traverses this apartment, and returns by N N to the orifice of the boiler H, where it turns vertically downwards, and descends to nearly the bottom of the boiler, discharging at that point the cooled and therefore denser particles of water to replace those which continually issue upwards at D. L R is a tube surmounted with a funnel for keeping the range of pipes always full of water; and K is a siphon orifice for permitting the escape of the disengaged air, which would otherwise be apt to occupy partially the pipes and obstruct the aqueous circulation.

1209



The faster the water gets cooled in the serpentine tubes, the quicker its circulation will be, because the difference of density between the water at the top and bottom of the boiler, which is the sole cause of its movement, will be greater. N represents small saucers filled with water, to supply the requisite moisture to the heated air, and to place the eggs, arranged along the trays M M, in an atmosphere analogous to that under the body of the hen.

When we wish to hatch eggs with this apparatus, the fire is to be kindled in the boiler, and as soon as the temperature has risen to about 100° F., the eggs are introduced; but only one-twentieth of the whole number intended, upon the first day: next day a like number is laid upon the trays, and thus in succession for twenty days, so that upon the twenty-first day the eggs first placed may be hatched for the most part, and we may obtain daily afterwards an equal number of chicks. In this way regularity of care is established in the rearing of them.

During the first days of incubation, natural as well as artificial, a small portion of the water contained in the egg evaporates by the heat, through the shell, and is replaced by a like quantity of air, which is afterwards useful for the respiration of the animal. If the warm atmosphere surrounding the eggs were very dry, such a portion of the aqueous part of the eggs would evaporate through the pores of the shells as would endanger the future life of the chick *in ovo*. The transpiration from the body of the hen, as she sits upon her eggs, counteracts this desiccation in general; yet in very dry weather many hatching eggs fail from that cause, unless they be placed in moist decomposing straw. The water-saucers N N are therefore essential to success in artificial incubation.

After the chickens are hatched, they are transferred into the nursery, O Q, on the front side of which there is a small grated trough filled with millet seed. Small divisions are made between the broods of successive days, to enable the superintendent to vary their feeding with their age.

In order to supply an establishment of the common kind, where 100 eggs are to be hatched daily, a dozen of hens would be needed, and 150 eggs must be placed under them, as only two-thirds in general succeed. At this rate, 4,300 mothers would be required to sit. Now supposing we should collect ten times as many hens, or 43,000, we should not be able to command the above number of chickens, as there is seldom a tenth part of hens in a brooding state. Besides, there would be in this case no fewer than 720 hens every day coming out with a fresh brood of chickens, which would require a regiment of superintendents.

Artificial Incubation by means of Hot Mineral Waters.—This curious process is described very briefly in a letter by M. D'Arcet. The following are extracts from his letter:—

'In June 1825, I obtained chickens and pigeons at Vichy, by artificial incubation, effected through the means of the thermal waters of that place. In 1827 I went to the baths of Chaudes-Aigues, principally for the purpose of doing the same thing there. Finding the proprietor a zealous man, I succeeded in making a useful application of this source of heat to the production of poultry.

'The advantage of this process may be comprehended, when it is known that the invalids who arrive at Vichy, for instance in the month of May, find chickens only the size of quails; whereas, by this means, they may be readily supplied six months old.

'The good which may be done by establishing artificial incubation in places where hot springs exist, is *incalculable*; it may be introduced into these establishments without at all interfering with the medical treatment of patients, since the hatching would go on in winter, at a time when the baths for other purposes are out of use.

'There is no other trouble required in breeding chickens, by means of hot baths, than to break the eggs at the proper time; for, when the apartments are closed, the whole of the interior will readily acquire a sufficiently elevated and very constant temperature.'

INDIA-RUBBER. See Caoutchouc.

INDIAN CORN. The *Zea Mays.* See Maize.

INDIAN FIRE. A pyrotechnic composition, sometimes used for signal-lights. It is composed of 7 parts of sulphur, 2 of realgar, and 24 of nitre.

INDIAN HEMP. A narcotic resinous substance obtained from *Cannabis Indica.* See Hemp.

INDIAN INK, or *China Ink.* A very beautiful black pigment, the best varieties of which are obtained from China. It is composed of a very fine black, cemented together with some kind of animal gelatine. See Ink.

INDIAN MATTING. Mats made in India from the reed *Papyrus corymbosus.*

INDIAN MILLET. The *Panicum miliaceum,* a grain cultivated in the East Indies.

INDIAN RED. A mineral substance from the Persian Gulf, which reaches us in a state of a dark red coarse powder: a silicate of iron and alumina, containing lime and magnesia. The same name is given to a pigment artificially prepared, which is essentially a sesquioxide of iron.

INDIAN TEAK. A hard wood used for ship-building, yielded by the *Tectona grandis.*

INDIAN YELLOW. This is a peculiar precipitate obtained from the urine of the cow, and, according to some authorities, of the camel, after the animal has been eating decayed and yellow mango leaves—the *Mangistana mangifer.* It appears to be composed of magnesia with a yellow body which may be prepared pure by boiling the mass with water, to which small quantities of muriatic acid are added, until the whole dissolves, and then filtering. On cooling, the liquor deposits the colouring matter in brilliant yellow scales, termed *purreic acid.* See Watts's 'Dictionary of Chemistry.'

INDIANITE. An Indian variety of anorthite, or lime-felspar.

INDICAN. A colourless substance existing in woad, and probably in other plants yielding indigo. Indigo-blue may be prepared from indican by treating it with sulphuric or hydrochloric acid. See Indigo.

INDICOLITE. A name applied to the blue varieties of tourmaline.

INDIGO. This invaluable dye-stuff consists essentially of a blue colouring matter, to which the name of *Indigo-blue* has been applied. This colouring matter occurs in the leaves of several species of plants, which, though few in number, belong to very different genera and orders. The only native European plant which is known with certainty to yield it is the *Isatis tinctoria,* or common woad. It has also been supposed to occur in the following plants, all of which are natives of Europe, viz.:—*Astragalus glycyphyllos, Centaurea Cyanus, Chelidonium majus, Cicer arictinum, Colutea arborescens, Coronilla Emerus, Galega officinalis, Hedysarum Onobrychis, Inula Helenium, Iris Germanica, Lotus corniculatus, Medicago sativa, Mercurialis perennis, Polygonum aviculare, Polygonum Fagopyrum, Rhinanthus Crista-galli, Sambucus nigra, Sambucus*

Ebulus, *Scabiosa succisa*, and *Vaccinium Myrtillus.* According to the investigations of Giobert and others, however, none of these plants afford any indigo-blue, though several of them, such as the *Mercurialis perennis*, contain a blue colouring matter of a peculiar nature. The indigo-bearing plants growing in tropical countries furnish far more indigo-blue than the *Isatis tinctoria.* Such are the various species of *Indigofera*, natives of the East and West Indies, the *Nerium tinctorium* and *Calanthe veratrifolia* of Hindostan, the *Asclepias tinctoria* and *Marsdenia tinctoria* of Sumatra, the *Polygonum tinctorium*, the *Isatis indigotica*, the *Justicia tinctoria*, and the *Bletia Tankervilleæ*, of China, and the *Amorpha fruticosa* of Carolina. Most of these plants belong to the natural order *Leguminosæ.* The others belong respectively to the orders *Cruciferæ*, *Apocyneæ*, *Asclepiadeæ*, *Polygoneæ*, *Acanthaceæ*, and *Orchideæ.* Indigo-blue has sometimes been observed to form in the milk of cows, especially such as have been fed exclusively on saintfoin. It has also been found by Prout, Hassall, and others in the urine of individuals suffering from various diseases; and Schunck has shown that the urine of men and animals, even when in a perfectly healthy state, may be made to yield indigo-blue in small quantities by treatment with strong acids. Hence it appears that this colouring matter may be obtained from a variety of sources, though it is nowhere found in great abundance.

The use of woad for the purpose of dyeing blue seems to have been known in Europe from the earliest times. We are told by Cæsar that the Britons stained their bodies blue with woad, in order to give themselves a more formidable appearance in battle; and Pliny informs us that their women, before entering on certain sacred rites, which were performed in a state of nudity, employed the same means of colouring their bodies, whereby they acquired the appearance of negroes. During the middle ages the cultivation of woad was carried on very extensively in several countries of Europe, especially in Thuringia in Germany, in the province of Languedoc in France, and in the neighbourhood of Rieti in Italy. The leaves of the plant were ground into a pulp, and then submitted to a long process of fermentation, by which means they were converted into a mass of a dark colour which was moulded into balls for the use of the dyer. (See WOAD.) No attempt to extract the blue colouring matter from the plant seems, however, to have been made before the commencement of the present century.

Whether indigo in its present form was known to the ancients has been doubted. Pliny and Dioscorides refer to a pigment called *Indicum*, which seems to have been of a blue colour, though there is little doubt that the article to which the name *Indicum nigrum* was applied was identical with our Indian ink. Of indicum Pliny says that it comes from India and is obtained from the slime adhering to reeds; that it is black when rubbed, but of a fine mixture of purple and blue when dissolved; and that there is another kind which is found swimming on the dye-vessels where purple is dyed, this being the scum of the purple-fish. He adds that those who adulterate indicum dye pigeons' dung or chalk with woad, but that the genuine substance may be known by heating it, when it gives a beautiful purple vapour and emits a smell like that of the sea, and for this reason it has been supposed to be obtained from the rocks. It can hardly be doubted that in this passage indigo is referred to, and that the second kind of indicum mentioned by Pliny consisted probably of the scum of indigo-blue found floating on the surface of the liquor in which the dyeing was performed. It seems, however, that at that time the colouring matter was not so completely separated from the other vegetable matters of the plant as at the present day, since pigeons' dung coloured with woad would bear very little resemblance to our present indigo, but would be a fair imitation of the preparation usually made from woad. It is probable, therefore, that at that period the process of manufacturing indigo was a very rude one, and consisted merely in the separation of a portion of the vegetable from the remainder. Even at the present day the natives of some countries, where the arts have not attained any high degree of development, produce an article from indigo-bearing plants which serves the purpose of dyeing blue, though not much resembling indigo in appearance. In Sumatra, for instance, as Marsden informs us, the natives do not manufacture indigo into a solid substance, but leave the stalks and branches for some days in water to soak and macerate, then boil it, and work with their hands some *chunam* (quicklime) among it, with leaves of the *pacoo saba* (a species of fern) for fixing the colour, after which they drain it off and use it in the liquid state. On the west coast of Africa the leaves of the indigo-plant are moulded into balls, which are then dried in the sun and stored up until they are wanted. These balls, which have a slight blue tint, may be preserved a long time, and be transported to great distances. When they are to be used for dyeing they are broken and reduced to a fine powder. This powder is then mixed with water to which the ashes of a certain plant are added, and the liquid is boiled in large earthenware vessels of a conical form, when it assumes a deep blue colour, and is then ready for dyeing the fabrics which are plunged into it.

The article known as indigo in the middle ages must have been very similar to the indigo of the present day; for though Marco Polo had described the manner in which the substance was produced from the plant, it was for a long time considered as a mineral; and even in the letters patent obtained, in 1705, by the proprietors of mines in the principality of Halberstadt, it was classed among minerals on account of which works were suffered to be erected.

Indigo seems to have been first extensively used in Europe by the Jewish dyers, who introduced it into the dye-houses of Italy. It was not, however, imported in any large quantities until the discovery of the passage round the Cape of Good Hope. At the beginning of the 17th century, the Dutch commenced carrying on an extensive trade with the East, and indigo was one of the articles which they imported in large quantities into European countries. Its use was found to be attended with so many advantages, that the employment of woad for the same purpose was gradually abandoned. The colour produced by it was more brilliant and far cheaper than the blue from woad. On the other hand, it was asserted that the goods dyed with indigo faded rapidly, and that the vitriol and other corrosive substances used along with it caused them, after some time, to rot. At the same time the exportation of large sums of money in payment for indigo, and the rapid decline in the cultivation of woad, which had previously furnished occupation to great numbers of people in various countries of Europe, and had been the source of great wealth to individuals, caused so much alarm, that the most stringent measures were adopted in order to prevent the use of indigo in dyeing. A decree of the Germanic Diet held at Frankfort, in 1577, prohibited, under the severest penalties, the newly-invented, pernicious, deceitful, eating and corrosive dye, called the *devil's dye*, for which vitriol and other cheaper materials were used instead of woad. This prohibition was renewed in 1594 and 1603. In the year 1650, the Elector of Saxony prohibited the sale and importation into his dominions of all fabrics dyed with other materials in the place of woad. This was followed by an Imperial mandate issued from Ratisbon, in the year 1654, forbidding the importation and the use by dyers of indigo and other injurious substances, and threatening with punishment and the confiscation of their goods all persons who should offer for sale any cloth dyed with forbidden and deceitful dyes, instead of with the permanent colour of woad. The people of Nuremberg even went so far as to compel their dyers by law annually to take oath, not to employ indigo, and this was continued down to a very recent period, though it was well known that its use was indispensable to them. In France, the use of indigo was forbidden in 1598, in consequence of an urgent representation by the states of the province of Languedoc, and this prohibition was afterwards repeated several times. But in the well-known edict of 1669, in which Colbert separated the fine from the common dyers, it was stated that indigo should be used without woad; and 1737, dyers were left at liberty to use indigo alone, or to employ a mixture of indigo and woad. In England the use of indigo was also forbidden, and by an act passed in the reign of Elizabeth, searchers were authorised to burn both it and logwood in every dye-house where they could be found. This act remained in force for nearly a century.

It has been doubted whether the plant which is employed in America for the manufacture of indigo is a native of that continent, or whether it was introduced by the Spaniards. It was remarked by the first voyagers on the new continent that the natives coloured their bodies and dyed their stuffs by means of indigenous plants which resembled the indigo-plant of Asia. Fernando Columbus, in the life of his father, says, that this plant grew in a wild state in the West India Islands, and that it was cultivated for the purpose of obtaining from it a blue pigment. Hernades mentions it among the native plants of Mexico, and says, that the Americans used it for dyeing their hair black. He adds, that they made from it a pigment, which they named *mohuitli* and *tleuohuitli*, the same as the *cæruleum* of the Latins, and he describes also the method of prepairing it. Nevertheless, it appears that the *Indigofera tinctoria* and *Anil* were really introduced into America by the Spaniards, and were the plants employed by them for the manufacture of indigo in Mexico, Guatemala, and St. Domingo, though some of the varieties produced by the influence of the climate and soil differ very widely in appearance from the parent stock. The manufacture of indigo was at one time carried on extensively in Central America and the West India Islands, and these countries formerly supplied the chief portion of the article consumed in Europe. The indigo of Guatemala at the same time surpassed all others in quality. In consequence, however, of the political disturbances in America, and the great improvements which have been effected in the manufacture of indigo by the zeal and perseverance of our countrymen in the East, its production in America has diminished very much; and at the present day, the indigo consumed in Europe is derived chiefly from India, and more especially from Bengal, Oude, and Madras. The remainder is imported from Java, Manilla, the Mauritius, and Senegal in the eastern hemisphere, and from Caraccas, Brazil, and Guatemala in the western. The East Indian and Brazilian indigo comes packed in chests; the Guatemala in ox-hides, called *serons.* Its quality depends upon the species of the plant, its ripeness, the soil and climate of its growth, and the mode of manufacture.

The plants which are cultivated in the East Indies, are the *Indigofera tinctoria, Anil, disperma,* and *pseudo-tinctoria.* The districts of Kishenagar, Jessore, and Moorshedabad, in Bengal, ranging from 88° to 90° east lat. and 22¾° to 24° north long., produce the finest indigo. That from the districts about Burdwan and Benares is of a coarser or harsher grain. Tyroot, in lat. 26°, yields a tolerably good article. The portion of Bengal most propitious to the cultivation of indigo, lies between the river Hoogly and the main stream of the Ganges. The ground having been ploughed in October, November, or beginning of December, the seed of the indigo plant is sown in the last half of March or beginning of April, while the soil being neither too hot nor too dry, is most propitious to its germination. A light mould answers best; and sunshine, with occasional light showers, are most favourable to its growth. From twenty-four to thirty pounds of seeds are required for sowing an acre of land. The plants grow rapidly, and will bear to be cut for the first time at the beginning of July, nay, in some districts, so early as the middle of June. The indications of maturity are the bursting forth of the flower-buds, and the expansion of the blossoms; at which period the plant contains most colouring matter. Another indication is taken from the leaves; which, if they break across, when doubled flat, denote a state of maturity. But this character is somewhat fallacious, and depends upon the poverty or richness of the soil. When much rain falls, the plants grow too rapidly, and do not sufficiently elaborate the blue pigment. Bright sunshine is most advantageous to its production. The first cropping of the plant is best; after two months a second is made; but at the present day, planters never undertake a third or fourth.

Two methods are pursued to extract the indigo from the plant: the first effects it by fermentation of the fresh leaves and stems; the second, by maceration of the dried leaves.

1. *From the recent leaves.*—In the indigo-factories of Bengal, there are two large stone-built cisterns, the bottom of the first being nearly upon a level with the top of the second, in order to allow the liquid contents to be run out of the one into the other. The uppermost is called the fermenting vat, or the steeper; its area is 20 feet square, and its depth three feet; the lowermost, called the beater or beating vat, is as broad as the other, but one-third longer. The cuttings of the plant, as they come from the field, are stratified in the steeper, until this is filled to within 5 or 6 inches from its brim. In order that the plant, during its fermentation, may not swell and rise out of the vat, beams of wood and twigs of bamboo are braced tightly over the surface of the plants, after which water is pumped upon them until it stands about 3 or 4 inches from the edge of the vessel. An active fermentation speedily commences, which is completed within 14 or 15 hours, a little longer or shorter, according to the temperature of the air, the prevailing winds, the quality of the water, and the ripeness of the plants. Nine or ten hours after the immersion of the plant, the condition of the vat must be examined; frothy bubbles are then seen rising like little pyramids, at first of a white colour, but soon becoming greyish-blue, and then deep purplish-red. The fermentation is at this time violent, the fluid being in constant commotion, and apparently boiling, innumerable bubbles mount to the surface, and a dense copper-coloured scum covers the whole. As long as the liquor is agitated, the fermentation must not be disturbed; but when it becomes more tranquil, the liquor is to be drawn off into the lower cistern. It is of the utmost consequence not to push the fermentation too far, because the quality of the whole indigo is thereby deteriorated; but rather to cut it short, in which case there is, indeed, a loss of weight, but the article is better. The liquor possesses now a glistening yellow colour, which, when the indigo precipitates changes to green. The average temperature of the liquor is commonly 85° Fahr.; its specific gravity at the surface is 1·0015; and at the bottom 1·003.

As soon as the liquor has been run into the lower cistern, ten men are set to work to beat it with oars or shovels 4 feet long, called *busquets.* Paddle-wheels have also been employed for the same purpose. Meanwhile two other labourers clear away the compressing beams and bamboos from the surface of the upper vat, remove the exhausted blue, set it to dry for fuel, clean out the vessel, and stratify fresh plants in it. The fermented plant appears still green, but it has lost three fourths of its bulk in the process, or from 12 to 14 per cent. of its weight, chiefly water and extractive matter.

The liquor in the lower vat must be strongly beaten for an hour and a half, when the indigo begins to agglomerate in flocks, and to precipitate. This is the moment for judging whether any error has been committed in the fementation; which must be corrected by the operation of beating. If the fermentation has been arrested too soon, much froth rises in the beating, which must be allayed with a little oil, and then a reddish tinge appears. If large round granulations are formed, the beating is continued, in order to see if they will grow smaller. If they become as small as fine sand, and if the water clears up, the indigo is allowed quietly to subside. Should the vat have been over-fermented, a thick fat-looking crust covers the liquor, which does not disappear by the introduction of a flask of oil. In such a case the beating must be moderated, and when the granulations become round, and begin to subside, and the liquor clears up, the beating must be discontinued. When the fermentation has been excessive, the froth or scum diffuses itself spontaneously into separate minute particles, that move about the surface of the liquor. On the other hand, a rightly-fermented vat is easy to work; the froth, though abundant, vanishing whenever the granulations make their appearance. The colour of the liquor, when drawn out of the steeper into the beater, is bright green; but as soon as the agglomeration of the indigo commences, it assumes the colour of Madeira wine; and speedily afterwards, in the course of beating, a small round grain is formed, which falls down and leaves the water transparent, when all the turbidity and froth vanish.

The object of the beating is threefold: first, it tends to disengage a great quantity of carbonic acid present in the fermented liquor; secondly, to give the newly-developed indigo its requisite dose of oxygen by the most extensive exposure of its particles to the atmosphere; thirdly, to agglomerate the indigo in distinct flocks or granulations. In order to hasten the precipitation, lime-water is occasionally added to the fermented liquor in the progress of beating; but those who manufacture the superior qualities of indigo, avoid the use of lime, as it has a tendency to make the indigo hard and red. In one side of the beating vessel a beam is fixed upright, in which three or more holes are pierced a few inches in diameter. These are closed with plugs during the beating, but, two or three hours afterwards, as the indigo subsides, the upper plug is withdrawn to run off the supernatant liquor, and then the lower plugs in succession. The state of this liquor affords, on being examined, an indication of the success of both the processes. When the whole liquor has run off, a labourer enters the vat, sweeps all the precipitate into one corner, and empties the thinner part into a spout which leads into a cistern, 20 feet long, 3 feet wide, and 3 feet deep. When all this liquor is once collected, it is pumped through a bag which retains the impurities into a boiler, placed at the side of the cistern and heated to ebullition. The froth soon subsides, leaving an oily-looking film upon the liquor. The indigo is by this process not only freed from the yellow extractive matter, but its density and the intensity of its colour are increased. From the boiler the mixture is run, after two or three hours, into a general receiver, called the *dripping vat* or table, which, for a factory of twelve pairs of preparation vats, is 20 feet long, 10 feet wide, and 3 feet deep, having a false bottom, 2 feet under the top edge. The cistern stands in a basin of masonry (made water-tight with *chunam* hydraulic cement), the bottom of which slopes to one end, in order to facilitate the drainage. A thick woollen web is stretched along the bottom of the inner vessel to act as a filter; but a piece of cotton cloth is generally preferred to wool, as the hairs which are detached from the latter injure the quality of the indigo. As long as the liquor passes through turbid, it is pumped back into the receiver. Whenever it runs clear, the receiver is covered with another piece of cloth to exclude the dust, and allowed to drain at its leisure. Next morning the drained magma is put into a strong bag and squeezed in a press. The indigo is then carefully taken out of the bag, and cut with brass wire into cubical pieces, measuring about 3 inches each way, which are dried in an airy house upon shelves of wicker work. During the drying, a whitish efflorescence appears upon the pieces, which must be carefully removed with a brush. In some places, particularly on the coast of Coromandel, the dried indigo lumps are allowed to effloresce in a cask for some time, and when they become hard they are wiped and packed for exportation.

From some experiments it would appear that the gas disengaged during the middle period of the fermentation is composed in 100 parts of 27·5 carbonic acid, 5·8 oxygen, and 66·7 nitrogen; and towards its conclusion, of 40·5 carbonic acid, 4·5 oxygen, and 55·0 nitrogen. Carburetted hydrogen does not seem to be disengaged. That the liquor in the beating vat absorbs oxygen from the air in proportion as the indigo becomes flocculent and granular, has been ascertained by experiment, as well as that sunshine accelerates the separation of the indigo-blue. Out of 1,000 parts of the fermented liquor of specific gravity 1·003, the blue precipitate may constitute 0·75 of a part. Such a proportion upon the great scale is, however, above the average, which is not more than 0·5. When lime-water is added, an extractive matter is thrown down, which amounts to from 20 to 47 parts in 1,000 of the liquor. It has a dark brown tint, a viscid appearance, an unpleasant smell, and a bitter taste. It becomes moist in damp air, and dissolves in water without decomposition. It is precipitated by lime, alkalis, infusion of galls, and acetate of lead. All indigo contains a little lime derived from the plant, even though none has been used in its preparation.

2. *Indigo from dried leaves.*—The ripe plant being cropped, is to be dried in sunshine from 9 o'clock in the morning till 4 in the afternoon, during two days, and threshed to separate the stems from the leaves, which are then stored up in magazines until a sufficient quantity is collected for manufacturing operations. The newly-dried leaves must be free from spots, and friable between the fingers. When kept dry, the leaves undergo, in the course of four weeks, a material change, their beautiful green tint turning into a pale bluish-grey, previous to which the leaves afford no indigo by maceration in water, but subsequently a large quantity. Afterwards the product becomes less considerable.

According to some manufacturers, the plants should be cut down in dry weather, an hour or two before sunset, carried off the field in bundles, and immediately spread upon a dry floor. Next morning the reaping is resumed for an hour and a half, before the sun acts too powerfully upon vegetation, and the plants are treated in the same way. Both cuttings become sufficiently dry by 3 o'clock in the afternoon, so as to permit the leaves to be separated from the stems by threshing. They are now thoroughly dried in the sunshine, then coarsely bruised, or sometimes ground to powder in a mill, and packed up for the operations of manufacture.

The following process is pursued to extract indigo from the dried leaves. They are infused in the steeping vat with six times their bulk of water, and allowed to macerate for two hours with continual stirring till all the floating leaves sink. The fine green liquor is then drawn off into the beating vat, for if it stood longer in the steeper, some of the indigo would settle among the leaves and be lost. Hot water, as employed by some manufacturers, is not necessary. The process with dry leaves possesses this advantage, that a provision of the plant may be made at the most suitable times, independently of the vicissitudes of the weather, and the indigo may be uniformly made; and moreover, the fermentation of the fresh leaves, often capricious in its course, is superseded by a much shorter period of simple maceration.

We are indebted to Dr. Roxburgh, for a description of the method employed for manufacturing indigo from the *Nerium tinctorium* or *Wrightia tinctoria.* (Vide 'Transactions of the Society of Arts,' vol. xxviii.) This plant, which attains the size of a small tree, is found on the lower regions of the mountainous tract near Rajamundry, and also on hills in the neighbourhood of Salem and Pondicherry, and grows in a sterile as well as rich soil. The leaves begin to appear in March and April, and at the end of April have attained their full size, when they are ready for gathering. At the end of August they begin to assume a yellowish rusty colour and soon fall off. The leaves yield no indigo until the plant is several years old, but the best leaves for making indigo are obtained from low bushy plants. They improve when kept for a day or two, but when they begin to wither, they yield but a small portion of very bad indigo, and when quite dry only a dirty brown fecula. In this they differ from the leaves of the common indigo-plant, which may be dried before extraction without loss of colour. They also differ from the latter in not yielding their colour to cold water. With cold water only a hard, black, flinty substance is obtained, not blue indigo. It is therefore necessary to employ hot water, which extracts the colour very readily. The leaves having been collected, are on the ensuing day thrown into copper scalding vessels, which are then filled with cold water to within 2 or 3 inches of the top. Hard water containing a large quantity of bicarbonate of lime is better adapted for the purpose than rain-water. The fire is then lighted and maintained rather briskly until the liquor acquires a deep green colour. The leaves then begin to assume a yellowish colour, the heat of the liquor being about 150° to 160° Fahr. The fire is then removed, and the liquor run off into the beating vat. Here it is agitated from 5 to 20 minutes. It is then mixed with about $\frac{1}{70}$th to $\frac{1}{100}$th part of lime-water, which produces a speedy granulation. After the indigo has subsided, the supernatant liquid appears of a clear Madeira wine colour. The quantity of indigo obtained, amounts to 1 lb. from 250 lbs. of green leaves; but it varies according to the season and the state of the weather. In August and September, the produce is only one-half or two-thirds of what it is in May and June, and even that is diminished if the weather is wet, or the leaves are treated immediately after being gathered. The scalding requires about three hours, and the agitation and precipitation the same time. The indigo is improved by treating it with a little sulphuric acid. The only fault it has is, that it breaks into small pieces, unless it has been dried slowly in the shade protected from the sun.

In the southern provinces of China a species of *Indigofera* is extensively cultivated for the sake of the dye which it affords. In the northern provinces two other plants are employed by the inhabitants for the same purpose. Mr. Fortune, the well-known Chinese traveller, to whom we owe the description of these plants and of the process of manufacturing indigo from them, states that one of them is grown in the neighbourhood of Shanghae, and he has given it the name of *Isatis indigotica*. The other, which is a species of *Justicia*, is largely cultivated in the hilly country near Ningpo, or rather in the valleys among the hills. It seems to be easily cultivated; it grows most luxuriantly, and is no doubt very productive. Having evidently been introduced from a more southern latitude, it is not hardy in the province of Chekiang any more than cotton is about Shanghae; but nevertheless it succeeds admirably as a summer crop. It is planted at the end of April or beginning of May, after the spring frosts are over, and it is cleared from the ground in October. During this period it attains a height of a foot or a foot and a half, becomes very bushy, and is densely covered with large green leaves. It is cut before any flowers are formed. The plants are grown, not from seed but from cuttings. These cuttings consist simply of a portion of the stems of the previous year, which after being stripped of their leaves are tied into bundles, each containing upwards of 1,000, and kept during the winter in a dry shed or outhouse, where after being firmly packed together they are banked round with dry loam, and covered with straw or litter so as to protect them from the frost. During the winter months the cuttings remain green and plump, and although no leaves are produced a few roots are generally found to be formed, or in the act of forming, when the winter has passed and the season for planting has come round. In this state they are taken to the fields and planted. The weather during the planting season is generally showery, as this happens about the change of the monsoon when the air is charged with moisture. A few days of this warm showery weather is sufficient to establish the new crop, which now goes on growing with luxuriance and requires little attention during the summer, indeed none except keeping the land free from weeds. In the country where this dye is manufactured there are numerous pits or tanks on the edges of the fields. They are usually circular in form, and have a diameter of about 11 feet and a depth of 2 feet. About 400 catties[1] of stems and leaves are thrown into a tank of this size, which is then filled to the brim with clear water. In five days the plant is partially decomposed, and the water has become yellowish-green in colour. At this period the whole of the stems and leaves are removed from the tank with a flat-headed broom made of bamboo-twigs. When every particle has been removed, the workmen employed give the water a circular and rapid motion with the brooms just noticed, which is continued for some time. During this part of the operation another man has employed himself in mixing about thirty catties of lime with water, which water has been taken out of the tank for the purpose. This is now thrown into the tank, and the rapid circular motion of the water is kept up for a few minutes longer. When the lime and water have been well mixed in this way the circular motion is allowed to cease. Four men now station themselves round the tank and commence beating the water with bamboo rakes made for the purpose. The beating process is a very gentle one. As it goes on, the water gradually changes from a greenish hue to a dingy yellow, while the froth becomes of a beautiful bright blue. During this process the head workman takes a pailful of the liquid out of the tank and beats it rapidly with his hand. Under this operation it changes colour at once, and its value is judged of by the hue it presents. The beating process generally lasts for about half an hour. At the end of this time the whole of the surface of the liquid is covered with a thick coating of froth of the most brilliant colours, in which blue predominates, especially near the edges. At this stage, it being desirable to incorporate the froth with the liquid below it, it is only necessary to throw a small quantity of cabbage-oil on the surface of the froth. The workmen then stir and beat it gently with their flat brooms for a second or two, and the whole instantly disappears. The liquid, which is now darker in colour, is allowed to repose for some hours, until the colouring matter has sunk to the lower stratum, when about two-thirds of the liquid is drawn off and thrown away. The remaining third part is then drawn into a small square tank on a lower level, which is thatched over with straw, and here it remains for three or four days. By this time the colouring matter has separated itself from the water, which is now entirely drained off, the dye occupying three or four inches of the bottom in the form of a thick paste and of a beautiful blue colour. In this state it is packed in baskets, and exposed for sale in all the country towns in this part of China. Like the Shanghae indigo, made from *Isatis indigotica*, it is called '*Tien-ching*' by the Chinese.—*Gardeners' Chronicle and Agricultural Gazette*, April 8, 1854.

---

[1] A Chinese catty is equal to 1⅓ lb.

The cultivation of indigo in Central America has fallen off very much of late years. Nicaragua formerly exported annually about 5,000 bales of 150 lbs. each. At present the export probably does not exceed 1,000 or 2,000 bales. Under the government of Spain, the state of San Salvador produced from 8,000 to 10,000 bales annually. A piece of ground equal to two acres generally produces from 100 to 120 lbs. at a cost of not far from 30 to 40 dollars.

There is an indigenous biennial plant, abounding in many parts of Central America, which produces indigo of a very superior quality, but gives less than half the weight which is afforded by the cultivated species. The *Indigofera disperma* is the species employed in cultivation. It attains its highest perfection in the richest soils. It will grow, however, upon almost any soil, and is very little affected by drought or by superabundant rains. In planting it, the ground is perfectly cleared, usually burnt over, and divided with an implement resembling a hoe into little trenches, 2 or 3 inches in depth, and 12 or 14 apart, at the bottom of which the seeds are strewn by hand, and lightly covered with earth. A bushel of seed answers for 4 or 5 acres of land. In Nicaragua it is usually planted towards the close of the dry season in April or May, and attains its perfection for the purpose of manufacture in from two and a half to three months. During this time it requires to be carefully weeded, to prevent any mixture of herbs, which would injure the quality of the indigo. When it becomes covered with a kind of greenish farina, it is in a fit state to be cut. This is done with knives at a little distance above the root, so as to leave some of the branches, called in the West Indies 'ratoons,' for a second growth, which is also in readiness to be cut, in from six to eight weeks after. The crop of the first year is usually small, that of the second is esteemed the best, although that of the third is hardly inferior. It is said that some fields have been gathered for ten consecutive years without being re-sown, the fallen seed obviating the necessity of new plantings.

After the plant is cut, it is bound in little bundles, carried to the vat, and placed in layers in the upper or larger one called the steeper (*mojadora*). This vat holds from 1,000 to 10,000 gallons, according to the requirements of the estate. Boards loaded with weights are then placed upon the plants, and enough water let on to cover the whole, which is now left to steep or ferment. The rapidity of this process depends much upon the state of the weather and the condition of the plant. Sometimes it is accomplished in 6 or 8 hours, but generally requires from 15 to 20. The proper length of time is determined by the colour of the saturated water; but the great secret is to check the fermentation at the proper point, for upon this, in a great degree, depends the quality of the product. Without disturbing the plant, the water is now drawn off by cocks into the lower vat or 'beater' (*golpeadoro*), where it is strongly and incessantly beaten, in the smaller estates with paddles by hand, in the larger by wheels turned by horse- or water-power. This is continued until it changes from the green colour, which it at first displays, to a blue, and until the colouring matter, or flocculæ, shows a disposition to curdle or subside. This is sometimes hastened by the infusion of certain herbs. It is then allowed to settle, and the water is carefully drawn off. The pulp granulates, at which time it resembles a fine soft clay; after which it is put into bags to drain, and then spread on cloths in the sun to dry. When properly dried it is carefully selected according to its quality, and packed in hide cases, 150 lbs. each, called *serons*. The quality has not less than 9 gradations, the best being of the highest figure. From 6 to 9 are called *flores*, and are the best; from 3 to 6 *cortes*; from 1 to 3, inclusive, *corbes*. The two poorer qualities do not pay expenses. A *mansana* of 100 yards square produces on an average about one ceroon at each cutting. After the plant has passed through the vat, it is required by law that it shall be dried and burnt; because in decomposing it generates by the million an annoying insect called the 'indigo fly.'

Burmese Indigo.—The political agent at the Court of Mandalay furnishes an interesting report on the cultivation of indigo in the territories of the King of Burmah. The manufacture of indigo in Upper Burmah on any scale, we are told, appears to have been first commenced in the year 1860, when His Majesty the King of Ava procured Bengal workmen from Calcutta, and had a factory erected in the city of Ameerapoora, under the superintendence of some Armenian gentlemen who had had experience in the indigo-factories in India. Subsequently four other factories were established: one at Shayet-Khan, of five vats, a short distance above Mandalay; one to the north-east of the Mandalay hill, of three vats; one about 12 miles to the west of Sagine, of ten vats; and one, on a small scale inside the Palace, in one of His Majesty's gardens. The agricultural subjects of His Majesty's within the capital and its suburbs are required to allot a third share of their land for the purpose of sowing indigo, wherever the land is found to be suitable within the vicinity of the factory; and in consideration of this, the land-tax is remitted on the remaining two-thirds of the land; but the cultivators have to give the out-turn of the indigo crop to His Majesty, and receive no renumeration for their labour, the seed only being supplied. The King obtains a yearly supply of the seed from Bengal, and has indigo-plantations of his own, which are set apart exclusively for this purpose. Indigo made from the Burmese plant, indigenous to the country, is found not to be equal to the Bengal indigo. The land upon which the seed is sown is ploughed in the same manner as that for wheat or grain cultivation, but not until the monsoon season is over; the seeds are then scattered about as in other grain cultivation, and in the course of a few weeks shoot up, and before four months have elapsed the young plants rise to the height of about 2½ feet, when they are cut down, tied up in bundles, and carted off to the nearest factory. The late Crown Prince sent several Burmese youths to Bengal some years ago to study the manufacture of indigo. They returned at the latter end of the year 1868, and are now engaged in superintending the plantations and manufacture of the dye. Chinese merchants of Mandalay export indigo to the Shan States and China. The average annual out-turn is about 8,000 viss, which is sold on His Majesty's account at the rate of 400 rupees for 100 viss or 4½ maunds. There is no prohibition as to the cultivation of the plant or manufacture of the dye.

The following account of the manufacture of indigo on the Senegal is taken from Perottet's 'Art de l'Indigotier':—

The land destined to the cultivation of the plant ought to be perfectly level and free from undulations, so as to prevent the seed from being washed into the hollows or lower parts by the heavy rains so frequent in the tropics. Soils of a greyish colour abounding in clay are not adapted for the purpose, as they are too compact and cold. Sandy soils of a whitish colour must also be avoided. Light soils, abounding in humus or vegetable remains, and having a colour between grey and dark brown, are to be preferred to all others. The soil should, at all events, not be one very retentive of moisture. The quantity of indigo obtained from the same weight of plant may vary, according to the soil, from 4 lbs. to 10 lbs., and the quality also varies in a corresponding degree. The extent of ground which is required for the production of indigo on a large scale is so great that the use of manure becomes almost impossible. Nevertheless, the employment of the refuse of the plant, after the extraction of the indigo, as a manure on fresh plantations is found to be attended with very beneficial results. The ground, if new, must be turned up by means of a plough or hoe, to the depth of at least 10 or 12 inches, three times successively, at intervals of 3 months, before the sowing takes place. The sowing must only be undertaken in fine weather, never during heavy rain. The seed employed should be perfectly ripe, and, if possible, not more than one year old. It is to be left in the seed-vessels in which it is contained until the time when it is wanted. The latter are then put into a wooden mortar and reduced to fragments, and the seed is separated by winnowing from the dust, *débris*, &c., with which it is mixed. The sowing is to be effected broad-cast, and as evenly as possible. It should take place, if possible, just before the approach of rain, in which case the use of a harrow is not required, as the rain generally has the effect of completely levelling the ground and covering up the seed with soil. The *Indigofera tinctoria*, and its varieties *macrocarpa* and *emarginata*, being a plant with numerous crowded branches, it is not necessary in sowing it, to take more than from 6 to 7½ kilogrs. of seed to 1 arpent of ground; but the *Indigofera Anil*, being more sparingly branched, and therefore taking up less room, requires to be more thickly sown. At about 10 or 12 days after sowing, when the young indigoferæ have attained a height of about 81 to 108 millimeters, the ground must be carefully weeded, and this operation must be repeated as soon as the weeds have again made their appearance and commenced to interfere with the growth of the crop. When the season is favourable, 3 months are generally sufficient to enable the plants to attain the degree of development necessary for the production of indigo. At the period when inflorescence commences, the plant is far richer in colouring matter than at any other. As soon, therefore, as there are any indications of flowering, and when the lower leaves, in the axils of which the flowers appear, begin to acquire a yellowish tint, and when pressed in the hands produce a slight crackling noise, no time must be lost in cutting down the plant. This is effected by means of good knives or sickles, and as near the ground as possible. The stems, after being cut, are tied together into bundles or sheaves, and carried to the manufactory. Since the colouring principle of the indigoferæ is extremely susceptible of change by the action of destructive agencies, it is necessary to use the utmost despatch in gathering the crop, and to have the manufactory of such a size in proportion to the plantation, that no time may be lost in working up the material as soon as gathered. The plants must on no account be cut when they are moistened either with rain or dew, because in this case they acquire a blackish tint in consequence of the friction to which they are exposed in cutting them and taking them to the manufactory, this tint being a sign of the disappearance of the colouring matter. Besides this, it has been observed that during the continuance of rain, the indigo-producing principle diminishes very considerably, and sometimes even disappears entirely, so that, if cut during or immediately after rain, the plants yield little or no indigo. The indigo-plant is subject to the attack of a green caterpillar, which sometimes appears in such quantities as to destroy the whole crop. No certain and easy means of destroying this pest is known. It has been recommended to pass wooden rollers over the ground, before the plants have attained any great size, so as to crush the caterpillars without injuring the plants, and this plan has been attended with partial success.

In order to obtain good results in the manufacture of indigo, it is necessary that the plants should be of the same age, of the same species, and from the same field. The *Indigofera Anil* begins to ferment several hours sooner than the *I. tinctoria*, so that if a mixture of both be taken, the produce from either one or the other will be lost, and the indigo obtained will also be of a bad quality. The plants should, as soon as possible after being gathered, be placed in the steeping-vat, which is a vessel built of bricks, and well lined with cement, from 3½ to 8 meters in length, of the same width, and about 1 meter deep. In this vessel the plants are arranged in successive layers, the lower layers being slightly inclined towards one end, in order to facilitate the subsequent running-off of the liquor. The vessel being full, a number of poles of fir-wood are laid lengthways over the plants, at a distance of 162 mill. from one another. Three beams are then laid crosswise over the poles, their ends being well secured by passing them through slits which are cut in the upright posts at the sides of the cistern, and then fixing them by means of iron pins, passing through holes in the posts. By this means the plants are prevented from rising above the surface of the liquor during the process of maceration. The vat is now filled with water from an adjacent cistern, in which it has been allowed to stand for 24 hours for the purpose of allowing all foreign matters contained in it to be deposited. After standing in contact with the leaves for about 6 hours, a change usually begins to manifest itself in the liquor, which must therefore, from that time forward, be carefully watched. As soon as this liquor begins to acquire a green colour, and when a little of it, on being kept for a short time in the mouth, leaves a slight impression of harshness (*âpreté*) on the tongue and the palate, it is a sign that the maceration is complete, and that the liquor should be drawn off without delay. If this be not done, the colour of the liquor changes from green to brown, a new species of fermentation commences, accompanied by the formation of acetic acid, and the plant begins to yield substances of a mucilaginous nature, which contaminate the indigo, and completely spoil its quality. It is therefore of the greatest importance to ascertain exactly when the maceration of the plant is complete. The following are the chief indications of this point having been attained:—1. When the water which was at first clear begins to become muddy, and acquires a slight greenish tinge. 2. When bubbles of a greenish colour rise to the surface here and there. 3. When towards the edge of the vat some mucilage, or a kind of greyish scum, commences to be formed. 4. When a very slight purple pellicle is observed on the surface of the liquor, especially near the corners of the vat. 5. When the liquor begins to exhale a slight but not disagreeable odour of herbs. When the fermentation has proceeded too far, the following phenomena present themselves:—1. A considerable quantity of large bubbles of air are disengaged, which burst at the surface, forming a layer of greyish mucilage. 2. The surface of the liquor becomes covered with a copper-coloured pellicle. 3. A heaving of the liquor in the vat is observed, giving rise to the disengagement of large greenish bubbles, which communicate a brownish colour to the water. 4. The liquor acquires a fetid smell, a strongly acid taste, and a soapy appearance. These phenomena manifest themselves when the weather is hot, after the fermentation has continued about 12 or 14 hours. It then becomes impossible to obtain indigo of good quality, the only product being a black matter resembling wax.

The liquor is now run off from the steeping-vat into the beater, which is a cistern of about the same dimensions as the former, but situated at a rather lower level. Here it is subjected to the beating process, the object of which is to expose the reduced indigo to the oxygen of the atmosphere, as well as to promote the disengagement of the carbonic acid gas with which the liquid is charged, and which prevents the precipitation of the indigo. The beating is performed by men, who, provided with paddles, agitate the liquid rapidly, so as to bring every part of it successively into contact with the air. It is of importance that this process should be broken off at the right moment, for if it be continued too long, the grain formed at first will redissolve and be lost. And if, on the other hand, it be arrested before the proper time has arrived, a portion of the indigo will remain unprecipitated. In order to ascertain in what state the liquor is, a little of it must be poured into a drinking glass and mixed with an equal volume of clear water. If there is formed round the circumference of the glass a line of a bluish-green colour, the beating must be continued; but if, on the contrary, the liquid appears of a uniform brown colour, and if on adding to it a few drops of clear lime-water with the finger the indigo precipitates immediately in grains, the process must be arrested. The beating usually occupies from an hour and a half to two hours. The liquid is now to be well mixed with about $\frac{1}{10}$th of its volume of clear lime-water, and allowed to rest until the indigo has quite settled. By opening successively the plugs which are placed at different heights in the side of the vessel, the clear liquor is then drawn off in separate portions and permitted to run away, care being taken that none of the indigo is allowed to be carried away with the water. By means of an opening situated near the bottom of the beating vat the indigo mixed with water is then run off, and flowing through a canal is received on a cloth strainer or filter. This filter rests on a round or four-cornered vessel, the top of which is on a level with the surface of the ground, and which is called the *diablotin.* When the liquid has run through the filter, the indigo which remains behind in a state of paste is mixed up again with water, and the mixture is poured on a canvas filter and allowed to run immediately into the boiler. The refuse matter, consisting of leaves of the plant, &c., remains on the canvas, while the indigo suspended in water runs through. The boiler is a vessel with sides of masonry, and a bottom consisting of a copper plate which rests on iron bars, and is well cemented to the sides. Underneath the copper plate is the fire-place. The top must be covered with a wooden lid, consisting of two flaps which are fixed to hinges at the sides and meet together over the top. At the moment when the mixture of indigo and water is introduced into the boiler, the latter must already be about one third full of hot water, the mixture being sufficient almost to fill it entirely. The heat is now raised gradually to the boiling-point, and the boiling is continued for about two hours. In order to prevent the indigo from adhering to the bottom and sides of the boiler, the liquor must be kept continually stirred with a wooden rake. The object of the boiling is to drive away all the carbonic acid that may still be present in the liquor, to remove the soluble extractive matters which would render the indigo dull and impure, to prevent the fermentation or putrefaction of the indigo which would otherwise take place, and lastly, to facilitate the subsequent processes of filtering and pressing. The fire having been removed, the liquor is allowed to stand for some time, and as soon as the indigo has settled, the supernatant liquid is drawn off by means of taps fixed in one of the sides of the boiler. The lowest tap is then opened, and the indigo is run off with the water and received on a filter, consisting of blue Guinea cloth stretched on a frame. The first portions of liquid which run through are usually coloured with indigo, and must therefore be caught in a suitable vessel and poured on the filter again. As soon as the liquid has percolated, the indigo, which is now a compact paste, is removed from the filter by means of a wooden ladle and put into a press, which consists of a wooden box pierced with holes. The press having been lined with cloth, the indigo is put in, the cloth is folded round it as evenly as possible, a wooden lid is dropped on the cloth, and the mass is submitted to pressure by means of a screw, until no more liquid runs through at the bottom, which takes place as soon as the indigo has been reduced to about a third of its original volume. The press is then opened, the indigo is taken out of the cloth, laid on a table and divided by means of a knife into pieces of a cubical shape. These cubes are then taken to the drying shed, where they are placed on trellises covered with matting or very thin cloth, so as to admit of the free passage of air. Care must be taken not to dry them too rapidly, otherwise the cakes would crack and split into fragments, which are then of little commercial value, and it is therefore necessary to protect them from currents of dry air by covering them with canvas or Guinea cloth. During the drying process, which occupies from 8 to 10 days, the cakes should be turned several times. They are then closely packed in boxes, each box holding about 25 kilogrammes. The boxes should be lined with paper.

It may be remarked, that when the indigo is of good quality, the volume of the paste diminishes very little when subjected to pressure. If the process of filtering takes up much time and the pressing is attended with difficulty, it may be anticipated that the indigo will turn out of bad quality. This may proceed from the plant having been overgrown, or from the maceration or the beating process having been continued too long, or from the employment of too large a quantity of lime-water. The difficulty experienced in pressing the indigo paste, and which is often so great as to cause the cloth in which it is enveloped to break, is caused by the presence of a mucilaginous or viscous substance mixed with the indigo, which may be removed by treating the paste again with boiling water, and repeating the operations of filtering and pressing.

In regard to the state in which indigo exists in the plants from which it is derived, and the nature of the process by which it is obtained, various opinions have been entertained by chemists. Berthollet in his work on dyeing says, 'that the three parts of the process employed have each a different object. In the first a fermentation is excited, in which the action of the atmospheric air does not intervene, since an inflammable gas is evolved. There probably results from it some change in the composition of the colouring particles themselves; but especially the separation or destruction of a yellowish substance, which gave to the indigo a greenish tint, and rendered it susceptible of undergoing the chemical action of other substances. This species of fermentation passes into a destructive putrefaction, because the indigo has a composition analogous to that of animal substances. Hitherto the colouring particles have preserved their liquidity. In the second operation, the action of the air is brought into play, which, by combining with the colouring particles, deprives them of their solubility, and gives them the blue colour. The beating serves, at the same time, to dissipate the carbonic acid which is formed in the first operation, and which by its action presents an obstacle to the combination of the oxygen. The separation of this acid is promoted by the addition of lime; but if an excess be introduced, it counteracts the free combination of the oxygen. The third part of the process has for its objects—the deposition of the colouring matter, become insoluble by combination with oxygen, its separation from foreign substances, and its desiccation, which gives it more or less hardness, whence its appearance varies.' De Cossigny was of opinion that volatile alkali was the agent by which the colouring matter was extracted from the plant and held in solution until volatilised by the agitation process. Roxburgh concluded from his experiments, 'that the indigo plants contain only the base of the colour, which is naturally green; that much carbonic acid is disengaged during its extrication from the leaves; that the carbonic acid is the agent whereby it is probably extracted and kept dissolved; that ammonia is not formed during the process; that the use of the alkalis employed is to destroy the attraction between the base and the carbonic acid; and that the vegetable base being thereby set at liberty, combines with some colouring principle from the atmosphere, forming therewith a coloured insoluble fecula, which falls to the bottom and constitutes indigo.'

Chevreul, who was the first chemist of any eminence to examine the indigo-bearing plants and their constituents, inferred from his analyses of the *Isatis tinctoria* and the *Indigofera Anil*, that these plants contain indigo in the white or reduced state, in the same state in which it exists in the indigo-vat; that in this state it is held in solution by the vegetable juices, and that when the solution is removed from the plant, it is converted, by the action of the atmospheric oxygen, into indigo-blue. Giobert, from an examination of the *Isatis tinctoria*, drew the following conclusions:—1. Indigo-blue does not pre-exist in the plant, but is formed during the operations by means of which we believe it to be extracted. 2. There exists in a small number of plants a peculiar principle, different from all the known proximate constituents of plants, and which has the property of being convertible into indigo; this principle may be called *indigogene*. 3. This principle differs from indigo in containing an excess of carbon, of which it loses a portion, in passing into the state of indigo-blue, by the action of a small quantity of oxygen which it takes up. 4. The loss of this portion of carbon must be attributed to its undergoing combustion, and being converted into carbonic acid. 5. It differs in its properties from common indigo in being colourless and soluble in water, and by its greater combustibility, which causes it to undergo spontaneous combustion at the ordinary temperature of the atmosphere. 6. Its combustibility is enhanced by heat and by combination with alkalis, especially lime; it is diminished by the action of all acids, even carbonic acid. About the year 1839, the *Polygonum tinctorium*, an indigo-bearing plant indigenous to China, became the subject of a series of investigations by several French chemists, chiefly with a view to ascertain whether this plant, if grown in France, could be advantageously employed in the preparation of a dyeing material as a substitute for foreign indigo. Baudrimont and Pelletier, after an examination of this plant, arrived at the conclusion that the indigo is contained in it as reduced indigo, in the same state as it is in woad, according to Chevreul. Robiquet, Colin, Turpin, and Joly, on the other hand, expressed a very decided conviction that indigo-blue pre-exists in the plant, but not in a free state; that it is combined with some organic substance or substances, which render it soluble in water, ether and alcohol; and that the operation of potent agencies is requisite in order to destroy this combination and set the indigo at liberty. The explanation of Chevreul, proceeding from an authority of such eminence, and being the simplest, has been adopted by most chemists. Nevertheless, there are objections to it which render it inadmissible. Reduced indigo is a body which is only soluble in alkalis, and cannot, therefore, be contained as such in the juice of indigo-plants, which is mostly acid. As it also takes up oxygen with the greatest avidity, and is converted into indigo-blue, it is difficult to conceive how the whole of it can be preserved in a colourless state in the cells of plants, in which it must occasionally come in contact with the oxygen eliminated by the vegetable organism. If these plants contained reduced indigo, the juice ought, moreover, to turn blue the moment it became exposed to the atmosphere, which is not always the case. The necessity for a long process of fermentation in order to obtain the colouring matter would also not be very apparent, the mere contact with oxygen being, it might be supposed, all that was necessary for the purpose. The facility with which the indigo-blue is destroyed if the process of fermentation is carried too far, is also inconsistent with the supposition that it is contained in plants either as such, or in a de-oxidised state, since indigo-blue is a body not easily decomposed, except by very powerful agents.

In order to throw some light on this subject, an investigation was undertaken by Schunck into the state in which indigo-blue exists in the *Isatis tinctoria*, or common woad, which is the only plant indigenous to Europe that yields any considerable quantity of the colouring matter. Schunck succeeded in obtaining from that plant a substance of very peculiar properties, to which he gave the name of *Indican*. This substance has the appearance of a yellow or light brown transparent syrup. It has a bitter taste. It is very easily soluble in water, alcohol, and ether; its solutions are yellow, and have an acid reaction. Its compounds with bases are yellow. When its watery solution is mixed with a strong acid, such as muriatic or sulphuric acid, no change takes place at first, but on leaving the solution to stand, or on heating it, it becomes blue and opalescent, then acquires a purple colour, and at length deposits a quantity of purplish-blue flocks, which are quite insoluble in water. These flocks consist for the most part of indigo-blue, but they contain also a red colouring matter and several brown substances of a resinous nature. The supernatant liquid contains a peculiar kind of sugar, and on being distilled, yields carbonic, formic, and acetic acids. Hence it follows that the plant does not contain indigo-blue ready formed either in the blue or colourless state, that the latter exists in the vegetable juice in a state of combination with sugar, forming a compound of that peculiar class known to chemists as *glucosides*. This compound is readily dissolved by water, and the indigo-blue may then be liberated and precipitated from the solution by means of acids, and probably also by other agents, but the simultaneous action of oxygen is not necessary during the process of decomposition, which the compound undergoes in yielding indigo-blue. Now if, as seems probable, the various species of indigofera contain indican or some similar substance, the phenomena which took place during the process of manufacturing indigo may easily be explained. During the steeping process the indican is dissolved, and, in consequence of the fermentation which then takes place in the liquor, it is decomposed into indigo-blue and sugar. The former would then be precipitated; but since ammonia is, according to most authors, evolved at the same time, the indigo-blue is, by the simultaneous action of the alkali and the sugar, or other organic matters contained in the liquid, reduced and dissolved, forming a true indigo vat, from which the colouring matter is afterwards precipitated by the combined action of the atmospheric oxygen and the lime, during the beating process. According to Schunck, two distinct periods may be observed in the decomposition of indican. During the first period, indigo-blue is the chief product of decomposition; during the second, the red and brown resinous matters make their appearance with very little indigo-blue. The formation of carbonic, acetic, and formic acids is, according to Schunck, dependent on that of the brown resinous matters. It would appear, therefore, that the copious disengagement of carbonic acid, as well as the acid taste, attributed to acetic acid, sometimes observed during the manufacture of indigo, are phenomena which indicate the formation, not of indigo-blue, but of other substances, which may prove very injurious to the quality of the indigo. These substances being soluble in alkalis, but insoluble in water, are precipitated, as soon as the liquid loses the alkaline reaction which it possesses at the commencement, and becomes acid. Though indigo-blue is a body of very stable character, not easily decomposed when once formed, except by potent agencies, still the assertion of Perottet and others, that 'nothing is more fugitive, and more liable to be acted on by destructive agencies, than the colouring principle of the indigoferæ,' will be easily understood when the following facts, mentioned by Schunck, are taken into consideration. If a watery solution of indican, this indigo-producing body, be boiled for some time, it then yields by decomposition, not a trace of indigo-blue, but only indigo-red; and if it be boiled with the addition of alkalis, it then gives neither indigo-blue nor indigo-red, but only the brown resinous matters before mentioned. The mere action of alkalis is, therefore, sufficient to cause the molecules, which would otherwise have gone to form indigo-blue, to arrange themselves in a totally different manner, and yield products which bear very little resemblance to it. It is evident, therefore, that one of the chief objects to be kept in view by the manufacturer of indigo, is the proper regulation of the process of fermentation, so as to prevent the formation of the other products, which take the place of indigo-blue, and are formed at its expense.

The indigo of commerce occurs in pieces, which are sometimes cubical, sometimes of an irregular form. These pieces are firm and dry, and are easily broken, the fracture being dull and earthy. It is sometimes lighter, sometimes *apparently* heavier than water, this difference depending on its being more or less free from foreign impurities, as well as upon the treatment of its paste in the boiling, pressing, and drying operations. Its colour is blue of different shades; as light blue, purplish-blue, coppery-blue, and blackish-blue. On being rubbed with the nail, or a smooth hard body, it assumes the lustre and hue of copper. It is usually a homogeneous mass, but it occasionally contains grains of sand or other foreign bodies, and sometimes presents inequalities of colour. It is frequently full of small cavities, which proceeds from the drying process having been conducted too rapidly, and it is also covered at times with a whitish matter consisting of mould. It varies very much in consistency, being sometimes dry, hard, and compact, whilst sometimes it is easily broken into thin flat pieces. Indigo is devoid of smell and taste. When applied to the tongue, however, it adheres slightly, in consequence of the property which it possesses of rapidly absorbing moisture, a property which is often had recourse to in order to ascertain its quality. When thrown on red-hot coals it yields vapours of a deep purple colour, which, when condensed on cold bodies, give shining needles having a coppery lustre. It is insoluble in water, cold alcohol, ether, muriatic acid, dilute sulphuric acid, cold, ethereal, and fat oils; but boiling alcohol and oils dissolve a little of it, which they deposit on cooling. Creosote has the property of dissolving indigo.

Indigo varies very much in quality, but it requires much discrimination in order to judge fairly of the quality of any sample from mere inspection and application of the tests usually employed by dealers. A cake of indigo being broken, and the nail or the edge of a shilling being passed with a tolerable degree of pressure over the fractured part, a fine coppery streak will be produced if the indigo is good. If the indigo furrows up on each side of the nail, it is weak and bad, and if the coppery streak be not very bright it is not considered good. When a piece of indigo is broken the fracture should be held up to the sun, and, if it has not been well strained from the dross, particles of sand will be seen glistening in the sun-light. The outside or coat should also be as free from sand as possible. When the squares are broken in the chests the indigo fetches a low price, and if it is very much crushed it is only bought by the consumers for immediate use. The methods employed for ascertaining the true amount of colouring matter in any sample of indigo will be described below.

Indigo is generally classified according to the various countries from which it is obtained. The principal kinds are the following:—Bengal, Oude, Madras, Manilla, Java, Egyptian, Guatemala, Caraccas, and Mexican.

At the present day the finest qualities of indigo are obtained from Bengal, the produce of that country having now taken the place in public estimation which was once occupied by that of the Spanish colonies. The export of indigo from Bengal, which in 1853 amounted to 120,000 maunds (of 74 lbs. 10 oz.) would require for its culture about 1,025,000 acres, and an annual expenditure of 1,300,000*l*. Of this extent of land about 550,000 acres is believed to be included in the Lower Provinces, and consists chiefly of alluvial lands rescued from the rivers. The best qualities of Bengal indigo are manufactured in the Jessore and Kishenaghaur districts, but each district produces a quality peculiar to itself, and differences of a less striking character may be perceived in the produce of different factories. The Bengal indigo, when packed in chests, consists of four principal qualities, viz., the blue, purple, violet, and copper. But these kinds, by passing over into one another, produce a number of intermediate varieties, such as purply-blue, blue and violet, purply-violet, &c. The various qualifications would, therefore, be distinguished as follow:—1. Blue. 2. Blue and violet. 3. Purple. 4. Purple and violet. 5. Violet. 6. Violet and copper. 7. Copper. The leading London brokers, however, classify Bengal indigo into the following grades: fine blue, fine purple and violet, fine red and violet, good purple and violet, middling violet, middling defective, consuming fine, middling and good, ordinary, ordinary and lean trash. The finest qualities of Bengal indigo present the following characteristics. They consist of cubical pieces, are light, brittle, of a clean fracture, soft to the touch, of a fine bright blue colour, porous, and adhering to the tongue. The lower qualities have a duller colour, assume more and more of a reddish tinge, are heavier, more compact, and less easily broken.

The indigo from the upper provinces of India comes chiefly from Tyroot, Oude, and Benares. It is inferior to Bengal indigo.

Of Madras indigo there are two kinds, viz.:—1. Dry leaf, made from dry stacked leaves. 2. Kurpah, which is manufactured from the wet leaf in the same way as Bengal indigo. The latter has only come into use since 1830. Both are of inferior quality to Bengal indigo.

The Manilla indigos present the marks of the rushes upon which they have been dried. The pieces are either cubical, or flat and square, or of irregular shape. The quality is very unequal. Java indigo occurs in flat, square, or lozenge-shaped masses, the quality approaching that of Bengal. Both these kinds are consumed chiefly on the continent of Europe.

Guatemala indigo is imported into this country in serons or hide wrappers, each containing about 150 lbs. nett. It occurs in small irregular pieces, which are more or less brittle, compact, lighter than water, and of a bright blue colour with an occasional tinge of violet. There are three kinds of Guatemala indigo, viz.: 1. Flores, which is the best, and approaches in quality that of the finer Bengal indigos; 2. Sobres; and 3. Cortes, which is the lowest in quality, being heavy, difficult to break, and of a coppery-red colour. Of the first kind very little now reaches the market. The indigo of Caraccas is, generally speaking, inferior to that of Guatemala.

The manufacture of indigo was formerly carried on in St. Domingo, but has for some time been entirely abandoned.

The indigo of commerce, even when not adulterated, is a mixture of different substances. When it is heated in a state of fine powder to 212° F. it loses from 5 to 10 per cent. in weight, the loss consisting of water. When the dry powder is heated in a crucible, a great part of it burns away, and there is left at last a greyish ash, consisting of the carbonates and phosphates of lime and magnesia, sulphate of lime, alumina, oxide of iron, clay, and sand. These matters are partly derived from the plant, partly from the lime and the impurities of the water employed in the manufacture. The quantity of inorganic matter contained in ordinary indigo varies very much. In the better qualities it amounts on an average to about 10 per cent. of the weight; whilst in the inferior qualities, especially of Madras indigo, it often rises to between 30 and 40 per cent. The organic portion of the indigo, or that which is dissipated when indigo is heated, also consists of several different substances.

By treating indigo with various solvents, Berzelius obtained, besides indigo-blue, the true colouring matter of indigo, three other bodies, viz. *indigo-gluten*, *indigo-brown*, and *indigo-red*, which seem to be contained in various proportions in all kinds of indigo. Indigo-gluten is obtained by treating indigo with dilute sulphuric, muriatic, or acetic acid, and then with boiling water. It is left on evaporation of its solutions as a yellow transparent extract, which is soluble in spirits of wine, and easily soluble in water, more difficultly in acid liquids. Its taste is like that of extract of meat. It yields by dry distillation much ammonia and a fetid oil, and behaves in most respects like vegetable gluten. On treating the indigo, after being freed from the indigo-gluten, with hot strong caustic lye, the indigo-brown together with a little indigo-blue dissolves, forming a dark brown, almost black solution, from which the indigo-brown after filtration from the portion insoluble in alkali is precipitated by means of acid. After being purified, indigo-brown has the appearance of a dark brown transparent resin, which is almost tasteless and quite neutral. By dry distillation it affords ammonia and empyreumatic oil. It is decomposed by nitric acid and chlorine. It combines both with acid and bases. Its compounds with alkalis are dark brown, and easily soluble in water. The compound with baryta is not easily soluble in water, and that with lime is insoluble. By boiling the alkaline compounds with lime in excess the indigo-brown may be separated and rendered insoluble. The green substance obtained by Chevreul from indigo seems to have been a compound of indigo-brown with ammonia containing a little indigo-blue, either in a state of combination or mechanically intermingled. Indigo-brown seems to bear a great resemblance in many of its properties to the brown resinous substances obtained by Schunck in the decomposition of indican with acids. From its constant occurrence in all kinds of indigo, it may be inferred that it is not a mere accidental impurity, but stands in some unknown relation to indigo-blue. As long, however, as its origin and composition are unknown, this must remain a mere supposition. After the removal of the indigo-gluten and indigo-brown, the indigo is exhausted with boiling alcohol of specific gravity 0·83. A dark red solution is obtained, which is filtered and distilled, when the indigo-red contained in it is deposited as a blackish-brown powder, which is quite insoluble both in water and in alkaline liquids. Indigo-red, according to Berzelius, is amorphous, but by distillation *in vacuo* yields a white crystalline sublimate, as well as unchanged indigo-red. Concentrated sulphuric acid dissolves it, forming a dark yellow solution, which deposits nothing on being mixed with water; the diluted solution is rendered colourless by wool, which at the same time acquires a dirty yellowish-brown or red colour. The description given by Berzelius leaves it doubtful whether the indigo-red obtained by him from indigo was a pure unmixed substance. From the leaves of the indigoferæ, as well as from those of the *Isatis tinctoria*, a substance may, according to Schunck, be extracted which has received from him the name of *indirubine*, but which seems to be merely indigo-red in a state of purity. This substance has, according to Schunck, the following properties: it crystallises in small silky needles of a brownish-purple colour, which when rubbed with a hard body show a slight bronze-like lustre. When carefully heated it may be entirely volatilised, yielding a yellowish-red vapour, which condenses in the form of long plum-coloured needles, having a slight metallic lustre. It dissolves in concentrated sulphuric acid, forming a solution of a beautiful purple colour, which when diluted with water yields no deposit and then imparts a fine purple colour to cotton, wool, and silk. It is insoluble in water, but dissolves in boiling alcohol with a splendid purple colour. It is insoluble in alkalis, but dissolves when exposed to the combined action of alkalis and reducing agents, just as indigo-blue does, forming a solution from which it is again precipitated on exposure to the oxygen of the atmosphere. This solution dyes cotton purple. In most of its properties this body bears a striking resemblance to indigo-blue, and the composition of the two is identical.

It has been doubted whether these various substances or impurities with which indigo-blue is associated produce any effect in the dyeing process on cotton. In a memoir by Schwarzenberg, to which a prize was awarded by the Société Industrielle de Mulhouse, the author arrives at the conclusion that neither indigo-gluten, indigo-brown, nor indigo-red gives rise to any appreciable effect when added to an indigo vat prepared with pure indigo-blue. Nevertheless differences are observable in dyeing with different kinds of indigo, which can only be explained on the supposition that something besides indigo-blue takes part in the process. In the ordinary blue vat, made with copperas and lime, any effect which might be produced in dyeing by the indigo-brown is neutralised by the lime, which forms with it an insoluble compound. Indigo-red, however, dissolves, as mentioned above, in contact with alkalis and reducing agents, and the solution imparts a purple colour to cotton. In the ordinary indigo vat its presence may be detected by precipitating a portion of the liquor, and treating the precipitate with boiling alcohol, which then usually acquires a red colour. It is possible, therefore, that a small part of the effect produced in dyeing with indigo may be due to indigo-red.

That portion of the indigo which remains after treatment with acid, alkali, and alcohol consists essentially of indigo-blue, the true colouring matter of indigo, mixed, however, with sand, earthy particles, and other impurities. In order to purify it, the residue, while still moist, is to be mixed with lime, the quantity of which must amount to twice the weight of the crude indigo, and which has been previously slaked with water. The mixture is then put into a bottle capable of holding about 150 times its volume of water, and the bottle is filled up with boiling water and shaken. A quantity of finely-powdered protosulphate of iron, amounting to ⅔rds of the weight of the lime is then added, the bottle is closed with a stopper, well shaken, and left to stand for several hours in a warm place. The mass gradually becomes green, and the indigo-blue is then converted by the precipitated protoxide of iron into reduced indigo, which dissolves in the excess of lime, forming a deep yellow solution. This solution when clear is poured off from the deposit into a vessel containing a sufficient quantity of dilute muriatic acid to supersaturate the whole of the lime. The reduced indigo which is precipitated in greyish-white flocks, is agitated with water until it has become blue, and the regenerated indigo-blue is collected on a filter and washed with water, in order to remove the chloride of calcium and excess of muriatic acid. The following method of obtaining pure indigo blue has been recommended by Fritzsche: 4 ozs. of crude indigo and the same weight of grape-sugar are put into a bottle capable of holding 12 lbs. of water; a solution of 6 ozs. of concentrated caustic soda-lye in alcohol is then added, after which the bottle is filled with hot spirits of wine of 75 per cent., and the whole is left to itself for some time. The liquid becomes at first wine-red, then yellow, and on being filtered and left exposed to the air, deposits the indigo-blue in small crystalline scales, which are to be filtered off and washed at first with alcohol, and then with water.

Pure indigo-blue has the following properties:—Its colour is dark blue inclining to purple. When rubbed with a hard body it assumes a bright coppery lustre. It has neither taste nor smell, possesses neither acid nor basic properties, and belongs, as regards its chemical affinities, to the class of indifferent substances. Its specific gravity is 1·50. When heated in the open air it melts, boils, and burns with a smoky flame, leaving a carbonaceous residue. But when it is heated in a vessel partially closed, or *in vacuo*, it begins to evolve at a temperature of about 550° F. a violet-coloured vapour, which condenses on the colder parts of the apparatus in the form of long crystalline needles, which are blue by transmitted light, but exhibit by reflected light a beautiful coppery lustre. These needles are unchanged indigo-blue. A great portion of the indigo-blue is however decomposed during the heating process. Indigo-blue is insoluble in water, alkalis, and dilute acids. Boiling alcohol and boiling oil of turpentine dissolve a minute quantity of it, and deposit it again on cooling. Fixed oils also dissolve a little of it at a heat exceeding that of boiling water, yielding blue solutions, the colour of which, when the heat is further increased, changes, according to Mr. Crum, first to crimson and then to orange. By the action of dilute nitric and chromic acids indigo-blue is decomposed and converted into *isatine*, a body soluble in water and crystallising in red needles. Chlorine also decomposes indigo-blue, changing it into *chlorisatine*, a substance having properties very similar to those of isatine. Both isatine and chlorisatine afford with different reagents a great number of products of decomposition, none of which have, however, as yet found any application in the arts. By the long-continued action of boiling nitric acid indigo-blue is converted, first into *indigotic acid*, a white crystalline acid, and then into *nitropicric acid*, which is yellow and crystallised. The latter is sometimes employed for imparting a yellow colour to silk and wool, but it is generally prepared from cheaper materials than indigo-blue. The action of concentrated sulphuric acid on indigo-blue is very remarkable. When the acid is poured on the pure substance and gently heated it acquires in the first instance a green colour, which changes after some time to blue. No gas of any kind is evolved. When however crude indigo is employed, there is a perceptible disengagement of sulphurous acid, resulting from the action of the sulphuric acid on the impurities of the indigo, such as the indigo-gluten, &c. On adding water, a solution of a beautiful deep blue colour is obtained. The filtered liquid contains a peculiar acid, to which the names of *indigo-sulphuric, sulphindigotic, sulphindylic*, or *cæruleo-sulphuric acid* have been applied.

This acid is a so-called *double acid.* It contains indigo-blue and sulphuric acid, but in such a peculiar state of combination, that neither of the two constituents can be detected by ordinary re-agents, nor again eliminated as such from the compound. It combines with bases, without either of the two constituents separating. The compounds are called *indigo-sulphates*, and are, like the acid, of a dark blue colour. When the solution of indigo-blue in concentrated sulphuric acid is diluted with water, there is usually formed a small quantity of a dark-blue flocculent precipitate, which is the *phenicine* of Mr. Crum, or the *indigo-purple* of Berzelius. It is a compound of indigo-blue with sulphuric acid, containing less of the latter than indigo-sulphuric acid. It is always formed when the quantity of sulphuric acid employed is not more than eight times that of the indigo-blue, or when the action of the acid on the latter has continued for only a short time. By heating it with an excess of acid it is changed into indigo-sulphuric acid. Though soluble in concentrated sulphuric acid, it is insoluble in the dilute acid, and hence is precipitated on the addition of water. On filtering and washing, however, it begins to dissolve, as soon as the free sulphuric acid has been removed, and may then be completely dissolved by pure water. The solution has a blue colour just like that of indigo-sulphuric acid. Its compounds with bases have a blue colour with a purplish tinge. The blue acid liquid filtered from the indigo-purple on being supersaturated with carbonate of potash or soda, deposits a dark blue powder, which consists of the indigo-sulphate of potash or soda. These compounds are insoluble in water containing a large quantity of neutral salts, and are therefore precipitated when the excess of sulphuric acid is neutralised by carbonate of potash or soda. As soon, however, as the sulphate of potash or soda has been removed by washing, the indigo-sulphate may be dissolved in pure water, yielding a dark-blue solution. The indigo-sulphates of the alkalis may also be prepared by steeping wool, previously well cleaned, into the solution in sulphuric acid. The wool takes up the colour, becoming of a dark blue colour, and after having been well washed with water, in order to remove the excess of acid as well as the impurities which are always present in the solution when crude indigo has been employed, is treated with carbonate of potash, soda, or ammonia, which separate the acid from the wool, and produce blue solutions containing the salts of the respective bases. The indigo-sulphates of the earths and metallic oxides, which are mostly insoluble blue powders, may be obtained from the alkaline salts by double decomposition. By an excess of caustic alkali, indigo-sulphuric acid is immediately decomposed, giving a yellow solution, from which it is impossible to obtain the acid again. By means of reducing agents, such as sulphuretted hydrogen, nascent hydrogen, protosalts of tin and iron, &c., indigo-sulphuric acid is decolorised, but the colour is restored by the oxygen of the atmosphere. Indigo-sulphuric acid, in a free state or in combination with alkalis, is employed in the arts for the purpose of imparting a blue colour to silk and wool. It has very little affinity for cotton fibre, but is nevertheless employed occasionally for blueing white cotton-yarn and other bleached goods.

By treatment with strong boiling caustic potash- or soda-lye, indigo-blue is gradually decomposed and converted into a colourless crystallised acid, *anthranilic acid.* By weak solutions of caustic alkalis it is not in the least affected. If, however, it be subjected to the combined action of an alkali or alkaline earth and some body having a strong affinity for oxygen, such as protoxide of iron and tin, sulphur, sulphurous or phosphorous acid, or organic matters, such as grape-sugar, &c., it disappears by degrees, yielding a yellow solution, containing in the place of indigo-blue another substance, which has been called *indigo-white*, *indigogene*, or *reduced indigo.* When an excess of some acid is added to the yellow solution, the indigo-white is precipitated in white or greyish-white flocks, which on filtration and exposure to the atmosphere rapidly become blue, and are re-converted into indigo-blue. Indigo-white is insoluble in water, but slightly soluble in alcohol. It is soluble in caustic alkalis, lime- and baryta-water. The solutions on exposure to oxygen become covered with a pellicle of regenerated indigo-blue. With an excess of lime it gives an insoluble compound. Its compounds with alumina and metallic oxides, which are insoluble in water, may be obtained by double decomposition. Salts of oxide of copper, when added to its solutions in alkali, convert it immediately into indigo-blue, the oxide of copper being reduced to suboxide. Indigo-blue is also converted into indigo-white, when it is exposed to the action of fermenting or putrefying substances, in the presence of water. Here the decomposing organic matter is the reducing agent, and ammonia, which is usually formed during the process of putrefaction, is the solvent of the indigo-white. If a piece of cotton, wool, or silk be dipped into an alkaline solution of indigo-white, and then exposed to the atmosphere, it acquires a blue colour, which may be made deeper by repeated dippings, and subsequent exposure. It is on this property of indigo-white that the dyeing with indigo depends.

The true chemical formula of indigo-blue, which was first discovered by Mr. Crum, is $C^{16}H^{5}NO^{2}$; and 100 parts contain therefore by calculation 73·28 carbon, 3·81 hydrogen, 10·68 nitrogen, and 12·23 oxygen. The formula of indigo-white is $C^{16}H^{6}NO^{2}$, and it differs therefore from indigo-blue by containing 1 atom more of hydrogen, which is taken up during the so-called reduction of the latter, and lost again by oxidation during its reconversion into indigo-blue.

Since the value of indigo depends entirely on the quantity of indigo-blue which it contains, it is of great importance to ascertain the exact amount of the latter in any given sample of the article. Before commencing the determination of the indigo-blue, a weighed portion of the indigo ought to be heated for some hours at 212° F., and then weighed again. The loss in weight which takes place represents the amount of water contained in the sample. A weighed quantity of the dried indigo is then to be heated over the flame of a lamp until all the organic matter has been burnt away. By weighing the residue which is left the amount of ash or inorganic matter is ascertained. In order, in the next place, to determine the amount of indigo-blue, several methods have been devised by various chemists, none of which however yield very accurate results. Of these methods the following are the principal ones:

1. A weighed quantity of finely-pounded indigo is rubbed with water in a porcelain mortar. An equal weight of pure lime is then slaked with water, and the hydrate is well mixed with the indigo. The mixture is then poured into a stoppered bottle of known capacity, and the mortar is well rinsed with water, which is added to the rest. The bottle is now heated in a water-bath for several hours, and a quantity of finely-pounded sulphate of iron is added; the bottle is then filled up with water, the stopper is inserted, and after the contents have been well shaken the whole is allowed to repose for some hours, until the indigo has become reduced and the sediment has sunk to the bottom. A portion of the clear liquor is then drawn off with a siphon, and the quantity of liquid having been accurately measured, it is mixed with an excess of muriatic acid, and the precipitate, after having been oxidised, is collected on a weighed filter and well washed with water. Lastly, the filter with the indigo-blue is dried at 212° F. and weighed, and the weight of the filter having been subtracted from that of the whole, the weight of the indigo-blue is ascertained. Supposing now that the whole quantity of liquid had been 200 measures, that 50 measures had been drawn off yielding 10 grains of indigo-blue, then the sample contained on the whole 40 grains of the latter. For 60 grains of indigo it is necessary to take from 1 lb. to 2 lbs. of water.

According to Mr. John Dale of Manchester, who has had great experience in the valuation of indigo for practical purposes, this method, though rather long and tedious, still gives more accurate results than any other. The quantity of indigo-blue indicated by it is generally below the actual quantity contained in the sample. According to Berzelius, this loss arises from the lime forming an insoluble compound with a portion of the reduced indigo-blue. Mr. Dale, however, is of opinion, that even when every precaution has been taken, a certain loss, proceeding from some hitherto unascertained cause, cannot be avoided. When, for instance, pure indigo-blue is treated with lime and copperas in the manner just described, the quantity which is again obtained by precipitation from any portion of the liquid is always less than what it should be by calculation, even when no excess of lime has been employed.

2. The second method of determining the indigo-blue is performed as follows:— About 15 or 20 grains of pure indigo-blue, obtained by precipitation from an indigo

vat, and the same quantity of the indigo to be tested, which must be previously ground to a fine powder, are weighed off, and each of them is treated with about 12 times its weight of concentrated sulphuric acid in a flask or porcelain basin. After being heated at a temperature of 120° to 140° F. for about 24 hours, and occasionally well agitated, the two liquids are mixed with water, so that the volume of the two shall be exactly equal. Two equal measures of a weak solution of hypochlorite of lime are then taken, and to the first is added a quantity of the solution of pure indigo. The chlorine liberated by the excess of sulphuric acid in the solution destroys the blue colour of the indigo-sulphuric acid. More of the solution must be added until the liquid begins to acquire a greenish tinge, and the number of measures necessary for the purpose is noted. The same experiment is then made with the solution of crude indigo. The quantity of indigo-blue in the latter is of course in inverse ratio to the number of measures which are requisite in order to take up the whole of the chlorine which is liberated. If, for example, the same quantity of hypochlorite of lime decolourises 167 measures of the solution of pure indigo-blue and 204 measures of the solution of crude indigo, then the quantity of indigo-blue contained in 100 parts of the latter is given by the following proportion:—$204 : 167 :: 100 : x = 81{\cdot}8$.

A number of samples of indigo may be tested in this manner at the same time. Care must be taken to prepare a fresh solution of indigo-blue for every series of trials, since this solution undergoes a change on standing, which renders it quite inapplicable as a standard of comparison. It is necessary also to pay great attention at the moment when the greenish colour indicating an excess of the sulphate of indigo begins to appear, for it will often be found that this colour disappears after standing a few minutes, and a fresh quantity of the blue solution must then be added cautiously, until the greenish tinge becomes permanent, even after standing for some time. Modifications of this process have been introduced by various chemists by the use of permanganate of potash, chlorate of potash, or bichromate of potash, in the place of hypochlorite of lime; but as the principle on which the process depends is in each case identical and the *modus operandi* is almost the same, it will be unnecessary to enter into any minute description of these modifications. The whole method is, however, open to serious objections, and the results which it affords cannot at all be depended on. In the first place, it is difficult to institute a strict comparison between the different shades of colour resulting from the decomposition of the sulphate of indigo in different cases, since the pure green tinge observed when an excess of the pure sulphate has been added to the decomposing agent, gives place to a dirty olive or brownish-green, when a solution of crude indigo is employed, in consequence of the impurities contained in the latter. Secondly, it is almost impossible to avoid the formation of a certain quantity of sulphurous acid during the action of concentrated sulphuric acid on crude indigo. This sulphurous acid during the following operation becomes oxidised before the blue sulphate is destroyed, and hence the percentage of indigo-blue is apparently raised. In employing this method, it is common to find more than 80 per cent. of indigo-blue in a good sample of indigo, whereas the best qualities seldom contain above 60 per cent., and average qualities between 40 and 50 per cent. This method may show a percentage of 70 indigo-blue, when the method first described indicates between 50 and 60.

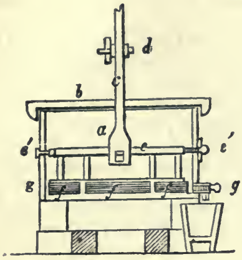
3. The third method of estimating the indigo-blue is performed in the following manner:—Equal weights of the samples to be tested are treated with equal quantities of concentrated sulphuric acid in the manner above described, and the solutions are then diluted with water and introduced into graduated glass cylinders, water being added to each until they all exhibit exactly the same shade of colour. The richer the sample is in indigo-blue, the greater will be the quantity of water necessary for this purpose, the number of measures of water required in each case indicating the relative amount. The great objection to this method consists in the circumstance, that the different kinds of indigo do not give the same shade of blue when their solutions in sulphuric acid are diluted with water, some exhibiting a pure blue colour, others a blue with a greenish, or purplish tinge. It therefore becomes difficult to institute an exact comparison between them.

Employment of Indigo in Dyeing.—As indigo-blue is insoluble in water, and as it can penetrate the fibres of wool, cotton, silk, and flax only when in a state of solution, the dyer must study to bring it into this condition in the most complete and economical manner. This is effected either by exposing it to the concurrent action of alkalis and of bodies which have an affinity for oxygen superior to its own, such as certain metals and metallic oxides, or by mixing it with fermenting matters, or finally, by dissolving it in a strong acid, such as the sulphuric. The first method is that which is employed in the

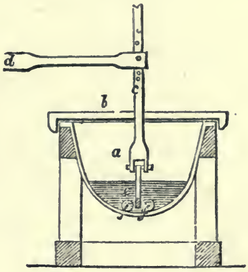
Copperas or Common blue Vat.—Before being used the indigo must be broken into small pieces, the size of nuts, moistened with hot water, and then left for a day; after which it is reduced to a soft paste in a mill. The indigo-mill is represented in *figs.* 1210 and 1211.

a, is a four-sided iron cistern, 2 feet 11 inches long, 19 inches broad, and 18 inches deep, cylindrical or rounded in the bottom, and resting upon gudgeons in a wooden frame. It has an iron lid *b*, consisting of two leaves, between which the rod *c* moves to and fro, receiving a vibratory motion from the crank *d*. By this construction, a frame *e*, which is made fast in the cistern by two points *e′ e′*, is caused to vibrate, and to impart its swing movement to six iron rollers *f*, *f*, *f*, four inches in diameter, three being on each side of the frame, which triturate the indigo mixed with water into a fine paste. This mill is capable of grinding 1 cwt. of indigo at a time. Whenever the paste is uniformly ground, it is drawn off by the stopcock *g*, which had been previously filled up by a screwed plug, in order to prevent any of the indigo from lodging in the orifice of the cock, and thereby escaping the action of the rollers.

1210



1211



Mills of other forms are also used occasionally. One of these consists of a hemispherical iron vessel open at the top, in which a stone of corresponding shape is fixed, so as to leave a small space between it and the sides and bottom of the vessel, in which the indigo undergoes the necessary trituration with water, the motion being produced by means of a vertical shaft fixed to the centre of the stone.

The other ingredients necessary for setting the vat are copperas or protosulphate of iron, newly slaked quicklime, and water. Various proportions of these ingredients are employed, as for instance, 1 part by weight of indigo (dry), 3 parts of copperas, and 4 of lime; or 1 of indigo, 2½ of copperas, and 3 of lime; or 8 of indigo, 14 of copperas, and 20 of lime; or 1 of indigo, ¾ of copperas, and 1 of lime. The sulphate of iron should be as free as possible from the red oxide of iron, as well as from sulphate of copper, which would re-oxidise the reduced indigo-blue. The vat having been filled with water to near the top, the materials are introduced, and the whole after being well stirred several times is left to stand for about twelve hours. The chemical action which takes place is very simple. The protoxide of iron which is set at liberty by the lime reduces the indigo-blue, and the indigo-white is then dissolved by the excess of lime, forming a solution, which, on being examined in a glass, appears perfectly transparent and of a pure yellow colour, and becomes covered wherever it comes into contact with the air, with a copper-coloured pellicle of regenerated indigo-blue. The sediment at the bottom of the vat consists of sulphate of lime, peroxide of iron, and the insoluble impurities of the indigo, such as indigo-brown in combination with lime, as well as sand, clay, &c. If an excess of lime is present, a little reduced indigo-blue will also be found in the sediment in combination with lime.

The copperas vat is employed in dyeing cotton, linen, and silk. For cotton goods no other kind of vat is used at the present day. The dyeing process itself is very simple. The vat having been allowed to settle, the goods are plunged into the clear liquor, and after being gently moved about in it for some time are taken out, allowed to drain, and exposed to the action of the atmosphere. Whilst in the liquid the fabric attracts a portion of the reduced indigo-blue. On now removing it from the liquid it appears green, but soon becomes blue on exposure to the air in consequence of the oxidation of the reduced indigo-blue. On again plunging it into the vat, the deoxidising action of the latter does not again remove the indigo-blue which has been deposited within and around the vegetable or animal fibre, but on the contrary, a fresh portion of reduced indigo-blue is attracted, which on removal from the liquid is again oxidised like the first, and the colour thus becomes a shade darker. By repeating this process several times, the requisite depth of colour is attained. This effect cannot in any case be produced by one immersion in the vat, however strong it may be. The beauty of the colour is increased by finally passing the goods through diluted sulphuric or muriatic acid, which removes the adhering lime and oxide of iron. After being used for some time, the vat should be refreshed or fed with copperas and lime, upon which occasion the sediment must first be stirred up, and then allowed to settle again, so as to leave the liquor clear. The indigo-blue, however, is in course of time gradually removed, and by degrees the vat becomes capable of dying only pale shades of blue. When the colour produced by it is only very faint, it is no longer worth while using it, and the contents are then thrown away. In dying cotton with indigo, it seems to be essential that the reduced indigo-blue should be in combination with lime. If potash or soda be used in its stead it is impossible to obtain dark shades of blue.

When cotton piece goods are to be dyed of a uniform blue, they are not submitted to any preparatory process of bleaching or washing, Indeed, the size contained in unbleached goods seems rather to facilitate than to impede the dyeing process. In dying these goods a peculiar roller apparatus is employed. When certain portions of the fabric are to retain their white colour a different plan is adopted. The pieces having been bleached, those portions which are to remain white are printed with so-called *resists.* These resists consist essentially of some salt of copper, mixed with an appropriate thickening material. The copper salt acts by oxidising the reduced indigo-blue at the surface, and thus rendering it insoluble before it can enter the interior of the vegetable fibre, since it is only when deposited within the fibre itself that the colouring matter becomes durably fixed. The pieces are now stretched upon square dipping frames, made of wood or of iron, furnished with sharp hooks or points of attachment. These frames are supended by cords over a pulley, and thus immersed and lifted out alternately at proper intervals. In dyeing, a set of 10 vats is used, the first vat containing 5 or 6 lbs. of indigo, and the quality increasing gradually up to 80 lbs. in the last vat. The pieces are dipped for 7½ minutes in the first vat, then taken out and exposed to the air for the same length of time, then dipped in the second vat, and so on to the last. After passing through the last vat, a small bit of the calico is dried, in order to see whether the colour is sufficiently dark. If it is not, the whole series must be dipped once more in the same vat in which the last dipping was performed. When the bottom of the vat is raked up so as to have more lime in suspension, the vat becomes what the dyer calls *hard*, that is to say, the oxide of copper of the resist is precipitated in a compact state, and consequently acts with more efficiency. But when the vat has been at rest for some time, and there is little lime in suspension, then it is called *soft.* When it is in this state, the oxide of copper is thrown down in a bulky form, and when the pieces are afterwards agitated in the liquor, in order to detach the oxide of iron which always floats about in the vat, and attaches itself to the fabric, and which, if left adhering, would cause light stains, technically called *grounding* ; then the oxide of copper is also detached, and the indigo penetrates to those parts which are to remain white. When cotton yarn is dyed in the copperas vat, the latter is generally heated by means of steam-pipes passing through the liquor, the object being to give to the colour the peculiar gloss or lustre, which is required in this class of goods. No preparatory process is required, except simply steeping in hot water. In dyeing, wooden pins are put through the hanks, their ends resting on supports passing over the top of the vat, and the yarn is then slowly turned over, one half being in the liquor, the other half over the pins. It is then taken out, wrung, exposed to the air, and again dipped, this operation being repeated until the requisite shade is obtained.

The methods employed for producing the colours called *China blue* and *pencil blue* on calico have been described under Calico-Printing.

The *urine vat* is prepared by digestion of the ground indigo into warmed stale urine, which first deoxidises the indigo-blue, and then dissolves it by means of its ammonia. Madder and alum are likewise added, the latter being of use to moderate the fermentation. This vat was employed more commonly formerly than at present, for the purpose of dyeing woollen and linen goods.

Woad Vat.—In former times, woad was the only material known to the dyers of Europe for producing the blue colour of indigo. For this purpose it was previously submitted to a peculiar process of fermentation, and the product was named *pastel* in France. For most purposes indigo has taken the place of woad in the dye-house, and for cotton goods it is now used alone. In the dyeing of woollen goods, however, the use of woad has been retained to the present day, for the purpose rather of exciting fermentation and thus reducing the indigo which is employed at the same time, than of imparting any colour to the material to be dyed. Indeed, the woad used by woollen dyers in this country contains no trace of colouring matter. Various substances, such as rhubarb-leaves, turnip-tops, weld, and other vegetable matters, have accordingly been tried, but without success, since the fermentation is more steadily maintained by means of woad than by any other material. Pastel, which does contain a little blue-colouring matter, is preferred to woad by many of the French dyers. The materials employed in the ordinary woad or pastel vat, in addition to woad and indigo, are madder, bran, and lime. In the so-called *Indian* or *potash vat*, madder, bran, and carbonate of potash are used: in the *German vat*, bran, carbonate of soda, and quicklime without woad. The chemical action which takes place in the woad vat is not difficult to understand. The nitrogenous matters of the woad begin, when the temperature is raised, to enter into a state of fermentation, which is kept up by means of the sugar, starch, extractive matter, &c., of the madder and bran. In consequence of the fermentation, the indigo-blue becomes reduced, and is then dissolved by the lime, thus rendering the liquid fit for dyeing. Great care is necessary in order to prevent the process of fermentation from passing into one of putrefaction, which if allowed to proceed would lead to the entire destruction of the indigo-blue in the liquor. If any tendency to do so is observed, it is arrested by the addition of lime, which combines with the acetic, lactic, and other organic acids that commence to form when putrefaction sets in. On the other hand, an excess of lime must also be avoided, since the reduced indigo-blue is thereby rendered insoluble, and unfit to combine with the material.

The following account of the method of dyeing woollen goods with indigo, as carried on at present in Yorkshire, may suffice to give a general idea of the process:—

The dye-vats employed are circular, having a diameter of 6 feet 6 inches, and a depth of 7 feet, and are made of cast iron $\frac{5}{8}$ths of an inch in thickness. They are surrounded by brickwork, a space of 3 inches in width being left between the brickwork and the iron, for the purpose of admitting steam, by means of which the vats are heated. The interior surface of the brickwork is well cemented. In setting a vat the following materials are used:—5 cwts. of woad, 30 lbs. of indigo, 56 lbs. of bran, 7 lbs. of madder, and 10 quarts of lime. The woad supplied to the Yorkshire dyers is prepared and grown in Lincolnshire. It is in the form of a thick brownish-yellow paste, having a strong ammoniacal smell. The indigo is ground with water in the usual manner. The madder acts in promoting fermentation, but it also serves to give a reddish tinge to the colour. The lime is prepared by putting quicklime into a basket, then dipping it in water for an instant, lifting it out again, and then passing it through a sieve, by which means it is reduced to a fine powder, called by the dyers *ware*. The vat is first filled with water, which is heated to 140° Fahr., after which the materials are put in, and the whole is well stirred until the woad is dissolved or diffused, and it is then left to stand undisturbed over night. At 6 o'clock the next morning the liquor is again stirred up, and 5 quarts more lime are added. At 10 o'clock, 5 pints of lime are again thrown in, and at 12 o'clock the heat is raised to 120° Fahr., which temperature must be kept up until 3 o'clock, when another quart of lime is introduced. The vat is now ready for dyeing. When the process of fermentation is proceeding in a regular manner, the liquid, though muddy from insoluble vegetable matter in suspension, is of a yellow or olive-yellow colour; its surface is covered with a blue froth or a copper-coloured pellicle, and it exhales a peculiar ammoniacal odour; at the bottom of the vat there is a mass of undissolved matter, of a dirty yellow colour. If there is an excess of lime present, the liquor has a dark green colour, and is covered with a greyish film, and when agitated, the bubbles which are formed agglomerate on the surface, and are not easily broken. Cloth dyed in a liquor of this kind loses its colour on being washed. This state of the vat is remedied by the addition of bran, and is of no serious consequence. When, on the other hand, there is a deficiency of lime, or in other words, when the fermentation is too active, the liquor acquires first a drab, then a clay-like colour; when agitated, the bubbles which form on its surface burst easily, and when stirred up from the bottom with a rake it effervesces slightly, or *frets* as the dyers say. If the fermentation be not checked at this stage, putrefaction soon sets in, the liquid begins to exhale a fetid odour, and when stirred evolves large quantities of gas, which burn with a blue flame on the application of a light. The indigo is now totally destroyed, and the contents of the vat may be thrown away. No further addition of woad is required after the introduction of the quality taken in first setting the vat, the fermentation being kept up by adding daily about 4 lbs. of bran, together with 1 quart or 3 pints of lime. Indigo is also added daily for about 3 or 4 months. The vat is then used for the purpose of dyeing light shades, until the indigo contained in it is quite exhausted, and its contents are then thrown away.

Woollen cloth before being dyed is boiled in water for 1 hour, then passed immediately into cold water. If it be suffered to lie in heaps immediately after being boiled, it undergoes some change, which renders it afterwards incapable of taking up colour in the vat. When a purple bloom is required on the cloth, it is dyed with cudbear to a light purple shade before being dipped. In dyeing, the cloth is placed on a network of rope attached to an iron ring, which is suspended by four iron chains at a depth of about 3 feet beneath the surface of the liquor. The cloth is stirred about in the liquor by means of hooks for about 20 or 30 minutes. It is then taken out and well wrung. It now appears green, but on being unfolded and exposed to the air rapidly becomes blue. When the vat contains an excess of lime the cloth has a dark green colour when taken out. It is then passed through hot water and dipped again, if a darker shade is required. When woollen flocks are to be dyed, they are placed in a net made of cord, which is suspended by hooks at the side of the vat. They are then transferred to a stronger net and wrung out by several men. In dyeing flocks a more active fermentation of the vat is required than with cloth.

The process of dyeing by means of sulphate of indigo is quite different from indigo dyeing in the vat. This process was discovered by Barth, at Grossenhayn in Saxony, about the year 1740, and the colour produced by it is hence called *Saxon blue.* The method of purifying sulphate of indigo, by immersing wool in the solution of crude indigo in oil of vitriol, previously diluted with water, has been described above. The process of making sulphate of indigo or *extract of indigo*, as it is called, as now practised on the large scale, is as follows:—1 lb. of indigo is mixed with from 8 to 9 lbs. of oil of vitriol, and the mixture is left to stand for some hours in a room, the temperature of which is 90° Fahr. It is then diluted with water, and filtered through paper. There is left on the filter a dirty olive-coloured residue, which is used for some purposes by woollen dyers. By now adding common salt to the liquid, a blue precipitate of sulphate of indigo is produced, which is collected on a filter, and washed with a solution of salt in order to remove the excess of acid. No neutralisation with alkali is required when this plan is pursued. The blue produced on wool and silk by means of sulphate of indigo is very fugitive, and is now seldom required, its place having been in a great measure taken by the blue from prussiate of potash. The chief use of sulphate of indigo is for dyeing compound colours, such as green, olive, grey, &c.—E.S.

On a new Method of Dyeing and Printing by means of Indigo.—By reason of its insolubility, alike in neutral and in alkaline solvents, the colouring matter of indigo cannot be fixed upon any textile fibre until it has been reduced, *i.e.*, converted into *white indigo*, which is soluble in alkalis and solutions of the alkaline earths. The energetic reducing properties of hydrosulphite of soda, and its almost instantaneous action upon indigo, which it converts into white indigo, in presence of an alkaline solution even at ordinary temperatures, have induced Messrs. Schutzenberger and Lalande to examine the practical employment of this salt in the various applications of indigo in the arts of dyeing and printing.

The indigo vats most generally used in modern times are the sulphate of iron (green copperas) vat for vegetable fibres, and the fermenting vat for wool-dyeing. The main defect of the copperas vat is the presence of a bulky sediment of oxide of iron and of sulphate of lime, which requires to subside before the clear portion of the liquid can be used for dyeing. The fermentation vat is difficult to work, and is subject to accidents, or morbid changes, which sometimes in the course of a few hours involve the entire loss of the indigo which they contain. (Such accidents are not unfrequently due to the malice of some workman, and are, of course, a kind of rattening.) The hydrosulphite vat, which the authors propose in lieu of the present methods, both for animal and vegetable fibres, is 'set' as follows:—Bisulphite of soda, marking 30° to 35° Baumé (1·26 to 1·30 specific gravity), is put in a covered cask filled up to the surface with coils of sheet zinc, or granulated zinc. This arrangement serves to increase the points of contact between the liquid and the metal. After standing for about an hour, the liquid is drawn off into milk of lime, which precipitates the salts of zinc. The whole is well stirred, and the clear liquid is separated either by filtration and pressure or by decantation, water having been previously added. During all these operations air should be as far as possible excluded. If the hydrosulphite of soda thus obtained is mixed with ground indigo, and the amounts of lime or soda needful to dissolve the reduced indigo, we immediately obtain a yellowish solution, which contains no insoluble matter except the earthy matters present in the indigo. By this process 1 kilogramme of indigo may be reduced and dissolved in such a concentrated state that the liquid does not exceed 10 to 15 litres. In dyeing the beck is filled with water—a suitable amount of reduced indigo added, and the operation is performed in the cold for cotton and at a hand-heat for wool. The dye-liquid being clear for its entire depth, the dyeing process can be conducted without loss of time. The excess of hydrosulphite present constantly reduces the scum of oxidised indigo which forms on the surface of the bath, and successive quantities of the concentrated solution of indigo are added from time to time as they are required. By means of this facility of keeping the vat at any degree of strength required, any shade may be produced with the least possible time and trouble. As regards cotton-dyeing the new process is distinguished for its ease and rapidity. In wool-dyeing all risk of spoiling the indigo is avoided. Shades are produced at once brighter and more solid than with the old vats, and it is easy to obtain upon wool bright blue bottoms such as were formerly producible only by means of the sulphate of indigo, and which were, of course, much more fugitive.

In printing with indigo, the process hitherto followed has been to use white indigo, or indigotate of tin obtained by precipitating a tin vat with hydrochloric acid or by adding to the clear portion of a copperas vat a mixture of hydrochloric acid and salt of tin. This precipitate is thickened with gum, and printed upon the calico. It is then fixed by treatment with milk of lime. The goods are then successively passed through bleaching-liquor, sulphuric acid, and a soap-bath. The process is at once difficult, delicate, and expensive. It is only by constant and anxious attention that running and injuries to the accuracy of the design are avoided during the treatment with lime-water, and only a very small fraction of the indigo is actually deposited upon the fibre. The numerous attempts hitherto made to replace the above-described process with some other means of fixing indigo have not proved successful. We need only mention as instances, China blue, pencil blue, and printing with a concentrated indigo-vat in an atmosphere of coal-gas in order to exclude atmospheric oxygen. The new method, as tested by the authors upon a manufacturing scale, consists mainly in printing with an alkaline solution of dissolved indigo suitably concentrated and thickened, the colour containing, moreover, a large excess of hydrosulphite of soda. The presence of this salt keeps the indigo-blue constantly in a perfectly-reduced state, which would otherwise become oxidised. It thus supersedes in a much more convenient manner the use of coal-gas. The printing can be carried on in common air with ordinary machines. Oxidation is so little perceived that after an hour of working the colour remains reduced to yellow. On the other hand, by printing on dissolved indigo, immediate fixation is secured as the colouring matter is almost entirely utilised. Experience shows that with shades of equal depth, solid blues are obtained at an expenditure of from 50 to 60 per cent. less indigo than with the old process. The shades obtained are more beautiful and solid, and the design comes out more distinct and better defined. The new blue not needing to be fixed by any subsequent process after printing, can be applied simultaneously with the majority of other colours, such as aniline-black, garancine colours, whether obtained by dyeing or steaming, catechu, chrome colours, albumen colours, &c. Novel styles can be thus originated, which could scarcely be executed by any other process. The new colour is obtained by thickening with gum, or any other suitable substance, an alkaline solution of white indigo sufficiently concentrated, and adding to the mixture a sufficient quantity of hydrosulphite of soda. After printing, the indigo is oxidised by hanging up the pieces for twelve to fourteen hours. They are finally washed and soaped.

Our *Imports* of indigo in 1871 and 1872 were as follows:—

INDIGO-BROWN. A brown substance of uncertain composition obtained from commercial indigo.

INDIGO-COPPER. The native protosulphide of copper, known also as *Covelline.*

INDIGO-GREEN. A green substance obtained from indigo by adding potash to an alcoholic solution of an alkaline hyposulph-indigotate.

INDIGO-PURPLE. Finely-powdered indigo is added to twenty times it weight of acid sulphate of soda in a state of fusion, and the mixture is heated and stirred till a sample colours water violet. The paste thus produced is then intimately mixed with 70 or 80 times its weight of water, and the colouring matter is precipitated by common salt and washed with saline water. After drying it forms a mass of interlaced silky crystals having a coppery lustre.

INDIGO-RED. A red substance found in commercial indigo. For particulars relative to this and other indigo colours, consult Watts's 'Dictionary of Chemistry,' and the authorities there quoted.

INDISINE. See Aniline-Violet.

INDIUM. This metal was discovered in 1863, by Professors Reich and Richter, who detected it, by the aid of spectrum analysis, in the zinc-blende of Freiberg in Saxony. The spectrum of salts of indium is characterised by two indigo-blue lines, one very bright, and the other fainter. Indium is a soft, malleable, lead-grey metal, of specific gravity 7·2. The atomic weight is believed to be 74. The metal is readily soluble in hydrochloric acid, forming a deliquescent chloride of indium. The salts of indium have hitherto been but imperfectly studied, and none of them have yet found any application in the arts.

INGRAIN. Wools, &c., are said to be dyed *ingrain* when they are subjected to that process before manufacture.

INK. (*Encre,* Fr.; *Tinte,* Ger.)

Writing Ink may be and is prepared in many different ways; but it is essentially a tanno-gallate of iron.

Nut-galls, sulphate of iron, and gum are the only substances truly useful in the preparation of ordinary ink; the other things, often added, merely modify the shade and considerably diminish the cost to the manufacturer upon the great scale. Many of these inks contain little gallic acid or tannin, and are therefore of inferior quality. To make 12 gallons of ink, we may take 12 pounds of nut-galls, 5 pounds of green sulphate of iron, 5 pounds of gum Senegal, 12 gallons of water. The bruised nut-galls are to be put into a cylindrical copper, of a depth equal to its diameter, and boiled during three hours, with three-fourths of the above quantity of water, taking care to add fresh water to replace what is lost by evaporation. The decoction is to be emptied into a tub, allowed to settle, and the clear liquid being drawn off, the lees are to be drained. The gum is to be dissolved in a small quantity of hot water, and the mucilage thus formed, being filtered, is added to the clear decoction. The sulphate of iron must likewise be separately dissolved, and well mixed with the above. The colour darkens by degrees, in consequence of the peroxidation of the iron, on exposing the ink to the action of the air. But ink affords a more durable writing when used in the pale state, because its particles are then finer and penetrate the paper more intimately. When ink consists chiefly of tannate of peroxide of iron, however black, it is merely superficial, and is easily erased or effaced. Therefore, whenever the liquid made by the above recipe has acquired a moderately deep tint, it should be drawn off clear into bottles and well corked up. Some ink-makers allow it to mould a little in the casks before bottling, and suppose that it will thereby be not so liable to become mouldy in the bottles.

From the comparatively high price of gall-nuts, sumach, logwood, and even oak bark are too frequently substituted, to a considerable degree, in the manufacture of ink; but always injuriously.

The ink made by the recipe given above, is much more rich and powerful than many of the inks commonly sold. To bring to their standard a half more water may safely be added, or even twenty gallons of tolerable ink may be made from that weight of materials.

Sumach and logwood admit of only about one half of the copperas that galls will take to bring out the maximum amount of black dye.

Lewis, who made exact experiments on inks, assigned the proportion of three parts of galls to one of sulphate of iron, which, with average galls, will answer very well; but good galls will admit of more copperas.

Red Ink.—This ink may be made by infusing for three or four days in weak vinegar, Brazil wool chipped into small pieces; the infusion may then be boiled upon the wood for an hour, strained and thickened slightly with gum arabic and sugar. A little alum improves the colour. A decoction of cochineal with a little water of ammonia, forms a more beautiful red ink, but it is fugitive. An extemporaneous red ink of the same kind may be made by dissolving carmine in weak water of ammonia, and adding a little mucilage.

Blue Ink.—Mr. Stephens's patent blue ink is made by dissolving Prussian blue in a solution of oxalic acid. The blue should be washed in dilute muriatic acid. M. Harnung has given the following as the best formula for blue ink:—

Mix 4 parts of perchloride of iron in solution with 750 parts of water, then add 4 parts of cyanide of potassium dissolved in a little water; collect the precipitate formed, wash it with several additions of water, allow it to drain until it weighs about 200 parts; add to this one part of oxalic acid, and promote solution of the cyanide by shaking the bottle containing the mixture. The addition of gum and sugar is useless, and even appears to exercise a prejudicial effect on the beauty of the ink. It may be kept without any addition for a long time.

Gold and Silver Inks are prepared by grinding upon a porphyry slab, with a muller, gold or silver leaves, with white honey, until they are reduced to the finest possible state of division. The honey is thoroughly washed from the powdered metals, and these are mixed up with gum-water.

Indelible Ink.—A very good ink, capable of resisting chlorine, oxalic acid, and ablution with a hair-pencil or sponge, may be made by mixing some of the ink made by the preceding prescription, with a little genuine China ink. It writes well. Many other formulæ have been given for indelible inks, but they are all inferior in simplicity and usefulness to the one now prescribed. Solution of nitrate of silver thickened with gum, and written with upon linen or cotton cloth, previously imbued with a solution of soda, and dried, is the ordinary permanent ink of the shops. Before the cloths are washed the writing should be exposed to the sunbeam, or to bright daylight, which blackens and fixes the oxide of silver. It is easily discharged by chlorine and ammonia.

A good permanent ink may be made by mixing a strong solution of chloride of platinum with a little potash, sugar, and gum to thicken. The writing made therewith should be passed over with a hot smoothing iron to fix it.

Another indelible ink may be prepared by adding lamp-black and indigo to a solution of the gluten of wheat in acetic acid. This ink is of a beautiful black colour, at the same time cheap, and cannot be removed by water, chlorine, or dilute acids. M. Herberger gives the following directions for its preparation:—Wheat gluten is carefully freed from the starch, and then dissolved in a little weak acetic acid; the liquid is now mixed with so much rain-water that the solution has about the strength of wine vinegar, that is, neutralises $\frac{1}{16}$th of its weight of carbonate of soda. 10 grains of the best lamp-black and 2 grains of indigo are mixed with 4 ounces of the solution of gluten, and a little oil of cloves added. This ink may be employed for marking linen, as it does not resist mechanical force.

Indelible ink of Dr. Traill is essentially the same as above.

French indelible ink is made of Indian ink diffused through dilute muriatic acid for writing with quills, and through weak potash-lye for writing with steel pens.

Marking Ink.—The inks used for marking linen generally consist of a solution of nitrate of silver, coloured with sap-green, Indian ink, or some other colouring agent, and thickened with gum. Under the combined influence of light and the organic matter, the salt of silver is decomposed, and a black stain is produced. This is indelible when washed with soap and water, but may be removed by a solution of cyanide of potassium.

A cheap indelible marking-ink, which resists the action of chlorine, and is employed by bleachers to mark their goods, is prepared by dissolving coal-tar in naphtha.

Ink-powders are occasionally used, but consist merely of the common constituents of ink in a dry state. A black ink of this kind may be prepared by mixing 4 parts of powdered gall-nuts with 2 parts of green copperas and 1 part of gum arabic. This mixture may be conveniently carried in the form of a powder, and may be prepared for use by simply dissolving it in water.

China or *Indian Ink.*—Proust says that lamp-black purified by potash-lye, when mixed with a solution of glue and dried, formed an ink which was preferred by artists to that of China. M. Merimée, in his interesting treatise entitled *De la Peinture à l'Huile*, says, that the Chinese do not use glue in the fabrication of their ink; but that they add vegetable juices, which render it more brilliant and more indelible upon paper. When the best lamp-black is levigated with the purest gelatine or solution of glue, it forms, no doubt, ink of a good colour, but wants the shining fracture, and is not so permanent on paper as good China ink, and it stiffens in cold weather into a tremulous jelly. Glue may be deprived of the gelatinising property by boiling it for a long time, or subjecting it to a high heat in a Papin's digester; but as ammonia is apt to be generated in this way, M. Merimée recommends starch-gum, made by sulphuric acid, to be used in preference to glue. He gives, however, the following directions for preparing this ink with glue. Into a solution of glue he pours a concentrated solution of gall-nuts, which occasions an elastic resinous-looking precipitate. He washes this matter with hot water, and dissolves it in a spare solution of clarified glue. He filters anew, and concentrates it to the proper degree for being incorporated with the purified lamp-black. The astringent principle in vegetables does not precipitate gelatine when its acid is saturated, as is done by boiling the nut-galls with lime-water or magnesia. The first mode of making the ink is to be preferred. The lamp-black is said to be made in China, by collecting the smoke of the oil of sesame. A little camphor (about 2 per cent.) has been detected in the ink of China, and is supposed to improve it. Infusion of galls renders the ink permanent on paper.

Printing Ink.—This is essentially a combination of lamp-black—finely-divided carbon—with oil. Mr. Underwood, in a communication made by him to the Society of Arts, well defines the necessary qualifications of a good ink:—

1. It must distribute freely and easily, and work sharp and clean.

2. It must not have too much tenacity for the type, but have a much greater affinity for the paper, and so come off freely upon it.

3. It must dry almost immediately on the paper, and not dry at all on the type or rollers: this is a great desideratum, especially for newspapers.

4. It should be literally proof against the effects of time and chemical reagents, and never change colour.

Great attention must be paid to the quality of the linseed-oil employed, and even the character of seed from which the oil is obtained should not be neglected.

The linseed-oil is clarified from the fatty matters, and the pure oil is boiled with great care at a carefully-regulated temperature; and, during the boiling, the best pale yellow soap is added to give it consistency, and the required dryers are also now mixed with it. The best black is that obtained from the smoke of naphtha, the combustion being carefully regulated. This black is ground up carefully with the drying oil, which has assumed the character of a varnish, and the ink is complete.

INKING-ROLLER. See Printing.

INOSITE. A variety of glucose, or grape-sugar, occurring in the muscles of the heart and of certain other organs. It is also found in the kidney-bean, whence it is sometimes termed *phaseomannite.*

INSTANTANEOUS MATCHES. See Matches.

INULIN. A substance similar in its properties to starch, discovered by Rose in 1804. It has been obtained from elecampane root, potato and dahlia tubers, from dandelion roots, and many other similar plants. See Watts's 'Dictionary of Chemistry.'

INVERTED SUGAR. A peculiar kind of sugar, formed by the prolonged boiling of ordinary cane-sugar with water.

IODIC MERCURY. See Mercury.

IODIDES. Compounds of iodine with metals or radicals. The more important are described under the respective metals, as iodide of potassium, under Potassium.

IODINE (*Iod*, Fr.; *Jod*, Ger.) is one of the elementary substances; it was accidentally discovered in 1812 by M. Courtois, a manufacturer of saltpetre at Paris. He found that, in the manufacture of soda from the ashes of seaweeds, the metallic vessels in which the processes were conducted became much corroded; and in searching for the cause of the corrosion, he discovered this now important substance. It was first described by Clement in 1813, but was afterwards more fully investigated by Davy and Gay-Lussac.

Gay-Lussac and Clement at first regarded hydriodic acid as hydrochloric acid, until Sir H. Davy suggested the idea of its being a new and peculiar acid, and iodine as a substance analogous in its chemical relations to chlorine.

It was named iodine from the Greek word ἰώδης, violet-coloured, on account of the colour of its vapour.

Iodine exists in many mineral waters, in combination with potassium and sodium.

In the mineral kingdom, iodine has been found in one or two rare ores, as in a mineral brought from Mexico, in which it existed in combination with silver, and also in one from Silesia in combination with zinc. See Iodite.

It exists also in very small quantities in sea-water, from which it is extracted by many seaweeds, which act therefore as concentrators of iodine; these seaweeds, when dried and ignited, yield an ash, technically called *kelp*, from which all the soda of commerce was previously obtained, but the chief value of the kelp now is on account of the iodine which it yields. The following is the process most generally adopted for the extraction of the iodine from the seaweeds:—

The sun-dried seaweed is incinerated in shallow excavations at a *low* temperature, for, if the temperature was allowed to rise too high, a considerable quantity of iodide of sodium would be lost by volatilisation. The half-fused ash or kelp which remains is broken into fragments, and treated with boiling water, which dissolves about one half of the ash.

The liquid thus obtained is evaporated, when, on cooling, the more crystallisable salts separate, viz., sulphate and carbonate of soda, with some chloride of potassium. The mother-liquor still contains the iodide of sodium, sulphide of sodium, and some carbonate of soda. This liquor is then mixed with about one-eighth of its bulk of sulphuric acid, and allowed to stand for twenty-four hours; carbonic and sulphurous acid, and sulphuretted hydrogen gases escape, a fresh quantity of sulphate of soda crystallising out, mixed with a precipitate of sulphur.

The supernatant acid liquor is then transferred to a leaden still, to which is adapted a double tubulated leaden head luted on with pipe-clay; it is then heated to 140° Fahr., when binoxide of manganese is added.

The temperature may be gently raised to 212° Fahr., but not higher, as some chlorine would come over, and combine with some of the iodine, forming chloride of iodine.

This iodine is condensed in spherical glass condensers, each having two mouths opposite to each other, and inserted the one into the other, the end one being fitted to the neck of the leaden head.

The iodine is purified by resublimation.

The following formula represents the reaction:—

Iodide of Sodium		Oxide of Manganese		Sulphuric Acid		Sulphate of Soda		Sulphate of Manganese		Iodine		Water
NaI	+	MnO^2	+	$2HSO^4$	=	$NaSO^4$	+	$MnSO^4$	+	I	+	$2HO$.
$\mathbf{2NaI}$	+	$\mathbf{MnO^2}$	+	$\mathbf{2H^2SO^4}$	=	$\mathbf{Na^2SO^4}$	+	$\mathbf{MnSO^4}$	+	$\mathbf{I^2}$	+	$\mathbf{2H^2O}$.

The British iodine is largely manufactured at Glasgow, from the kelp of the west coast of Ireland and the western islands of Scotland.

In Mr. E. C. C. Stanford's method of preparing kelp, the dried and compressed seaweed, instead of being burnt in the open air, is distilled in retorts with superheated steam, and thus all loss of iodine is prevented.

The methods of preparing iodine from the mother-liquor of the kelp have been variously modified. Thus, the use of oxide of manganese may be dispensed with; or chlorine of gas may be transmitted through the mother-liquor; or the liquor may be distilled with chloride of iron.

Another source of commercial iodine is to be found in Chili saltpetre, or native nitrate of soda. This salt in its raw state always contains iodine, though in only very small proportion. This iodine may be extracted from the mother-liquor left in the process of refining the salt, by treating the liquor with sulphurous or with nitrous acid.

Iodine is a crystallisable solid, its primary form being a rhombic octohedron. It is however usually met with in micaceous, soft, friable scales, having a greyish-black colour, a metallic lustre, and an acrid hot taste. Even at ordinary temperatures, and more especially when moist, it is sensibly volatile, emitting an odour like that of chlorine, only much weaker.

At 225° F. it fuses, and at 347° F. boils, and is converted into a magnificent violet vapour. It may nevertheless be distilled, in the presence of steam, at a temperature of 212°, as is seen in the process of manufacture.

Iodine, in the solid state, has a specific gravity of 4·947, the specific gravity of the vapour being, according to Dumas, 8·716. Iodine is only very slightly soluble in water, it requiring 7,000 parts of water to dissolve it; even then it imparts a yellow colour to the solution, and is used in that state as a test for starch, with which it forms a beautiful blue compound, which is, however, destroyed by heat.

Alcohol and ether dissolve it more readily; but the most powerful solvents of iodine are the solutions of the iodides. Iodine stains the skin, and most organic substances, of a brown colour; it attacks the metals rapidly; iron or zinc being readily dissolved by it if placed in water with it, an iodide of the metal being formed.

All the compounds of iodine with the metals and with hydrogen are decomposed by chlorine, and even by bromine, iodine being set free. Advantage is taken of this fact in detecting the presence of iodine. If the iodine exists in combination with a metal, or as hydriodic acid, its solution will not form the characteristic intense blue compound with starch, but on the addition of a little chlorine, or solution of bleaching powder, the iodine is set free and forms the blue compound with the starch. If, however, the iodine exists as iodic acid, it will not act upon starch until reduced by some reducing agent, as sulphurous acid. In using the chlorine care must be taken not to use too much, as it would unite with the iodine and prevent it acting on the starch.

Iodine is used to a considerable extent in medicine; particularly for glandular swellings, and goître. It is also much used in photography, and in the preparation of certain coal-tar colours. The chemical symbol for iodine is I; its atomic weight 126·88; and the combining volume of its vapour 2.

The price of iodine has suffered recently (1873–4) some remarkable fluctuations.

Messrs. Evans, Lescher, and Evans, in their monthly Drug-market Report for February, state that, in consequence of the makers having failed to carry out the combination which has hitherto kept up the price, iodine has suddenly, though not unexpectedly, fallen more than 50 per cent. in value, and in like manner iodide of potassium has equally declined. The immediate result of the fall is an immense demand from all quarters, everyone having let their stocks run out, greater than can be supplied at the moment. The decline has been followed immediately by a slight advance, which has now been considerably further augmented.

IODITE, or **IODYRITE.** A native iodide of silver, consisting of iodine 53·109 and silver 46·380. It is found at Guadalajara in Spain, at Albarradon near Mazapil in Zacatecas (Mexico), and at Delirio mines near Chañarcillo in Chili. See Silver.

IOLITE. A name applied to the mineral otherwise known as *cordierite* or *dichroite*, in allusion to the violet colour which it frequently presents. See Dichroite.

IPECACUANHA. The root of the *Cephaëlis Ipecacuanha*, valued in medicine as an expectorant, emetic, purgative, and sedative. It owes its active principle to an alkaloïd called *emetina*. The cultivation of the ipecacuanha plant has recently been introduced into India.

IRIDIUM. A rare white metal, found in connection with platinum and osmium. Smithson Tennant in 1804 discovered that certain black scales which remained after native platinum was dissolved in nitro-muriatic acid, was an alloy of two metals, iridium and osmium. For a full account of the methods of separating this native alloy from platinum, and of separating iridium and osmium from each other, consult Watts's 'Dictionary of Chemistry.' The native alloy on account of its hardness is used to point metallic pens. See Iridosmine.

IRIDIUM OXIDE. A substance is so known in the Russian mint. It consists, according to Deville, of:—volatile substances (and oxygen), 28·0; soluble salts, 12·0; platinum, 3·8; rhodium, 1·8; palladium, 0·4; copper, 0·6; iron, 0·7; iridium and loss, 52·7 = 100·0.

IRIDOSMINE. A native alloy of iridium and osmium found with native platinum.

IRISH DIAMONDS. A name sometimes applied to rock-crystal found in Ireland. It is occasionally cut and polished by the jeweller, and mounted in bog-oak.

IRISH GREEN. An architect's name for the green serpentinous marble of Connemara in Western Galway.

IRISH MOSS. A term applied to the seaweed, otherwise known as Carrageen moss (*Chondrus crispus*). It is used in the preparation of bandoline, and of a jelly for invalids. See Algæ.

IRON (*Fer*, Fr.; *Eisen*, Ger.) is a metal of a bluish-grey colour, and a dull fibrous fracture, but it is capable of acquiring a brilliant surface by polishing. Its specific gravity is 7·78. It is the most tenacious of metals, and the hardest of all those which are malleable and ductile. It is singularly susceptible of the magnetic property, but in its pure state soon loses it. When rubbed it has a slight smell, and it imparts to the tongue a peculiar astringent taste, called chalybeate. In a moist atmosphere iron speedily oxidises, and becomes covered with a brown coating called rust.

Every person knows the manifold uses of this truly precious metal. It is capable of being cast in moulds of any form; of being drawn out into wires of any desired strength or fineness; of being extended into plates or sheets; of being bent in every direction; of being sharpened, hardened, and softened at pleasure. Iron accommodates itself to all our wants, our desires, and even our caprices; it is equally serviceable to the arts, the sciences, to agriculture, and war; the same ore furnishes the sword, the ploughshare, the scythe, the pruning hook, the needle, the graver, the spring of a watch or of a carriage, the chisel, the chain, the anchor, the compass, the cannon, and the bomb. Iron in the state of peroxide, and in several chemical combinations, enters largely into our Pharmacopœias, this metal having been long a favourite medicine.

This metal has been found in a native state; but it is obtained by a metallurgical process from certain ores of iron, which are scattered over the crust of the globe with a beneficent profusion proportioned to the utility of the metal. They are found under every latitude, and every zone; in every mineral formation, and are disseminated in every soil.

The minerals containing iron as an essential constituent, and in considerable quantity, are very numerous, as the metal is found in the native state, forming very complicated mixtures with other elements, in masses of mainly extra-terrestial origin, and combined with arsenic, and sulphur, in various proportions in the different varieties of copper-iron- and arsenical-pyrites, and also with oxygen forming different oxides, which in their turn unite with water and with carbonic acid, forming the hydrates and carbonates of iron; these being the only minerals available for metallurgical treatment under ordinary circumstances. The silicates, sulphates, and phosphates of iron are also of great importance, in studying the production, of the ores of iron proper and in influencing their qualities for the smelter, but the interest is only an indirect one.

It is thought advisable in this place to describe only such native productions of iron as are of some such economic value, reserving for notice under their mineralogical names such as are merely interesting as minerals.

Useful Iron Ores.—See Iron Ores in its alphabetical place for the rare varieties.

Native Iron.—This species, which is very rare, occurs in small grains and plates, or massive and disseminated. It is malleable and ductile, more so than ordinary malleable iron, and ranges in specific gravity between 7 and 7·8. It contains carbon, and occasionally some other metal, but *not nickel.* A specimen from Gross Kamsdorf, in Thuringia, analysed by Klaproth, yielded 92·5 iron, 6 lead, and 1·5 copper: its structure was foilated and its texture crystalline. Native iron was found by Schreiber, in a vein at Oulle, near Allemont in Dauphiné. A specimen containing 91·8 iron and 7·0 carbon (*Shepard*), was observed at Canaan in Connecticut, in a vein, two inches broad, lying in mica slate; another specimen was found in sandstone at Penn Yan, in New York. *John* states that it is mixed with the platinum grains from South America, and more recently M. Molnar has affirmed that he has found native iron in the gold sands at Oláhpian. Mossier has found volcanic iron in lava at Graveneire in Auvergne; it had a steel-grey or silver-white colour, foilated texture, and hackly fracture; and Dr. Andrews states that he detected native iron in grains in the basaltic rock from the Giant's Causeway. These instances would seem to prove the actual existence of native iron, which was for a long time disputed.

Native Meteoric Iron.—This species is distinguished from the last by containing *nickel* and sometimes *cobalt.* It is very malleable, often cellular, but sometimes compact, and in parallel plates which pass into rhomboids or octohedrons. When polished and etched with acids, it exhibits linear and angular markings, or *Widmanstatt's* figures, as they have been termed, and from which an impression may be printed on paper. A great number of undoubted meteorites have been described and analysed. The following Table from Nicol's 'Manual of Mineralogy' exhibits the composition of some of the most remarkable:—

	Iron	Nickel	Cobalt	Copper	Manganese	Magnesium	Sulphur	Chlorine	Insol. matter	Total
1	93·78	3·81	0·21	...	...	...	...	...	2·20	100

10	44·1	24·50	11·4	? 10·0	...	...	90·0

The above analyses are of:—1. A mass of 103 lbs. weight, which fell at Bohumilitz, in Bohemia, in 1829. 2. A mass weighing 1,600 lbs., found in 1748, near Krasnojarsk, on the Yenisei. 3. The so-called 'Verwünschte Burggraf,' from Elbogen in Bohemia, which weighed 191 lbs. 4. A mass of 71 Vienna pounds weight, which fell at Hraschina, near Agram, in Croatia, on May 26, 1751. 5. A mass in the Haarlem Museum, found in 1793, on the plain between the Great Fish River and Graf Reynet, in the Cape Colony, originally weighing 300 lbs. 6. Found at Lenarto, in Hungary, original weight 194 lbs. 7. From Clairborne in Alabama. 8. From Petosi.

9. Is a more recent analysis of the same. 10. From Lockport in North America. 11. From Bitburg, near Trèves, which weighed above 3,300 lbs.

According to *Shepard* ('Silliman's American Journal'), the fall of meteoric stones is confined principally to two zones. The one, belonging to America, lies between 33° and 44° N. lat., and is about 25° in length. Its direction is more or less from N.E. to S.W., following the general line of the Atlantic coast. Of all the occurrences of this phenomenon during the last 50 years, 92·8 per cent. have taken place within these limits, and mostly in the neighbourhood of the sea. The zone of the eastern continent, with the exception that it extends 10° further to the north, is bounded by the same degrees of latitude, and follows a similar north-east direction; but it has more than twice the length of the American zone. Of the observed falls of aërolites, 90·9 per cent. occurred within this area, and were also concentrated in that half of the zone which extends along the Atlantic.

Amongst the remarkable masses of meteoric iron the following must be named:—that found by Don Rubin de Celis, in Tucuman in South America in 1783, weighing 300 cwts.; that discovered in 1784 on the Riacho de Bendego in Brazil, estimated to measure 32 cubic feet, and to weigh 17,300 lbs.; and that on the Red River in Louisiana, weighing above 3,000 lbs., and presenting distinct octahedral crystals.

The Swedish expedition to Greenland discovered some enormous masses of meteoric iron in 1870, and in 1871 it brought back twenty specimens, amongst which were two of enormous size; the largest, weighing more than 49,000 Swedish pounds, or about 21 tons English, with a maximum sectional area of 42 square feet, is now placed in the hall of the Royal Academy of Stockholm; whilst, as a compliment to Denmark, on whose territory they were found, the second largest, weighing 20,000 lbs., or about 9 tons, has been presented to the museum of Copenhagen. Chemical analyses of these remarkable masses have proved them to contain nearly 5 per cent. of nickel, with from 1 to 2 per cent. of carbon, and to be quite identical with many aërolites of known meteoric origin. These masses were discovered lying loose on the shore, but immediately resting upon basaltic rocks, in which they appear to have been originally imbedded. Professor Nordenskjöld and several others familiar with meteoric irons consider these masses to be meteorites. See Aërolites.

Franklinite.—This ore of iron usually crystallises in octahedra, but is also found massive. According to Rammelsberg, it consists of iron 45·16, manganese 9·38, zinc 20·30, oxygen 25·16. It is said to occur in amorphous masses at Altenberg, near Aix-la-Chapelle, but it is found abundantly at Hamburgh, New Jersey, where it occurs in a metamorphic Silurian limestone with red oxide of zinc and garnet. It is also found at Stirling Hill in the same locality, where it is associated with *Willemite* in a large vein, in which cavities occasionally contain crystals from 1 to 4 inches diameter. The attempts to use this ore have not been very successful. Dana says it is ground up and used for a dark paint, and some of it has been smelted for iron, to which the zinc is thought to give tenacity. The zinc has also been separated and the residues smelted for spiegeleisen. See Franklinite.

Magnetite, *Magnetic Iron Ore*, *Native Loadstone*, or *Octahedral Iron Ore.*—This very rich and valuable ore occurs especially in igneous or metamorphic rocks, either in distinct crystals, or, as in many basalts, disseminated through the mass, when it frequently imparts magnetic properties to the rocks, especially to greenstone, serpentine and basalt. It also forms beds in gneiss, in chlorite-, mica-, hornblende-, and clay-slates, in marble, greenstone, and other rocks, but seldom appears in veins. The largest known masses occur in the northern parts of the globe, in Scandinavia, Lapland, Siberia, and North America. Less extensive masses occur in the Hartz, in Saxony, Bohemia, Silesia, and Styria; and in Southern Europe, in Elba and Spain. Magnetite is the most important ore of iron in Norway, Sweden, and Russia. The Dannemora mines in Sweden, wrought in an open quarry 150 feet broad, and 500 feet deep, furnish the fine Oeregrund iron, largely imported into England for the manufacture of steel. Some highly magnetic varieties, especially from Siberia and the Hartz, form natural magnets, possessing distinct polarity. Others become polar only after contact with magnets of sufficient power. Magnetic iron ore is found in rather considerable masses not far from Haytor on Dartmoor, and near the village of Brent, at the southern extremity of Dartmoor. It is also found in Cornwall, in the vicinity of the Indian Queens; near Penryn, Ponsanooth, and a few other localities. Magnetic iron ore fuses with extreme difficulty; it is not acted upon by nitric acid, but when powdered is soluble in hydrochloric; its specific gravity varies from 4·24 to 5·4. The chemical formula of pure magnetite is FeO,Fe^2O^3, corresponding to 31·03 of protoxide, and 68·77 of peroxide of iron, or of 72·40 iron, and 27·60 oxygen, which agrees closely with the analyses of Berzelius, Kobell, and Karsten.

Analyses I. and II. are of magnetic iron ore from Cornwall by Noad; III. of Dannemora magnetite by Ward:—

	I.	II.	III.
Water	2·50	3·20	0·11

Insoluble residue . .	24·20	9·40	12·54
Total . .	99·60	98·95	100·61
Metallic iron . . .	46·8	57·56	61·16

Hæmatite; Specular Iron; Fer oligiste; Micaceous Iron Ore.—This ore has a metallic lustre; colour, iron black to steel grey, but often tarnished; the light transmitted through the thin edges of its crystals appears of a beautiful red colour. Its powder is always of a well-marked brown-red hue, passing into cherry red, which distinguishes it from the black oxide ore; its fracture is conchoidal or uneven; it is brittle, and its specific gravity is 5·2. Its chemical composition is Fe^2O^3, or 70·03 iron, and 29·97 oxygen; in the reducing flame of the blowpipe, it becomes black and magnetic.

Specular iron includes specimens of a perfect metallic lustre. The specular variety occurs chiefly in crystalline rocks in large beds or veins. The mines of the island of Elba, celebrated from antiquity, still furnish the finest crystals, which occur in druses of the massive variety, along with pyrites and quartz; fine crystals are likewise produced from St. Gotthard, Framont, in the Vosges mountains, the Hartz, Altenberg in Sweden, and from Katharinenburg in the Ural.

Micaceous iron ore is that variety of hæmatite which has a distinctly micaceous character. Beautiful specimens of the micaceous variety occur at Zorge and other parts of the Hartz. At Hennock, not far from Haytor on Dartmoor, a very large lode of the micaceous ore exists; it is also found near Tavistock in Devonshire, at Huel Owles tin mine, and Botallack tin and copper mine at St. Just in Cornwall, and in Wales, Cumberland, and Perthshire. It also occurs in volcanic rocks, as in Auvergne, on Vesuvius, Ætna, and the Lipari Islands, especially Stromboli, where some fine crystals, three inches broad and four long, have been procured.

Hæmatite is a term more strictly applied to the red varieties of the specular iron ores, on account of the red colour of its powder, from ἁιμα, blood. The red hæmatites are those which have a distinctly red colour when scratched, or which yield a red streak. One variety is known as *fibrous red iron.* If soft and earthy, it is called *red ochre*; a peculiar variety of this kind is found near Rotherham in Yorkshire, and is known as *raddle.* It is used for polishing lenses in Sheffield, and largely employed for marking sheep. The *red chalk* used for drawing is a variety of the same kind.

Red hæmatite.—This ore is found in the greatest abundance in the mountain or carboniferous limestone formations. The most abundant deposits in this country are those of Lancashire and Cumberland.

The hæmatite of Whitehaven occurs in the carboniferous limestones near the outcrop or surface-edge of the slaty rocks upon which that formation rests. The greater part of the excavations from which it is extracted are subterraneous, and so extensive is often the mass of iron ore in which the workings are carried on, that it is difficult in such situations to obtain a clear idea of the nature of this important deposit. (*Warington Smyth.*)

The following are the quantities of red hæmatite produced since 1868:—

	1868	1869	1870	1871	1872
Lancashire:	tons	tons	tons	tons	tons
Barrow-in-Furness	767,625	784,507	871,938	931,048	909,077
Cumberland:					
Hodbarrow . .	201,380	198,705	174,943	207,146	211,771
Whitehaven . .	725,248	848,974	1,014,143	976,874	954,505
Total . .	1,694,253	1,932,186	2,061,024	2,115,068	2,075,353

The price, which was about 11*s.* or 13*s.* a ton in 1865, varies now (1873) from 30*s.* to 36*s.* per ton, owing to the great demand for hæmatite pig-iron for Bessemer-steel making.

In addition to the above, it is thought desirable, as showing the very large quantities of ore which are raised from these hæmatite mines, to give the detailed produce for a single year, 1872:—

Lancashire.

The carboniferous limestones of Derbyshire and Somersetshire also contain veins and deposits of hæmatite, though of a quality not equal to those of Lancashire; the same ore is also met with in the Devonian series of Devon, West Somerset, and Cornwall. See HÆMATITE.

Brown Hematite.—Under this term are included the following minerals:—

1. Turgite, of the composition $2Fe^2O^3+HO$ with 5·6 per cent. of water.
2. Göthite „ Fe^2O^3+HO „ 10·1 „
3. Limonite „ $2Fe^2O^3+3HO$ „ 14·4 „

Of these minerals, the first also known as *hydro-hæmatite*, resembles the ordinary red hæmatite, giving a bright red streak, but decrepitates when heated. It has hitherto been considered to be of rare occurrence; but latterly it has been generally recognised that the red ore of Bilbao is to a considerable extent of this composition, and probably all hydrated ores giving a red as distinguished from a brown streak may be referred here. Göthite is a finely-crystallised mineral, which has been found at Restormel in Cornwall in great abundance; other varieties are known as *Lepidocrocite* and *Stilpnosiderite.*

Limonite includes all the massive and earthy varieties. The so-called *hydrate of iron* is a calcareous brown hæmatite, occurring at the base of the Cheadle coal-field in North Staffordshire. It is highly esteemed in South Staffordshire for making special classes of pig-iron.

Brown hæmatites being in all cases produced by the alteration of other ores, their quality is in great part determined by the composition of the mineral from which they have been derived. Substantially they may be referred to the action of atmospheric air and water upon two minerals—namely, carbonate of protoxide of iron, and iron pyrites—and in a lesser degree they may be formed from magnetite or silicates containing protoxide of iron. Beds of clay ironstone (argillaceous carbonate) are usually altered at the surface into an earthy brown hæmatite, and lodes of spathic carbonate are at times changed to considerable depths into a similar substance, which change in composition is often not attended with any alteration of form, but the mass becomes spongy in the interior, giving a free passage to the reducing gases in the furnace, which renders them easily reducible; a change that is further accelerated by the fissuring produced by the expulsion of the confined water on heating. The great brown iron ore lodes of Bilbao, which occur in cretaceous limestones, are supposed to be likely to produce spathic ores when worked to greater depths.

The change of iron pyrites into brown iron ore is familiar to all miners under the term of gozzan, where the pyritic contents of lodes have been changed to a red rusty mass, which is taken as an indication of the presence of the sulphides of the more valuable metals in depth. These gozzans are not workable as iron ores, mainly from the presence of quartz, and sulphides and arsenides of other metals. A very good ore derived from the alteration of iron pyrites is shipped in considerable quantities from Santander, and masses of the original mineral may be found unchanged in the centre of some of the larger masses.

When the original carbonate contains manganese, the derived brown ore will generally be associated with pyrolusite or other highly-oxidised manganese ores, forming an intimate mixture suitable for simultaneous reduction, with the production of a highly manganesiferous pig-iron. Such ores are common in the Siegen districts of Rhenish Prussia, and in the neighbourhood of Carthagena in Spain, from which latter locality they are largely exported to England, Belgium, and other parts of Europe.

The largest developments of this class of ore in England are in the lower secondary strata, where it is found at different horizons in the oolitic rocks all through the midland counties, from Wiltshire to Lincolnshire; the most important localities being in Northamptonshire. As a rule these are of a low quality, containing not more than 35 per cent. of iron, with a considerable quantity of sand, and a high proportion of phosphorus; but from the low cost at which they can be raised, being got in open quarry workings, they are in great demand for mixing with the higher class but more expensive ores of Wales and South Staffordshire, besides being largely smelted on the spot.

In addition to the ordinary atmospheric action, the production of brown iron ores is largely due to organic agency in the so-called bog- and lake-ores, which are produced by the action of minute vegetable organisms (*diatoms*), on iron in solution in stagnating waters. These ores are generally very impure, containing large quantities of sand and a good deal of phosphorus; bog-ore is usually found in irregular concretions, forming at times connected beds, but more generally they are detached in swampy and forest-ground at a short distance below the surface. The lake-ores which are found in Sweden and Finland are entirely of organic origin; they form small granular or disc-like concretions, which are dredged up from the beds of lakes during the winter. The formation goes on continuously, so that, after clearing the ground, a fresh deposit of workable thickness is re-formed in about twenty years. The varying nature of ores of this class will be seen from the following analyses:—

I. Black brush ore; II. Smith ore—Forest of Dean. III. Llantrissant ore. IV. Froghall calcareous ore, or 'Hydrate of iron.' V. Northampton ore, from the inferior oolite, Wellingborough. VI. Lake ore, from Platen, Wermland, Sweden. VII. Bog iron ore, from Lingen, in East Friesland. VIII. Belfast aluminous ore, containing in addition 3·51 of titanic acid. IX. Bauxite, from Baux, in the south of France, with 3·10 of titanic acid.

A special class of brown iron ores has of late become of considerable importance. These are the aluminous ores, consisting essentially of mixtures of hydrated peroxide of iron and alumina. The proportion of iron varies considerably, but they are valued chiefly for the alumina, on account of its fluxing power, being used to prevent the reduction of silica and the formation of extra siliciferous iron when smelting hæmatite containing quartz. These ores are known as 'Belfast aluminous ores,' from their occurrence in the county of Antrim; and by the mineralogical name of Bauxite, from the locality in the south of France where it was first discovered. A yet more aluminous variety is obtained in Carniola. The Irish ore occurs in a thin irregular bed of concretionary pisolitic structure, interstratified in the great mass of basalt covering the whole of the county of Antrim north of Belfast.

Passing east from Slievananee, the iron-beds are worked from the face of the basaltic escarpment overhanging Milltown, Red Bay, at the entrance of Glenariff Glen. The beds dip west about 5°, and are about 200 feet above the upper limit of the White Limestone. Further to the east the iron-band has been traced to near Garron Point. Two miles to the west of Carnlough the ferruginous series is seen at a height of 600 feet above the sea-level, dipping at an angle of about 40° E. magnetic. The matrix of the pisolitic ore, 22 inches in thickness, is of a bright vermilion-red colour, becoming browner as it passes downward; it then passes into a friable yellowish ochre, 4½ feet thick, which, in its turn, graduates into a blue lithomarge 35 feet thick. Overlying the pisolitic ore is a semi-prismatic basalt, the columns of which are perpendicular, and consequently include with the underlying strata an angle of 50°.

Other outcrops are worked at Ballyvaddy and Tully, near Glenarm, and at Anteville, Kilwaughter, and Shane's Hill, near Larne.

The following Table of analyses of the pisolite ores of Antrim is from Messrs. Tate and Holden's paper, published in the 'Quarterly Journal of the Geological Society':—

I. Slieve Gallion; Dr. Apjohn. II. Antrim; Professor Hodges. III. Lithomarge; Germany. IV. Drumrankin, near Ballymena; Dr. Apjohn. V. Bole, Germany.

'There can be no doubt that the lithomarge and bole alternating with compact basalts are but decomposed basalts. The passage from basalt to lithomarge and bole can be traced in all cases; not unfrequently large masses of basalt are to be seen in the midst of the lithomarge, the concentric layers presenting all the varieties of texture and colour between the hard and black basalt of the interior and the purple or yellowish argillaceous masses in which the basalt appears to be imbedded. Again, the boles often contain cavities filled with the ordinary zeolites of the amygdaloid basalts.

'Observations in the field and the preceding comparative analyses go far to prove that the bole and lithomarge are the resultants of aqueous action in combination with acidulated gases, which, dissolving out certain mineral substances, has effected the decomposition of the basalts, especially of the more felspathic ones.'—*Tate and Holden.*

The following is a series of analyses of Forest of Dean ores, by Dr. Noad:—

	I.	II.	III.	IV.	V.

	100·80	100·00	100·00	100·26	100·02

This brown iron ore is also found at Alston Moor and Weardale, Durham, but is only used to a limited extent on account of its association with lead and zinc. It occurs at Llantrissant, near Cardiff; in many parts of Devon, especially at Smallacombe, near Newton Abbot; and at Sharkam Point, near Brixham. It has also been recently found at Poltimore, near South Molton, in Devonshire, much of it containing considerable quantities of manganese. In Cornwall the brown hæmatite is worked at Restormel, near Lostwithiel; at several places around St. Austell; in Constantine; and other parts.

Some of the brown hæmatites contain a large percentage of manganese. Their general composition is illustrated in the following analyses (*Dr. Noad*):—

	I.	II.	III.	IV.
Water	12·85	12·80	12·40	13·20
Oxide of manganese . . .	3·08	9·60	8·80	11·20

Insoluble residue	12·00	9·50	8·80	11·200
	100·54	101·20	99·79	100·85

The brown iron ores of the secondary formations have of late years assumed considerable importance. In the Lias, the Oolite, and in the Lower Greensand formations, brown hæmatites (that is, hydrated oxides of iron), generally impure and sandy, are found. They range almost continuously from the northern parts of Wiltshire to the wolds of Yorkshire, passing through Oxfordshire, Northamptonshire, and Lincolnshire, appearing as an ochreous brown oolitic rock. The most important bed is that occurring in the lower part of the great oolite, from the neighbourhood of Banbury through Northamptonshire. The extent of the workings in Northamptonshire will be best judged of by the following details of the quantities of iron ore produced from the mines of *Northamptonshire* in 1872:—

No.	District or mine	Quantity		Value		
		tons	cwts.	£	s.	d.
1	Blisworth	83,514	0	31,317	15	0
2	Brixworth (Denby)	10,850	7	4,168	15	0
3	Castle Dykes (Stowe)	1,500	0	562	10	0
4	Cogenhoe	25,000	0	9,357	0	0
5	Duston, *Northampton*	63,703	0	23,889	0	0
6	Duston	87,019	0	32,632	0	0
7	Gayton	33,961	0	12,735	0	0
8	Wellingborough	149,953	3	56,232	0	0
9	Glendon	98,148	10	36,805	10	0
10	Finedon					
11	Burton					
12	Gayton	...		...		
13	Chapter Lands, *Irthlingboro'*	114,868	11	43,074	0	0

15	Ditto					
16	Newbridge (*Twywell*)	70,000	0	26,250	0	0
17	East End, Wellingboro'	65,914	0	24,715	15	0
18	Woodford	73,502	0	27,563	5	0
19	Ringstead	43,498	15	16,311	15	0
20	Irchester	46,961	1	18,735	0	0
	Total of Northamptonshire	1,004,093	7	377,736	15	0

In some places the Northamptonshire ore appears to be the result of an alteration of an argillaceous carbonate, similar to the Cleveland ore.

The importance of the iron ores of Yorkshire (North Riding or Cleveland District) will be shown by the production of Cleveland ore in 1872.

The Yorkshire ores occupying a somewhat uncertain position are placed with the *argillaceous carbonates*, p. 930.

The iron ores of Lincolnshire—which are placed by Mr. Judd in the greensand or lower cretaceous formation (the neocomian of D'Orbigny)—are thus described by him:—

'The existence in this district (the neighbourhood of Claxby) of fragments of iron-slag, calcined ore, and charcoal, associated with Roman pottery, indicates that these ores were known and worked at a very early period.

'The only ironstone in this district (between Claxby and Nettleton) which is now sufficiently rich to repay the working, is a rock almost entirely made up of small and beautifully-polished oolitic grains of hydrated peroxide of iron. The earthy material, full of large concretionary masses of ironstone, which was at first thought to be equally valuable, is found to yield so small an average percentage of iron, that it is not worked. The oolitic ironstone rock is crowded with fossils, the shells of the gigantic *Pecten cinctus* being especially abundant. It also frequently exhibits veins of beautifully-crystallised calcspar. The ore is thus an eminently calcareous one: it yields on analysis from 28 to 33 per cent. of metallic iron.

'The useful bed of ironstone averages 6 feet 6 inches in thickness. It is mined by means of adits driven into the face of the hill.'—*Quarterly Journal of the Geological Society*, 1870.

In 1872, 62,653 tons were raised at Claxby; while at Froddingham, near Brigg, 256,149 tons were produced.

Carbonate of iron; Sparry iron; Spathose iron; Spathic iron; Sphærosiderite; Spatheisenstein.—This important species has been divided into two varieties; spathose iron proper, and the compact carbonate, the clay-ironstone of the coal-formation. Sparry iron appears to range through nearly the same series of formations as the anhydrous hæmatites: it occurs in beds and masses often of immense extent, especially in Styria and Carinthia. In the Erzberg, near Eisenerz in Styria, it rests on gneiss, and is wrought in an open quarry. The Stahlberg and Momel, near Schmalkald, the vicinity of Siegen, and Müsen in Westphalia, show similar extensive masses; whilst in Anhalt and the Hartz it forms large veins in greywacke or in Devonian limestone. Other very extensive deposits of this ore are found in the Pyrenees, and the Basque provinces of Spain, as near Bilbao; and at Pacho near Bogotà in New Granada. Most of these localities yield fine crystals; and these also occur in metallic veins at Joachimsthal in Bohemia, Freiberg in Saxony, Clausthal in the Hartz, Beeralston in Devonshire, Alston Moor in Cumberland, and in many of the mines of Cornwall, where the rare hexagonal prisms have been found. In England the crystalline carbonate of iron occurs in the Devonians of South Somersetshire and North Devon. It exists in numerous lodes upon Exmoor, although they have been but partially worked. On the Brendon and Eisen hills there have been mines for several years, those mines producing in 1872, 27,913 tons. At Perranzabuloe in Cornwall an immense deposit of spathose iron exists, and is now (1874) being worked to a considerable extent, a railway having been constructed to carry the ore to the southern ports. It is also found in the carboniferous limestones of Northumberland and Durham, especially in Weardale, which district produced in 1872, 97,953 tons.

The specific gravity of sparry carbonate of iron varies from 3·00 to 3·67. Its primitive form is, like that of carbonate of lime, an obtuse rhombohedron. Without changing this form, its crystals are susceptible of containing variable quantities of carbonate of lime, till it passes wholly into this mineral. When heated before the blowpipe, it turns brown without melting, and becomes attractable by the magnet after being slightly heated in the flame of a candle. Even by a short exposure to the air after its extraction from the mine, it also assumes the same brown tint, but without acquiring the magnetic quality; after long exposure to the air it becomes wholly converted into hydrated hæmatite.

The variations in composition of this important mineral are shown in the following analyses:—

	Steinheim, Hanau	Rancié, Pyrenees	Müsen, Siegen	Ehrenfriedersdorf	*Henry*, Somersetshire	*Noad*, Somersetshire
Protoxide of iron .	63·75	53·50	43·59	36·81	37·33	52·56
Sesquioxide of iron .	...	...	...	...	8·52	...
Protoxide of manganese	0·75	6·50	17·87	25·31	12·65	4·82
Magnesia . . .	0·25	0·70	0·08	...	4·52	2·41
Lime	traces	...	0·24	...	traces	1·25
Carbonic acid . .	34·00	39·20	38·22	38·35	35·80	38·68
	98·75	99·90	100·00	100·47	98·82	99·72

Spathic ores vary very much in appearance according to the amount of manganese present; the richest, such as those of Siegen, are coarsely crystalline with curved cleavage faces of a pearly lustre; while the Styrian, which contains but little manganese, although otherwise very pure, is of a dull granular fracture. The Cornish ore from Perran is also very dull and unlike the crystalline mineral.

Coal-measure iron stones.—The compact carbonate of iron has no relation externally with the sparry variety. It comprehends most of the clay-ironstones, particularly those which occur in flattened spheroidal masses of various sizes among the coal-measures. The colour of this ore is often a yellowish brown, reddish grey, or a dirty brick-red. Its fracture is close grained, it is easily scratched, and gives a yellowish brown or grey powder. It adheres to the tongue, has an odour slightly argillaceous when breathed upon; blackens at the blowpipe without melting, and becomes attractable by the magnet after calcination. The ironstones of the coal-formation admit of a natural division into two great classes, viz. the *argillaceous*, and the *blackband* or *carbonaceous*. The earthy or lithoid carbonates occur in some regions in the upper limestone shales, and they extend upwards through the coal-measures proper towards their higher limits; they likewise occur in extensive beds in the Jurassic formation. particularly in North Yorkshire; near the upper limit of the Lias, or base of the oolites proper; and again higher, as nodules and perhaps as beds, in the middle oolites, or Oxford clays. They are also found extensively as courses of nodules in the Wealden series, and as beds in the Greensand. When these grey carbonates contain lime in abundance, and when clay is not largely present, they are sometimes changed by atmospheric influences into hydrated hæmatites; in Northamptonshire, for example, and widely in France. The only great coal-fields in Great Britain in which these ores do not occur in sufficient abundance to form the basis of a large production of iron, are those of Northumberland and Durham, and of Lancashire. The great importance of the argillaceous and blackband ironstones of our coal-fields is clearly shown by the fact, that they supply a very large proportion of the entire iron produced (*Blackwell*). They vary considerably in their percentage of iron, which is generally not more than 30 to 33 per cent., but occasionally ranges as high as 40 per cent. They are rarely used when they contain less than 25 per cent. The varying proportions of iron, silica, and alumina which they contain is shown in the subjoined analyses of the ore from different localities:—

Titanate of iron ; Titanitic iron ; Ilmenite.—This variety occurs in various formations, as in the *miascite* of the Ilmen mountains ; in *talc*, with dolomite, at Gastein in Salzburg ; in the *zircon-syenite* at Egersund in Southern Norway ; and in *gneiss*, with magnetic iron ore, at Tvedestrand, and Krageroe, near Arendal ; and in enormous quantities in the Upper Laurentian or Labrador series of the lower St. Lawrence Valley, and Labrador in Canada, with hypersthene and rutile in Labradorite gneiss, the so-called *norite rock*. The sand produced from the waste of these rocks produces the titaniferous iron sands, which are treated in the American bloomary. Its chemical composition is a titantite of protoxide of iron and magnesia in variable proportions, with peroxide of iron or magnetite; its value as an iron ore depends upon the predominance of the latter components. Titaniferous ores, when not containing more than 8 per cent. of titanium, may be treated advantageously, as they yield good iron from the absence of sulphur and phosphorus; but with larger proportion of titanium they become too refractory, and require too much flux to be smelted alone, the proportion of fuel required being greatly increased.

History of Iron-Smelting.—There is abundance of evidence that iron was well known in the early ages, and was applied to various useful purposes. The earliest method of working the furnace where ores were smelted seems to have been by exposing them to the wind: the furnaces, perforated with holes, were built on eminences, and could only be worked when there was a strong breeze; the fire was regulated by opening and shutting the apertures. Mungo Park gives, in his 'Travels in Africa,' the following interesting account of an iron-smelting operation in Kamalia, at which he himself assisted: 'The ironstone was broken into pieces the size of a hen's egg; a bundle of dry wood was first put into the furnace, and covered with a considerable quantity of charcoal; over this was laid a stratum of ironstone, and then another of charcoal, and so on until the furnace was quite full. The furnace was a circular tower of clay, about 10 feet in height and 3 in diameter, surrounded in two places with withes, to prevent the clay from cracking and falling to pieces by the violence of the heat. Round the lower part, on a level with the ground, but not so low as the bottom of the furnace, which was somewhat concave, were made seven openings, into each of which were placed three tubes of clay, and the openings again plastered up in such a manner that no air could enter the furnace but through the tubes, by the opening and shutting of which the fire was regulated. The fire was applied through one of the tubes, and blown for some time with bellows made of goat's skin. The operation went on very slowly at first, and it was some hours before the flame appeared above the furnace; but after this it burnt with great violence all the first night, and the people who attended put in at times more charcoal. On the day following the fire was not so fierce, and on the second night some of the tubes were withdrawn, and the air allowed to have free access to the furnace; but the heat was still very great, and a bluish flame rose some feet above the top of the furnace. On the third day from the commencement of the operation all the tubes were taken out, the ends of many of them being vitrified with the heat, but the metal was not removed until some days afterwards, when the whole was perfectly cool; part of the furnace was then taken down, and the iron appeared in the form of a large irregular mass, with pieces of charcoal adhering to it. It was sonorous, and when any portion was broken off, the fracture exhibited a granulated appearance like broken steel.'

That the iron ores of Monmouthshire and Gloucestershire were extensively worked by the Romans during the period of their reign in Britain is certain, from the immense beds of iron cinders that have been discovered in the Forest of Dean; it is probable that Bath was the principal seat of their foundries; relics of their operations, in the form of cinders and coins, have likewise been discovered in Yorkshire and in other counties. During the reign of William the Conqueror, Gloucester was the city where the trade of forging iron was chiefly carried on, the Forest of Dean supplying the ores. It is uncertain when the art of casting was first discovered; cannon are supposed to have been first used in England by Edward III., who used them in his invasion of Scotland in 1327, at Cressy, and at the siege of Calais in 1346. These cannons were not, however, cast, but were constructed on the same principles as coopers construct their barrels; a number of iron bars, fitting as close as possible to each other, were arranged round a cylinder of wood, and were then bound together by strong iron hoops; the wood being driven out, there remained an iron pipe which formed the barrel. This mode was superseded by *casting* the cannon of bronze.

During the 14th and 15th centuries, iron and steel were imported into this country from Germany, Prussia, and other places, and also iron from Spain; but as several improvements in the manufacture has taken place in the course of this period in England, laws were made towards the conclusion of the 15th century, prohibiting the importation of any of the articles manufactured in this country in iron and steel. During the reign of Elizabeth, the consumption of charcoal by the iron furnaces was so great, that it was deemed necessary to enact laws to prohibit the erection of new furnaces, and to prevent the felling of timber for fuel; persons interested in the manufacture of iron were consequently compelled to turn their attention to the finding of some substitute for charcoal, and in the reign of James I. and Charles I. many attempts were made to smelt iron with pit-coal, but without success; the consequence was the entire abandonment of iron-making in many parts of the country, and a great decrease in the manufacture in others; so complete indeed was the failure of all the experiments made to substitute pit-coal for charcoal, that all attempts were abandoned till the early part of the next century, when pit-coal was first used (1713) by Mr. Abraham Darby in his furnace at Colebrook Dale; and in the 44th volume of the Philosophical Transactions, published in 1747, it is stated, that 'Mr. Ford, from iron and coal, both got in the same Dale (Colebrook), makes iron brittle or tough as he pleases, there being cannon thus cast so soft, as to bear turning like soft iron.' Notwithstanding, however, the establishment of the fact that iron ore could be smelted, and iron manufactured with pit-coal, and although great efforts were made, by increasing the column of blast by the substitution of steam-power for that of horses and human labour, there appears to have been a steady and progressive diminution in the quantity of iron produced in this country; and recourse was had to foreign markets, particularly to those of Sweden and Russia, for the necessary and increasing demand. Thus, the imports of iron between the years 1711 and 1776 were as follow:—

	Tons
1711 to 1718	15,642
1729 „ 1735	25,501
1750 „ 1755	34,072
1761 „ 1766	48,980

In 1740 there were only 59 blast-furnaces in work in England and Wales, the total make of which amounted to not more than 17,350 tons, being an average of 294 tons per annum for each furnace, a quantity very little exceeding that sometimes made in a *single week* in some of the furnaces in Wales at the present day.

The earliest contrivance for throwing a powerful and constant blast into the furnace was a forcing pump, worked by a water-wheel or by a steam-engine; and it appears that the first cylinders, at least of any magnitude, were erected at the celebrated Carron Iron Works in the year 1760 by Mr. John Smeaton. These cylinders were four feet six inches in diameter, exactly fitted with a piston, moved up and down by means of a water-wheel; in the bottom of the cylinder was a large valve, like that of a bellows, which rose as the piston was lifted up, and thus admitted the air into the cavity of the cylinder below. Immediately above the bottom was a tube which went to the furnace, and as it proceeded from the cylinder, was furnished with a valve opening outwards. Thus when the piston was drawn up, the valve in the bottom rose and admitted the air that way into the cylinder, while the lateral valve shut, and prevented any air from getting into it through the pipe. When the piston was thrust down, the valve in the bottom closed, while the air, being compressed in the cavity of the cylinder, was violently forced out through the lateral tube into the furnace. There were four of these large cylinders applied to blow the furnace, and so contrived, that the stroke of the pistons, being made alternately, produced an almost uninterrupted blast. A large column of air, of triple or quadruple density, was thus obtained, and effects equivalent to these great improvements followed. The same furnace that formerly yielded ten and twelve tons weekly, now sometimes produced forty tons in the same period, and on the average in one year 1,500 tons of metal (Scrivenor); and such was the impulse given to the trade by this unexpected success of a powerful blast with pit-coal, that in 1788 the manufacture of pig-iron in England, Wales and Scotland, amounted to 68,300 tons, being an increase of 50,950 tons on the quantity manufactured previous to the introduction of pit-coal.

A new era in the history of the iron manufacture may be considered to have been established in 1788–90, by the introduction of the double power-engine of James Watt, the regular and increased effects of which powerful machine was soon felt in most of the iron districts; the proprietors of furnaces greatly increased their make, and fresh capital was embarked in the trade; in the short period of eight years the manufacture of pig-iron was nearly double, being in the year 1796 (according to the return sent to the Chairman of the Committee of the House of Commons, on the subject of the coal trade, when Mr. Pitt had in contemplation to add to the revenue by a tax upon coal at the pit-mouth) 125,079 tons from 121 furnaces—104 English and Welsh, and 17 Scotch; the English and Welsh furnaces producing an average of 1,048 tons each per annum, and the Scotch furnaces 946 tons. In 1806, the number of furnaces in blast in Great Britain was 173, and the make 258,206 tons of pig-iron, being an increase in ten years of 133,127 tons per annum; of these 162 were coke-furnaces, the average produce of each of which had risen to 1,546 tons. In this year great excitement existed in the iron trade, in consequence of the proposal of Lord Henry Petty to levy, as a war-tax, a duty of 40*s.* per ton on pig-iron; he introduced a bill into the House of Commons having this object, and succeeded in carrying it, notwithstanding a powerful opposition, by a majority of ten members; the measure was however abandoned.

In France in 1801, the quantity of cast-iron produced amounted to 140,000 tons, from 550 blast-furnaces, of which only one (that of Creusot) was worked with coke. In 1809 a description of the English process of making iron was published by Order of Council, by M. de Bonnard (an engineer of mines); another engineer of mines (M. de Gallois), after having passed several months in England, established at St. Etienne the second blast-furnace in France, wherein the minerals were treated in the same manner as the English, and in which coke was employed; but the difficulties he had to encounter proved a bar to his success, and he is said to have died prematurely from the grief and trouble which the enterprise occasioned him (Scrivenor). The employment of pit-coal in the manufacture of iron received a very slow development in France, for in 1818 the quantity of cast iron made with coke was very small, and no wrought iron was prepared with pit-coal; in 1824 not more than 3,000 tons of cast iron were made with coke, but in 1828 it had risen to 17,000 tons. Though this did not amount to a tenth of the whole produce, nevertheless the quantity of bars made with pit-coal amounted in this year to 48,000 tons, being nearly one-third of the total manufacture of wrought iron.

Theory of Iron Smelting—The production of metallic iron from its ores is effected by exposing the ore at a suitable temperature to the action of a reducing gas, such as hydrogen, carburetted hydrogen, or carbonic oxide; the first of these is employed in the laboratory, but for practical purposes only the latter can be used. If the reduction is effected at a comparatively low heat such as a dull redness, the product is a dark grey powder which is stable if kept out of contact with the air, but which burns when shaken out into the air at ordinary temperatures, and still more brilliantly in oxygen, forming the so-called pyrophoric iron. This substance is only of interest as a pharmaceutical product (*Ferrum reductum*). The reduction by carbonic oxide is effected in all cases where the ore is exposed to the gases arising from the combustion of carbonaceous matter, whether the fuel be burnt separately, as in reverberatory gas or cementation furnaces, or in contact with ore, as in the various forms of blast-furnace. The simplest cases which can occur under these circumstances are represented by the following equations:—

I. With hydrogen as the reducing agent $Fe^2O^3 + 3H = 2Fe + 3HO$
II. „ carbonic oxide „ „ $Fe^2O^3 + 2CO = 2Fe + 2CO^2$

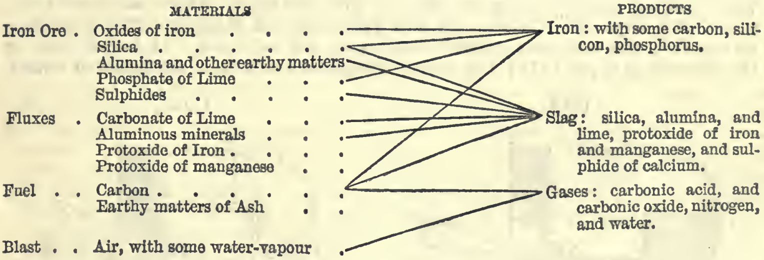
The products vary: in the first case, two equivalents of iron and three of water, and in the second two equivalents of carbonic acid to the same quantity of iron for each equivalent of peroxide of iron. Such a result cannot, however, be got on the large scale, from the fact that finely-divided metallic iron when exposed to a high temperature in contact with carbon either in the solid or gaseous form takes up a proportion of the latter substances, forming carbonised compounds, which are known as *malleable iron*, *steel*, and *cast iron*, according to the amount present. In the first case, the amount is very small, not exceeding a few thousandths of an unit per cent.; but the presence of carbon may be verified by the production of fetid hydrogen gas, owing to the presence of volatile hydrogen-carbons when even the finest and softest wrought iron is dissolved in an acid. Steel contains from about 0·10 to about 2 per cent. of carbon. When the proportion exceeds 2 per cent., and it may in some cases reach as high as 6 per cent., the product is known as cast iron.

In addition to carbon, iron is found on the large scale to contain other substances; the most important of these in modifying its physical properties are *silicon*, *phosphorus*, and *sulphur*. These are derived from the impurities of the ore; quartz, phosphate of lime, and some metallic sulphide, being almost invariably present in the minerals treated on the large scale, and a proportion of these substances is certain to be reduced if the conditions of temperature and exposure be favourable; silica, under the action of carbon in the presence of iron, being readily reducible in almost any proportion, according to the temperature; thus, at a very high heat as much as 22 per cent. of silicon may be combined with iron; practically, however, nothing like as much can be obtained; about 6 per cent. may be regarded as a maximum. When phosphate of lime is present in the ore under the ordinary condition of reduction in the blast-furnace, almost the whole of the phosphorus is obtained in the iron. Sulphur is obtained in like manner from metallic sulphides.

Of the alloys of iron with other metals there is only one of any practical importance, namely, that with the allied metal manganese, which may combine with it in all proportions up to about 30 per cent. Copper, when present in iron, even in minute quantity modifies its properties in a marked and prejudicial manner, but there is no proof of these two metals actually combining.

The earthy and foreign substances, besides modifying the quality of the iron, by their partial reduction play another and more important part in the economy of iron-smelting in procuring the so-called slag, cinder, or scoriæ, that is a fusible product usually more or less glassy, which is formed by the addition of appropriate solvents or fluxes, in order that the otherwise infusible earthy matters such as quartz, sand, clay, at present in the ore, and the ash of the fuel may be separated and removed from the reduced metal, which would otherwise be incapable of coalescing into a connected mass, whether by fusion or otherwise. These fluxes, according to the nature of the process, may be either lime, magnesia or other alkaline bases, alumina, or in some cases the oxides of iron or manganese. The heat required for this operation is very considerable, and requires a considerable consumption of fuel above that necessary for the reduction and fusion of the metal. A further and still larger source of expenditure of heat is due to the fact that when the carbonic acid produced in the reduction of the ore is exposed to carbon at a high temperature it is partially reduced with the production of carbonic oxide, which escapes, carrying a large proportion of the total heating power of the fuel, unless special arrangements are adopted for utilising it.

Practically, therefore, the reactions of iron-smelting may be expressed synoptically in the following manner:—



Production of malleable iron directly from the ore.—The simplest processes of iron-smelting are those in which malleable iron is produced directly from the ore. They are still practised to a considerable extent in India and other parts of the East, and were formerly universally employed in Europe, but now they have become almost extinct; the latest representatives being the Catalan and Corsican forges, and the *Stück-Öfen*, or lump-furnace, which is to be found in one or two places in eastern Europe. These processes consist essentially in the exposure of pure ore to the action of heat in small blast-furnaces, which may be either open hearth-fires, like a smith's forge, or have low shafts or stacks, a few feet high, in which the ore and fuel are charged alternately, the combustion being urged by a blast of air introduced through one or more nozzles below. The operation is continued until a lump of malleable iron is formed in the bottom of the furnace from the reduction of the ore, or a portion of the ore; the remainder being employed in fluxing the silica and other earthy matters both in the ore and the ash of the fuel. This is effected by a partial reduction of the ore from peroxide of iron—which is chemically indifferent to silica at a high temperature—to the state of protoxide, which combines readily with it; forming a fusible slag or cinder at the welding temperature of iron. The spongy and slightly-alloyed mass of iron so produced is then consolidated by hammering, which compacts it to a solid mass, the liquid cinder being expelled by the blows of the hammer. The same reaction takes place in all processes where no special fluxes are added for fluxing the silica, the flux being essentially silicates of protoxide of iron, infusible at comparatively low temperatures; and, under these conditions, only wrought iron can be produced, the ore not being kept in contact with carbon for a sufficiently long time to produce cast iron, except to a very small extent.

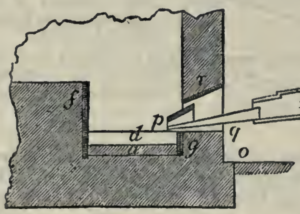
The following are the principal processes in which malleable iron is produced directly:—

1. The Catalan and Corsican forge.
2. The German and American bloomary fires.
3. The Stück-Öfen or lump-furnace.
4. The Chenot or retort-furnace.
5. The Siemens' direct-furnace.

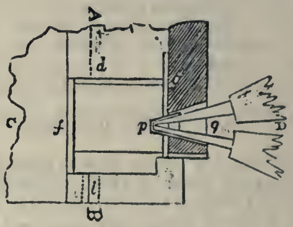
Of these the first and second are conducted in open fires, and differ only in details of manipulation; the former using the ore partly in the state of lumps, which are reduced, and partly in the state of fine dust or *greillade*, which principally goes into the slag; while in the latter the whole of the ore is powdered and clayed in alternate layers with the fuel. The *Stück-Öfen* is larger than the open fire, and the operation is continued for several hours; the lump of reduced iron being removed by breaking away the breast of the furnace, instead of pulling it out from the top. The common Indian method of making iron is conducted in a furnace of this class, but of very small dimensions; not more than 5 or 6 feet high, instead of 15 or 20 feet, as is used in Europe. In the Chenot and similar processes the reduction is effected in fire-clay retorts, with the production of spongy masses of iron; while in the last, or Siemens' process, which is of recent introduction, the ore is melted in a cylindrical vessel, with a refractory lining, and reduced by churning it up with carbonaceous matter; lime, or other fluxes, being previously introduced to combine with the silica, and prevent unnecessary loss of iron by scorification.

In the Catalan, or French method, the ore previously roasted in a kiln is afterwards strongly torrefied in the forge before the smelting begins; operations which follow in immediate succession. Ores treated in this way should be very fusible and very rich; such as black oxide of iron, hæmatites, and certain spathose iron ores. From 100 parts of ore, 50 of metallic iron have been procured, but the average product is 35. The furnaces employed are rectangular hearths, *figs.* 1212 and 1213, the water-blowing machine being employed to give the blast. There are three varieties of this forge: the Catalan, the Navarrese, and the Biscayan. The dimensions of the first, the one most generally employed, are as follow: 21 inches long, in the direction *p f*, *fig.* 1213; 18½ inches broad, at the bottom of the hearth or *creuset*, in the line A B; and 17 inches deep, *fig.* 1212, The tuyère, *q p*, is placed 9½ inches above the bottom, so that its axis is directed towards the opposite side, about 2 inches above the bottom. But it must be moveable, as its inclination needs to be changed, according to the stage of the operation, or the quantity of the ores. It is often raised or lowered with pellets of clay; and even with a graduated circle, for the workmen make a great mystery of this matter. The hearth is lined with a layer of *brasque* (loam and charcoal-dust worked together), and the ore, after being roasted, is sifted; the small powder being set aside to be used in the course of the operation. The ore is piled up on the side opposite to the blast in a sharp saddle ridge, and it occupies one-third of the furnace. In the remaining space of two-thirds the charcoal is put. To solidify the small ore on the hearth, it is covered with moist cinders mixed with clay.

1212



1213



The fire is urged with moderation during the first two hours, the workman being continually employed in pressing down more charcoal as the former supply burns away, so as to keep the space full, and prevent the ore from crumbling down. By a blast so tempered at the beginning the ore gets well calcined, and partially reduced in the way of cementation. But after two hours, the full force of the air is given; at which period the fusion ought to commence. It is easy to see whether the torrefaction be sufficiently advanced by the aspect of the flame, as well as of the ore, which becomes spongy or cavernous; and the workman now completes the fusion, by detaching the pieces of ore from the bottom, and placing them in front of the tuyère. When the fine siftings are afterwards thrown upon the top, they must be watered, to prevent their being blown away, and to keep them evenly spread over the whole surface of the light fuel. They increase the quantity of the products, and give a proper fusibility to the scoriæ. When the scoriæ are viscid, the quantity of siftings must be diminished; but if thin, they must be increased. The excess of slag is allowed to run off by the *chio* or floss-hole. The process lasts from five to six hours, after which the pasty mass is taken out, and placed under a hammer to be cut into lumps, which are afterwards forged into bars.

Each mass presents a mixed variety of iron and steel, in proportions which may be modified at pleasure; for, by using much of the siftings, and making the tuyère dip towards the sole of the hearth, iron is the chief product; but if the operation be conducted slowly, with a small quantity of siftings, and an upraised tuyère, the quantity of steel is more considerable. This primitive process is favourably spoken of by M. Brongniart. The weight of the lump of metal varies from 200 lbs. to 400 lbs. As the consumption of charcoal is very great, amounting in the Palatinate or Rheinkreis to seven times the weight of iron obtained (though in the Pyrenees it is only thrice), the Catalan forge can be profitably employed only where wood is exceedingly cheap and abundant.

In smelting and refining by a continuous operation, three different stages may be distinguished:—1. The roasting of the ore to expel the sulphur, which would be less easily separated afterwards. The roasting dissipates likewise the water, the carbonic acid, and any other volatile substances which the minerals may contain. 2. The deoxidisement and reduction to metal by exposure to charcoal or carburetted vapours. 3. The melting, agglutination, and refining of the metal to fit it for the heavy hammers where it gets nerve. There are several forges in which these three operations seem to be united in a single one, because, although still successive, they are practised at one single heating without interruption. In other forges, the processes are performed separately, or an interval elapses between each stage of the work. Three systems of this kind are known to exist:—1. The Corsican method; 2. The Catalan with wood charcoal; and, 3. The Catalan with coke.

The furnaces of Corsica are a kind of semicular basin, 18 inches in diameter, and 6 inches deep. These are excavated in an area, or a small elevation of masonry, 8 or 10 feet long by 5 or 6 broad, and covered in with a chimney. This area is quite similar to that of the ordinary hearths of our blast-furnaces.

The tuyère stands 5 or 6 inches above the basin, and has a slight inclination downwards. In Corsica, and the whole portion of Italy adjoining the Mediterranean shores, the iron ore is an oxide similar to the specular ore of the Isle of Elba. This ore contains a little water, some carbonic acid, and occasionally pyrites, but in small quantity. Before deoxidising the ore, it is requisite to expel the water and carbonic acid combined with the oxide, as well as the sulphur of the pyrites.

The operations of roasting, reduction, fusion, and agglutination are executed in the same furnace. These are indeed divided into two stages, but the one is a continuation of the other. In the first, the two primary operations are performed at once:—the reduction of a portion of the roasted ore is begun at the same time that a portion of the raw ore is roasted: these two substances are afterwards separated. In the second stage, the deoxidisement of the metal is continued, which had begun in the preceding stage; it is then melted and agglutinated, so as to form a ball to be submitted to the forge-hammer.

The roasted pieces are broken down to the size of nuts, to make the reduction of the metal easier. In executing the first step, the basin and area of the furnace must be lined with a *brasque* of charcoal-dust, 3, 4, or even 5 inches thick: over this *brasque* a mound is raised with lumps of charcoal, very hard, and 4 or 5 inches high. A semicircle is framed round the tuyère, the inner radius of which is 5 or 6 inches. This mass of charcoal is next surrounded with another pile of the roasted and broken ores, which must be covered with charcoal-dust. The whole is sustained with large blocks of the raw ore, which form externally a third wall.

These three piles of charcoal, with roasted and unroasted ore, are raised in three successive beds, each 7 inches thick: they are separated from each other by a layer of charcoal-dust of about an inch, which makes the whole 24 inches high. This is afterwards covered over with a thick coat of pounded charcoal.

The blocks of raw ore which compose the outward wall form a slope; the larger and stronger pieces at the bottom, and the smaller in the upper part. The large blocks are sunk very firmly into the charcoal-dust, to enable them better to resist the pressure from within.

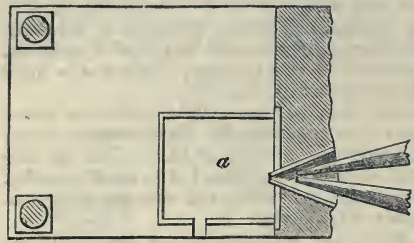
On the bottom of the semicircular well formed within the charcoal lumps, kindled pieces are thrown, and over these, pieces of black charcoal; after which the blast of a water-blowing machine (*trompe*) is given. The fire is kept up by constantly throwing charcoal into the central well. At the beginning of the operation it is thrust down with wooden rods, lest it should affect the building; but when the heat becomes too intense for the workmen to come so near the hearth, a long iron rake is employed for the purpose. At the end of about 3 hours, the two processes of roasting and reduction are commonly finished: then the raw ore no longer exhales any fumes, and the roasted ore, being softened, unites into lumps more or less coherent.

The workman now removes the blocks of roasted ore which form the outer casing, rolls them to the spot where they are to be broken into small pieces, and pulls down the *brasque* (small charcoal) which surrounds the mass of reduced ore.

The second operation is executed by cleaning the basin, removing the slags, covering the basin anew with 2 or 3 *brasques* (coats of pounded charcoal), and piling up to the right and the left two heaps of charcoal-dust. Into the interval between these conical piles two or three baskets of charcoal are cast, and on its top some cakes of the reduced crude metal being laid, the blast is resumed. The cakes, as they heat, undergo a sort of liquation, or sweating, by the action of the earthy glasses on the unreduced black oxide present. Very fusible slags flow down through the mass; and the iron, reduced and melted, passes finally through the coals, and falls into the slag basin below. To the first parcel of cakes others are added in succession. In proportion as the slags proceeding from these run down, and the melted iron falls to the bottom, the thin slag is run off by an upper overflow or *chio* hole, and the reduced iron kept by the heat in the pasty condition, remains in the basin: all its parts get agglutinated, forming a soft mass, which is removed by means of a hooked pole in order to be forged. Each lump or *bloom* of malleable iron requires 3 hours and a half for its production.

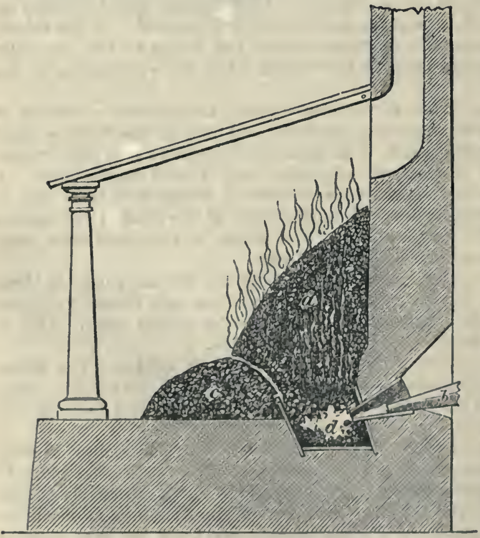
The iron obtained by this process is in general soft, very malleable, and but little steely. In Corsica four workmen are employed at one forge. The produce of their labour is only about 4 cwts. of iron from 10 cwts. of ore and 20 of charcoal, mingled with wood of beech and chestnut. Though their ore contains on an average 65 per cent. of iron, only about 40 parts are extracted; evincing a prodigious waste, which remains in the slags.

1214



The difference between the Corsican and the Catalonian methods consists in the latter roasting the ore at a distinct operation, and employing a second one in the reduction, agglutination, and refining of the metal. In the Catalonian forges, 100 pounds of iron are obtained from 300 pounds of ore and 310 pounds of charcoal; being a produce of only 33 per cent. It may be concluded that there is a notable loss, since the sparry iron ores, which are those principally smelted, contain on an average from 54 to 56 per cent. of iron. The same ores smelted in the ordinary blast-furnace produce about 45 per cent. of cast iron.

1215



In some parts of America, particularly in the States of Vermont and New Jersey, the *Catalan* forge was at one time employed for smelting the rich magnetic ores which there abound. The form of this fire (which is nearly uniform everywhere), and the manipulation with it in America, is thus described by Overman:—The whole is a level hearth of stone-work, from 6 to 8 feet square, *fig.* 1214, at the corner of which is the fireplace, *a*, from 24 to 30 inches square, and from 15 to 18, often 20, inches deep. Inside it is lined with cast-iron plates, the bottom plate being from 2 to 3 inches thick. *Fig.* 1215 represents a cross section through the fireplace and tuyère, commonly called tue iron; *d* represents the fireplace, which, as remarked above, is of various dimensions. The tuyère *b* is from 7 to 8 inches above the bottom, and more or less inclined according to circumstances. The blast is produced by wooden bellows of the common form, or more generally by square wooden cylinders, urged by water-wheels. The ore chiefly employed is the crystallised magnetic ore. This ore very readily falls to a coarse sand, and when roasted varies from the size of a pea to the finest grain. Sometimes the ore is employed without roasting. In the working of such fires much depends on the skill and experience of the workman. The result is subject to considerable variation, that is, whether economy of coal or that of ore is our object. Thus a modification is required in the construction either of the whole apparatus or in parts of it. The manipulation varies in many respects. One workman by inclining his tuyère to the bottom, saves coal at the expense of obtaining a poor yield. Another by carrying his tue iron more horizontally at the commencement, obtains a larger amount of iron, though at the sacrifice of coal. Good workmen pay great attention to the tuyère, and alter its dip according to the state of the operation. The general manipulation is as follows:—The hearth is lined with a good coating of charcoal-dust; and the fire-plate, or the plate opposite the blast, is lined with coarse ore, in case any is at our disposal. If no coarse ore is employed, the hearth is filled with coal, and the small ore piled against a dam of coal-dust opposite the tuyère, *a*. The blast is at first urged gently, and directed upon the ore, while the coal above the tuyère is kept cool. Four hundred pounds of ore are the common charge, two-thirds of which are thus smelted, and the remaining third, generally the finest ore, is held in reserve, to be thrown on the charcoal when the fire becomes too brisk. The charcoal is piled to the height of two, sometimes even three and four feet, according to the amount of ore to be smelted. When the blast has been applied for an hour and a half, or two hours, most of the iron is melted, and forms a pasty mass at the bottom of the hearth. The blast may now be urged more strongly, and if any pasty or spongy mass yet remains, it may be brought within the range of the blast and melted down. In a short time the iron is revived, and the scoriæ are permitted to flow through the tapping hole *c*, so that but a small quantity of cinder remains at the bottom. By means of iron bars, the lump of pasty iron is brought before the tuyère. If the iron is too pasty to be lifted, the tuyère is made to dip into the hearth; in this way the iron is raised from the bottom, directly before, or to a point above the tuyère, until it is welded into a coherent ball, twelve or fifteen inches in diameter. This ball is brought to the hammer or squeezer, and shingled into a bloom, which is either cut in pieces to be stretched by a hammer, or sent to the rolling mill to be formed into marketable bar iron. A mixture of fibrous iron, cast iron, and steel, is the result of the above process; the quality of the iron depends entirely on the quality of the ore, for there are no opportunities for the exercise of any skill to create improvements in the process—poor ores cannot be smelted at all. In Vermont, where the rich magnetic ores are employed, 4 tons of ore and 300 bushels of charcoal are required to produce 1 ton of blooms.

Although the old process of making iron directly from the ore has been completely abandoned in Germany, it is still employed to a considerable extent in the United States, where it was introduced early in the eighteenth century; and has latterly been employed in Canada for the treatment of the black magnetic and titaniferous sands of the Labrador. The following description of the process has been given by Dr. Sterry Hunt:—The hearth or furnace (also known as the bloomary fire, Jersey or Champlain forge) varies in length and breadth in different localities from 27 by 30 inches to 28 by 32 inches, and the depth from 20 to 25 inches above the tuyère, and from 8 to 14 inches below; the sides are made of cast-iron plates, and the bottom usually of beaten earth or cinders, but in the best-constructed hearths a hollow casting cooled by water is preferred. At East Middlebury in Vermont, the bottom plate is 4 inches thick, with a hollow space of 2 inches within it. The side plates, which are 1¼ inch thick, are slightly inclined inwards, and rest on ledges on the bottom plate. A water-box, measuring 12 by 8 inches, is let into the tuyère plate; and the water, after cooling the tuyère, passes through the bottom plate. The tuyère is placed 12 inches above the bottom at such an inclination that the blast may strike the middle of the hearth. It is of segmental form, measuring 1 inch in height by ¾ inch wide. In front of the furnace, at a height of 16 inches above the bottom, is placed a flat iron hearth 18 inches wide. The side plate beneath it is provided with a tap-hole for drawing off the cinders from time to time. The cast-iron plates used in the construction of these furnaces last for two years.

The blast employed has a pressure of from 1½ to 1¾ lb. to the square inch, and is heated by passing through a stove of the ordinary siphon-pipe pattern, placed in an upper chamber above the furnace, and heated by the waste flame. The temperature at East Middlebury is said to be from 280° to 320°. The use of hot blast is attended with a considerable saving both of time and fuel, 240 bushels of charcoal being sufficient to produce a ton of bloom with hot, while 300 are required with cold blast. The weight of the charcoal may be estimated at from 16 to 18 lbs. per bushel.

The working of the furnace is conducted in the following manner:—The fire having been made up and the furnace heaped with charcoal, the ore in coarsely-pulverised form is scattered at short intervals over the top of the burning fuel, and in its passage downwards is reduced to the metallic state, the grains agglomerating to an irregular mass or lump at the bottom, while the earthy matters form a liquid slag or cinder, which is drawn off from time to time through the openings in the front plate. Fresh ore and coal are continually added, until at the end of 2 or 3 hours a sufficiently large loup is formed. This is then lifted before the tuyère to get a good welding heat, and shingled to a bloom under the hammer, the reheating of which is usually effected in the same fire.

In the larger sized furnaces a loup of 300 lbs. is produced every 3 hours, making the produce per day of 24 hours, 2,400 lbs. of blooms; in some cases it is said 1,500 lbs., or even more, are produced in 12 hours.

The essential difference between the Catalan and the American forge consists in the method of charging. In the former the greater part of the charge of ore, in comparatively large lumps, is placed at the commencement of the operation on the sloping wall of the hearth opposite the tuyère, only the small ore, or *greillade*, being added subsequently. In the American or German method, on the contrary, the whole of the ore is reduced to a fine state of division, and is added by small proportions: a plan which dispenses with the charging of the furnace after each operation, and permits of a continuous system of working.

In order further to economise the waste heat, the plan is usually adopted in the Franche-Comté fire, of passing the flame and gases from two hearths into a chamber, which serves for the reheating of the blooms when it is required to draw them out into bars; a set of small blast-pipes, placed just above the forge, serves to heat a portion of air, which is led into the chamber to burn any carbonic oxide gas that may have escaped. The gases from the reheating chamber are afterwards employed to heat the principal blast of the forge in the usual manner.

At Ausable, in the State of New York, the ores employed are dressed so as to yield about 50 per cent. of iron—2 tons being required to make 1 ton of blooms; while at the New Russia forges, where a nearly pure magnetite is smelted, 3 tons of dressed ore are stated to yield 2 tons of blooms. The loss at this rate would not be more than 5½ per cent. on the theoretical contents of the ore: a result which could scarcely be obtained by any other method.

At Moisie in Quebec, where titaniferous black sand is treated, the results obtained are not so favourable, owing to the more refractory character of the ore. The tuyère is laid nearly horizontal, as it was found that the strong inclination used with coarser ores could not be advantageously used with the fine sands. A less dense blast is also used, the average working pressure being about 1 lb. to the square inch. Each hearth yields eight loups, or about 15 cwts. in the day of 24 hours; the consumption of charcoal being at the rate of 466 bushels to the ton of blooms. This charcoal is chiefly produced from small and light wood, such as spruce, fir, and birch, the weight being only 15 lbs. to the bushel, about 62½ cwts. being consumed to make a ton of iron.

This very unfavourable result is due to the imperfectly cleaned state in which the ore is smelted; the quartz, but more especially the titanic acid, using up a large portion of the protoxide of iron, in order to form a slag. The amount of titanic acid in the slags is in some cases as high as 34 per cent. and the iron from 40 to 52 per cent. By the use of magnetic machines for separating the ore before treating it in the furnace, it would be possible to remove the non-magnetic and more highly titaniferous part, which is practically worthless, leaving a comparatively pure magnetite, which could be more advantageously smelted.

The quality of the iron produced in the bloomary fire at Moisie is said to be very superior, as the result of experiments made upon it in England shows that it possesses a tensile strength equal, or superior, to that of the best Yorkshire iron, and works easily both cold and hot. This excellence is to be attributed to the almost perfect freedom of the magnetic sand from sulphur and phosphorus. A sample taken from a bloom when examined gave only ·0094 per cent. of sulphur and ·00184 per cent. of phosphorus, and no trace of titanium could be found.

The *Fourneaux à pièce* of the French, or *Stück-Öfen* of the Germans, resembles *fig.* 514, Copper. The tuyère (not shown there), having a dip towards the bottom of the hearth where the smelted matter collects. When the operation is finished, that is at least once in every 24 hours, one of the sides of the hearth must be demolished, to take out the pasty mass of iron, more or less pure. This furnace holds a middle place in the treatment of iron, between the Catalan forge and the cast-iron *Floss-Öfen*, or high blast-furnaces. The *Stück-Öfen* are from 10 to 15 feet high, and about 3 feet in diameter at the hearth. Most usually there is only one aperture for the tuyère and for working; with a small one for the escape of the slag; on which account, the bellows are removed to make way for the lifting out of the lump of metal, which is done through an opening left on a level with the sole, temporarily closed with bricks and potter's clay, while the furnace is in action.

This outlet being closed, and the furnace filled with charcoal, fire is kindled at the bottom. Whenever the whole is in combustion, the roasted ore is introduced at the top in alternate charges with charcoal, till the proper quantity has been introduced. The ore falls down; and whenever it comes opposite to the tuyère the slag begins to flow, and the iron drops down and collects at the bottom of the hearth into the mass or *Stück*; and in proportion as this mass increases, the *floss-hole* for the slag and the tuyère is raised higher. When the quantity of iron accumulated in the hearth is judged to be sufficient, the bellows are stopped, the scoriæ are raked off, the little brick wall is taken down, and the mass of iron is removed by rakes and tongs. This mass is then flattened under the hammer into a cake from 3 to 4 inches thick, and is cut into two lumps, which are submitted to a new operation; where it is treated in a peculiar refinery, lined with charcoal *brasque*, and exposed to a nearly horizontal blast. The above mass seized in the jaws of powerful tongs, is heated before the tuyère; a portion of the metal flows down to the bottom of the hearth, loses its carbon in a bath of rich slags or fused oxides, and forms thereby a mass of iron thoroughly refined. The portion that remains in the tongs furnishes steel, which is drawn out into bars.

This process is employed in Carniola for smelting a granular oxide of iron. The mass or *Stück* amounts to from 15 to 20 hundred-weight after each operation of 24 hours. Eight strong men are required to lift it out, and to carry it under a large hammer, where it is cut into pieces of about 1 cwt. each. These are afterwards refined, aud drawn into bars as above described. These furnaces are now almost generally abandoned on the Continent, in favour of *charcoal high* or *blast-furnaces.*

Chenot's Process.—As far back as 1823, M. Adrien Chenot introduced a process for preparing metallic iron, in a spongy form, direct from the ore by cementation in charcoal. The ore usually employed in this process is brown hæmatite, which, in the form of lumps, is mixed with wood-charcoal in more than sufficient quantity to effect its deoxidation. The furnace used for reduction consists of a cubic pedestal of masonry, surmounted by a truncated cone, and containing two rectangular chambers or retorts, which widen in the lower part to facilitate the descent of the reduced charge. Each retort is surrounded by a series of vertical flues, communicating below with the fireplaces and above with a large flue. The reduced iron is discharged from the retorts on to a special cooler, where oxidation is prevented. The daily charge of a furnace, working with a single retort, at Hautmont, consisted of about 1½ ton of calcined Sommorostro ore (containing 55 per cent. of iron), and about ½ ton of wood-charcoal. This charge would yield about 12 cwts. of iron-sponge, and about 2 cwts. of charcoal would be regained as the excess over the quantity needed for reduction. At the same time there is about 1 ton 6 cwts. of coal consumed as fuel. The reduction occupies three days, but as the freshly-formed sponge is allowed to remain three days in the cooler, the entire process occupies six days. When perfectly reduced, the iron sponge presents a bright grey colour, and is so soft that it may be readily sliced with a knife; it is easily ignited, and when set on fire burns until it is completely oxidised. The specific gravity is very variable, but the average is about 1·25.

In addition to the 'external' or 'indirect' method described above, Chenot's sponge may be obtained by an 'internal' or 'direct' method, in which the ore is reduced not by means of solid charcoal, but by a hot current of carbonic-oxide gas. The furnace in which this reduction is effected is similar to that used for the indirect process, excepting that the reducing chamber is connected with gas-furnaces for generating the carbonic oxide. A modification of Chenot's direct method, by M. Tourangin, has been used both in France, and near Bilbao, in Spain. The iron-sponges are balled up in a charcoal hearth. It should be remarked, that the raw material suited for Chenot's process should be a pure ore, such as hæmatite or spathose ore, porous in texture, and not fusible at the temperature at which the reduction is effected.

Gurlt's Process.—In 1857, Dr. Adolph Gurlt introduced a process for reducing iron-ores by means of gaseous fuel, maintaining that either cast-iron steel, or wrought-iron could be obtained according to the proportion of carbon in the reducing gases. It was said that the process effected a saving of about 50 per cent. of fuel, compared with that consumed in the blast-furnace. The reduction and cementation of the ore requires a current of reducing gases, which may be generated at a moderate temperature; but the fusion of the reduced iron must be effected at a higher temperature in a current of neutral gas, that is to say, neither reducing nor oxidising. Hence the process was resolved into two operations conducted in separate furnaces. The reduction was effected in a furnace with a shaft similar to that of an ordinary blast-furnace, and supplied with carbonic oxide from a gas-generator. The fusion was conducted in a closed hearth, connected with two gas-generators, and supplied with a blast through tuyères. Experiments made by Gurlt, in 1857, at the Rheinbach Hütte, near Bonn, decidedly failed, but the process was afterwards successfully worked, in a modified form, at Santa Aña de Bolueta, in Biscay. The ore used at Bolueta was

Sommorostro brown hæmatite, containing about 65 per cent. of iron. The gases were generated from oak- and beech-wood charcoal. The iron was obtained in spongy masses, having the form of the pieces of ore from which they were reduced. The sponge was protected from oxidation by cooling under charcoal-dust. Three charges were worked daily; these consisted in the aggregate of 72 cwts. of ore, with 18¾ cwts. of charcoal, and produced 26¾ cwts. of iron-sponge. Gurlt's fusion-furnace was not employed at Bolueta, but the sponges were welded in the Catalan forge. Every 100 lbs. of finished bar-iron represented a consumption of 285 lbs. of raw ore, and 174 lbs. of wood-charcoal. It is maintained that the loss of iron is compensated by the saving in fuel; hence the process has been recommended where fuel is dear, and a supply of pure and porous ores is readily accessible.

Siemens's processes for the direct production of malleable iron.—The production of wrought iron or steel directly from the ore has recently been brought prominently into notice by Mr. Siemens, who has adopted several methods based upon the use of his regenerative gas-furnace for this purpose. The following are some of the methods employed, as described by the inventor:—

A Method of producing spongy iron by means of a rotative furnace.—This furnace consisted of a long cylindrical tube of iron of about 8 feet diameter, mounted upon antifriction rollers; the brick lining of it was mounted with longitudinal passages for heating currents of air and gas, prior to their combustion at the one extremity of the rotary chamber. The flame produced passes thence to the opposite or chimney end, where a mixture of crushed ore and carbonaceous material was introduced. By the slow rotation of this furnace, the mixture advanced continually to the hotter end of the chamber, and was gradually reduced to spongy iron. This dropped through a passage constructed of refractory material on to the hearth of a steel melting furnace, where a bath of fluid pig-metal had been provided. The supply of reduced ore was continued till the carbon in the mixture was reduced to the minimum point before indicated. The rotation was then arrested to prevent further descent of reduced ore; spiegel was added, and the contents of the melting-furnace tapped into a ladle, and thence into ingots.

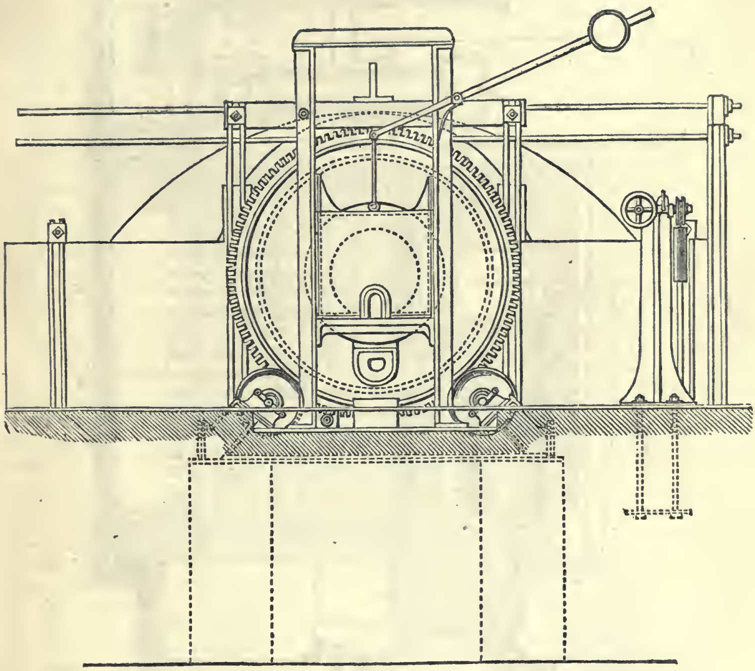
This rotary furnace was erected by Mr. Siemens at the Landore Works, in 1869, and it was so far successful, as the reduction of the ore was accomplished in a comparatively short time. A difficulty, however, presented itself, which led to its immediate abandonment; it was found that the spongy metal produced absorbed sulphur from the heating gases, and was rendered unfit for the production of steel; the spongy iron, moreover, upon its introduction into the steel melting furnace, floated upon the metallic bath without being readily absorbed into it, and was in great part reoxidised and converted into slag by the action of the flame in the furnace.

These experiments proved that the successful application of reduced ores could not be accomplished through their conversion into spongy metals, and fully explained the want of success which had attended the previous efforts of Clay, Chenot, Yates, and others to produce iron directly from the ore. On the other hand, Mr. Siemens observed that in melting iron ores no sulphur was absorbed from the flame; and it occurred to him that by melting ores mixed with fluxing materials in a furnace so arranged as to accomplish its fusion in a continuous manner and on a large scale, the fused ore might be acted upon by solid carbonaceous matter, so as to separate the metallic iron in a more compact form, while the earthy constituents of the ore would form a fusible slag with the fluxing material. Experiments proved that this reduction by precipitation of the iron could be accomplished only at an intense heat, exceeding the welding heat of iron, but that the iron so produced was almost chemically pure, although the ores and the fuel used might contain a very considerable percentage of sulphur and phosphorus.

The furnace used for carrying out this process of fusion and precipitation consists of a reverberatory gas-furnace, having two beds formed by the ore itself: on the upper bed a lake of fused ore is formed, which can be let off into the lower bed by piercing the intervening bank of unfused ore; the lower bed is divided into two compartments, each provided with a door, used alternately. The dense carbonaceous material, such as anthracite or hard coke, to be used for the precipitation of the iron in the lower bed, is reduced to a state of powder and mixed with about an equal weight of pulverulent ore. This mixture is spread over the bottom surface of the working bed, and the fluid ore is let in upon it. By stirring with a rabble it is transformed into a pasty and foaming mass, which in the course of from 40 to 50 minutes is shaped into a metallic ball in a bath of fluid cinder, which may be shingled in the usual manner and formed into bar-iron, or transferred to the pig-iron bath of a steel melting furnace, where it readily dissolves. The accomplishment of this process involves, however, a certain degree of manual labour and skill, as, if it be carelessly conducted, the yield of iron will be unsatisfactory. The analysis of the slags shows a variable percentage of iron, amounting rarely to less than 15 per cent., but reading occasionally up to 40 per cent.

A form of rotating furnace, represented in *fig.* 1217 in longitudinal section, and in an end elevation in *fig.* 1216, has been found to give very successful results in practice. It consists of a cylindrical chamber of wrought iron mounted upon friction-rollers, and capable of receiving motion at different speeds from pairs of spur-wheels driven by a steam-engine. The arrangements for forcing, which are those of the usual regenerative gas-furnace, are placed at one end of the cylinder, while the other is closed by a working door with a stopper-hole like that of an ordinary reverberatory furnace, as seen in *fig.* 1216. The slags are received into a waggon, which runs upon a railway, in a pit below the cylinder. The lining or fettling of the cylinder is formed of a bauxite or aluminous iron ore, which is ground up with a little graphite, and strongly heated. The iron of the ore is thus reduced to the metallic state; and the alumina, from the intense and long-continued heating, is converted into a dense substance resembling emery, which is capable of resisting abrasion by the materials of the charge, as well as being unaffected chemically.

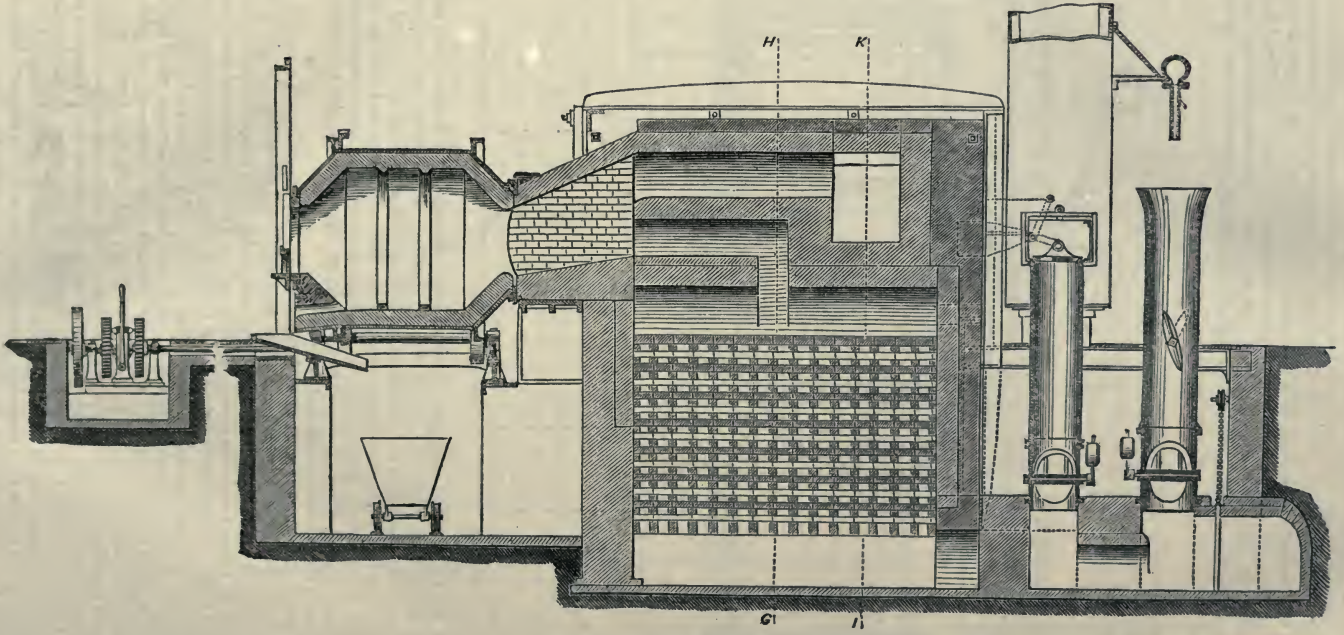
1216



The rotative furnace is worked as follows :—

The ore to be smelted is broken up into fragments, not exceeding the size of peas or beans; to it is added lime or other fluxing material in such proportion that the gangue contained in the ore and flux combines with only a little protoxide of iron into basic and fluid slag. If the ore is hæmatite, or contains silica, it is preferable to add alumina in the shape of aluminous iron ore; manganiferous iron ore may also be added with advantage. A charge of say 20 cwts. of ore is put into the furnace when fully heated while it is slowly revolving. In about 40 minutes this charge of ore and fluxing material will have been heated to a bright redness, and from this time from 5 cwts. to 6 cwts. of small coal of uniform size (not larger than nuts) are added to the charge, whilst the rotative velocity is increased in order to accelerate the mixture of coal and ore. A rapid reaction is the result; the peroxide of iron being reduced to magnetic oxide begins to fuse, and at the same time metallic iron is precipitated by each piece of carbon, while the fluxing materials form a fluid slag with the siliceous gangue of the ore. The slow rotative action is again resorted to, whereby the mass is turned over

1217



and over, presenting continually new surfaces to the heated lining and to the flame within the rotator.

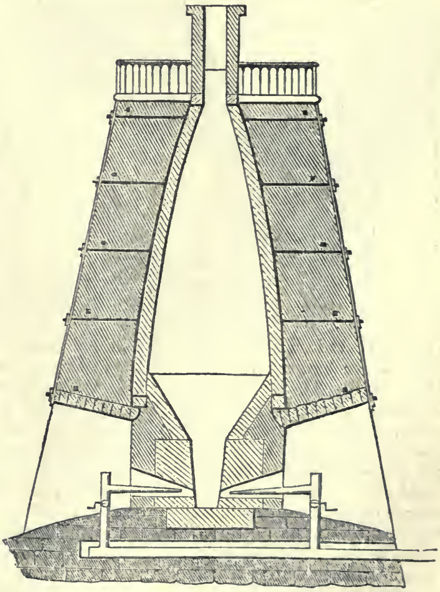
During the time of this reaction, carbonic oxide gas is evolved from the mixture of ore and carbon, and heated air only is introduced from the regenerator, to effect its combustion within the rotating chamber. The gas from the gas-producers is entirely, or almost entirely, shut off during this portion of the process. When the reduction of the iron ore is thus nearly completed, the rotator is stopped in the proper position for tapping off the fluid cinder; after this the quick speed is imparted to the rotator, whereby the loose masses of iron contained in it are rapidly collected into two or three metallic balls. These are taken out and shingled in the usual way of consolidating puddled balls; the furnace is tapped again, and is ready to receive another charge of ore. The time occupied in working one charge rarely exceeds two hours: and supposing that 10 cwts. of metallic iron is got out per charge, the apparatus is capable of turning out at least 5 tons of puddled bar per diem. If anthracite or hard coke is available for effecting the reduction of the ore, it should be crushed much finer than when coal or brown coal is used, the idea being that each particle of the reducing agent should be consumed during the period of chemical reduction. If wood is used, it must be charged, for the same reason, in still larger pieces.

It is feasible to push the operation within the rotator to the point of obtaining cast steel. If this is intended, the relative amount of carbonaceous matter is somewhat increased in the first instance, so that the ball if shingled, would be of the nature of puddled steel, or contain even more carbon mechanically enclosed.

It may however be asked, why the rotating furnace should admit of the complete combustion of carbon, whereas in the blast-furnace such complete combustion is, as is well known, not possible, because each atom of carbonic acid formed would immediately split up into two atoms of carbonic oxide by taking up another equivalent of carbon from the coke present? The following explanation will serve to elucidate this point:

In the rotative furnace streams of carbonic oxide are set up within the mass under reaction, and this carbonic oxide on reaching the surface meets the current of intensely-heated air proceeding from the regenerators, and completes with its perfect combustion within the free space of the chamber. The carbonic acid thus generated comes in no further contact with the carbon, consequently it cannot split up, but is drawn away unchanged into the chimney, while the evolved heat is taken up by the sides of the chamber, and transmitted by reverberation and conduction to the mixture of ore, fluxes, and coal.

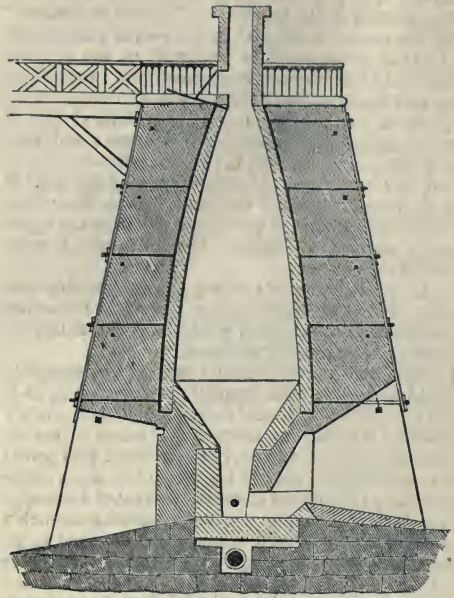
1218



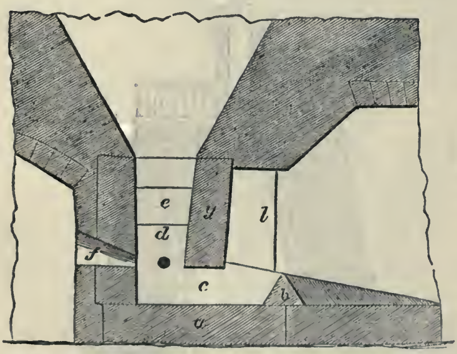
Charcoal Blast-Furnace.—The general form of the charcoal blast-furnace, as used in the United States, where this fuel is common, is shown in vertical section in *fig.* 1219, and in section through the tuyère arches in *fig.* 1218. The ores designed to be smelted in this furnace are hydrated oxides of iron, such as brown hæmatite, brown ironstone, pipe-ore, and bog-ores. The height is 35 feet; hearth from base to the boshes, 5 feet 6 inches; width at the bottom, 24 inches; and at top, 36 inches. The tuyères are 20 inches above the base. The boshes are 9 feet 6 inches in diameter, and measure from the top of the crucible 4 feet, which gives about 60° slope. The blast is conducted through sheet-iron or cast-iron pipes laid below the bottom stone into the tuyères. The top is furnished with a chimney, by which the blaze from the tunnel head is drawn off. Around the top is a fence of iron or wood. *Fig.* 1220 shows the method of preparing and arranging the hearthstones. *d* is the bottom stone, made of a fine close-grained sandstone, from 12 to 15 inches thick, at least 4 feet wide, and

6 feet long; it reaches underneath at least half of the dam-stone *b*. This bottom stone is well bedded in fire-clay, mixed with three-fourths sand. After the bottom stone is placed, the upper part of which must be three-fourths of an inch lower at the dam-stone than at the back, the two side stones, *c*, are laid embedded in fire-clay. These stones must be at least 6 feet and a half long, reaching from 18 inches behind the crucible to the middle of the dam-stone. Their form is most commonly square, that is, a prism of four equal sides; the transverse section of the grain must be in all cases placed towards the fire; the side stones are sometimes square, but often bevelled according to the slope of the hearth. Upon these stones the tuyère stones, *d*, are bedded; the latter suffer much from heat, and therefore ought to be of the best quality. They should be from 20 to 24 inches square, or even larger: the tuyère holes, *f*, a kind of taper arch, are cut out before the stones are bedded. These stones do not reach further than to the front or tymp-stone, *g*, and are therefore scarcely 4 feet long; the top stone *e*, is generally sufficiently high to raise at once the crucible to its destined height. After both sides are finished, the back stone *l* is put in, and then the tymp-stone, *g*; the space between the hearthstones and the rough wall of the furnace stack is filled and walled up with common brick or stones.

1219



1220



In starting a charcoal furnace, it is first thoroughly dried by burning a fire for several weeks in the interior, which has a temporary lining of bricks. The lower part of the furnace or the hearth is then filled gradually with charcoal, and when the fuel is well ignited, and the furnace half filled, ore may be charged in; but it is sometimes advisable to increase the draught by forming grates by laying across the tymp a short iron bar, as high up as the dam-stone, by resting upon this bar six or seven other bars or ringers, and by pushing their points against the back stone of the hearth. There is not much iron made during the first 24 hours; most of the ore is transformed into slag, and the iron which comes down gets cold on the bottom stone, where it is retained; the blast should not be urged too fast at first, but increased gradually, in order to avoid the serious evil arising from a cold hearth; if all goes on well, the hearth will be free from cold iron or clinkers in a week, the yield of iron will increase, and the burden may be increased likewise. The average charge of charcoal, which should be dry, coarse, and hard, is about 15 bushels. According to Overman's experience, the most favourable height for a charcoal furnace is 35 or 36 feet; if below this standard they consume too much fuel, if above they are troublesome to work; if it be desired to enlarge the capacity of a furnace, he thinks it better to increase the diameter of the boshes, or to curve the vertical section. There is much difference of opinion amongst managers of furnaces on the subject of the proper size for the throat of the furnace; the tendency of narrow throats would seem to be to consume more coal than wide ones, inasmuch as in Pennsylvania and throughout the whole west, where narrow tops are preferred, the consumption of charcoal per ton of iron is from 160 to 180 bushels, while in the State of New York, and further east, where the furnace throats are wider, the consumption is from 120 to 130 bushels. Another subject which demands the strictest attention is the regulation of the blast. A weak soft charcoal will not bear a much greater pressure than from half a pound to five-eighths of a pound to the square inch; strong coarse charcoal will bear from three-quarters of a pound to a pound; and again, it may be laid down as a rule, that the larger the throat in proportion to the boshes, the stronger ought to be the blast, and that a narrow top and wide boshes, while they permit a weaker blast, involve the loss of much fuel. In every case a careful roasting of the ores at charcoal furnaces will prove advantageous; this is the surest means of saving coal and blast, and of avoiding more annoyances in the working of the furnaces.

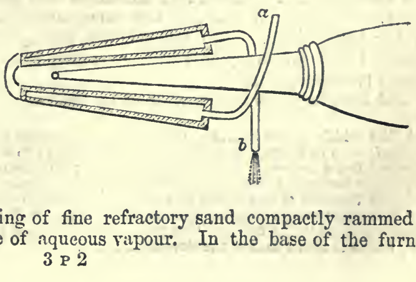
The above account represents the form of blast-furnace as constructed at the time of the former edition of this work. Other modifications have since been introduced mainly in the direction of increased size, and the avoidance of strongly-contracted slopes as sudden changes in dimensions.

English Process of Iron-making.—The 'Mineral Statistics' gives us the quantity of pig-iron produced in Great Britain in the year 1872, as follows:—

	Tons
Northumberland	38,766
Durham	760,172
Yorkshire, North Riding	1,122,114
Do. West Riding	148,636
Derbyshire	283,375
Lancashire	524,041
Cumberland	440,575
Shropshire	133,046
North Staffordshire	275,925
South Staffordshire and Worcestershire	673,470
Northamptonshire and Lincolnshire	96,413
Gloucestershire, Wilts, and Somerset	97,481
North Wales	54,698
South Wales	1,002,623
Scotland	1,090,000

Of the Blast-Furnace.—The blast-furnaces at present in use are of various sizes, being from 35 to 90 feet in height, and at the *boshes*, or widest part, from 12 to 30 feet. The internal form commonly adopted consists essentially of two frustums of cones meeting each other at their bases, at the point where the widest part or the top of the boshes is situated. From this point the furnace gradually contracts both upwards to its mouth, and downwards to the level of the tuyères below. The hearth, properly speaking, is that part of the furnace only which receives the fluid metal and cinder, as they fall below the level of the tuyères. It forms a short prolongation from that point of the lower inverted cone. From the boshes upward the width gradually decreases to the tunnel-head, which varies from 7 to 9 feet in diameter, according to the size of the furnace. The hearth is generally a cube, from 2½ to 3 feet square. The air is introduced by one, two, or three small apertures, called *tuyères*. When two tuyères are used, the orifices of their blow-pipes are about 3 inches in diameter, and the pressure of the blast is from 2½ to 3 lbs. on the square inch. To prevent the tuyères from being melted by the intense heat to which they are exposed, a stream of cold water is caused constantly to flow round their nozzles by an arrangement which will be immediately understood by an inspection of *fig.* 1221, which represents a section of a tuyère nozzle thus protected, the cold water entering the casing by the tube *a*, and the hot water running off by the tube *b*. The upper part of the furnace above the boshes is called the *cone* or *body*. It is formed by an interior lining of fire-brick, about 14 inches in thickness, between which and the exterior masonry is a casing of fine refractory sand compactly rammed in, air-holes being left for the escape of aqueous vapour. In the base of the furnace

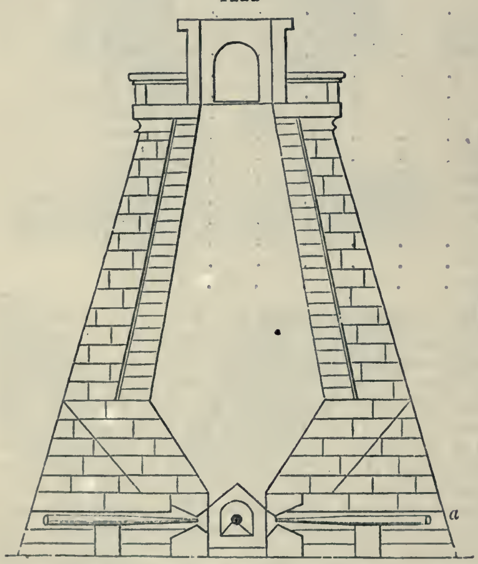
1221



four arches are left, the back and sides are called *tuyère houses*, the front is called the *cinder fall*; the bottom of the furnace is formed either of large blocks of coarse sandstone or of large fire-bricks. The materials are charged into the furnace through the tunnel-head, which is provided with one or more apertures for the purpose. The general form of a blast-furnace is shown in *fig.* 1222, and the following measurements represent the interior structure of two that worked well:—

	No. 1 feet	No. 2 feet
Height from the hearth to the throat or mouth . .	45	49
„ of the crucible or hearth	6½	6
„ of the boshes	8	7
„ of the cone	30½	36
„ of the chimney or mouth	8	12¾
Width of the bottom of the hearth[1]	2½	2
„ at its upper end	3	2⅔
„ of the boshes[2]	12⅔	13½
„ at one-third of the belly	12	11½
„ at two-thirds of ditto	8⅓	9½
„ at mouth	4½	3⅙
Inclination of the boshes[3]	59°	52°

1222



1223

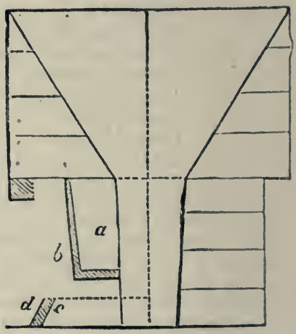


Fig. 1223 represents the hearth and boshes in a vertical side section. *a* is the tymp-stone, and *b* the tymp-plate, for confining the liquid metal in the hearth; the latter is wedged firmly into the side-walls of the hearth; *c* is the dam-stone, which occupies the whole breadth of the bottom of the hearth, excepting about 6 inches, which space, when the furnace is at work, is filled before every cast with a strong binding sand. This stone is faced outside by a cast-iron plate *d*, called the *dam*-plate, of considerable thickness and peculiar shape. The top of the dam-stone, or rather the notch of the dam-plate, lies from 4 to 8 inches under the level of the tuyère-hole. The space under the tymp-plate, for 5 or 6 inches down, is rammed full for every cast with a strong loamy earth or even fine clay, a process called tymp-stopping.

The blowing-machines employed in Staffordshire are generally cast-iron cylinders,

---

[1] The width of the hearth differs greatly in the furnaces in different localities. In Scotland it varies from 6 to 8 feet; in the Welsh furnaces from 5 to 8 feet. When coke is used as fuel, Mr. Truran thinks 6 feet a sufficient width for all purposes; but with coal, with full-sized furnaces, 16 to 19 feet across the boshes, he thinks a 7-feet hearth to be more advantageous.

[2] The diameter of the boshes in some of the Welsh furnaces is as much as from 18 to 19 feet.

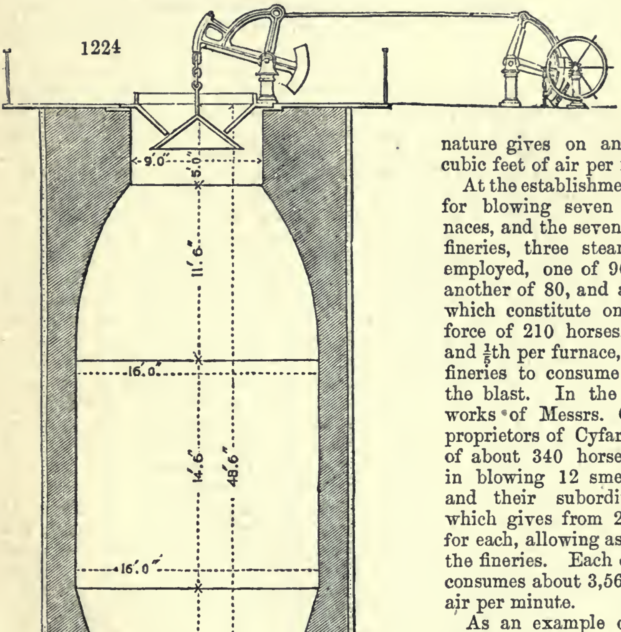
[3] The angle with which the boshes rise in different furnaces varies from 50° to 80°. Mr. Truran thinks that when the full smelting power of the furnace is desired, the angle should not be less than 70°, which is about that of the Scotch furnaces.

in which a metallic piston is exactly fitted as for a steam-engine, and made in the same way. Towards the top and bottom of the blowing-cylinders orifices are left covered with valves, which open inside when the vacuum is made with the cylinders, and afterwards shut by their own weight. Adjutages conduct into the iron globe or chest the air expelled by the piston, both in its ascent and descent, because these blowing-machines have always a double stroke.

The pressure of the air is made to vary through a very considerable range, according to the nature of the fuel and the season of the year; for as in summer the atmosphere is more rarefied, it must be expelled with a compensating force. The limits are from $1\frac{1}{2}$ to $3\frac{1}{2}$ lbs. on the inch, the average in Staffordshire being 3 lbs. The orifices, or nose-pipes, through which the air issues, also vary with the nature of the coke and the ore.

In a blast-apparatus employed at the Cyfartha works, moved by a 90-horse steam-power, the piston-rod of the blowing-cylinder is connected by a parallelogram mechanism with the other end of the working-beam of the steam-engine. The cylinder is 9 feet 4 inches in diameter, and 8 feet 4 inches high. The piston has a stroke 8 feet long, and it rises 13 times in the minute. By calculating the sum of the space percursed by the piston in a minute, and supposing that the volume of the air expelled is equal to only 96 per cent. of that sum, we find that 12,588 cubic feet of air are propelled every minute. Hence a horse-power applied to blowing-machines of this nature gives on an average 137 cubic feet of air per minute.

1224



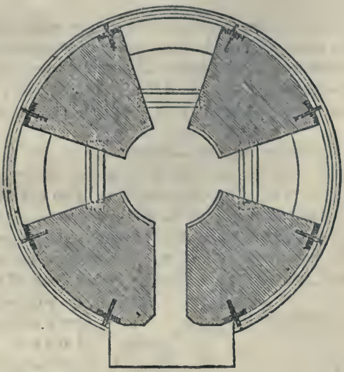
At the establishment of Cyfartha for blowing seven smelting furnaces, and the seven corresponding fineries, three steam-engines are employed, one of 90 horse-power, another of 80, and a third of 40, which constitute on the whole a force of 210 horses, or 26 horses and $\frac{1}{8}$th per furnace, supposing the fineries to consume one-eighth of the blast. In the whole of the works of Messrs. Crawshay, the proprietors of Cyfartha, the power of about 340 horses is expended in blowing 12 smelting furnaces and their subordinate fineries; which gives from 25 to 26 horses for each, allowing as before $\frac{1}{8}$th for the fineries. Each of the furnaces consumes about 3,567 cubic feet of air per minute.

As an example of the blowing power used in Cleveland, the blast-furnaces at Ayresome may be selected. They are four in number: each 18 feet high; 25 feet width of boshes; 15 feet broad at throat, with cup and cone; 10 feet 6 inches broad. The hearth is 8 feet diameter; 3 feet deep below tuyères, and 4 feet above them. There are 10 boilers for four furnaces, but only 8 are in use at a time. They are plain cylinders, 60 feet long, and $4\frac{1}{2}$ feet in diameter.

There are 3 blast-engines; but 2 only required to blow the four furnaces. They have 96-inch blast- and 40-inch steam-cylinders; the steam-pressure is 50 lbs., and the blast $4\frac{1}{4}$ lbs. in the engine house, equal to 4 lbs. at the tuyères.

One engine, blowing two furnaces making 750 tons of pig-iron per week, gives 11,500 cubic feet of blast per minute, at 30 strokes per minute; but when making 800 tons, 32 strokes are required.

1225



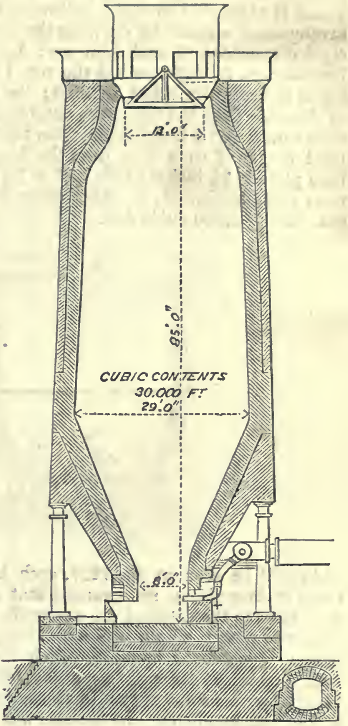
The form of the blast-furnace from the boshes to the throat is exhibited in *fig.* 1222 as a truncated cone, and such was formerly invariably the construction; of late years, however, considerable variations have been introduced. In Scotland the body of the furnace frequently is carried up cylindrical, or nearly so, for a considerable height, terminating with the usual truncated cone to the mouth; in other places a curved line is substituted for a straight one. The form adopted in some furnaces at Ebbw Vale and Blaina is shown in *fig.* 1224 in vertical section, and in *fig.* 1225 in horizontal section at the tuyère level.

The diameter of the throat or filling place is a subject of very great importance to the operations of the furnace. Most iron masters are, we believe, agreed as to the impolicy of the narrow tops formerly adopted; the waste of fuel in such furnaces, where the width of the throat scarcely averaged one-fourth of the diameter of the furnace, was very great, the average yield of coal to the ton of crude iron exceeding 6 tons; by enlarging the throat to one-third, the consumption of coal was reduced to 4 tons; and by continuing the enlargement to one-half, it was reduced to 2 tons. Mr. Truran states that, on reducing the diameter of the throat of a furnace at Dowlais from 9 feet to 6, the make of pig-iron weekly fell off from 97 tons to an irregular make of from 50 to 70 tons; and that while with the 9-feet throat the consumption of coal was 45 cwts. to the ton of iron, it rose with the 6-feet throat to 70, 80, and 90 cwts., the quality of the iron being exceedingly bad. On enlarging the throat to 9½ feet, the make, for a period of six months, averaged over 160 tons, with a good yield of coal and other materials. Mr. Truran appears to question the utility of reducing the diameter of the furnace at the top, which was only adopted in the first place from an erroneous impression that the furnace could be filled best through a contracted mouth; but it may be questioned whether this widening of the throat may not be carried too far, so as to disperse the heated gases too rapidly, and whether a diameter much greater than one-half of the largest dimensions of the furnace above the boshes can with utility be adopted. On this subject Mr. Kenyon Blackwell says:—

'If that part of the blast-furnace commencing at the point where it attains its greatest width were continued of the same wide dimensions upwards to its mouth, two objectionable results would ensue: first, the upper part of the furnace would be cooled by the too rapid dispersion of the ascending column of heated gases, and by the entire absence of the reverberating effect of the contracted mouth; and, secondly, the materials could not be equally spread from the filling-holes over so wide a surface. The diameter of the upper part of the furnace ought, therefore, to be such as will cause the materials thrown in at the filling-holes to distribute themselves equally in their descent over every part of the sectional area of the furnace, and will produce such a reverberation only of heat as shall be sufficient to expel the water and carbonic acid contained in the materials, without consuming any of the carbon of the fuel, which ought to remain intact until it reaches the lower regions of the furnace, where it is vaporised as carbonic oxide, and produces the reactions on which the reduction of the ore depends.'

An example of the largest and most improved modern type of blast-furnace as used in the Cleveland district is shown in *fig.* 1226, which represents one of the Newport furnaces at Middlesbrough in a vertical section. The foundation, up to the ground level, consists entirely of brickwork resting upon clay. From this point a circular base is carried to a height of 7 feet in solid brickwork, mainly of fire-brick, with a stone curb all round, on which the supporting columns rest. These columns are 18 feet 6 inches in height, averaging 2 feet 4 inches in diameter, with a thickness of metal of 2 inches. They serve to support the structure from the angle of the bosh upwards; the lower part being carried partly by the wrought-iron conical casing, and partly by the brickwork and stanchions which surround the hearth. The whole of the furnace from the tuyères upwards is cased with wrought-iron plates, those of the lower or conical part being $\frac{1}{2}$ inch thick, while those of the barrel vary from $\frac{7}{16}$ths of an inch below to $\frac{3}{8}$ths of an inch at the top. The interior of the furnace is lined throughout with fire-brick lumps 5 inches thick, and of dimensions varying with the internal diameter, no two courses being alike. The backing between the inner lining and the shell is of ordinary fire-brick. Up to a short distance above the tuyères every fire lump is chisel-dressed on both beds and joints, and the same is also the case with the hearth lumps, which consist of two courses set on an edge and breaking joint; the lower course being 18 inches deep and the upper one 3 feet. The following are the principal dimensions of the furnace:—Diameter of the hearth, 8 feet; depth at tuyères, 3 feet 6 inches; diameter at the bosh, 28 feet; diameter of the bell-opening, 13 feet; total height from the hearth to the platform, 83 feet; the cubical capacity is 30,085 cubic feet. There are four tuyères, each with a nozzle 6 inches in diameter, and the dam opening is 2 feet wide. The pig-beds are necessarily of large dimensions, being capable of holding 1,200 moulds for each furnace. The slag-boxes are eight in number, and large enough to contain upwards of 3 tons of slag each.

1226

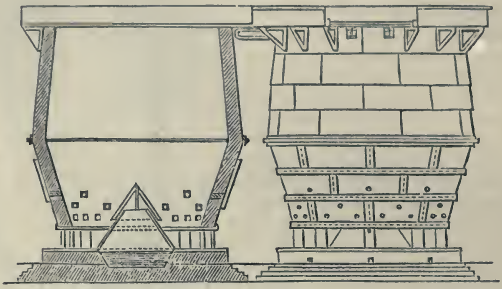


Calcination of the Ironstone.—This is effected either in kilns, or in the open air; the object being to separate carbonic acid, water, sulphur, and other substances volatile at a red heat. The operation is performed most effectually, and probably at the smallest cost, in kilns. The interior shape of the calcining-kilns differs in different works, but they may all be reduced to that of the common lime-kiln. A coal-fire is first lighted at the bottom of the kiln, and the ironstone is placed over and around, until the floor is covered with red-hot ore; a fresh layer of ironstone, with about 5 per cent. of coal, is then laid on, to the depth of 8 or 9 inches; and when this is red hot, a second layer is added, and so on gradually till the kiln is filled. By the time this is done, the lowermost layer is cold and fit to draw; so that the working of the kiln is a continuous operation. When the ore is calcined in the open air, a heap mingled with small coal (if necessary) is piled up over a stratum of larger pieces of coal, the heap being 5 or 6 feet high, by 15 or 20 feet broad. The fire is applied at the windward end, and, after it has burnt a certain way, the heap is prolonged at the other extremity, as far as the nature of the ground, or the convenience of work, requires. From the impossibility of regulating the draught, and from exposure to the weather, the calcination of ore cannot be so well performed in the open air as in kilns; and as to the relative cost of the two methods, Mr. Truran calculates that the quantity of coal per ton of ore is, in the kiln, one hundred-weight of small, and in the open air, two hundred-weights of small, and a half hundred-weight of large; and that while the cost of filling the kiln is barely a penny per ton, that of stacking the heaps on the open-air plan, and watching them during the period they are under fire, amounts to fourpence per ton. Against this must, however, be placed the cost of erecting the kiln, which according to the same authority amounts, for a kiln of a capacity equal to 70 tons of argillaceous ore, which will calcine 146 tons weekly, to 160*l*. The ironstone loses by calcining from 25 to 30 per cent. of its weight; it has undergone a remarkable change by the operation; in the raw state, it is a grey or light brown stony-looking substance, not attracted by the magnet; after calcination it has a dry feel, adheres strongly to the tongue, is cracked in all directions, is of a light reddish colour throughout, and acts powerfully on the magnet. It should be carried to the furnace as soon as possible, or if kept should be carefully protected from the rain.

The calcining kilns, *fig.* 1227, were erected at Middlesbrough, from the designs of

John Gjers. They were of a circular form, and have wrought-iron shells; but unlike ordinary kilns of this class, the shells are made of the same shape as the interior of the kilns, so that there is a uniform thickness of 15 inches of fire-brick lining in all parts. The shell and lining of each kiln rest upon an annular cast-iron entablature, which is supported by eight hollow cast-iron pillars cast on the base plate. By this arrangement a space for drawing the charge is left all round the bottom. The principal dimensions of each kiln are: Internal diameter at the bottom, 14 feet; at the largest part, 20 feet; and at the top, 18 feet. The height from the base plate to the top of the columns, 2 feet 3 inches; the thickness of the entablature, 4 inches. Height of the shell from the top of the entablature on which it rests to the level of the largest diameter, 9 feet 2 inches; and from that level to the top of the shell, 12 feet 2 inches; total height of each kiln, from the base plate to the top of the shell, 22 feet. The base plate is 2½ inches thick, and is 20 feet in diameter; it is cast in eight pieces, and rests upon brickwork, in which the air-passages are formed. The cubic contents of each kiln is 5,500 cubic feet.

1227

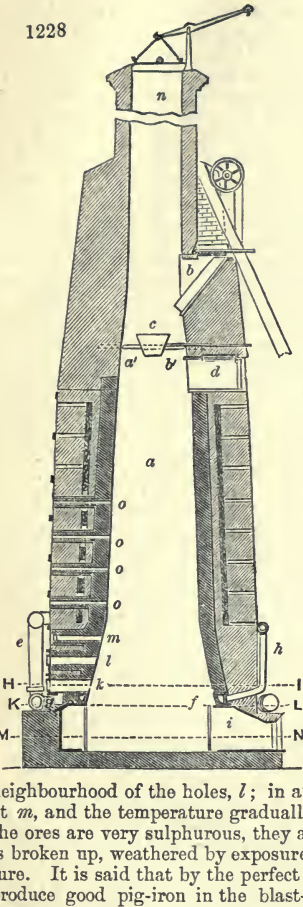


As will be seen in *fig.* 1227, each kiln is provided with a cast-iron central cone, made in two pieces, so arranged that an annular space is left between them. This cone spreads the calcined ore outwards towards the openings through which it can be withdrawn, and it also acts beneficially in assisting to break up any large scars or lumps partly fused together, which may happen to come down. The central cone might, as far as the mere spreading action is concerned, be made plain and in a single piece; but the form shown in the figure has been adopted by Gjers with a view of, in some cases, employing the annular space between the two cones for the admission of waste gas from the furnace. Where the quantity of furnace-gas is not sufficient to be applicable to this purpose, the double cones still furnish the means of giving a good air-supply to the kilns.

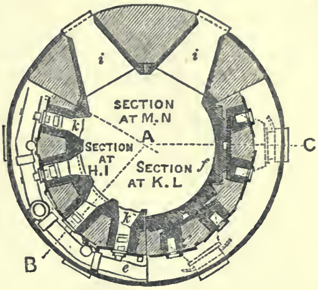
In the case of the particular kilns we are describing, the central cones are each 8 feet in diameter at the bottom, and 8 feet high, and the air is conducted to them through eight channels or flues formed in the brickwork at the base of each kiln. In addition to these passages, there are a number of holes, *fig.* 1127, for the supply of air formed in the outer shell. The kilns are placed at a distance of 25 feet apart from centre to centre, and each is surrounded at the top by a gallery formed of wrought-iron brackets covered with cast-iron plates. The galleries of four kilns are connected with each other at four points, the space between the kilns being bridged over with wrought-iron girders.

Westman's Calcining Kiln.—Kilns in which the waste gases of the blast-furnace are applied to the calcination of ores are extensively used in Sweden, and have thence been introduced into Russia and the United States. The improved form given to these kilns by Westman, in which the gases are burnt by introduction of a blast of air, is represented in the accompanying woodcuts. *Fig.* 1228 is a vertical section of the kiln, the right half being taken through the line A B, and the left half through A C in *fig.* 1229. *Fig.* 1229 shows horizontal sections at different heights along the lines M N, K L, and H I of *fig.* 1228. The shaft, *a*, is everywhere circular in horizontal section. The raw ore is introduced through the shoot, *b*, which when not in use is closed by a trap-door, and is delivered in the middle of the kiln through the moveable hopper, *c*. The opening, *d*, allows the throat, *a′ b′*, to be examined, and thus it may be seen whether the kiln is properly filled and the ore duly distributed, whilst it also allows the ore to be re-arranged when necessary. The gas is conveyed through the circular main, *e*, and passing through the channel, *g*, enters the furnace through the twelve passages, *k*; the supply of gas may be regulated by means of horizontal sliding valves. The air necessary for combustion is introduced through the tube, *h*, and enters the furnace through twenty-four openings in the hollow ring, *f*. The roasted charge is withdrawn through six passages, *i*, and air serving to oxidise the sulphur in the hot ore also gains access through these apertures. The openings, *l*, *m*, serve for introducing bars for working the ores when necessary; *o*, *o*, are sight-holes; and, *n*, is the chimney, furnished with a damper for regulating the draught.

1228



1229



The diameter of the shaft varies in different kilns from 6 to 10 feet, and the number of passages for withdrawing the roasted ore may vary from 5 to 10. The following figures have been given by Westman as representing the quantities of ore roasted in 24 hours with kilns of various sizes:—

With	5	passages for drawing the charge . .	22 to 30 tons.
,,	6	,, ,,	28 ,, 36 ,,
,,	8	,, ,,	35 ,, 48 ,,
,,	10	,, ,,	45 ,, 60 ,,

The temperature in Westman's kiln can be governed by regulating the admission of air and gas, and if necessary by addition of solid fuel. When the kiln is at a proper working temperature, it exhibits a red heat in the neighbourhood of the discharge passages, *i*; the ore sinters in front of the gas-openings, *k*; is in a pasty condition in the neighbourhood of the holes, *l*; in an almost pasty state, but having the edges sharp, at *m*, and the temperature gradually diminishes in the upper part of the furnace. If the ores are very sulphurous, they are roasted twice. After the first roasting the ore is broken up, weathered by exposure to the air, and again roasted at a higher temperature. It is said that by the perfect method of roasting in this kiln, it is possible to produce good pig-iron in the blast-furnace from Swedish ores containing too much sulphur to be otherwise smelted.

Flux.—The flux that is used in the blast-furnace is *limestone*, either in the state of carbonate as it comes from the quarry, or calcined in kilns, by which it is deprived of water and carbonic acid. The lowest bed of the coal-formation usually rests on limestone, and in the coal-formation itself are found not only the ore and its most appropriate fuel, but the pebbly grits which afford the blocks of refractory stone necessary for building those parts of an iron furnace that are required to endure the utmost extremity of heat, as well as those seams of refractory clay, of which the fire-bricks are composed, with which the middle and upper parts of the furnace are lined. In Styria where the spathic ores contain large quantities of protoxide bases, such as lime, magnesia and manganese, siliceous and aluminous fluxes are sometimes required in the form of quartzose schists and clay-slate. Very siliceous hæmatites are beneficially fluxed by the addition of coal-measure shale, in addition to the limestone, or preferably by the aluminous brown hæmatite found in the basalt of Antrim. Titaniferous iron ores also require the use of aluminous fluxes, such as Labrador felspar or even ordinary brick in addition to limestone.

The composition of the limestone to be used in smelting operations is of considerable importance; where calcareous ores are used, the presence of silicic acid in the limestone is advantageous; if clay ores are the main material from which iron is manufactured, a magnesian limestone is preferable, but an aluminous limestone should be used where siliceous ore predominates. Chemical analysis alone can determine to which class a particular limestone belongs, as there is often nothing in the external appearance by which a pure limestone may be distinguished from one containing 40 or 50 per cent. of foreign matter.

Carbonised pit-coal, or coke was, till within the last twenty-five years, the sole combustible used in the blast-furnace. Coal is coked either in the open air or in kilns. In the former, as practised in Staffordshire, the coal is distributed in circular heaps about 5 feet in diameter by 4 feet high, and the middle is occupied by a low brick chimney piled with loose bricks, to open or to leave interstices between them, especially near the ground. The larger lumps of coal are arranged round this chimney, and the smaller ones towards the circumference of the mass. When everything is adjusted a kindling of coals is introduced into the bottom of the brick chimney, and, to render the combustion slow, the whole is covered with a coat of coal dross, the chimney being loosely covered with a slab of any kind. Openings are occasionally made in the crust, and afterwards shut up, to quicken and retard the ignition at pleasure during its continuance of twenty-four hours. Whenever the carbonisation has reached the proper point for forming good coke the covering of coal dross is removed, and water is thrown on the heap to extinguish the combustion, a circumstance deemed useful to the quality of the coke. In this operation in Staffordshire coal loses the half of its weight, or two tons of coal produce one of coke.

In order to prepare larger quantities of coke at once, long ridges are often substituted for circular heaps, the length of which varies with circumstances and the consumption of coke; they sometimes extend to the length of 200 feet. On erecting one of these ridges a string is stretched along the coking station, in the direction of which large pieces of coal are placed slanting against each other, leaving a triangular space between them, so that a longitudinal channel (ignition passage) is formed, through which the string passes. In arranging the pieces it is necessary to pay attention to the natural stratification of the coals, which should be at right angles to the longitudinal direction of the ridge. Parallel with the first series of coals is placed a second, and then a third, and so on; but the pieces constantly diminish in size until the station measures 6 feet on both sides. Upon this substructure the heap is then made, without particular care in the arrangements, the largest pieces below and the smallest above, until it has reached a height of about 3 feet. To facilitate the ignition, stakes are rammed in at distances of 2 feet from each other, projecting above throughout the whole length of the ridge, which, when subsequently removed, leave vacant spaces for the introduction of burning coal. The ridge, being thus kindled at more than 100 distinct spots, soon breaks out into active combustion. As soon as the burner observes the thick smoke and flame cease at any one part, and a coating of ash making its appearance, he endeavours immediately to stop the progress of the fire by covering it with powdered coal-dust, repeating the operation until the whole ridge is covered, when it is left two or three days to cool; the covering on the side exposed to the wind should be thicker and increased in stormy weather. When the fire is nearly extinguished, which occurs in two or three days, the coke is drawn. This mode of coking is simple, but not very economical. The fire proceeding from the upper part of the ridge in a downward direction, towards the lower and interior parts, converts the coal in the upper strata into coke before that in the interior has acquired the temperature necessary for charring, and is still in want of a supply of air, which can only be furnished from without, and must not be excluded by a covering. During the time, therefore, that the inner parts of the heap are being converted into coke, the outer portions are being uselessly, though unavoidably consumed. For further details concerning coking, see the articles Coal and Coke.

The 'blowing-in' of a coal blast-furnace is an operation which requires much care and experience. A fire of wood is first lighted on the hearth; upon this is placed a quantity of coke, and when the whole is well ignited, the furnace is filled to the throat with regular charges of calcined ore, limestone, and coke, and the blast, which should at first be moderate, is turned on. At the works around Merthyr Tydvil, the first charges generally consist of 5 cwts. of calcined argillaceous ore and $1\frac{3}{4}$ cwt. limestone, to 4 cwts. of rich coke; this burden is kept on for about 10 days, it is then increased to 6 cwts. of calcined ore and $2\frac{1}{2}$ cwts. of limestone (*Truran*). The cinders usually make their appearance in about 12 hours after blowing; the metal follows in about 10 hours after, collecting in the hearth to the amount of 3 or $3\frac{1}{2}$ tons in 60 hours after blowing. If all goes on well about 22 tons of metal will be produced in the first week, 38 tons in the second, 55 in the third, and nearly 80 in the fourth; after 10 or 12 weeks the produce will average 110 tons. By forcing the furnace in its infancy a much greater produce of iron may be obtained, though to the injury of its subsequent working. Mr. Truran relates the following case in point. A furnace was blown in at the Abersychan works with such volumes of blast and rich burden of materials that a cast of several tons was obtained within 14 hours after applying blast. The first week's blowing produced 200 tons, at which rate it continued for two or three weeks, when it rapidly diminished, falling so low as 19 tons for one week's make. From this deplorable state it was made to produce 26 tons, and, after considerable delay, 100 tons; but with a large increase in the yield of materials over that at the other furnaces. When a furnace is first blown in it should be made to produce grey iron; but the tendency of forcing is to produce a white iron with a dark scouring cinder.

The quantity of air thrown into a blast-furnace in full work is enormous, exceeding in weight the totals of all the solid materials used in smelting. A furnace working on foundry iron of a capacity of 275 yards receives 5.390 cubic feet of air per minute, which amounts weekly to 1,695 tons; when working on white iron a larger volume of blast is employed, averaging 7,370 cubic feet per minute, or 2,318 tons per week.

The disorders to which blast-furnaces are liable have a tendency to produce white cast iron. The colour of the slag or scoriæ is the surest test of these derangements, as it indicates the quality of the products. If the furnace is yielding an iron proper for casting into moulds, the slag has an uniform vitrification and is slightly translucid. When the dose of ore is increased, the slag becomes opaque, dull, and of a greenish yellow tint, with blue enamelled zones. Lastly, when the furnace is producing white metal, the slags are more or less black and glossy. The scoriæ from a coke are much more loaded with lime than those from a charcoal blast-furnace. This excess of lime appears adapted to absorb and carry off the sulphur which would otherwise injure the quality of the iron. From numerous analyses Dr. Noad made of blast-furnace cinders, we select the following as illustrating their general composition under different conditions of the furnace:—

Analyses of Blast Furnace Cinders.

Mean of four analyses of grey iron (cold blast) cinders from Pontypool, South Wales. IV. Mean of four analyses of green cinders from a furnace at Ebbw Vale, Monmouthshire, smelting spathose ore. V. Mean of four analyses of blast-furnace cinders from Sweden. VI. Mean of four analyses of white iron cinders from a furnace at Cwm Celyn Iron Works, Monmouthshire. VII. Mean of four analyses of white iron cinders from the same works, the furnace 'scouring.'

The following Table exhibits the 'yields' of materials per ton on the iron made in various works. During the month ending July 25, 1857, there were consumed in four furnaces at Ebbw Vale 1,354 tons 14 cwts. of coke; 1,792 tons of coal; 2,440 tons 19 cwts. of calcined mine; 1,818 tons of 10 cwts. red ore; 1,347 tons 6 cwts. of calcined cinders; and 1,226 tons 7 cwts. of burnt lime. The quantity of pig-iron made was 2,305 tons 7 cwts.:—

The 'cinders' mentioned in the foregoing Table are not those from the blast-furnace, but are derived from the cast iron during the processes of 'refining,' 'puddling,' &c., by which the cast iron is converted into wrought iron. These cinders are very rich in iron, which exists in them principally in the form of silicate of the protoxide. They often occur beautifully crystallised, particularly after they have been calcined: an operation which is always performed on them in well-conducted works, and which has for its object the removal of the sulphur and the peroxidation of a portion of the iron. These cinders, though very rich in iron, are always contaminated to a considerable extent with both sulphur and phosphorus, as might be expected, seeing that they are the results of operations which have for their objects the removal of the foreign matters contained in the pig-iron. The tendency of the former is to make the metal what is called 'hot short,' so that it cannot be worked while hot under the hammer; the tendency of the latter element is to make the iron 'cold short,' so that it breaks when an attempt is made to bend it when cold. The separation of sulphur is very perfectly effected by the calcination of the cinder, and it is interesting to trace the progress of its gradual elimination. In some parts of the heap (which often contains several thousand tons of cinder) large masses of prismatic crystals of pure sulphur may be found, but usually nearly the entire surface of the heap is covered with a thin layer of sulphate of iron, sometimes crystallised, but generally in various stages of decomposition; lower down in the heap, where the heat is greater, the sulphate of iron disappears, and in its place red oxide of iron, without a trace of sulphur, is found. In calcining a heap of cinders care is required not to allow the heat to rise too high, or immense masses will become melted together, involving the necessity of blasting, which entails much expense. After the heap has been burning for some months, streams of water are directed over the surface, by which much soluble sulphate of iron is removed. Unfortunately, the process of calcination does not remove any of the phosphoric acid, which necessitates a judicious employment of these cinders in the blast-furnace. Dr. Noad repeatedly submitted 'forge cinders' to analysis, and we give in the following Table the average results of his experiments:—

Hot-blast.—One of the greatest improvements ever made by simple means in any manufacture, is the employment of hot air instead of the ordinary cold air of the atmosphere, in supplying the blast of furnaces for smelting and founding iron. The discovery of the superior power of a hot over a cold blast in fusing refractory lumps of cast iron was accidentally observed by Mr. James Beaumont Neilson, engineer to the Glasgow Gas Works, about the year 1827, at a smith's forge in that city, and it was made the subject of a patent in the month of September in the following year. No particular construction of apparatus was described by the inventor by which the air was to be heated, and conveyed to the furnace; but it was merely stated that the air may be heated in a chamber or closed vessel, having a fire under it, or in a vessel connected in any convenient manner with the forge or furnace. From this vessel the air is to be forced by means of a bellows into the furnace. The quantity of surface which a heating furnace is required to have for a forge is about 1,260 cubic inches; for a cupola furnace, about 10,000 cubic inches. The vessel may be enclosed in brickwork, or fixed in any other manner that may be found desirable, the application of heated air in any way to furnaces or forges, for the purpose of working iron, being the subject claimed as constituting the invention.

Whenever a forced stream of air is employed for combustion, the resulting temperature must evidently be impaired by the coldness of the air injected upon the fuel. The heat developed in combustion is distributed into three portions: one is communicated to the remaining fuel; another is communicated to the nitrogen of the atmosphere and to the volatile products of combustion; and a third to the iron and fluxes, or other surrounding matter, to be afterwards dissipated by wider diffusion. This inevitable distribution takes place in such a way, that there is a nearly equal temperature over the whole extent of a fire-place, in which an equal degree of combustion exists.

We thus perceive that if the air and the coal be very cold, the portions of heat absorbed by them might be very considerable, and sufficient to prevent the resulting temperature from arising to a proper pitch; but if they were very hot they would absorb less caloric, and would leave more to elevate the common temperature. Let us suppose two furnaces charged with burning fuel, into one of which cold air is blown, and into the other hot air, in the same quantity. In the same time, nearly equal quantities of fuel will be consumed with a nearly equal production of heat; but notwithstanding this, there will not be the same degree of heat in the two furnaces, for the one which receives the hot air will be hotter by all the excess of heat in its air above that of the other, since the former air adds to the heat while the latter abstracts from it. Nor are we to imagine that by injecting a little more cold air into the one furnace, we can raise its temperature to that of the other. With more air indeed we should burn more coals in the same time, and we should produce a greater quantity of heat, but this heat being diffused proportionally among more considerable masses of matter, would not produce a greater temperature; we should have a larger space heated, but not a greater intensity of heat in the same space.

Thus, according to the physical principles of the production and distribution of heat, fires fed with hot air should, with the same fuel, rise to a higher pitch of temperature than fires fed with common cold air. This consequence is independent of the masses, being as true for a small stove which burns only an ounce of charcoal in a minute, as for a furnace which burns a hundred-weight; but the excess of temperature produced by hot air cannot be the same in small fires as in great, because the waste of heat is usually less the more fuel is burned.

This principle may be rendered still more evident by a numerical illustration. Let us take, for example, a blast-furnace, into which 600 cubic feet of air are blown per minute; suppose it to contain no ore but merely coal or coke, and that it has been burning long enough to have arrived at the equilibrium of temperature, and let us see what excess of temperature it would have if blown with air of 300° C. (572° F.), instead of being blown with air at 0° C.

600 cubic feet of air, under the mean temperature and pressure, weigh a little more than 45 lbs. avoirdupois; they contain 10·4 lbs. of oxygen, which would burn very nearly 4 lbs. of carbon, and disengage 16,000 times as much heat as would raise by one degree per cent. the temperature of 2 lbs. of water. These 16,000 portions of heat, produced every minute, will replace 16,000 other portions of heat, dissipated by the sides of the furnace, and employed in heating the gases which escape from its mouth. This must take place in order to establish the assumed equilibrium of caloric.

If the 45 lbs. of air be heated beforehand up to 300° C., they will contain about $\frac{1}{8}$th part of the heat of the 16,000 disengaged by the combustion, and there will be therefore in the same space $\frac{1}{8}$th of heat more, which will be ready to operate upon any bodies within its range, and to heat them $\frac{1}{8}$th more. Thus the blast of 300° C. gives a temperature which is $\frac{9}{8}$ths of the blast at zero C., or at even the ordinary atmospheric temperature; and as we may reckon at from 2,200° to 2,700° F. (from 1,200° to 1,500° C.), the temperature of blast-furnaces worked in the common way, we perceive that the hot-air blast produces an increase of temperature equal to from 270° to 360° F.

Now, in order to appreciate the immense effects which this excess of temperature may produce in metallurgic operations, we must consider that often only a few degrees more temperature are required to modify the state of a fusible body, or to determine the play of affinities dormant at lower degrees of heat. Water is solid at 1° under 32° F.; it is liquid at 1° above. Every fusible body has a determinate melting point, a very few degrees above which it is quite fluid, though it may be partly below it. The same observation applies to ordinary chemical affinities. Charcoal, for example, which reduces the greater part of metallic oxides, begins to do so only at a determinate pitch of temperature, under which it is inoperative, but a few degrees above it is in general lively and complete. It is unnecessary in this article to enter into any more details to show the influence of a few degrees of heat more or less in a furnace upon chemical operations, or merely upon physical changes of state.

Figs. 1230, 1231, exhibit the apparatus of a hot blast as mounted at the Codner Park works, belonging to William Jessop, Esq., in every requisite detail. The drawings from which the wood-cuts are faithfully copied were kindly furnished for this work by Mr. Joseph Glyn, F.R.S., the distinguished engineer of the Butterly Iron Works.

The smelting furnaces have now generally three tuyères, and three sets of air-heating furnaces. The figures show two sets built together; the third set being detached on account of peculiar local circumstances. The air enters the horizontal pipe A, in the ground plan, *fig.* 1230, on one side of the arched or siphon pipes, shown in upright section in *fig.* 1231, and passes through these pipes to the horizontal pipe B, on the other side; whence it proceeds to the blast-furnace. These siphon pipes are flattened laterally, their section being a parallelogram, to give more heating surface, and also more depth of pipe (in the vertical plane), so as to make it stronger, and less liable to bend by its own weight when softened by the red heat. This system of arched pipe apparatus is set in a kind of oven, from which the flue is taken out at the top of it; but it thence again descends before it reaches the chimney, entering it nearly at the level of the fire-grate (as with coal-gas retorts). By this contrivance the pipes are kept in a bath of ignited air, and not exposed to the corroding influence of a current of flame. The places and directions of these oven-flues are plainly marked in the drawing.

1230

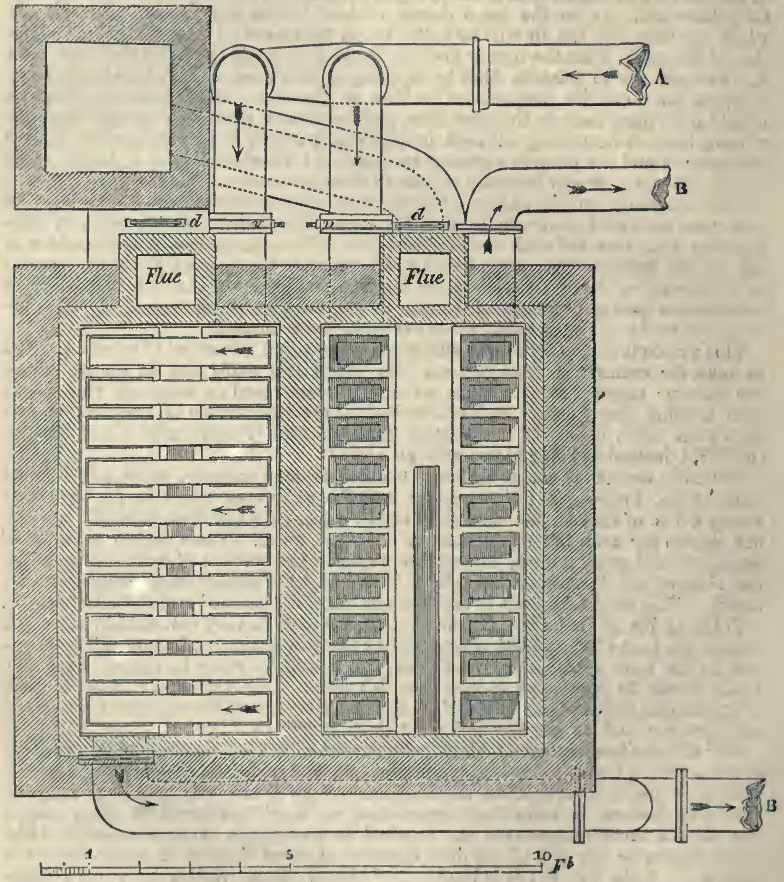

Fig. 1232 is a plan of the blast-furnace, drawn to a smaller scale than that of the preceding figures.

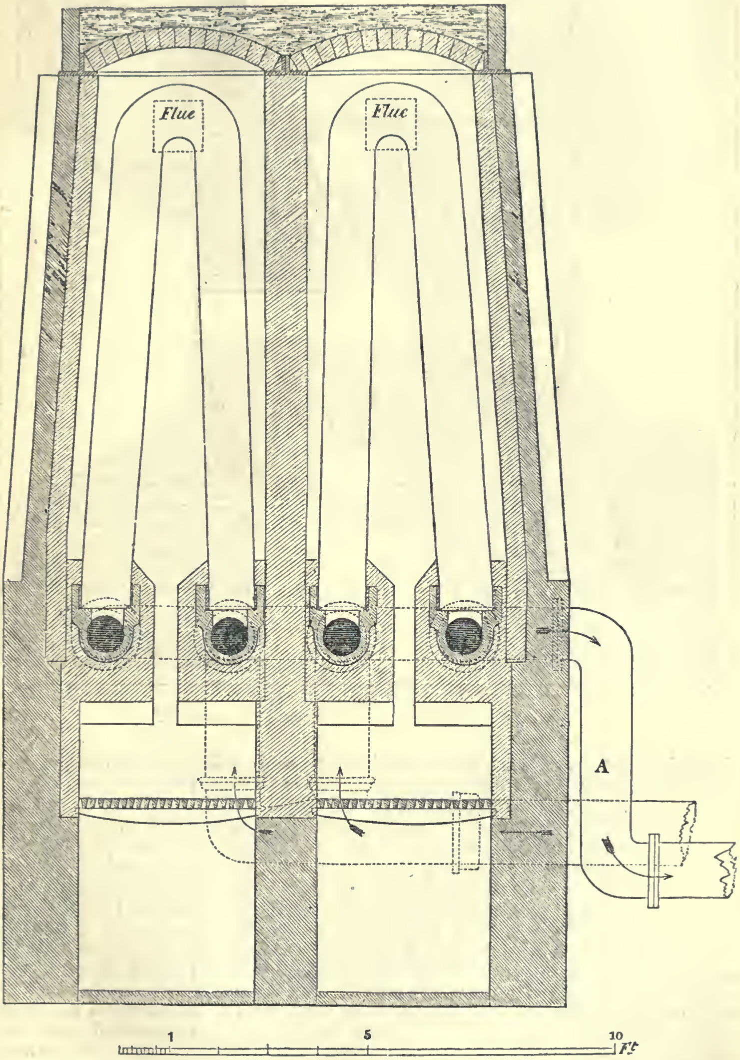
The three sets of hot-blast apparatus all communicate with one line of conducting pipes A, which leads to the furnace. Thus in case of repairs being required in one set, the other two may be kept in full activity, capable of supplying abundance of hot air to the blast, though of a somewhat lower temperature.

During a visit which Dr. Ure made to Mr. Jessop, at Butterly, he found this eminent and very ingenious ironmaster had made several improvements upon his hot-blast arrangements, whereby he prevented the alteration of form to which the arched pipes were subject at a high temperature, as also that he was about to employ five tuyères instead of three. For a drawing and explanation of his furnace-feeding apparatus, see SMELTING.

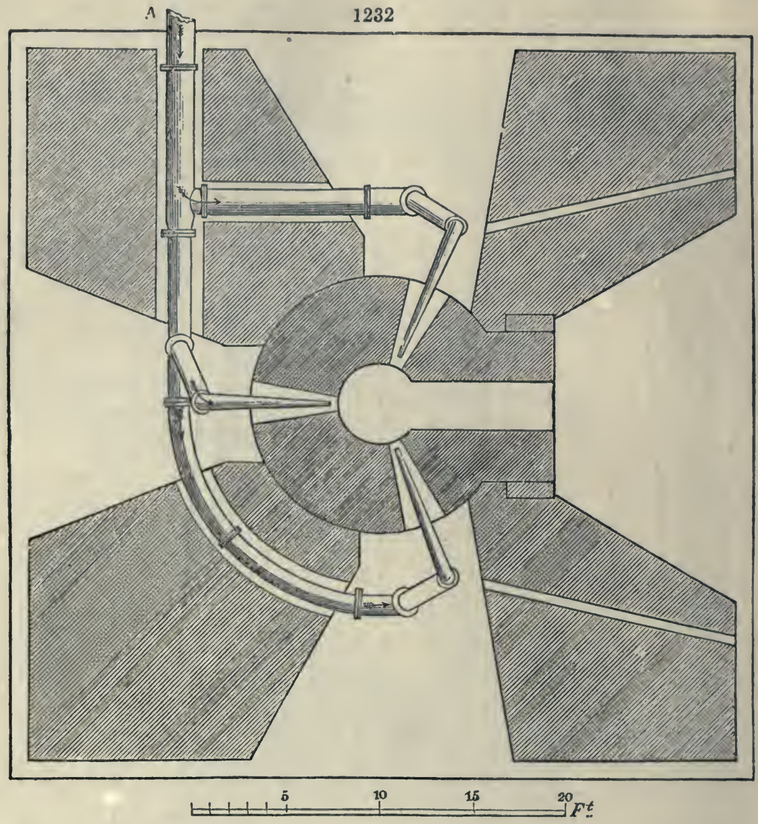
The experiments through which Mr. Neilson's important discovery was introduced into the iron manufacture were made at the Clyde Iron Works, where the fuel generally made use of was coke, derived from splint coal; during its conversion into coke, this coal sustained a loss of 55 per cent. During the first six months of the year 1829, when all the cast iron in the Clyde Iron Works was made by means of the cold blast, a single ton of cast iron required for fuel to reduce it, 8 tons $1\frac{1}{4}$ cwt. of coal converted into coke. During the first six months of the following year, while the air was heated to near 300° Fahr., 1 ton of cast iron required 5 tons $3\frac{3}{4}$ cwts. of coal converted into coke. The saving amounted to 2 tons 18 cwts. per ton of iron,

1231



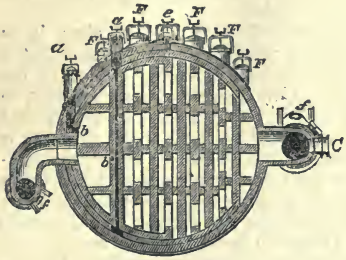
from which must be deducted the coal used in heating the air, which was nearly 8 cwts. This great success induced the Scotch ironmasters to try a higher temperature, and to substitute raw coal for coke; and during the first six months of the year 1833, the blast being heated to 600°, 1 ton of cast iron was made with 2 tons 5¼ cwts. of coal. Add to this 8 cwts. of coal for heating, and we have 2 tons 13¼ cwts. of coal to make 1 ton of iron. An extraordinary impetus was given by this discovery to the iron manufacture of Scotland, where, from the peculiar nature of the coal, and from the circumstance that, with a heated blast, Mushet's blackband ironstone could be exclusively used, its importance was more highly felt than in England and Wales. According to Mr. Finch's statement (Scrivenor's 'History of the Iron Trade'), there were in 1830 only eight works in operation in Scotland, which made in that year 37,500 tons of pig-iron; in 1838 there were eleven works, consisting of 41 furnaces, which made 147,500 tons, being an increase in eight years of 110,000 tons per annum; in 1859 there were fifty furnaces in blast, making 195,000 tons; in 1851, 750,000 tons of pig-iron were made; and in 1856, with 127 furnaces in blast, the make rose to 880,500 tons. The influence of hot blast has likewise been felt in the anthracite districts of South Wales, where that coal is now successfully used, and where several new furnaces have in consequence been erected. In short, notwithstanding the opposition with which the introduction of hot blast was met by engineers, as being destructive of the quality of the iron, so great have been the advantages derived from it that at the present time more than nineteen-twentieths of the entire produce of the kingdom is made in furnaces blown with heated air.

1232

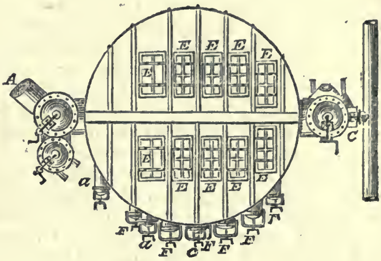


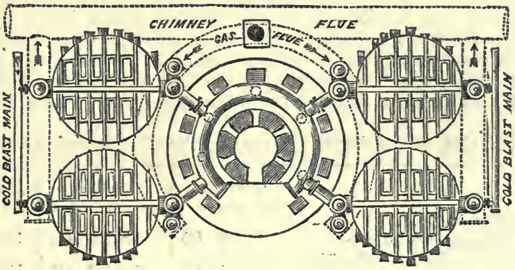
Of late years there has been a constantly increasing demand, especially in the Cleveland district, for more highly heated blast; and furnaces are now blown with air at a red heat, or almost beyond the power of endurance of cast-iron heating pipes. For this purpose the regenerative principle of Siemens has been advantageously applied. It consists of storing up the heat of the burning fuel in cellular piles of fire-brick, which are subsequently made to give up their heat to the blast before it enters the furnace. The most successful form of this apparatus is that known as Whitwell's stove which is represented in *figs.* 1233–1237. It consists of a series of parallel walls of fire-brick, connected by ribs and arches into a system of rectangular flues, which are alternately heated by the combustion of the waste gas from the top of the furnace, and cooled by passing a current of cold air in the reverse direction. For the more perfect combustion of the gases, ventilating holes for the admission of air are perforated through the walls at *a* and *d*. The arches at the top of the stove are provided with moveable covers at E, and similar covered holes are placed at the bottom of the stove at F, for the purpose of clearing out the dust which always accumulates on the brick-work when the furnace is used for heating. *f* is the gas inlet valve; C, the chimney valve used during the heating period; D, the cold-blast inlet valve, and A, the hot-blast valve. The latter is made with a hollow water cooled shell and seat,

1233



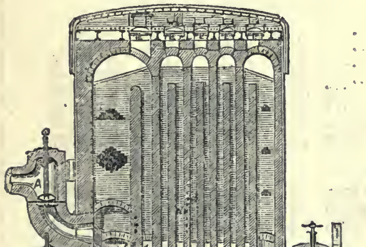
1234



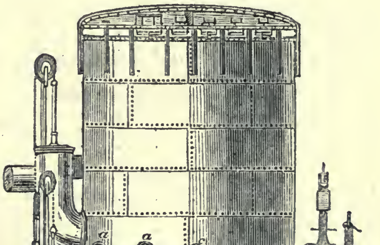


1235

1236



1237



and the outlet main, 3 feet in diameter, is lined with fire-brick 9 inches thick. *Fig.* 1235 shows the general arrangement of these stoves as applied to a blast-furnace at Consett in Durham. They are four in number, each being 22 feet in diameter, and 25 feet high, and containing 250 tons of brick, arranged so as to give 9,000 feet of heating surface. They are worked in pairs, the current being changed every two hours. The furnace makes from 400 to 500 tons of pig-iron per week, with an average consumption of coke of 19 to 19½ cwts. per ton; the ore yields about 45½ per cent. The effective blast-temperature is from 1,100° to 1,300° Fahr.

Mr. Truran, in his work on the iron manufacture of Great Britain, gives it as his opinion that the effects of hot blast have been greatly exaggerated, and that it is to improvements in the preparation of fuel and ore in the furnaces, in blowing engines, and in the smelting process, far more than to the heating of the blast, that we must refer the great reduction in the yields of coal in recent times; he thinks that the comparatively large produce which has been obtained from the Scotch furnaces is to be referred to the general use of carbonaceous ore, which melts at a low temperature; and which, from its comparative freedom from earthy matters, requires but a minimum dose of limestone for fluxing. Against this opinion of an English writer on iron smelting, we may place that recorded by an American metallurgist, Mr. Overman, who has written a large and in many respects a valuable treatise on the manufacture of iron, as conducted in America. 'The economical advantages arising from the application of hot blast, casting aside those cases in which cold blast will not work at all, are immense. The amount of fuel saved in anthracite and coke furnaces varies from 30 to 60 per cent. In addition to this, hot-blast enables us to obtain nearly twice the quantity of iron within a given time that we should realise by cold blast. These advantages are far more striking with respect to anthracite coal than in relation to coke or to bituminous coal. By using hard charcoal, we can save 20 per cent. of fuel, and augment the product 50 per cent. From soft charcoal we shall derive but little benefit, at least where it is necessary to take the quality of the iron into consideration.'

ments on the relative strength and other mechanical properties of cast iron, obtained by the hot and cold blasts, are extracted from a report presented to the British Association (1837) by Messrs. Eaton, Hodgkinson and William Fairbairn.

Of the three columns of numbers, the first represents the strength or other quality in the *cold* blast iron, the second that in the *hot*, the third is the ratio of these qualities; the figures included in parentheses indicate the number of experiments from which the results have been deduced.

These results contain nearly the whole of the information afforded by the investigation. From the numbers in the tables, it will be seen that in Buffery iron No. 1 cold blast somewhat surpasses hot blast in all the following particulars: 1, direct tensile strength; 2, compressive strength; 3, transverse strength; 4, power to resist impact; 5, modulus of elasticity or stiffness; 6, specific gravity: while the only numerical advantage possessed by the hot-blast metal is that it bends a little more than the cold before it breaks. In No. 2 the advantages of the rival kinds are more nearly balanced, still rather in favour of the cold blast. No. 3 hot-blast Carron iron resists both tension and compression better than cold blast of the same denomination; and No. 3 hot blast from the Devon works in Scotland is remarkably strong, while No. 3 cold blast is comparatively weak, notwithstanding its high specific gravity. On the whole it would appear from the experiments, that while the irons of No. 1 have been somewhat deteriorated in quality by the hot blast, those of No. 3 have been benefited by its mollifying powers; while those of No. 2 have been but very slightly affected; and from the evidence brought forward, it is rendered highly probable that the introduction of a heated blast, whilst it has, perhaps, to a certain extent, injured the softer irons, has improved those of a harder nature; and considering the small deterioration that the irons of the quality No. 2 have sustained, and the apparent benefit of those of No. 3, together with the saving effected by the heated blast, there seems good reason for the process becoming so general as it has done.

The following *general* summary of results, as derived from the experiments of Messrs. Hodgkinson and Fairbairn on the transverse strength of hot and cold blast iron exhibits at one view the ultimatum of the whole investigation:—

	Ratio of Strength: that of Cold Blast being represented by 1000	Ratio of Powers to sustain Impact: Cold Blast being 1000
These irons are from Mr. Hodgkinson's experiments:—		
Carron iron, No. 2	1000 : 990·9	1000 : 1005·1

Mean	1000 : 1024·8	1000 : 1226·3

Dr. Thompson's chemical examination of several samples of hot and cold blast iron is appended to this report. According to the experiments of this distinguished chemist, iron smelted by *hot* blast contains a greater proportion of iron, and a smaller proportion of silicon, carbon, and aluminium, than when smelted by cold air. The mean specific gravity of 8 specimens of Scotch cold blast iron No. 1 was 6·7034; the mean of 5 specimens of hot blast from the Carron and Clyde iron works was 7·0263, so that the density of cold-blast iron is less than that of hot. The mean of 6 analyses of cold-blast iron No. 1 gave 3½ atoms of iron, 1 atom of carbon, silicon, and aluminium; the proportion of these three constituents being very nearly 4 atoms of carbon, 1 atom of silicon, and 1 atom of aluminium; consequently Scotch cold-blast iron consists of 20 atoms of iron (with a little manganese), 4 atoms of carbon, 1 atom of silicon, and 1 atom of aluminium. The mean of 5 analyses of hot-blast iron No. 1 gave 6½ atoms of iron and manganese to 1 atom of carbon, silicon, and aluminium, from which it would appear that cast iron smelted with a hot-blast is *purer* than when the blast is cold. This, however, is not the case, as the numerous analyses of both varieties that have been made during the last few years concur in proving. Hot-blast grey-iron smelted with mineral coal, contains a much higher percentage of silicon than the same variety of cast iron smelted from the same ores by cold blast; in other respects, provided the process of reduction is complete, *i.e.* when little or no iron passes off with the slag, there is very little chemical difference between the two varieties, as will be seen in the following Table, which contains the results of a series of analyses of hot- and cold-blast iron, which Dr. Noad had occasion to make, under circumstances peculiarly favourable for instituting the comparison, the furnaces working with the same ores, and making the same class of iron, viz., good No. 3 grey pig.

The true reason of the frequent inferiority of hot-blast iron has been correctly given by Mr. Blackwell. Furnaces blown with heated air exert greater reductive power than those in which a cold blast is used. This has led, since the introduction of hot blast, to the extensive use in iron smelting of refractory ores not formerly smelted, a large part of which have been ores of a class calculated to produce inferior iron; and it is to the use of ores of this nature, far more than to any deterioration in quality, arising from a heated blast, that this inferiority of hot-blast iron is to be ascribed.

Utilisation of the waste gases given off from the furnace-head.—The agent in the blast-furnace by which the oxide of iron is reduced is carbonic oxide, the presence of which therefore in great excess is indispensable to the operation of the furnace. The flames rising from the tunnel-head, which makes a blast-furnace at night such an imposing object, are occasioned principally by the combustion of this gas, on coming into contact with the oxygen of the atmosphere. The attention of practical men was first called to the enormous waste of heat which this useless flame entailed by Messrs. Bunsen and Playfair, and the application of the gas to a useful purpose may be ranked next to that of the heated blast, as the most important of the recent improvements in the iron manufacture. The gases evolved from iron furnaces where coal is used as the fuel contain the following constituents: viz. *nitrogen*, *ammonia*, *carbonic acid*, *carbonic oxide*, *light carburetted hydrogen*, *olefiant gas*, *carburetted hydrogen of unknown composition*, *hydrogen*, *sulphuretted hydrogen*, and *aqueous vapour*. The nature of the combustible gas stands in a relation so intimate to the changes suffered by the materials put into the furnace, that its different composition in the various regions of the furnace indicates the changes suffered by the materials introduced as they descend in their way to the entrance of the blast. Now as the examination of this column of air in its various heights in the furnace must be the key to the questions upon which the theory and practice of the manufacture of iron depend, it was of the first importance to subject it to a rigid examination; this accordingly has been done by the above-named eminent chemists, and subsequently by M. Ebelmen. We shall return to a consideration of the results they obtained presently, confining our attention at present to the composition of the gases at the mouth of the furnace, and to the methods which have been adopted to utilise them.

In order to arrive at a knowledge of the composition of these gases, M. Bunsen first studied minutely the phenomena which would ensue were the furnace filled with fuel only: by a careful distillation of a known weight of coal, and analysing of the products, he obtained results embodied in the subjoined table:—

Carbon	68·925
Tar	12·230
Water	7·569
Light carburetted hydrogen	7·021
Carbonic oxide	1·135
Carbonic acid	1·073
Condensed hydrocarbon and olefiant gas	0·753
Sulphuretted hydrogen	0·549
Hydrogen	0·499
Ammonia	0·211
Nitrogen	0·035
	100·000

Now, in the furnace, the oxygen introduced by the blast is consumed in the immediate vicinity of the tuyère, being there converted into carbonic oxide, and the coal loses all its gaseous products of distillation much above the point at which its combustion commences, near, in fact, the top of the furnace; the fuel with which the blast comes into contact is therefore coke, and upon calculating the amount of carbonic oxide produced by the combustion of 68·925 per cent. of carbon, and the nitrogen of the air expended in the combustion, we get as the composition by volume of the gases escaping from a furnace filled with Gasforth coal the following:—

Nitrogen	62·423
Carbonic oxide	33·163
Light carburetted hydrogen	2·527
Carbonic acid	0·139
Condensed hydrocarbon	0·151
Sulphuretted hydrogen	0·091
Hydrogen	1·431
Ammonia	0·070
	100·000

With this preliminary information, Bunsen proceeded to calculate the modification of the gaseous mixture occasioned by the introduction into the furnace of iron-ore and limestone. The materials used for the production of 140 lbs. of pig-iron were:— 420 lbs. calcined iron-ore; 390 lbs. coal; 170 lbs. limestone. From 100 parts of the coal, 67·228 parts of coke were obtained; but from this must be deducted 2·68 ashes, and 1·18 carbon entering into combination with the iron; which leaves as the quantity of carbon actually burnt into carbonic oxide before the tuyère 63·368; part of this carbonic oxide undergoes oxidation into carbonic acid at the expense of the oxygen in the oxide of iron which it reduces; a further quantity of carbonic acid is derived from the limestone; so that the gases returned to the mouth of the furnace by the combustion of the 67·228 parts of coke, the reduction of the corresponding quantity of ore, and the decomposition of limestone, consist of—

Nitrogen	282·860
Carbonic acid	59·482
Carbonic oxide	121·906
	464·248

Add to this the products of the distillation of the coal, and we get the following as the percentage compositions by weight and measure of the gases issuing from the mouth of the furnace:—

	By weight.	By volume.
Nitrogen	59·559	60·907
Carbonic acid	12·765	8·370
Carbonic oxide	26·006	26·846
Light carburetted hydrogen	1·397	2·536
Hydrogen	0·078	1·126
Condensed hydrocarbon	0·108	0·112
Sulphuretted hydrogen	0·053	0·045
Ammonia	0·054	0·058
	100·000	100·000

The calculations of the quantity of heat capable of being realised in the furnace by the combustion of the furnace-gases are founded on the data on the heat of combustion given in the posthumous papers of Dulong, according to which—

1 kilogramme, or 15,444 grains, of

Carbon burning to CO, heats 15,444 grs. of water to	1499°C
„ „ CO^2,	7371°
Carbonic oxide	2502°
Hydrogen	34706°
Light carburetted hydrogen	13469°
Olefiant gas	12322°
Sulphuretted hydrogen	4476°
Ammonia	6060°

Using these numbers, it is found that by the combustion of 100 of the furnace-gases, there are generated from the

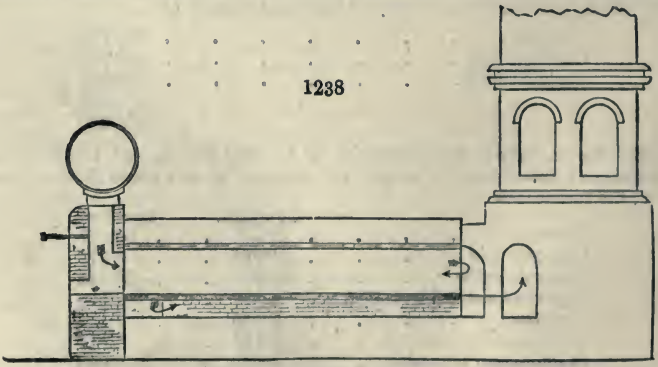
59·559 nitrogen	0000
12·765 carbonic acid	0000
26·006 carbonic oxide	65067
1·397 carburetted hydrogen	18826
0·078 hydrogen	2704
0·108 olefiant gas	1331
0·053 sulphuretted hydrogen	238
0·034 ammonia	208
	88374 =

units of heat *generated*, the *unit* being understood to mean the amount of heat necessary to raise 1 kilogramme = 2·204 lbs. = 15,444 grains of water from 0° Centigrade to 1° cent. The amount of heat *realized* in the furnace is limited to that produced by the expenditure of the oxygen, corresponding to 59·559 nitrogen in the production of carbonic oxide; this amounts to 20,001 units: hence follows the remarkable conclusion, that in the furnace which was the subject of experiment not less than 81·54 per cent. of the fuel is lost in the form of combustible matter still fit for use, and that only 18·46 per cent. of the whole fuel is realised in carrying out the processes in the furnace.

A more practical measure of the economy of fuel in the blast-furnace is that given by Mr. Lowthian Bell. See p. 978.

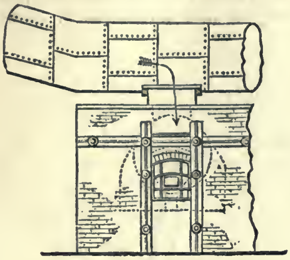
The temperature which should be produced by the flame of the furnace-gases when burnt with air is found by dividing the units of heat, viz. 883·74 arising from the combustion of 1 kilogramme of the gases by the number resulting when the quantity of the products of combustion is multiplied by their specific heat (1·9338 × 0·2696): we thus get the number 3083° F.; but this is below the truth, inasmuch as there is an accession of combustible gases at the mouth of the furnace, arising from the decomposition of the liquid products of the distillation of the coal in its passage over the red-hot fuel. Making proper correction for this, and using numbers derived from actual experiments, Messrs. Bunsen and Playfair calculated the temperature of the gases when generated under favourable conditions at 3214° F., and even this may be increased to 3632° F., a temperature far above that of cast iron, by the using a blast sufficiently heated. In utilising these waste gases, care must be taken not to remove

1238

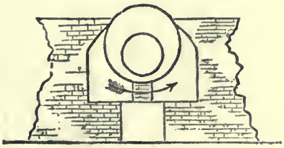


them from the furnace till they really are *waste*, that is, until they have done their work in the furnace. It is obvious that no combustible matter could be removed from the lower regions of the furnace without seriously deranging the operations essential to the reduction and smelting of the ore. In order to remove the gases effectually, and without injury to the working of the furnace, and in such a state as will permit their combustion to be effected with most advantage, the height of the furnace must

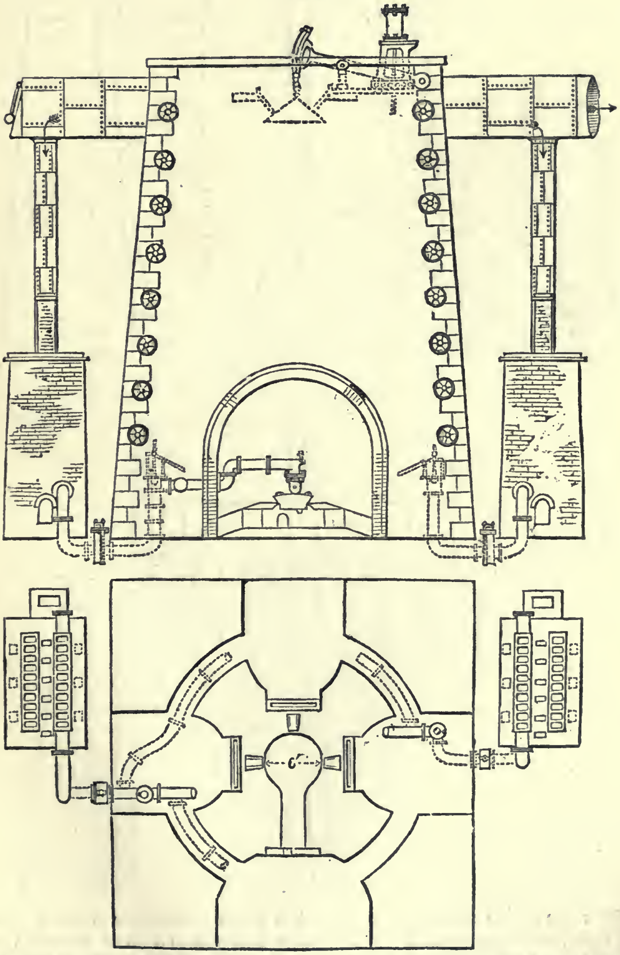
1239



1240



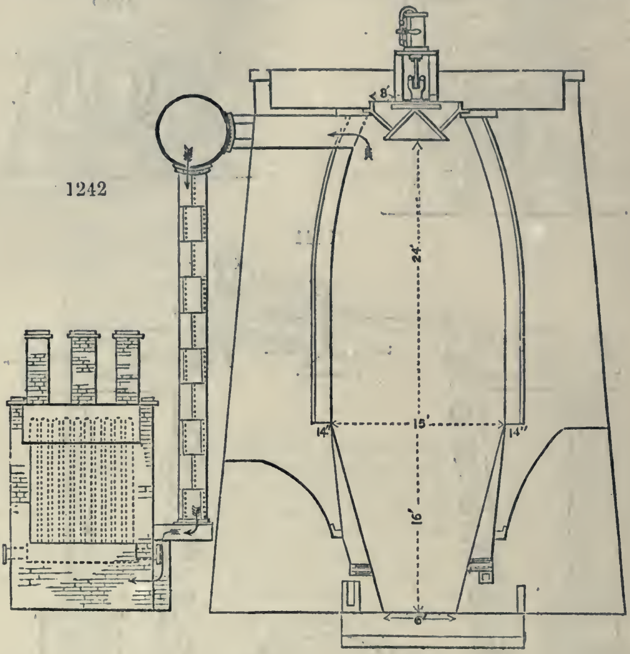
1241



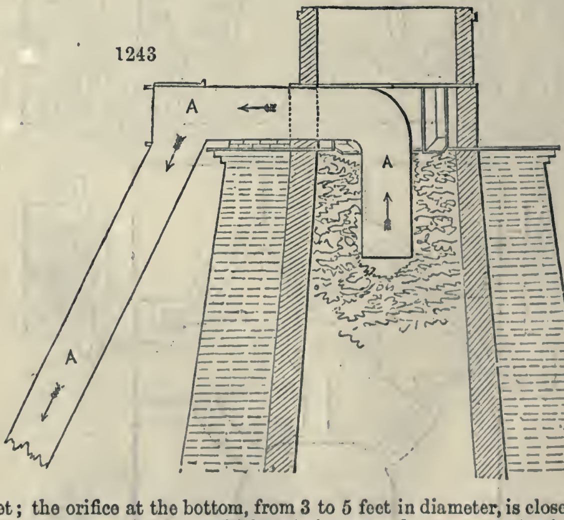
be raised, the full width of the mouth being retained, and the gases must be withdrawn sufficiently far below the mouth for them to be obtained dry, and also beneath the point where they begin to enter into combustion from contact with the atmospheric air.

Various modes of collecting the gases have been tried; the best seems to be that adopted at Ebbw Vale, Sirhowy, and Cwm Celyn. A funnel-shaped casting, equal in its largest diameter to the throat of the furnace, projects into the interior a depth of 4 or 5 feet; the orifice at the bottom, from 3 to 5 feet in diameter, is closed by a conical casting, the apex upwards, from which a chain proceeds to a lever having a counterpoise at the other end. (See *fig.* 1241.) The materials are filled into the funnel-shaped receptacle, and are charged into the furnace with a uniform distribution, by lowering the cone by means of suitable machinery, which again returns it to its place when

1242



1243



emptied. The circular space around the funnel, inside the furnace, forms a chamber for the reception of the gases, from which they are conveyed by brick tunnels or iron piping to the place of combustion. The whole arrangement will be clearly understood by an inspection of the accompanying plans, *figs.* 1238, 1239, 1240, 1241, 1242, kindly furnished to the writer by the proprietor of the Cwm Celyn and Blaina Iron Works.

Fig. 1243 shows the plan of extracting the gases which is adopted at the Brymbo Iron Works, near Wrexham, the same being the patent of C. E. Darby.

It consists of a large pipe or tube inserted into the middle of the top part of the furnace, which descends a short distance down into the materials, and is carried over the top of the side of the furnace in the form of a siphon, a continuation of which pipe is taken to the boilers, or hot air-stoves, where the gas is burned in the usual way. The principal advantage claimed by this method, is that it puts no check on the free escape of the gases, by which the driving of the furnace is impeded, and the quality of the iron deteriorated. The patentee estimates the saving of fuel with two furnaces making 240 tons of iron per week, by applying the gas to the blast-engine boilers and hot air-stoves, 1,200*l.* a year. Thus:—Consumption of fuel at engine and stoves equal to 7 cwts. of good coal per ton of iron, made at 3½*d.* per cwt., is 2*s.* 0½*d.*, say 2*s.* per ton on 12,480 tons, or 1,248*l.*

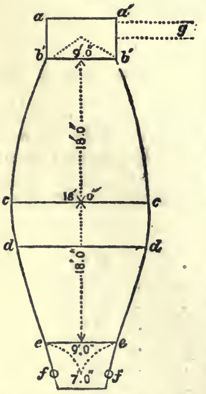
The causes of derangement in the working of blast-furnaces when the gases are drawn off to be utilised elsewhere, have been diligently studied by Mr. George Parry, of Ebbw Vale; and he has kindly furnished us with the following *résumé* of his observations, for insertion in this article—

The manner in which the waste gases were formerly collected was by sinking an iron tube, 7 feet deep, into the throat of the furnace, the diameter of the tube being about 3 feet less than that of the throat, thus leaving an annular space of 18 inches between the walls of the furnace and the sides of the tube. From this space the gases were allowed to pass off by the pressure within the furnace, through a pipe which penetrated the ring and walls. When the tube was kept full of minerals, about ⅓rd or ¼th only of the gas escaped into the open air, the rest passing into the annular chamber; and when this state of things was continued, those troublesome adhesions of masses of semifused materials above and around the boshes, technically termed 'scaffolds,' occurred, with the usual accompaniments of black cinder and inferior iron. It is evident that when the tube was kept full of materials, the contents acted as a loose stopper to the current of hot gases forced up by pressure from beneath, and diverted them towards the annular space where there was no such resistance, thus leaving the minerals in the central parts of the furnace insufficiently supplied with the upward current, and consequently with heat; the minerals, on the other hand, surrounding this cold central cone, were supplied with more than their usual quantity of heat, as was evidenced by the burning of tuyères, and by the destruction of the brickwork in their neighbourhood. In this state of things, the ores in the external portions of the furnace would become reduced and converted into grey metal; while those in the central portion would, according to the degree of deviation of the ascending current of heated gases from them, descend to the point of fusion either thoroughly deoxidised, and slightly carbonised, or possibly with a portion still in the state of oxide, and mixing there with the properly-reduced ores, enter into fusion with them, producing a mixture of irons which must necessarily prove of inferior quality, and a black cinder from the unreduced oxides. When the iron tube in the throat of the furnace was kept only partially filled with minerals, much more gas escaped into the open air, as might have been expected, and consequently more traversed the central parts of the furnace; and it was always observed that when that mode of filling was adopted, the furnace worked much better; but then the object, viz. that of economising the gases, was not attained. Differently-formed furnaces were found to be disturbed in different degrees by this system of drawing off the gases: the old conical *narrow* topped furnaces were affected very much less than the improved modern *domed* top furnace of large capacity, from which all attempts to take off any useful portion of the gases proved absolute ruin. It might be argued, that as the same quantity of blast and fuel were used as heretofore, the ascending current of heated gases ought to produce the same deoxidising and carbonising effect on the superincumbent mass, whatever direction they might take in making their escape at the upper region of the furnace; for if the central part should not have been sufficiently acted upon, the external annulus would have more than its usual share of chemical influences. But when it is considered that iron is only capable of taking up a certain quantity of carbon, and no more, it follows that after having received this dose, its further exposure in the external parts of the furnace where the heated gases abound can do nothing towards supplying the deficiency of carbon in the metal reduced in the central part. From these considerations it became evident, that no system of drawing off the gases around the sides, whether by the insertion of an iron tube into the throat, or by lateral openings through the walls into a chamber surrounding the top of the furnace, can be adopted without more or less injury to its action; and that the only unobjectionable mode would be to take the gases from a chamber above the surface of the minerals, thus equalising the pressure on the whole sectional area of the mouth, and thereby allowing an equally free flow for the ascending current up the middle, as well as up the sides of the furnace. By this method the whole of the waste gases would become utilised, instead of a portion only, and the furnace would be restored to its original state, inasmuch as the direction of the flow of heated gases would not be interfered with by unequal resistance. To form this chamber, the furnace must be covered in, and fed through a hopper, a plan long adopted at the Codner Park Iron Works, with the supposed advantage of scattering the minerals around the sides of the furnace, and preventing their accumulating in the centre: a conical charger of this description, but fixed in the throat of the blast-furnace, was in use at the Cyfartha Works more than half a century ago, the minerals being thrown by baskets to the centre of the cone, and allowed to roll down to the sides of the furnace, thus giving a cup form to the surface of the minerals, the larger lumps of course rolling to the centre, and affording a freer passage in that direction for the upward current. It was not, however, until January 1851, that a trial was made, at the Ebbw Vale Works, of an apparatus of this description for collecting the gases. It was then supplied to one of the old forms of conical furnace with a narrow top, and the trial proved eminently successful, the furnace producing any quantity of iron required according to the burden, as usual. Several other furnaces were similarly furnished in and around the neighbourhood, and it was now thought that the principle of taking off the gases from a chamber above the surface of the minerals, together with the conical mode of charging, were the only indispensable conditions to success for all furnaces; and some even which were originally built too narrow at the mouth were actually improved by the new method of charging, which did not allow of the surfaces of the minerals rising higher than about 6 feet from the top; thus giving to the furnace a diminished height, and, as a consequence of its conical shape, a wider mouth. Further experience, however, demonstrated the fallacy of this general conclusion.

A large domed furnace was furnished with the same kind of charging-apparatus which proved so successful in former instances; but, to the astonishment of all, it turned out a complete failure, the same derangements occurring as in the former cases, where a portion only of the gases was collected, by sinking a tube into the throat. Now this furnace could not be filled to within 6 or 7 feet of the top, and at that depth the diameter was 13 feet 6 inches, owing to the sharp sweep of the dome; the actual working furnace was therefore 37 feet high, instead of 44 feet, with a mouth 13 feet 6 inches, instead of 8 feet; and as the minerals cannot lie so close against the smooth sides of the walls as they do locked in each other in the more central region of the furnace, a much freer discharge of the gases up the sides must take place; and on boring a hole through the side of the furnace, in the neighbourhood of the boshes, it was found that, 2 feet in, the coke and other minerals were at a white heat, but a little further on towards the centre, lumps of black blazing coal were found, with ironstone which had not even attained a red heat. The charging-apparatus was now raised with the furnace 5 feet, and the minerals drawn up an inclined plane to the charging-cup, thus enabling it to be kept full to within a short distance of the old mouth, after which the furnace worked as usual. That diminished height was not the cause of the bad working of the furnace was afterwards proved, the furnace having been blown out for repairs, and re-lined with brickwork, giving it that form and proportion deemed necessary from the experience gained; the height being now only 37 feet instead of 44, and the diameter of the mouth 7 feet 6 inches, or one-half of that of the boshes. The same charging-apparatus which failed before, mounted 6 feet above the mouth, was used, and the furnace has now been working uninterruptedly for five years, turning out as much as 160 tons of grey pig-iron per week, or, when burdened for white-iron, 200 tons; economising the whole of its gas, and as much under the control of the manager as any furnace, either closed-top or open-top, can reasonably be expected to be. It is clear, therefore, that the covering of the top has nothing whatever to do with the action of a furnace kept full to the mouth, and having the proper form and proportions from that point downwards. The mouth must be understood to be that part of the furnace which represents the mean height of the surface of the minerals, and not the top of the masonry, and the question arises, what proportion should that bear in diameter to the boshes or widest part, and what the latter should be with reference to height in order to secure a maximum economical effect on the quality of the iron made, and on the yield of fuel. This state of perfection can exist only when the *isothermal* lines in the furnace are parallel to the horizon. The temperature of the minerals at any given height above the tuyères being the same through the whole horizontal sectional area at that height, and consequently arriving at the zone of fusion in an equally prepared state. If the mouth of the furnace be too wide, the heated gases have a greater tendency to pass up the sides than through the centre, thus destroying the horizontality of the lines of equal temperature, and giving them a curved form with the *convex* side downwards; hence ores, at different temperatures, and of various stages of preparation, will occupy any given horizontal sectional area of the furnace; these descending together and mixing in the zone of fusion will produce evils in proportion to the extent of the deflection of the curves from a horizontal line. On the contrary, if the mouth of the furnace be too narrow in proportion to the other parts, we may expect an undue portion of the gases to pass up the centre, leaving the minerals around the sides comparatively unacted upon. It is easy to see that evils of the same kind as before must exist here, the isothermal lines becoming now *concave* downwards, instead of *convex*, giving as before, through any horizontal section of the furnace, ores at various temperatures, and at different degrees of deoxidation or carburation, according to the depth which they may have attained in the furnace. There are several instances of furnaces originally built with too narrow tops, being greatly improved by widening them; this may conveniently be done by feeding them through a conical charger, which, by lowering the surface of the minerals, *virtually* increases the width of the mouth: on the other hand, furnaces having the opposite defect of being too wide at the top, may be benefited to some extent, provided the walls are nearly perpendicular, or do not widen too rapidly downwards, by employing as large a cone as it is possible to work in the throat; for, by the use of this feeder, the minerals must fall close to the sides, and the larger lumps roll to the axis of the furnace, and so facilitate the passage of the gases in that direction, besides giving to the surface a concave or cup form, and consequently a diminished height and resistance to the upward current in the middle. This principle of improving the charging of such defective furnaces is even carried out to some extent in feeding open-top furnaces where the gases are wasted. The charging-plate is so placed as to prevent the nose of the barrow from projecting any distance into the furnace; the minerals, being thus discharged close to the edge, the larger lumps have a tendency to roll over towards the centre, leaving the smaller at the ring-walls, to check the upward current in that direction.

The above considerations will materially assist in furnishing an answer to the oft-repeated and very important question, 'What form and proportions should a blast-furnace have to produce the best results in quality of iron, and in economy of fuel, whether worked on the open-top principle, or enclosed for the purpose of utilising the waste gases?' Experience has proved that when the mouth of the furnace is one-half the diameter of the widest part, good work is obtained, and that any deviation from that proportion, if in excess, has been productive of great derangement in its action. The height of the furnace should also bear a certain proportion to the greatest diameter, in order to secure an uniform flow of the ascending current through all its parts; for if the widest part bear too great a relation to the height, the boshes must necessarily be of a low angle, and consequently the minerals around the sides near their top be at too great a distance out of the direct line of passage of the ascending current, and consequently remain only partially prepared for fusion.

1244



The proportions recommended by Mr. Parry, and which have been practically tested most satisfactorily in several instances, are as shown in *fig.* 1244. The mouth *b′ b′* one-half the diameter of the widest part *c c*, and this should not be at a less depth than its own diameter. The sides of the furnace to this depth should be formed slightly dome-fashioned, for the purpose of giving to that region a larger capacity than would be obtained by a conical form. The radius of the curve should be at right angles to the axis of the furnace, and formed by a prolongation of the line representing the greatest diameter. When the radius is set at a great angle with this line, which is often done to give greater capacity to the domed part, the distortion produced by the sharpness of the curve may leave a segment of the minerals unacted upon by the gases in their passage to the mouth, and entail greater evils than would be compensated for by increased capacity. The curve is continued below the widest part of the furnace till it meets the top of the boshes *d d*, the angle of which should not be less than 70°, and start from the point of the tuyères *f f*. The depth also from the widest part to the tuyères should not be less than its own diameter *plus* half the diameter of the tuyères. These proportions give a blast-furnace, of any determinate height fixed upon, the largest possible capacity it is capable of receiving, while remaining free from any distortion of form, likely to give a place for minerals to lie out of the way of the action of the upward gaseous current; when the height exceeds the proportion to its greatest diameter indicated in the figure, an unnecessary sacrifice in its capacity is the only loss entailed. The height above the mouth must be regulated by the kind of hopper used for charging, where it is intended to carry off the gases.

Doubtless when the true principle of collecting these gases without injury to the blast-furnace becomes more generally known, attention will be directed to the easiest and most convenient mode of introducing the minerals. The conical charger has only one disadvantage, that namely of allowing a great waste of gas during the charging; probably some kind of revolving hopper may be contrived to remedy this defect. It is of course assumed that the furnace is supplied with a proper quantity of blast, and of a density proportionable to the diameter across the tuyères, so as to maintain a vigorous combustion of the fuel to the very centre of the hearth, the top of which is indicated by the letters *e e*, for unless this is attained, a cold cone of minerals will remain in the centre, and produce derangements which no degree of perfection in the form of the furnace in the higher region can remove.

Theory of the Blast-furnace.—Analyses of the gases from a furnace at Alfreton, in Derbyshire, at various depths below the surface, gave to Messrs. Bunsen and Playfair the results embodied in the subjoined Table. The furnace was supplied with 80 charges in the course of 24 hours, each charge consisting of 390 lbs. of coal, 420 lbs. of calcined ironstone, and 170 lbs. of limestone, the product being 140 lbs. of pig-iron. The gases were collected through a system of tubes of malleable iron, 1 inch in diameter, and were received in glass tubes 4 inches long, and $\frac{3}{4}$ of an inch in diameter. The well-known skill of M. Bunsen as a gas analyst is a guarantee of the accuracy of the determinations.

Composition of the Gases taken from different depths in the Furnace.

From these analyses it appears:—

1. That at a depth of 34 feet from the top, within 2 feet 9 inches of the tuyère, the gas was entirely free from carbonic acid, but contained an appreciable quantity of cyanogen.
2. That the nitrogen is at a minimum at 14 feet.
3. That carburetted hydrogen is found so low as 24 feet, indicating that at that depth coal must be undergoing the process of coking.
4. That hydrogen and olefiant gases are at a maximum at 14 feet.
5. That the proportions between the carbonic acid and carbonic oxide are irregular, which is probably to be explained by the fact that water is decomposed as its vapour passes through the layers of hot coal.

The average composition of the gases evolved from the materials used in the blast-furnace is somewhere between the two following numbers:—

Nitrogen	60·907 . .	57·378
Carbonic acid	8·370 . .	9·823
Carbonic oxide	26·846 . .	24·042
Light carburetted hydrogen	2·536 . .	2.743
Hydrogen	1·126 . .	4·972
Olefiant gas	0·112 . .	0·392
Sulphuretted hydrogen	0·045 . .	0·035
Ammonia	0·058 . .	0·115
	100·000	100·000

The proportion of nitrogen to oxygen, as an average deduced from these analyses, is 79·2 to 27. The product of the combustion of coal gives the same proportions as those existing in atmospheric air, viz. 79·2 : 20·08. The excess of oxygen must therefore depend upon the carbonic acid of the limestone, and the oxygen of the ore given to carbon during the process of reduction. Now, as at a depth of 24 feet the gas collected contained 27·6 and 26·5 oxygen to 79·2 nitrogen, it is held that at this depth the gas must already have accumulated all the oxygen of the ore, and the carbonic acid of the limestone; and the conclusion is drawn that, in hot-blast furnaces fed with coal, the reduction of the iron and the expulsion of the carbonic acid from the limestone takes place in the boshes of the furnace. The exact region of the furnace in which the melting of the iron and the formation of slag are effected is not exactly defined, but it is assumed that the point of fusion is at the top of the hearth. The region of reduction in a furnace smelting with coal must be much lower than when the fuel is coke or charcoal, because a large portion of the body of the furnace must be taken up in the process of coking, and the temperature is thereby so depressed, that it is sufficient neither for the reduction of the ore, nor for the expulsion of carbonic acid from the limestone.

The mean general results obtained by M. Ebelmen from a charcoal-furnace at Clerval are given below. The methods of analysis adopted by this chemist were altogether different from those employed by Messrs. Bunsen and Playfair. For details, we refer to his memoir in the *Annales des Mines*, vol. xix. p. 89, 1851.

I. Gas taken a short time after the introduction of the charge: II. the same taken a quarter of an hour after charging: III. gas collected through a cast-iron tube four inches in diameter; it rushed out with a noise and gave a sheet of flame, carrying with it particles of charcoal and dust: IV. gas collected by boring the masonry; it rushed out violently, burning with a blue-coloured flame: V. the same taken an hour after: VI. gas collected by boring the masonry at the back of the furnace about 3½ feet above the tuyère; it burnt with a white flame, giving off fumes of oxide of zinc; it was collected through porcelain tubes: VII. gas collected through gun-barrels lined with porcelain; it was evolved with sufficient force to project scoriæ and even cast iron.

The furnace was working with cold blast under a pressure of ·44 inch of mercury. The charges had the following composition:—Charcoal, 253 lbs.; minerals (various), 397 lbs.; limestone, 254 lbs. Thirty-two charges were driven in twenty-four hours; the furnace was stopped after every twenty charges; the produce being 3,970 lbs. of black cast iron; the daily yield being about 6,175 lbs.

The experiments show that while the carbonic acid progressively diminishes downwards, the carbonic oxide progressively increases, the former altogether disappearing at a depth of 27 feet. On examining the numbers representing the oxygen and carbon referred to 100 nitrogen, it is seen that they diminish progressively to a depth of 19 feet, the oxygen combined varying from 42·5 to 28·2. The proportion of carbon in the same zone rises from 28·5 to 32·8: a result brought about as much by the carbonic acid disengaged from the minerals as from the gaseous products of the distillation of the charcoal. It is seen that the reduction of the mineral is already considerably advanced at the depth of 19½ feet; and this, so to speak, without any consumption of charcoal, but through the conversion of carbonic acid into carbonic oxide. The hydrogen decreases as the carbonic oxide increases; showing that this gas exercises no influence in the reduction of the ore.

The results obtained by M. Ebelmen from a coke-furnace at Seraing were as under:—

I. Gas obtained by plunging an iron tube, three centimeters in diameter, about one foot into the furnace: II. the same; the gas burnt spontaneously: III. and IV. two consecutive analyses of the same gas: V. the gas was collected by an iron tube: VI. gas collected by piercing the masonry two feet above the tuyères; the gas was accompanied by fumes of cyanide of potassium, but no cyanogen could be detached.

The furnace was 50 feet high; the air was supplied through two tuyères, and was heated to 212°; it was driven at the rate of 26,840 gallons per minute under a pressure of ·5 of mercury. The charges were composed of, unroasted minerals 1,434 lbs., forge cinders 1,434 lbs., limestone 948 lbs., coke 1,765 lbs. The metal was run every twelve hours, and 17,500 lbs. of white crystalline cast iron obtained, which was run on thin plates and run directly to the puddling-furnace. The yield of the mineral was 42 per cent., and the consumption of coke 1,500 per 1,000 of cast iron, rising from 1,800 to 2,000 per 1,000 of iron when the furnace was working for foundry iron.

The analyses show a rapid diminution of carbonic acid, and indicate that in the upper regions of the furnace an energetic reduction of ore takes place by the oxide of carbon under the influence of the high temperature of the ascending gases. Between one and nine feet the limestone is calcined. The reduction of the ore takes place at this region by the conversion of carbonic oxide into carbonic acid, without change of volume and without consumption of carbon. The increase in the hydrogen is too small to induce a supposition that aqueous vapour in decomposing can dissolve any notable quantity of carbon. The gases collected at a depth of about 12 feet represent about the mean composition of the gaseous mixture; from that point to a depth of 45 feet, two-thirds of the total height of the furnace, the gases do not sensibly vary, and are combined almost entirely of carbonic oxide and nitrogen. At 12 feet the oxygen is to the nitrogen as 29·9 to 100; in atmospheric air it is as 26·3 to 100. The difference, 3·6, represents the oxygen arising from the reduction of the silicates of iron constituting the forge cinders, which is thus seen to take place between the tuyère and a depth of 12 feet. These silicates are well known to be decomposed with difficulty, but they are reduced at the high temperature prevailing in that zone of the furnace, and their reduction gives rise to a corresponding quantity of carbonic oxide, to a consumption of fuel, and to a considerable absorption of latent heat. The other minerals are reduced higher up in the furnace, and this is common to all coke-furnaces, being due to the high temperature of the ascending gases, a temperature much higher than exists in charcoal-furnaces, a far larger quantity of combustible being consumed. Hence it is that forge cinders can be successfully used in coke-furnaces; while in charcoal-furnaces the introduction of small quantities only alters the working of the furnace, makes the iron *white*, and corrodes rapidly the walls of the furnace in consequence of the imperfect reduction.

From his eudiometric experiments on the gases from coke- and charcoal-furnaces, M. Ebelmen deduces the following conclusions:—

1. That the amount of carburetted hydrogen is too small to exercise any influence over the chemical phenomena of the furnace.

2. That the atmospheric air thrown into the furnace by the tuyère produces successively carbonic acid and carbonic oxide, at a small distance from the opening. The first of these reactions gives rise to an exceedingly high temperature; the second, on the contrary, causes a great absorption of latent heat, and a corresponding lowering of the temperature of the gaseous current. The limit of the *zone of fusion* bears

relation to the space in which the transformation of carbonic acid into carbonic oxide takes place.

3. That the ascending current, which consists of carbonic oxide and nitrogen, with a little hydrogen, produces in ascending two distinct effects: it communicates one part of its sensible heat to the materials of the descending column; it becomes charged with all the volatile products disengaged at different heights, and it reduces the oxide of iron to the metallic state. Sometimes this transformation gives rise to an increase in the quantity of carbonic oxide; sometimes, on the contrary, it effects the conversion of carbonic oxide into carbonic acid without change of volume, and without combustion of fuel. Whenever the reduction of oxide of iron takes place with the production of carbonic oxide, there is a consumption of fuel, and an absorption of latent heat. It is essential, therefore, to the good working of the furnace, that the minerals should arrive completely reduced to that part where the temperature is sufficiently elevated for the conversion of carbonic acid into carbonic oxide by contact with carbon: this condition is nearly always realised when the oxide of iron is in a free state in the mineral. The reduction of the oxide when in combination with silica requires, on the other hand, a high temperature, and it can only take place in that zone of the furnace where the carbonic acid has completely disappeared.

4. That the zone where carbonic oxide exists alone is much more extended in coke- than in charcoal-furnaces, and is nearer the mouth in the former than in the latter; it falls lower, however, in the cylinder with hot blast, the quantity of heat remaining the same.

5. That the volatile gaseous matters from the distillation of the charcoal pass into the escape gases, and exert no influence on the reduction of the minerals.

The mutual relation of the carbonic acid and carbonic oxide, which is observable in the analyses of M. Ebelmen, is not found in those of Messrs. Bunsen and Playfair; this is attributed by M. Ebelmen to the circumstance that the latter chemists collected their gases through narrow iron tubes, which, becoming intensely heated and partially choked by the fragments of ore and fuel introduced by the rapid stream of gas, so modified the composition of the gases, that the analysis, however carefully conducted, could not represent accurately their real composition. M. Ebelmen collected his gases through wide tubes, and from the lower parts of the furnace, by piercing the solid masonry. It is obvious, however, that none but very general conclusions can be drawn from the analysis of the furnace-gases, in whatever way they may be collected, for their composition cannot be the same under all circumstances, the nature of the fuel, the pressure of the blast, and (as Mr. Parry's experiments prove) the shape of the furnace itself, must each exert an influence in modifying the circumstances which affect their composition. Although, therefore, it is impossible to fix the precise region of the furnace where the reduction of the oxide of iron begins to take place, that is, to define precisely the limits of the 'zone of reduction,' we may, in considering the theory of the production of crude iron, divide the furnace into four zones: 1. The zone of reduction; 2. The zone of carburation; 3. The zone of fusion; 5. The zone of oxidation. The zone of reduction will vary in extent according as the furnace is working with coal or with coke, with hot blast or with cold. The zone of carburation commences just below the top of the bosses, the reduced metal in a soft and malleable state here acquires carbon, its rapid sinking being retarded by the contraction which the sides of the furnace begin to undergo from this point downwards. As the carburized metal passes through the zone of fusion it melts, together with the earthy matters which serve to protect it from the oxidising effects of the fourth zone, that of oxidation, through which it passes in its passage to the crucible. If the temperature of the zones of fusion and oxidation be not much higher than the melting point of specular iron, the metal in the crucible will be white, with little or no graphite; and if the iron remain sufficiently long in the zone of carburation to take up the maximum quantity of carbon, it will be bright iron. The reduction of silicon appears to take place at about the melting temperature of specular iron: it exists therefore in small quantity in white iron, and in the greatest abundance in the grey iron smelted from refractory ores, which require a high temperature.

The proportion of carbonic acid in the gases obtained from different heights in a furnace, has been studied by MM. E. Montefiore Levi and Dr. Emil Schmidt (*Zeitschrift des öster Ingenieurvereines*, 1852). They found that the zone from which this gas is entirely absent is of very limited extent, for although it is not met with at a height of 8 feet from the tuyère, it exists at 9 feet to the extent of 4·78 per cent., above which point it diminishes up to 15 feet, where it is 0. From this point it again increases, amounting at a height of 30 feet to 3·5 per cent. It then gradually diminishes, until, at a point from 37 to 39 feet above the tuyère, it amounts to only 1·69 or 1·91 per cent.; after which it goes on increasing with rapidity and regularity up to the furnace mouth. The carbonic acid existing in the furnace-gases between

15 and 30 feet is referred by these chemists to the decomposition of the limestone used as a flux: and its gradual diminution above this point indicates a reaction of considerable importance, that, namely, of the carbonic acid upon the ignited coke carbon being taken up and carbonic oxide formed. Now, the quantity of carbon taken up by 275 parts of carbonic acid to convert it into carbonic oxide, amounts to 75 parts, and as in the furnace experimented with, 20,000 kilogrammes of limestone, containing about 8,000 kilogrammes of carbonic acid were consumed every 24 hours, a loss of fuel equivalent to 2,173 kilogrammes of carbon was daily occasioned by the conversion of this carbonic acid into carbonic oxide, and this may be considered equivalent to 2,500 kilogrammes of coke with 11 per cent. of ash. The heat absorbed by the conversion of the carbonic acid of the limestone into a gaseous state is found by calculation, taking the specific heat of carbonic acid at 0·22, and the heating power of coke at 600, to be equivalent to that developed by the combustion of 322 kilogrammes of coke. Now it was demonstrated by Dulong that the quantity of heat disengaged in the conversion of carbon into carbonic oxide is much *less* than that disengaged in the conversion of carbonic oxide into carbonic acid, although the same quantity of oxygen is required in both cases. The conversion of carbonic acid into carbonic oxide by passing over ignited carbon is essentially a twofold action: a combination of carbon with oxygen, and a decomposition of carbonic acid into carbonic oxide and oxygen; the former is accompanied by development, the latter by absorption of heat; the latter preponderates to such an extent as to indicate a loss of temperature equivalent to the heat developed by the combustion of 1,609 kilogrammes of coke.

These considerations led the authors to employ burnt lime in working blast-furnaces, and thus to obviate the loss of heat: the results were not at first satisfactory, the management of the furnace being very difficult, and the slags black and pasty; but subsequently the working was regular and good, and the saving of coke and the increase of production are stated to have been very evident; moreover, the raw iron was of better quality, and all the interior parts of the furnace, especially the tymp-stone, remained in a much better state of preservation than when limestone was used. The following table shows the quantity of coke consumed for every 100 kilogrammes of raw iron, and the production during six months. The figures in the first column refer to the furnace, in which limestone alone was used; the second column to the same furnace, in which burnt lime alone was used; and the third column to the furnace in which limestone was used for three months, and burnt lime for the next three months:—

	Quantity of coke in kilogrammes consumed for every 100 kilogrammes raw iron			Reduction during 28 days, in kilogrammes		
	1. With limestone	2. With burnt lime	3. With limestone	1. With limestone	2. With burnt lime	3. With limestone
April	165	145	163	436,000	601,000	459,000
May	165	147	159	447,000	582,000	461,000

			With burnt lime			With burnt lime
July	161	146½	149¾	462,000	555,000	537,000
August	158¾	145	146	465,000	536,000	552,000
September	153	147¾	146	477,000	577,000	600,000
Mean	160½	146¼	154⅔	461,000	573,000	516,000
Average from April to June	...	...	162	...	...	469,000
Average from July to September	...	...	147¼	...	...	563,000

The very regular and uniform results given in this table, show that by the use of burnt lime, the consumption of coke for every 100 kilogrammes of raw iron was reduced by 14 to 15¾ kilogrammes, while at the same time the production of iron increased, within a certain period, as much as 22 to 24 per cent.

Hitherto the opinion of metallurgists, with regard to the use of burnt lime, was rather unfavourable than otherwise, but since the above experiments were made (at Ougrée), it has been employed with good results in England and Wales, and as much as 12 kilogrammes of coke have, it is stated, been saved for every 100 kilogrammes of limestone, which was replaced by 63 of burnt lime.

Mr. Lowthian Bell considers that the economy in the use of caustic lime in blast-furnaces depends chiefly upon the difference in price in the fuel used, as the lime is burnt with small coal in kilns, saving an equivalent of coke, a more expensive fuel in the furnace. He has, however, found that when caustic lime is exposed to carbonic acid at a red heat, there is a re-formation of carbonate of lime to some extent, which is decomposed again at a higher temperature, and that therefore the fuel saved in the furnace is less than the calorific equivalent of that required for burning the lime.

The greatest development in blast-furnace economy has taken place in the Cleveland district, where the amount of fuel required for the production of a ton of pig-iron has been reduced from 35 to 40 cwts. of coke to 20 cwts. and even in some cases as low as 17 cwts. This saving has been produced by increasing both the dimensions of the furnaces and the temperature of the blast, the waste gases being in all cases econo-

mised. How very great the change has been may be seen in the preceding table giving the dimensions and dates of the erection of new furnaces at the different works since iron-smelting was commenced in Cleveland in 1851, in furnaces of the Staffordshire type.

Mr. Lowthian Bell, to whom we are indebted for an elaborate work on the chemistry of the blast-furnace, considers that it is not certain whether any greater saving can be effected by the use of furnaces of 30,000 feet cubic capacity than by those of 10,000 or 12,000 feet, as in either case for similar charges he finds the composition of the waste gases and their temperature will be about the same.

Mr. Bell has pointed out that when peroxide of iron is exposed to carbonic oxide at temperatures between 750° and 850° Fahr., that simultaneously with the reduction of the ore to metallic iron, with the production of carbonic acid, a converse action takes place to a small extent, the carbonic oxide being split up into carbon and carbonic acid, the former being absorbed by the partially-reduced ore. This action is supposed to play a considerable part in modifying the ordinarily-accepted theory of blast-furnace action, as it is supposed that the carbon so absorbed is carried down with the ore into the highly-heated region of the hearth and boshes, where the last traces of oxygen are removed by its combustion, and the iron becomes fully carburised.

This absorption of carbon is attended with the disintegration of the ore—a fact which accounts for the disappearance of the lumps of ore in the interior of blast-furnaces when examined through holes in the brickwork of the stack made by accident or design. In such cases the flux and coke retain their original form; but the ore is changed in many cases to a black crumbled mass, in which the separate lumps can no longer be distinguished. The reduction by carbonic oxide of peroxide of iron to the metallic state commences at the temperature of about 300° to 400° Fahr., but at the higher point, of about 800°, the spongy metal is reoxidised when brought into contact with carbonic acid. The reducing action, therefore, of carbonic oxide in blast-furnace gas must at the higher temperature become balanced by the oxidising action of carbonic acid in proportion as the two gases approach to an equality. This is a point of great importance as affording a true measure of the working of a furnace, which may be considered to have consumed its fuel properly, when the gases at the throat are cooled to such a point that the particular dilution of carbonic oxide by carbonic acid, to which they correspond, is no longer capable of reducing the ore. This is attained in the Cleveland furnaces when the volume of carbonic oxide to that of carbonic acid is as 2 to 1, and the temperature from 600° to 700°. Beyond this point the gases have only a calorific value, namely, their sensible heat and the amount that can be developed by their combustion in stoves and boilers instead of coal.

The increase of heat in the blast has in general been attended with a marked economy of fuel up to temperatures of about 1000° Fahr. With more highly heated blast, such as is obtained in the Siemens and Whitwell stoves, it is less certain whether any greater saving can be effected. At Consett a distinct saving is claimed for blast at 1300° over the same furnace when blown at 1000°. At Barrow, on the other hand, no saving was effected by the use of blast at 1500° instead of 1100°, the consumption of coke being the same, in either case about 20·18 cwts. to the ton of pig-iron produced.

Varieties and Chemical Constitution of Cast Iron.—In commerce there are four principal varieties of cast iron, known respectively as Nos. 1, 2, 3, and 4, or *dark grey*, *bright grey*, *mottled*, and *white*; these terms, although convenient, do not, however, indicate the intrinsic value of the iron thus denominated, as the variable qualities of ore, fuel, and limestone may exercise such an influence on the resulting crude iron, as to render a low denomination of one manufacturer of greater commercial value than a higher denomination of other makers. The general characters of the four varieties are these:—No. 1. Colour, dark grey, in large rounded grains, obtained commonly near the commencement of the casting when the furnace is in good working order, and when an excess of carbon is present; in flowing it appears pasty, and throws out blue scintillations. It exhibits a surface where crystalline vegetations develop themselves rapidly in very fine branches; it congeals or fixes very slowly; its surface, when cold, is smooth, concave, and often charged with plumbago; it has but a moderate tenacity, is tender under the file, and susceptible of a dull polish. When melted over again, it passes into No. 2, and forms the best castings. No. 2, colour bright grey, of small-grained structure, and interspersed only with small graphite laminæ; possesses great tenacity, is easily filed, turned, and bored; may even be hammered to a certain extent; does not readily crack from change of temperature. No. 3 is a mixture of white and grey iron. On *strongly mottled* iron, little stars and spots of grey iron are found, interspersed in bright or flowery iron; *weakly mottled* iron exhibits white specks on a grey ground. In *streaked iron*, grey iron is found above and below, and bright iron in the middle, with strong demarcations. No. 4. *White* *iron* varies from tin white to greyish white; it is very brittle, cracking easily, even by change of temperature; it is extremely hard, sometimes even more so than hardened steel, so that it will resist the strongest file, and scratches glass easily. Fracture sometimes laminar, sometimes lamino-radiating, sometimes finely splintered, sometimes dense and conchoidal. As the fracture changes from laminal to conchoidal, the colour likewise varies from white to greyish. Mean specific gravity, 7·5. Expands less than grey cast iron when heated, cannot be welded, because it becomes pasty at the very lowest welding heat. When heated to the melting point it does not suddenly pass into the fused state like grey pig-iron, but is converted before fusing into a soft pasty mass. In this variety of pig-iron the whole of the carbon is united to the iron; it is never used for casting, but always for conversion into malleable iron. The bright iron obtained from spathic iron-ore contains the largest proportion of carbon (5·3 per cent. according to Karsten). The white iron resulting from derangement flows imperfectly, and darts out in casting abundance of white scintillations; it fixes very quickly, and on cooling exhibits on its surface irregular asperities, which make it extremely rough; it is exceedingly hard, though it is easily broken, the fracture being radiated and lamellar; the bar-iron it affords is of inferior description. This kind of iron is always produced when the furnace is carrying a heavy burden of forge cinders containing sulphur and phosphorus.

Thus there are two distinct kinds of white cast iron: 1st. That obtained from ores containing a large proportion of manganese crystallising in iron plates; this variety is highly prized for making steel. 2nd. That resulting from a heavy mineral burden, or from a general derangement of the furnace, or from the rapid chilling of fused grey iron crystallising in small plates; both are hard and brittle, the first more so than the last. Cast iron, which by slow cooling is grey, becomes white when it is cooled rapidly; on the other hand, when white iron is melted and allowed to cool very gradually, a portion of the carbon crystallises out as graphite, and grey cast iron is produced.

In some iron works *six* varieties of pig-iron are recognised, which may be classified thus:—1. First foundry iron, large crystals; 2. Second foundry iron, large and small crystals mixed; 3. Dark grey, all small crystals; 4. Bright grey; 5. Mottled; 6. White, verging on mottled.

The subjoined table exhibits the composition of some different varieties of Continental, English, and American crude irons. The methods of determining the various elements which nearly always accompany cast iron, are given at the end of this article.

a, *Very grey pig*, from Lerbach in the Hartz, cold blast; *b*, *Mottled* iron, from the royal works in the Hartz, cold blast; *c*, *Normal* grey pig, from the same works, hot blast; *d*, Grey charcoal pig, cold blass; *e*, White pig, from Firmy, very short and brittle; *f*, American grey pig, charcoal; *g*, American *mottled* iron; *h*, American charcoal, white iron; *i*, Silesian white charcoal iron, very crystalline; *j*, The same, but less crystalline; *k*, Grey Scotch coke pig, from the Calder iron works; *l*, Scotch coke, No. 3 pig-iron; *m*, Glengarrick, No. 3 pig; *n*, Coalbrookdale Lightmoor best first foundry iron; *o*, Grey pig-iron, from Dudley, Staffordshire; *p*, Ordinary Aberdare white pig; *q*, Grey cinder pig; *r*, White crystalline pig-iron, smelted from manganiferous ore; *s*, The same; *t*, The same; *u*, Ordinary white pig.

Besides the substances enumerated in the above table, other metals, such as copper, arsenic, chromium, titanium, cobalt, zinc, tin, aluminium, and the metals of the alkalis and alkaline earths, are occasionally found in crude iron, but very rarely in quantities that can at all affect the qualities of the product. The elements, the quantitative estimation of which has been given in the above analyses, *do*, however, materially modify the physical qualities of cast iron. We shall, therefore, offer a few observations on each.

Carbon.—Iron can take up any quantity of carbon up to a little over 5 per cent., at which point it becomes saturated: the compound thus formed is the white crystalline pig or specular iron (*i*) (*r*) (*s*) (*t*); when absolutely pure, its composition is 94·88 iron, and 5·12 carbon: it is a *tetra-carburet*, Fe^4C. The most highly carburetted iron which Faraday and Stodart could produce consisted of 92·36 iron, 5·64 carbon. There seems no reason for admitting, as some metallurgists have done, the existence of a polycarburet of iron, containing 18·3 per cent. of carbon, inasmuch as iron containing under 6 per. cent. appears to be completely saturated. The specific gravity of pure tetra-carburet of iron is 7·66; it is the most fusible of all the carburets of iron, its melting-point being 1600° Cent.; it is brittle and silver-white, and crystallises in oblique prisms, which are frequently tabular. According to Gurlt the carburet of iron existing in grey pig is the *octo-carburet*, Fe^8C, the crystals of which belong to the regular or cubic system, but almost always appears in grey iron in the form of confused octohedral groups. The specific gravity of pure octo-carburet of iron, according to the same authority, is 7·15, and its composition 97·33 iron, and 2·63 carbon; its colour is iron-grey, its hardness is inferior, and its fusibility less than that of specular iron; the groups of crystals often found in cavities in large castings are composed of this peculiar carburet. Gurlt very ingeniously endeavours to show that in grey pig-iron the carbon of the octo-carburet is partially replaced by *silicon*, *sulphur*, and *phosphorus*, and the iron by manganese and other metals. In like manner the carbon of the *tetra-carburet* may be partially replaced by silicon, phosphorus, or sulphur, the eliminated carbon appearing in the form of graphite: the same decomposition is effected by heat, and specular iron, if exposed to a temperature considerably above its fusing-point, becomes *grey*; if cooled slowly, the graphite separates in large flakes, if rapidly, in minute particles. Some metallurgists suppose that in grey cast iron a portion only of the iron is chemically united with carbon, the rest of the metal being dissolved in the carburetted compound in the form of malleable iron. Dr. Noad inclines to the opinion of Gurlt, that the whole mass of the iron is in a state of combination with the electro-negative constituents, such as carbon, sulphur, phosphorus, and silicon. Thus in the white pig-iron of heavy burden (*u*), there is a deficiency of carbon, that element being replaced by sulphur and phosphorus.

Karsten gives as the mean of several analyses, 3·5865 per cent. as the quantity of carbon in cast iron smelted with charcoal from spathic ore. He states that iron containing as little as 2·3 per cent. of carbon still retains the properties of cast iron, particularly the faculty of separating graphite when allowed to cool slowly. With 2 per cent. of carbon iron is not forgeable, and scarcely so if it contain only 1·9 per cent. With this quantity of carbon it is steel, though not of the weldable kind (cast steel); even with so small a proportion of carbon as 1·75 per cent. it is weldable only in a slight degree; the latter property increases as the hardness of the iron decreases. An amount of from 1·4 to 1·5 per cent. of carbon in iron denotes the maximum of both hardness and strength. Iron containing 0·5 per cent. of carbon is a very soft steel, and forms the boundary between the steel (*i.e.* iron which may yet be hardened) and malleable or bar-iron. These limits lie perceptibly higher if the iron be pure; and lower if it contain silicon, sulphur, and phosphorus.

The composition of the various carbides of iron, according to Berthier, is as under:—

	FeC^3	FeC^2	FeC	Fe^2C	Fe^4C	Fe^6C
Iron . .	0·600	0·690	0·819	0·899	0·947	0·9643
Carbon .	0·400	0·310	0·183	0·101	0·053	0·0357

In the blast-furnace, the reduced iron may take up carbon in two different ways: 1. By immediate contact with the incandescent fuel; and 2. By taking carbon from carbonic oxide; thus $Fe + 2CO = FeC + CO^2$. That iron decomposes carbonic oxide is considered by Le Play and Laurent to be proved by the following experiment: pure oxide of iron and charcoal were heated in two *separate* porcelain boats, placed in a glass tube; the air in the tube furnished oxygen to the carbon; carbonic oxide was formed, which was converted into carbonic acid, at the expense of the oxygen of the oxide of iron; the carbonic acid was again transformed into carbonic oxide, by taking up a fresh quantity of carbon, which was again converted into carbonic oxide by taking oxygen from the oxide of iron, and this went on until the whole of the oxide of iron was reduced; the metallic iron then decomposed carbonic oxide, producing carbonic acid and carbide of iron: and this went on till a certain quantity of carbon had combined with the iron, when the action ceased. If the charcoal be very strongly ignited previous to the experiment, the carbonisation of the iron does not take place, neither does pure carbonic oxide carbonise iron when passed over the metal at a red heat: the effect in the experiment above described may therefore be due to the carburetted hydrogen evolved from the charcoal. Iron begins to take up carbon when heated only to the softening-point, the carbon gradually penetrates the metal, converting it first into steel and then into cast iron; conversely melted cast iron gives up carbon to soft iron, which it converts into steel. When white iron (Fe^4C) is heated with acids, nearly the whole of the carbon is eliminated in combination with hydrogen. Grey iron only gives up to hydrogen the carbon which was chemically combined with the iron, the uncombined carbon or graphite remains unacted upon; the dark spot produced upon grey iron by a drop of nitric acid arises from this separation of graphite. For the amounts of carbon in the different varieties of steel, see STEEL.

Phosphorus.—In very few specimens of crude iron is this element wholly absent; when it exists in small quantities only, it is said rather to improve the iron for castings, as it imparts to the metal the property of fusing tranquilly; in a larger proportion, it weakens the iron. In like manner a very small quantity of phosphorus hardens bar iron, without materially influencing the other properties, but when it exceeds ·5 per cent. it renders the bar brittle, *cold-short*, as it is termed. According to Schafhaeutl, both cast iron and steel are improved by phosphorus and by arsenic; he found the latter in the celebrated Dannemora iron, and in the Lowmoor iron, and the former in the equally famous Russian (CCND) iron.

Sulphur.—This element imparts to crude iron the property of becoming viscid, and of solidifying quickly with cavities and air-bubbles. It is not certain to what extent, or if at all, the presence of minute proportions of sulphur reduces either the tenacity or the toughness of cast iron of given quality in other respects. It is stated in the Report of the Commission of Inquiry, as to the manufacture of ordnance on the Continent, on the authority of Schür and Mitscherlich, that in certain Swedish works *pyrites* is thrown into the furnace, with the other constituents of the charge, to produce the fine grey *mottled* iron required for gun founding, and it is added that the effect may be analogous to that of the oxidising flame in a reverberatory-furnace. It is certain that sulphur possesses the property of concentrating carbon in iron: and as mottled iron is a mixture of white and grey iron, it is not difficult to see how the addition of pyrites may determine the formation of this variety of cast iron in a furnace, which without it would produce grey iron only: but it is scarcely credible that any intelligent founder would resort to such a method of making iron for casting cannon, in which the highest possible degree of tenacity is required. The fine grey mottled iron, which from its tenacity is known to be best fitted for large castings, is said to be prepared without difficulty, by charging the furnace partly with roasted and partly with raw ore, and so regulating the blast that the yield shall be regular, and the slag nearly colourless: these two ores, having different degrees of fusibility, are reduced after different periods in the furnace, and hence afford one of them grey, and the other white iron; the result being, provided the minerals are properly proportioned, a mottled iron, harder and more tenacious than grey iron, obtained by mixing or smelting in the cupola. It is desirable that the temperature of the furnace should be kept as low as possible, the production of dark grey graphitic iron resulting always from intensity of heat.

When sulphur is melted with iron containing the largest amount of chemically-combined carbon, sulphuret of iron is formed on the surface; underneath, a layer of graphite, and beneath that, a layer of iron with the *maximum* of carbon; and when *grey* iron containing 3·31 per cent. of graphite is melted with sulphur, *white* iron (containing 94·03 iron, 4·93 combined carbon, and no graphite), is formed. The tendency of sulphurous ores to produce white metal in their treatment in the blast-furnace has long been known. It was supposed that this was occasioned by the too great fusibility which the sulphur gave to the cast iron; but ores containing large proportions of phosphoric acid will produce very grey iron, notwithstanding their fusibility, so that this explanation does not serve: the experiments above described point to the true reason. The sulphur present in the ore (if as sulphuric acid reduced in the furnace) enters into combination with the iron, displacing a corresponding proportion of carbon, which becomes concentrated in the remainder of the metal, forming white iron. To guard against this, and in order to obtain a metal which shall contain a *minimum* amount of sulphur, the slags should contain the *maximum* amount of lime, M. Berthier having shown that this earth decomposes sulphuret of iron at a high temperature, in the presence of carbon. M. Janoyer states that the proportion of lime and silica in the slag may be as 54 to 36: it is doubtful whether such a highly basic cinder would be sufficiently fusible. Direct experiments, however, have shown that the amount of sulphur in cast iron diminishes in proportion as the amount of lime in the slag increases. A still better flux is oxide of manganese, and it is found that when the manganiferous spathose ore constitutes part of the burden of the furnace, sulphur almost entirely disappears from the crude iron. M. Janoyer believes that he has proved experimentally, that the whitening of cast iron smelted from sulphurous ores, is due, in part at least, to the subtraction of a portion of its carbon, and its volatilisation in the form of sulphuret of carbon, by which the temperature of the furnace is lowered; but his experiments on this point require confirmation. The presence of a very small quantity of sulphur acts very injuriously upon bar iron, so small a proportion as $\frac{4}{10000}$ rendering the metal 'hot-short,' that is, incapable of being worked at a red-heat under the hammer. If the quantity of sulphur in the crude iron exceeds 0·4 per cent., it is scarcely possible to manufacture it into good wrought iron.

Silicon.—Like carbon this element enters into combination with iron in all proportions up to as high as 8 per cent. The largest quantity found by Karsten in pig-iron was 3·46 per cent., but in the above table a specimen (*n*) is quoted from Coalbrookedale containing 4·88 per cent.: and Dr. Noad found it in a sample of Nova Scotia iron, as much as 5·8 per cent. Generally speaking, grey cast iron contains more silicon than white, and the greater the quantity of graphite in the crude iron the larger the amount of silicon, because the higher the temperature of the furnace; but this again will depend materially on the quality of the coal, from the ash of which the silicon is probably principally derived. A clean strong coal yielding a small percentage of ash furnishes a cast iron with less silicon than an inferior coal, the mineral burden being the same. Pig-iron smelted with hot blast contains more silicon than when the blast is cold, because of the higher temperature which prevails in the fusion-zone of the furnace. Some analyses illustrating this fact have been already given. According to the experiments of MM. Janoyer and Gauthier the amount of silicon in hot-blast cast iron may be greatly influenced by varying the proportion of limestone in the furnace. Pig-iron obtained with a charge yielding a cinder in which the lime and alumina were to the silica as 7 is to 10, had little strength, breaking readily, and analysis showed that it contained 3 per cent. of silicon. By increasing the amount of lime in the charge, so as to obtain a cinder in which the bases were to the silica as 8 is to 10, and at the same time employing a blast of the highest attainable temperature, the iron produced had a much greater strength. When the proportion of bases to silica in the cinder was as 20 is to 19, the iron contained only an inappreciable amount of silicon, and the strength was increased in the proportion of 65 to 45. When the maximum quantity of lime was used, the consumption of fuel was on the average increased to the extent of 6 per cent.

The experiments of MM. Janoyer and Gauthier induced the furnace manager of the Blaina Iron Works to increase the yields of lime on one of his furnaces to as great an extent as in his judgment it would bear, and when the furnace was under the full influence of the excess of flux to forward him samples of the grey pig for analysis. The following results show that, contrary to the statement of MM. Janoyer and Gauthier, no advantage, as regards a diminution in the amount of silicon, was hereby obtained, the proportion of that element being not perceptibly altered, though there is a slight diminution observable in the percentage of sulphur.

	Grey pig, with usual burden of lime.	Grey pig, with extra burden of lime.
Sulphur	0·067	0·045
Silicon	2·900	2·930

As the presence of silicon in pig-iron affects in a remarkable degree the yield as well as the strength of puddled bars, it is of importance that this element should be removed as effectually as possible by a refining process before the crude iron is submitted to the puddling process. Pigs with 3 per cent. of silicon gave about 6 per cent. of silica, and this requires somewhere about 12 per cent. of iron to form a cinder sufficiently fluid to allow the puddled iron to become aggregated into balls; this can of course be obtained only by *burning* that amount of iron in the puddling furnace after the expulsion of the carbon, and while the mass is in a powdery state. This powdery mass is composed of small granules of iron mixed up with a *gluey* infusible cinder. The puddler turns over this mass repeatedly to expose the iron to the oxidising influence of the furnace; the silica now taking up sufficient oxide of iron to give it fluidity begins to separate from the iron, and forms a pool at the bottom. After some time the puddler, finding the mass of cinder accumulating pretty fast, makes the first attempt to 'ball up.' In order to save as much iron as possible, he keeps the damper down and works the powdery mass at as low a red heat as possible. The balls, even when made, will not bear much heat under the hammer without falling to pieces, hence an imperfect weld in the hammered mass and rolled bar is the result, and although the iron may be chemically pure it is deficient in *strength.* By protracting the process and wasting more iron, there is no doubt but that the iron might be improved, for the cinder would become richer in oxide, more fluid, and consequently offer less resistance to a perfect weld. Iron, on the contrary, with a small percentage of silicon may be 'balled up' directly it is 'dried,' and the short time required for that operation can be conducted at the highest part of the furnace. A good welding of the mass is the consequence: such iron is *strong*, and the labour of the puddler in obtaining it is much less than in the former case. Every pound of silica must have twice its weight of iron to form a cinder sufficiently rich in oxide to allow the particles of iron to become properly agglutinated. Such being the influence of silicon on both the yield and the strength of wrought iron, and such being the waste attendant on its removal in the refinery, it becomes an object of much practical importance to prevent as far as possible the formation of a silicide of iron in the blast-furnace, and the observations of MM. Janoyer and Gauthier on this point require careful verification.

Manganese.—The presence of this element in pig-iron does not appear to exert much influence either for good or for bad on the quality of the metal, and even when it exists in quantity amounting to 4 or 5 per cent. in the crude iron, it disappears almost entirely during the conversion of the cast iron into wrought or malleable. It has already been observed that the cinder from iron smelted from manganiferous ores contains, generally speaking, more sulphur than slags or cinders from iron ores containing no manganese. We have had numerous opportunities of confirming this, and have therefore on this account alone attached more importance to the existence of manganese in iron ores; but our attention has more recently been directed to another point which we think especially worthy the notice of iron manufacturers, namely, to the almost perfect removal of phosphorus from pig-iron containing a very large proportion of that element, and at the same time a high percentage of manganese. We shall merely here quote a few analyses in illustration of the purifying action we have alluded to.

Iron made from a highly phosphorised ore containing no manganese:—

	Phosphorus per cent.
Pig	3·030
Puddled bar	0·838
Rough down bar	0·572

The finished bar was cold-short in the highest degree, it was in fact nearly worthless.

Iron made from a highly phosphorised ore containing a large percentage of mangenese:—

	Phosphorus.	Manganese.
Pig	2·60	7·20
Puddled bar	0·30	0·30
Do.	0·20	
Finished bar	0·11	

The iron was carefully watched during the puddling process. It melted very thin, and took rather more work than usual; as soon as the boiling commenced it was very violent, the metal forcing itself out of the door-hole until it was checked. When it 'came to nature,' as the workmen term it, it worked beautifully and stood any amount of heat, in fact the heat could with difficulty be raised to the requisite degree. The yield was 22 cwts. 2 qrs. 24 lbs. of pig to produce one ton (of 22 cwts.) of puddled bar; this is about the yield of good mine iron when properly puddled. The finished bar exhibited none of the cold-short quality, it was exceedingly ductile, indeed excellent horseshoes were made from it. The puddling cinder had the following composition:—

Silica	8·240
Protoxide of iron	70·480
Oxide of manganese	12·800
Phosphoric acid	7·660
Sulphur	·535
	99·715

Other observations have shown that highly manganiferous pig (without phosphorus) is puddled with difficulty, and sometimes with considerable waste, so that the advantages of an alloy of manganese would seem to be confined to those varieties of crude iron into the composition of which phosphorus largely enters.

Spiegeleisen is at present made, on the large scale, in Germany, Russia, and Sweden, and curiously enough, the ores from which it is reduced are of extremely different and distinct characters in each of these countries. In Germany it is made chiefly from the manganiferous spathic carbonate of iron; in Russia, it is reduced from ferruginous oxides of manganese; and in Sweden, it is produced by smelting a mixture of knebelite and manganiferous garnet, both of which minerals are compound silicates of iron and manganese. In one point, however, they all agree, which is, that in all these ores the oxides of manganese and iron, if not in actual combination as compound silicates, or carbonates, are at any rate in a very intimate admixture with one another, and therein lies one of the most important points connected with this manufacture; for it would appear, wherever true ores of manganese have been added to the usual charge of the blast-furnace, in the expectation of obtaining spiegeleisen rich in manganese, that this has not succeeded, or at most, that only a small fraction of the manganese added has combined with the iron, the major part having been carried off in the slag; for which reason, when it is desired to produce a cast iron containing much manganese, it is requisite that this metal should be added to the charge in the shape of some strongly ferruginous compound, thereby facilitating the process of reduction, since a mixture of the two oxides of manganese and iron is much more easily reduced to the metallic state, and so enabled to unite with the iron from the rest of the charge than oxide of manganese alone, which unless the heat is very intense, and the reducing action of the furnace nearly perfect, is extremely apt to go into the slag in the state of silicate from which it subsequently cannot, or can only with great difficulty, be recovered. The oxides of manganese are, it must be remembered, infinitely less easily reduced, and require more time as well as a much higher temperature than the oxides of iron; and from what has already been said, it will naturally follow that in making spiegeleisen particular attention should be paid to the following points:—

1. The mineral used as a source of manganese should be in itself highly charged with iron, so as to facilitate and ensure the reduction of as large an amount of the manganese contained in it as possible.

2. The charge of the furnace should be highly basic, or, in other words, an excess of limestone or, preferably, burnt lime, should be used.

3. The working of the furnace should be much slower than is usual in iron smelting, in order to allow more time for the reduction of the oxides of manganese.

4. The temperature of the blast-furnace should be as high as possible, using as hot a blast as can be obtained; and, as coke admits of the use of a sharper blast, and affords a greater heat, it is to be preferred to charcoal in this manufacture.

In Russia, the spiegeleisen produced at Nischne-Tagilsk is smelted with charcoal, and is known for its good character, it is reduced from a mixture of the native oxides of iron, which in themselves contain some manganese with ferruginous Braunite, which contains about 40 per cent. metallic manganese, with 10 per cent. metallic iron, in intimate admixture.

In order to increase the amount of manganese in grey pig-iron, which already contained 1·2 per cent. of manganese, so as to obtain a spiegeleisen, trials have been made at Wotkinski, by re-melting this pig-iron in a cupola, with the addition of from 12 to 15 per cent. of clean native oxide of manganese (manganite or pyrolusite), which have resulted in making a spiegeleisen containing between 5 and 6 per cent. metallic manganese.

In Sweden, spiegeleisen has been produced in several parts but principally at Schisshyttan and Ramshyttan, in Dalecarlia, where it is obtained by smelting a mixture of knebelite and manganiferous garnet, which contains an average of about 42 per cent. iron with 13 per cent. manganese, in the blast-furnace (which is 47 feet high, and has two tuyères) with as hot a blast as could be obtained from an iron-pipe apparatus. The fuel employed is a mixture of half charcoal half coke, and the ore is fluxed with 30 per cent. of its weight of limestone. The ore frequently contains visible specks of galena, pyrites, and zinc blende, but it is stated that no sulphur is found in the spiegeleisen, although the slag which, when the furnace is working well, has a peculiar yellowish green colour, is said to contain 4 per cent. sulphur up to as much as 16 per cent. oxide of manganese.

The ordinary spiegeleisen obtained at Schisshyttan contains an average of 13 per cent. manganese, with about 4 per cent. carbon, or 5 per cent. carbon, silicon, &c. Occasionally it has been as high as 17 per cent. Mr. Alexander Keiller, the manager of these works, found that some which averaged 15 per cent. of manganese with only 2½ per cent. carbon was altogether different in appearance, and could not be made to assume the crystalline bladed reflecting fracture, peculiar to spiegeleisen, and from which its name is derived, and in consequence, was regarded with prejudice in the market by the buyers, who judge from appearance alone. He also stated that he had latterly succeeded in producing a cast iron, containing as much as 23 per cent. of manganese, along with only 2 per cent. of carbon; such an alloy would be a considerable step in advance, as it would to a great extent overcome the objection to the employment of spiegeleisen, which, from its containing a large percentage (4 to 5) of carbon, is less suited for the production of very soft qualities of Bessemer steel. An alloy of iron and manganese made in Carniola, containing 33 per cent. of manganese, has a granular fracture very unlike spiegeleisen.

It appears when the quantity of manganese contained in a cast iron exceeds a certain point, that there is a tendency for the carbon to diminish in percentage. Mr. Henderson, of Glasgow, states on this subject: 'It is a well-established fact, that in proportion to the increase of manganese in the alloys with iron, so the carbon decreases, so much so, that when you get to 30 per cent. manganese, the carbon is down to 0·25 or 0·40 per cent.'

In the Filipstad mining district in Sweden, numerous attempts to produce spiegeleisen by adding the native oxides of manganese, particularly Hausmannite, which contains 72 per cent. metallic manganese, and occurs abundantly in that district, had failed, the iron so produced not containing more than about 4 per cent. of manganese, as the excess of that metal was invariably carried off in the blast-furnace slag. We understood that a considerable quantity of Hausmannite had been exported to Sheffield from this part of Sweden in the summer of 1871, for the use of steel manufacturers there. The German manufacture of spiegeleisen, which is by far the largest of all, is principally carried on in the northern part of Nassau, and the southern portion of Westphalia. The ores used for the production of spiegeleisen are found in mineral lodes which traverse the Devonian geological formation on the eastern bank of the Rhine. They are the so-called spathic iron ores, which are carbonates of iron containing variable quantities of carbonate of manganese in intimate combination with one another. They usually contain more or less copper and iron pyrites, with, occasionally, traces of galena and zinc blende, and more frequently a large admixture of quartz, which is picked out as cleanly as possible by hand after the ore has been roasted, when the quartz is more easily distingushed by the eye, since it remains whole whilst the iron has become reddish-brown through oxidation.

The following analyses show the chemical composition of the ores from three of the principal mines:—

	Stahlberg	Kirschenbaum	Huth
Carbonate of iron . . .	74·47	76·04	75·39
„ manganese . .	17·08	13·50	18·20
„ lime . . .	1·34	1·13	1·50
„ magnesia . .	5·75	7·87	5·08
Insoluble matter . . .	1·08	0·95	0·18
	99·72	99·49	100·35
Percentage of metallic iron .	41·70	42·58	42·21
„ „ manganese	8·16	6·46	8·70

Before being smelted, these ores are roasted in kilns from 18 to 20 feet high, with two grates one above the other; they are filled with coke (small) and ore, using 8·4 cubic feet of the former to 2½ tons of the latter, and lighting the whole from the lower grate. The ore in each kiln (about 7 tons) is raked out once a day through an aperture made by removing some of the upper grate bars. The object of this roasting, in which the ore loses about one-third its original weight, is to expel the carbonic acid from the ore and convert it into oxide; it also enables, as before mentioned, the quartz mixed with the ore to be picked out by hand.

At the Lohe blast-furnace, which belongs to the Coeln-Muesener Company, the fuel employed is either charcoal or coke alone or more often a mixture of both. The charges employed are with charcoal alone, 1,035 lbs. roasted ore, with 180 lbs. limestone to each cubic feet of charcoal, which is chiefly made from beech and oak woods; with coke alone, it is 2,197 lbs. roasted ore, with 602 lbs. limestone to each 42 cubic feet of coke; and with the mixture of charcoal and coke the charge was 1,233 lbs. roasted ore, with 360 lbs. of limestone to each 10½ cubic feet of coke, mixed with 20 cubic feet of charcoal. As a rule, about 40 such charges would be run down in the 24 hours, or a total of about from 1,700 to 1,800 centners per week.

The dimensions of the blast-furnace are as follow:—Total height, 42·4 feet; height from sole of hearth to tuyères, 2·1 feet; height from sole to top of hearth, 4·3 feet; height from top of hearth to boshes, 9·0 feet; and thence to top of furnace, 28·5 feet.

The diameter of the hearth, the sides of which were parallel, was 4·3 feet; diameter at boshes, 11·3 feet; and at top of furnace, 5·3 feet: the top being covered with a moveable cover, which opens to admit the charge.

The temperature of the hot-blast was lower than it ought to be; rarely exceeding 572° Fahr. The blast is introduced into the furnace by three tuyères, the diameter of which, and the pressure of blast, being varied according to the nature of the fuel made use of, being from 16·6 lines in diameter, and 16 lines mercurial pressure up to 21 lines diameter, with 22 lines pressure.

It is found by experience that the peculiar bladed texture of spiegeleisen depends more on the percentage of carbon than of the manganese; for with very high percentages of the latter, this crystalline structure is not more, if as much, developed as with low percentages of that metal. This structure is also much better developed if the iron, when tapped, be covered with slag, so as to allow it to cool more slowly, for which reason it is usual to let a considerable quantity of slag accumulate in the furnace, so as to cover the cast when it is tapped out. When the iron is poor in carbon, that portion of the cast which has cooled under the slag is invariably more bladed in texture than when not so covered; but if the iron is very rich in carbon (containing, say, 5 per cent. carbon), but little difference is observable. It is therefore advisable to let the iron run out of the furnace as quickly as possible, as, if not so done, it frequently happens that the iron does not have the desired bladed texture well developed in it. When the percentage of manganese in the cast iron is large, and the iron is tapped very hot, a strong oxidation, with evolution of flames, is seen on the surface of the cast, and presents a very curious appearance.

In these works, in order to get good results, care is taken to work the furnaces slowly, so as to keep the manganiferous ore exposed as long as possible to a powerful reducing action, in order to get as much of the manganese reduced along with the iron as possible; and for this purpose a strong pressure, very hot blast, and very basic charge, are required. The zone of combustion must not (as occasionally happens in Westphalia) be allowed to rise too high above the tuyères; and should this take place, the remedies in general use are, to diminish the pressure of the blast, and use the ore in a finer state of division, and wet it with water. In Westphalia this is generally attributed to the charcoal or coke being of a worse and more open porous texture than usual.

Coke is becoming more and more used, and is now alone employed at the Charlottenhütte, which produces nearly one-half the spiegeleisen made in the district. All accounts agree that it is much superior to either charcoal or the mixture of charcoal and coke, provided only it be of good quality, and free from sulphur; and it is stated, when coke is employed, that several per cent. units more of manganese can be got into the spiegeleisen than when the same charge is smelted with charcoal, and, for this reason, it is particularly suited for smelting ores rich in manganese. It is also stated that in this district the attempts to increase the amount of manganese in the spiegeleisen, by manganese ores added to the charge, have not succeeded, and that the manganese in such additions has for the most part gone into the slag.

The charge at this furnace consists of about ⅔rds roasted spathic ores, ⅓rd brown hæmatite, containing manganese, and a portion of the latter being replaced by a brown manganese ore from Nassau, containing 25 per cent. Fe. and 19 to 20 per cent. Mn., which is now generally used throughout the Rhenish district; with good fuel, and about 50 per cent. of limestone on the weight of the ore, about ½ of the manganese, or even more, may be reduced. When making spiegeleisen, the furnace produces up to 70 tons per day, with a consumption of about 22 cwts. of coke to the ton.

Spiegeleisen, showing an apparently identical fracture to the eye, may vary immensely in its percentage of manganese, and in practice each cast or tapping should be assayed for itself. This, however, is not done in the Siegen district, where, although it is the general custom to regard the spiegel as containing an average of 10 per cent., it will be found in actuality to vary from 7 to 11 per cent. when analysed.

The following analyses show the chemical composition of spiegeleisen from this district when made with coke:—

	Hamm.	Hochdahl.
Carbon . . .	4·129	5·04
Silicon . . .	0·468	0·41
Sulphur . . .	0·015	0·08
Copper . . .	0·291	0·16
Manganese . . .	8·706	7·57
Iron	85·929	86·74
	99·528	100·00

In Styria and Austria, where the coke used is very impure, containing $3\frac{1}{2}$ per cent. of sulphur, only about $\frac{1}{4}$ to $\frac{1}{3}$ of the total manganese is reduced.

At Newark, in New Jersey, spiegeleisen is made from the residues obtained in the treatment of the mixed zinc and iron ores of Franklin, in the same State. The ore is an intimate mixture of franklinite and red zinc ore, with a massive green variety of willemite or silicate of zinc. It occurs in crystalline limestone, forming an irregular bed, which in places is 52 feet thick, the different minerals being very intimately mixed. A mixture of finely-crushed ore, with lime and anthracite, is treated in an oven-shaped calciner, having a cast-iron bed perforated with numerous narrow slits, through which air is blown by a fan in sufficient quantity to burn the coal and oxidise the zinc-vapour as it forms. The oxide of zinc produced in this process passes through a long series of condensing-tubes and cooling-chambers, the current being kept up by exhausting-fans until it is sufficiently cooled to be collected by bags made of cotton cloth. The residue remaining in the furnace after the removal of the zinc is a black cindery mass, containing the whole of the iron and manganese of the franklinite, and the silica of the willemite, besides some undecomposed zinc oxide: it is estimated to contain 25 per cent. of iron, and 4 per cent. of zinc, and is smelted for spiegeleisen. The furnaces employed are very small, being only 20 feet high, and 7 feet across the boshes; the hot-blast is of about 200° temperature, and a pressure of 4 lbs. is used. The fuel used is anthracite, and some limestone is added as a flux. Four blank charges of clean slags are made in twenty-four, to prevent scaffolding. Great difficulty is experienced in working the furnaces, owing to the large amount of zinc remaining in the ore, which deposits in the gas-flues at the throat, and necessitates the use of an elaborate system of wrought-iron condensers for separating the oxide of zinc from the gases, before they can be burnt in the hot-blast stoves and steam-boilers. The oxide of zinc obtained in cleaning out the condenser being too much discoloured to use as paint, is sent to the spelter furnaces for reduction, and makes a very high quality of zinc. The consumption of fuel is very high, being at the rate of $3\frac{1}{2}$ tons per ton of iron. The weekly make of the furnace is about 25 tons.

When making spiegeleisen, the slags are of the usual bright-green colour characteristic of manganese; but when the furnace is too heavily burdened, and produces No. 2 iron, corresponding to the German *Weisstrahlig*, the colour changes to a deep brown. Owing to the large relative proportion of manganese to iron in the residues, the spiegeleisen produced is very rich in manganese, and at times is said to contain as much as 10 per cent.

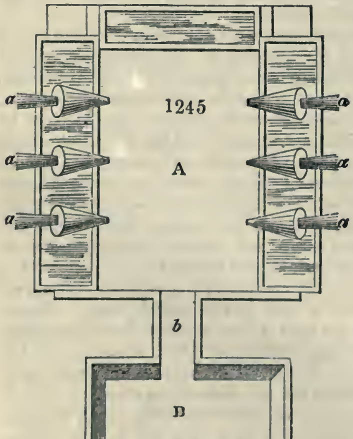
In connection with the production of spiegeleisen, sundry improvements in the manufacture of manganese have been proposed. Among others, the following processes are said to be most advantageously used in America:—

Manganese may be produced in a condition pure, or nearly so, without melting, and used in the manufacture of ferro-manganese and spiegeleisen in a manner producing a better quality of product, in less time, and at less expense than by the old processes. The process consists in a thorough mixture of pulverised oxide of manganese 10 parts, and 3 parts of solid carbon, like coke or charcoal. These ingredients are inclosed in metallic or earthen cases, large enough for the desired charge, and having the opening temporarily closed with a metallic sheet, or covering of earth, to prevent the admission of air while allowing the escapement of gases. These cases are charged in an ordinary furnace to a bright red, bare yellow, and are subjected to this heat for twelve or fifteen hours, according to quantity. In the process the carbon unites with the oxygen, and passes off as carbonic acid gas, and gives as a product nearly pure manganese. To secure spiegeleisen the pig-iron is melted, and about 12 per cent. of the manganese is charged into it and melted. The proportion of ingredients is run off when melted into ingots, as spiegeleisen, when it is used in the ordinary way. Ferro-manganese is produced by charging a greater per cent. of manganese into the molten pig-metal, say 25 or 30 per cent. The manganese counteracts red shortness in the steel, apparently by uniting with the free oxygen or metallic oxides which may be in the steel, being particularly useful in the manufacture of boiler-plate steel.

The inventor considers his process will be most valuable to those using an open hearth steel-melting furnace, such as the Siemens, as it has been for a long time a great desideratum to obtain a pure metallic manganese, especially in manufacturing the softer grades of steel, such as roller-plate, tank-plate, &c. He claims that the use of ferro-manganese conduces to the life of the furnace, because when rails are desired containing from $\frac{1}{4}$ to $\frac{1}{3}$ of one per cent. carbon, the bath of molten metal has to be run down in carbon as low as wrought iron, otherwise when the spiegeleisen is added the percentage of carbon will be higher than desired, and also adding some silicon, which is injurious. It is well known that a much greater heat is required to keep a bath of molten metal liquid, containing no more carbon than wrought iron, than when it contains about ¼ of one per cent. carbon. It has also been proved that a furnace making steel that never runs lower in carbon than ¼ of one per cent. lasts from three to four times as long as one that runs the steel down to wrought iron. Therefore it is cheaper to use manganese or ferro-manganese than spiegeleisen.

The Conversion of Crude or Carburised Iron into Malleable Iron.—This is effected by one or more operations, which are necessarily of an oxidising nature, the object being to eliminate from the cast iron the carbon in the form of carbonic oxide gas, and the silicon, sulphur, phosphorus, and other foreign bodies in the form of oxidised products, which pass either partially or wholly into the scoriæ or cinders. The pig-iron is either subjected to a preliminary decarburation in the oxidising blast hearth, or 'refinery,' and the operation thus commenced afterwards completed in the oxidising air furnace, or 'puddling furnace;' or the complete conversion of the crude iron is effected by one operation in the puddling furnace, by the process called 'boiling.' It is said (*Blackwell*) that, at several works abroad, the attempt to arrest the progress of decarburation in the puddling or boiling furnace at that point in which the conversion has proceeded only so far as to leave the iron in the state of steel, or subcarburet, has been successful, and that a valuable natural or puddled steel, not requiring cementation before conversion into refined or cast steel, has been the result.

English Method of Refining.—The finery furnace is composed of a body of brickwork, about 9 feet square, rising but little above the surface of the ground. The hearth, the bottom of which is of millstone grit, placed in the middle, is 2½ feet deep; it is rectangular, being in general 3 feet by 2, with its greatest side parallel to the face of the tuyères, and it is made of cast iron in four plates. On the side of the tuyères there is a single brick wall, on the three sides sheet-iron doors are placed, to prevent the external air from cooling the metal, which is almost always worked under an open shed or in the open air, but never in a space surrounded by walls. The chimney, from 15 to 18 feet high, is supported upon four columns of cast iron; its lintel is 4 feet above the level of the hearth, in order that the labourers may work without restraint. The air is supplied by the blowing cylinders which supply the blast-furnace, and enter the hearth through 6 tuyères, so arranged that the current issuing from those on the opposite sides of the crucible are not disposed in the same plane. These tuyères, like those in the furnaces in which cast iron is made, are provided with double casings, through which a current of cold water is constantly flowing, and each pipe is furnished with a suitable stop valve for regulating the volume of the blast. The tuyères are placed at the height of the lip of the crucible or hearth, and are inclined towards the bottom, at an angle of from 25° to 30°, so as to point upon the bath of melted metal as it flows. The quantity of air blown into the fineries is considerable, being nearly 400 cubic feet per minute for each finery. The ground plan of a finery is shown in *fig.* 1245, A being the hearth, *b* the tapping-hole, B the chill mould, and *a a a a a a* the nozzles of the tuyères. The operation of refining crude iron is conducted as follows: A fire is lit in the centre of the hearth, which is first urged by a gentle blast; a charge of pig, about 2 tons, is then laid on, and the whole is covered up dome-form with a heap of coke; the full power of the blast is now turned on, the cast iron melts, and flowing down gradually collects in the crucible, more coke being added as the first quantity burns away. The operation proceeds by itself, the melted metal is not stirred about as in some modes of refinery, and the temperature is always kept high enough to preserve the metal liquid. During this stage the coals are observed continually heaving up: a movement due in part to the action of the blast, but in part to an expansion caused in the metal by the discharge of carbonic oxide gas. When all the pig-iron is collected at the bottom of the hearth, which happens in about two hours, it is blown vigorously for some time longer, the tap-hole is opened, and the *fine* metal runs out with the slag into the chill mould, or pit, as it is called, which has been previously washed with a thin clay liquid, to prevent the refined metal from adhering to its surface. The chill mould is in a prolongation of the tapping-hole; it is a heavy cast-iron trough, about 10 feet long, 3 feet broad, and 2 to 2½ inches deep.



1245

The slag, from its inferior specific gravity, forms a crust on the surface on the metal: its separation is facilitated by throwing cold water in large quantities on the fluid mass immediately that the entire charge has left the refinery. This sudden chilling of the metal makes it exceedingly brittle, so that it can be broken into smaller pieces by heavy hammers, for the subsequent operation of puddling, The refined metal is very white, hard, and brittle, and possesses in general a fibrous radiated texture; or sometimes a cellular, including a considerable number of small spherical cavities, like a decomposed amygdaloid rock. The loss of iron in the refinery process is very large, varying from 10 to 20 per cent. In the Welsh iron works, 1 ton of white iron takes from 1¾ to 2 hours to refine, the consumption of coke being from 6 to 8 cwts., and the loss about 3 cwts. Grey iron takes from 7 to 9 cwts. of coke per ton, the time required to refine being from 2½ to 3 hours, and the loss of iron per ton 4 cwts. The pig-iron to be decarburised in the refinery is frequently mixed with rich silicates (forge cinders), and occasionally with oxides of iron, the object being to protect the melted metal in some degree from the oxidising effects of the blast, and to react on the carbon which it contains. The quantity employed depends on the degree to which the pig-iron is carburised. The crude iron, from which wrought iron of the best quality is produced, is that possessing a medium degree of carburation, or what is generally termed grey pig-iron. White iron, which possesses an inferior degree of fluidity to grey pig-iron, and which comes as it is termed more rapidly to nature, is that quality which is most generally employed in the manufacture of wrought iron, especially when the conversion is effected in the single operation of boiling in the puddling furnace; but this species of pig-iron being the result of imperfect re-actions in smelting, is always more impure than grey iron obtained from the same materials, and does not produce wrought iron of the best quality.

The coke employed in the refinery should be as free as possible from shale, and should contain only a low percentage of ash; it should especially be free from sulphuret of iron, which it often contains in considerable quantity, as it is found that nearly the whole of this sulphuret enters into combination with the metal, and does not pass off in the slags.

Refineries are sometimes worked on hot fluid iron, run direct from the hearth of the blast-furnace, a considerable saving, both of time and fuel, being hereby effected. Various proposals have been patented for the employment of fluxes to assist in the removal of the impurities of cast iron, both in the refining and puddling furnaces. Thus Mr. Hampton patented, in 1855, a flux, prepared by slaking quicklime with the solution of an alkali, or alkaline salt. MM. Du Motay and Fontaine propose, in a patent secured in 1856, to purify and decarbonise iron in the refining and puddling furnace, by the employment of fluxes prepared from the scoriæ of the puddling furnace, from oxides of iron and silicates or carbonates of alkalis, or other bases. Mr. Pope (1856) proposes to add the residue obtained by the distillation of Boghead or Torbane mineral to such fuel as is employed in the refining of iron. Mr. Sanderson, of Sheffield (1855), employed for the refining of iron such substances as sulphate of iron, capable of disengaging oxygen or other elements, which will act upon the silicium, aluminium, &c., contained in the metal. These and various other schemes have been suggested with the object of lessening the enormous waste which pig-iron undergoes on its passage through the refinery: for as the process is at present conducted, the partial elimination of the carbon, sulphur, phosphorus, &c., is only effected at the expense of a large quantity of iron, which is oxidised by the blast, and passes in the form of silicate into the slag; the desideratum is the discovery of some method of reducing the oxide of iron, and substituting for it some other base, which will form with silica a sufficiently fusible silicate. Mr. Blackwell suggests that the decarburation of pig-iron might be effected by remelting it in a cupola-furnace, either alone, or with minerals containing nearly pure oxides of iron; the oxide of iron would be reduced by the carbon of the pig-iron, while the silicates of the fuel, with the silica, alumina, and other easily oxidisable alloys eliminated from the crude iron, would be separated in the form of fusible earthy glass. The employment of steam as a purifying agent for crude iron has been patented by several persons. Mr. Nasmyth in 1854 obtained a patent for the treatment of iron in the puddling furnace with a current of steam, which being introduced into the lower part of the iron, passes upwards, and meeting with the highly heated metal, undergoes decomposition, both elements acting as purifying agents. The steam employed is at a pressure of about 5 pounds per square inch, and passes into the metal through a species of hollow rabble, the workman moving this about in the fused metal until the mass begins to thicken, which occurs in from five to eight minutes after the introduction of the steam; the steam-pipe is then removed and the puddling finished as usual.

The advantages are said to consist in the time saved at each heat or puddling operation (from ten to fifteen minutes); the very effective purification of the metal; and the possibility of treating highly carbonised pig-iron at once in the puddling furnace, the preliminary refining being thus avoided. In October 1855, Mr. Bessemer patented for a somewhat similar process for the conversion of iron into steel: the steam highly heated, or a mixture of air and steam, being forced through the liquid iron run from the furnace into skittle-pots, steam being used only at an early stage of the process, and the treatment finished with heated air. In the early part of the same year Mr. Martien of New Jersey obtained a patent for a partial purification of crude iron, by causing air or steam to pass up through the liquid metal, as it flows along gutters from the top-hole of the furnace or finery forge; and he subsequently proposed to include with the air or steam, other purifying agents, such as chlorine, hydrogen, and coal-gas, oxides of manganese, and zinc, &c. Other methods of treating crude iron with air and steam were made the subjects of patents by Mr. Bessemer in December 1855 and January 1856. In October a patent for the employment of steam in admixture with cold blast in the smelting furnace and fining forge, was obtained by Messrs. Armitage and Lee, of Leeds, and in August a patent was obtained by Mr. George Parry, of the Ebbw Vale Iron Works, for the purification of iron by means of highly-heated steam. The fluid iron is allowed to run into a reverberatory furnace previously heated, and the steam is made to impinge upon it from several tuyères, or to pass through the metal. Steel is to be obtained by treating highly carburetted iron with the steam, and then running it into water, and fusing it with the addition of purifying agents, or adding to it in the furnace a small quantity of clay, and afterwards about 10 or 15 per cent. of calcined spathose ore. Mr. Parry observing that when steam was sent through the molten iron, as in Mr. Nasmyth's process, the iron quickly solidified, conceived the idea of communicating a high degree of heat to the steam by raising the steam-pipe a couple of inches above the surface of the metal, so that it might be exposed to the intensely-heated atmosphere of the furnace; and also of inclining the jet at an angle of 45°, so as to give the molten mass a motion round the furnace while the pipe was maintained in the same position at a little distance beyond the centre: when this was done, in a few minutes the iron began to boil violently, the rotatory motion of the fluid bringing every part of it successively into contact with the highly-heated mixture of steam and atmospheric air, and no solidification taking place. Having thus ascertained the proper way of using steam as a refining agent, it occurred to Mr. Parry that, as the presence of silicon in the pigs for puddling affects in a remarkable degree the yield of iron, as well as its strength, it is a matter of consequence that this element should be removed as completely as possible previous to the puddling operation; the steaming of the iron would probably therefore be more profitably applied in the refinery than in the puddling furnace. Pig-iron containing 3 per cent. of silicon gives 6 per cent. of silica, which, to form a cinder sufficiently fluid to allow the balling-up of the iron, would require from 10 to 12 per cent. of iron; and this can, of course, only be obtained by burning that amount of iron in the puddling furnace, after the expulsion of the carbon, and while the mass is in a powdery state. The superheated steam is injected on the surface of the iron in the refinery by water tuyères, similar to those used for hot blast at smelting furnaces; they are inclined at an angle of about 45°; some are inserted at each side of the door of the furnace, and are pointed so as to cross each other, and give the iron a circulating motion in the furnace. The tuyères are from $\frac{3}{8}$ths to $\frac{1}{2}$ an inch in diameter; a little oxide of iron or silicate in a state of fusion on the surface of the iron accelerates the action, as in common refineries, and increases the yield of metal, but to a much greater extent than when blasts of air are used. The steam having been turned on, the mass of iron commences circulating around the inclined tuyères, and soon begins to boil, and the action is kept uniform by regulating the flow of the steam. The most impure oxides of iron may be used in this process, such as tap cinder or hammer slag from puddling furnaces, without injury to the quality of the refined metal made; the large quantities of sulphur and phosphorus which they contain being effectually removed by the detergent action of the heated steam. When 4 cwts. of cinders are used to the ton of pig, 20 cwts. of metal may be drawn, the impurities in the pig being replaced by refined iron from the cinders.

Dr. Noad had several opportunities of witnessing this refining process at the Ebbw Vale Iron Works, and made the following analysis of the cinders and metal, which fully bear out the above statements:—

	Pig-iron	Refined metal
Graphite	2·40	0·30
Silicon	2·68	0·32
Slag	0·68	0·00
Sulphur	0·22	0·18
Phosphorus	0·13	0·09
Manganese	0·86	0·24

	Forge cinders thrown into the refinery	Cinder run out of the refinery
Sulphur	1·34	0·16
Phosphoric acid	2·06	0·129

A ton of grey iron may be refined by steam in half an hour, using seven jets of steam ⅜ths of an inch in diameter, and with a pressure of from 30 to 40 lbs.; the temperature of the steam being from 600° to 700° F., the orifices of the tuyères being 2 or 3 inches above the surface of the iron. As the fluidity of the metal depends upon the heat which it is receiving from the combustion of the fuel in the grate, and not on any generated in it by the action of the steam, it is evident that the supply of the latter in a given time must not exceed a certain limit, or the temperature of the fluid iron will become reduced below that of the furnace. This, however, partly regulates itself, and does not require much nicety in the management, for, if too much steam be given the ebullition becomes so violent, as to cause the cinders to flow over the bridges, giving notice to the refiner to slack his blast. The 'forge cinders' used in the steam refinery contain 66 per cent. of iron; the 'run out' cinder contains only 26; 40 per cent. of iron, or thereabouts, have therefore been converted into refined metal, and the resulting cinder is as pure as the ordinary Welsh mine, with its yield of 25 per cent. of iron. The following is the result of one week's work of the steam refinery:—

	cwts.	qrs.	lbs.
Pigs used	396	0	15
Metal made	393	3	1
Loss	2	1	14
Yield	20	0	14

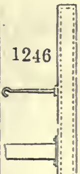
The quantity of cinder (puddling) used was 3½ cwts. per ton of pig. When 1½ cwt. of cinders were used to 1 ton of pig, the yield was invariably 20 cwts. over a make of about 100 tons.

Refining by Gas (*German method*).—The most simple form of gas reverberatory furnace is that known as Eck's furnace (*figs.* 1251 to 1256), which is employed at the government works of Gleiwitz and Königshütte, for refining iron made on the spot. The following description and plan of this furnace are extracted from a report to the Secretary of State for War, from the superintendent of the Royal Gun Factories, Colonel Wilmot, R. A., and the chemist of the War Department, Professor Abel.

The gas-generator (which replaces the fire-place of the ordinary reverberatory furnace) is an oblong chamber, the width of which is 3 feet 9 inches, and the height from the sole to the commencement of the sloping bridge 6 feet 4 inches. It tapers slightly towards the top, so as to facilitate the descent of the fuel, which is introduced through a lateral opening near the top of the generator. Its cubical contents are about 44 feet.

1248

1246



1247

1250

The air necessary for the production of the gas is supplied by a feeble blast, and enters the generator from the two openings or tuyères of a long air-chest of iron plate (*figs.* 1246, 1247, 1248) fixed at the back of the chamber, near the bottom. The space between the air-chest and the sole of the chamber serves as a receptable for the slag and ash from the fuel. There are openings on the other side of the chamber, opposite the tuyères, which are generally closed by iron plugs, but are required when the tuyères have to be cleaned out. There is an opening below the air-chest, through which fire is introduced into the chamber, when the furnace is set to work, and which is then bricked up, until at the expiration of about 14 days it becomes necessary to let the fire die out, when the slag and ash which have accumulated on the sole of the chamber are removed through this opening.

The hearth of the furnace is constructed of a somewhat loamy sand; its general thickness is about 6 inches, its form is that of a shallow dish, with a slight incline towards the tap-hole; the iron is prevented from penetrating through the hearth by the rapid circulation of cold air below the fire-bridge and the plate of the hearth.

Figs. 1249 and 1250 represent the upper oblong air-chest provided with a series of tuyères, which enter the top of the furnace just over the fire-bridge at an angle of 30°. The air forced into the furnace through the tuyères serves to inflame and burn the gases rushing out of the generator, and the direction of the blast throws the resulting flame down upon the metal on the hearth, in front of the bridge. This air-chest communicates, like the other one, by pipes, with the air accumulator of the neighbouring blast-furnace. The amount of pressure employed is about 4 lbs.; but the supply of air, both to the generator and the inflammable gases, admits of accurate regulation by means of valves in the connecting pipes. There is an opening in the

arch at both sides of the furnace, not far from the bridge, into which, at a certain stage of the operations, tuyères are introduced (being placed at an angle of 25°) also connected with the blast-apparatus, and provided with regulating valves.

The refining process is conducted as follows:—The hearth of the furnace having been constructed or repaired, a brisk coal-fire is kindled in the generator, through the opening at the bottom, which is afterwards bricked up. About 20 cubic feet of coals are then introduced from above, and the necessary supply of air admitted to the generator through the lower air-chest. When these coals have been thoroughly ignited, the generator is filled with coals, and a very moderate supply of air admitted through the tuyères below (for the generation of the gas), and those over the bridge (for its combustion) until the furnace is dried, when the supply of air at both places is increased, so as to raise the hearth to the temperature necessary for baking it thoroughly, upon which, about 40 cwts. of iron are introduced; the metal being distributed over the whole hearth as uniformly as possible, and the size of the pieces being selected with the view to expose as much surface as possible to the flame. The fusion of the charge of metal is effected in about three hours, the coal used amounting to about 3¾ cubic feet per hour. The gas-generator is always kept filled with coal, and the supply of air admitted from below is diminished by a regulation of the valve, whenever fresh coal is supplied, as the latter, at first, always yields gas more freely. The arrangement of the upper row of tuyères effects the combustion of gases just as they pass from the generator on to the hearth. The hottest portion of the furnace is of course near the fire-bridge, *i.e.* where the blast first meets with the gases. During the melting process the iron is shifted occasionally, so that the cooler portion near the flue may in its turn become melted without loss of time. When the iron is ascertained to be thoroughly fused, about 5 lbs. of crusted limestone are thrown over its surface for the purpose of converting the dross which has separated into fusible slag. The two side tuyères are now introduced into the furnaces through the openings above alluded to, the width of the nozzle employed depending upon the power of the blast used. The air rushing from these tuyères impinges with violence upon the iron, and the two currents meeting an eddying motion is imparted to the fused metal. In a short time the motion produced in the mass is considerable; the supernatant slag is blown aside by the blast, and the surface of the iron thus exposed undergoes refinement, while it changes continually, the temperature of the whole mass being raised to a full white heat, by the action of the air. The iron is stirred occasionally, in order to insure a proper change in the metal exposed to the action of the blast. A shovelful of limestone is occasionally thrown in (the total quantity used being about 1 per cent. of the crude iron employed). The slag produced is exceedingly fusible, and is allowed to remain in the furnace until the metal is tapped, and on cooling it separates from it completely.

The duration of the treatment in this furnace after the metal is fused, varies from two hours and a half to five hours, according to the product to be obtained. For the preparation of perfectly white iron, the treatment is carried on for five hours. A sample is tapped to examine its appearance when it is believed to be sufficiently treated.

When the charge is to be withdrawn from the furnace, the side tuyère nearest the tap-hole is withdrawn, so that the blast from the opposite tuyère may force the metal towards the hole. The fluid iron, as it flows from the tap-hole is fully white hot, and perfectly limpid; it chills, however, very rapidly, and soon solidifies. A few pails of water are thrown upon those portions of the metal which are not covered with the slag, which flows out of the furnace, the object being to cool it rapidly, and thus prevent the oxidation of any quantity of iron. The loss of metal during the treatment is said not to exceed 5 per cent.

With regard to the purification which the iron undergoes in the gas reverberatory furnace, it appears to be confined chiefly to the elimination of carbon and silicium, the amount of sulphur and phosphorus undergoing but little alteration, as appears from the following analyses (*Abel*):—

	Pig-iron	Refined iron
Silicium	4·66	0·62
Phosphorus	0·56	0·50
Sulphur	0·04	0·03

Nevertheless, the iron thus refined is highly esteemed for all castings which are required to possess unusual powers of resistance; some experiments made to ascertain the comparative strain borne by the refined metal, and the same metal as obtained from the blast-furnace, showing the strength of the former to be greater by one half than that of the latter.

The Operation of Puddling.—In the year 1783 and 1784, Mr. Henry Cort of Gosport obtained two patents, one for the puddling, and the other for the rolling of iron, 'Discoveries,' says Mr. Scrivenor, 'of so much importance in the manufacture, that it must be considered the era from which we may date the present extensive and flourishing state of the iron trade of this country.'

The object of Mr. Cort's process was to convert into malleable iron, cast or pig-iron, by means of the flame of pit-coal in a common air furnace, and to form the result into bar by the use of rollers in the place of hammers. The process was managed in the following manner:—

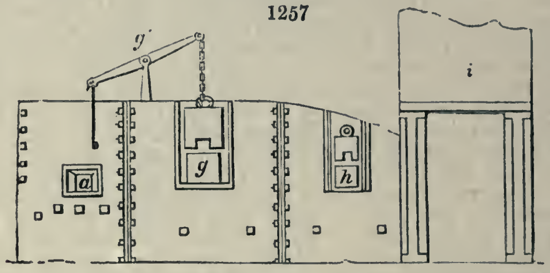
'The pigs of cast iron produced by the smelting furnace are broken into pieces, and are mixed in such proportions according to their degree of carbonisation, that the result of the whole shall be a grey metal. The mixture is then speedily run into a blast-furnace, where it remains a sufficient time to allow the greater part of the scoriæ to rise to the surface. The furnace is now tapped, and the metal runs into moulds of sand, by which it is formed into pigs, about half the size of those which are broken into pieces. A common reverberatory furnace heated by coal is now charged with about 2½ cwts. of this half-refined grey iron. In a little more than half an hour the metal will be found to be nearly melted; at this period the flame is turned off, a little water is sprinkled over it, and a workman, by introducing an iron bar through a hole in the side of the furnace, begins to stir the half-fluid mass, and divide it into small pieces. In the course of about 50 minutes from the commencement of the process, the iron will have been reduced by constant stirring to the consistence of small gravel, and will be considerably cooled. The flame is then turned on again, the workmen continuing to stir the metal, and in three minutes' time the whole mass becomes soft and semifluid, upon which the flame is then turned off. The hottest part of the iron now begins to heave and swell, and emit a deep lambent blue flame, which appearance is called *fermentation*; the heaving motion and accompanying flame soon spread over the whole, and the heat of the metal seems rather to be increased than diminished for the next quarter of an hour; after this period the temperature again falls, the blue flame is less vigorous, and in a little more than a quarter of an hour the metal is cooled to a dull red, and the jets of flame are rare and faint. During the whole of the fermentation the stirring is continued, by which the iron is at length brought to the consistency of sand; it also approaches nearer to the malleable state, and in consequence adheres less than at first to the tool with which it stirred. During the next half hour the flame is turned off and on several times, a stronger fermentation takes place, the lambent flame also becomes of a clearer and lighter blue, the metal begins to clot and becomes much less fusible and more tenacious than at first. The fermentation then by degrees subsides, the emission of blue flame nearly ceases, the iron is gathered into lumps and beaten with a heavy-headed tool. Finally, the tools are withdrawn, the apertures through which they were worked are closed, and the flame is again turned on in full force for six or eight minutes. The pieces being thus brought to a high welding heat are withdrawn and shingled; after this they are again heated and passed through grooved rollers, by which the scoriæ are separated, and the bars thus forcibly compressed acquire a high degree of tenacity.' But this mode of refining did not produce altogether the desired result. It was irregular; sometimes the loss of iron was small, but at others it was very considerable, and there were great variations in the quality of the iron, as well as in the quantity of fuel consumed. These difficulties, were, however, removed by the introduction of the coke finery by the late Mr. Samuel Homfray, of Penydarran, upon which the puddling and balling furnaces came immediately into general use, with the addition of rollers in lieu of hammers.

Mr. Cort's first patent, which is for 'rolling,' is dated January 17, 1783; his second, that for 'puddling,' is dated February 13, 1784. It has been attempted, though we think very unjustly, to detract from Cort's merits as an original inventor, by referring to the patents of John Payne, and Peter Onions, dated respectively November 21, 1728, and May 7, 1783. The first was to a certain extent, undoubtedly, a patent for 'rolling;' for the bars rendered malleable by a process indicated, are '*to pass between the large metall rowlers which have proper notches or furrows upon their surface*;' but there is no proof that any practical use was made of Payne's process, while that of Cort was almost immediately and universally adopted; it may be true, therefore, that Cort was the *rediscoverer* and not the actual *discoverer* of the process of rolling, but this in no way detracts from his merit, inasmuch as by his improvements he was enabled to make available that which was previously useless. The same observation applies to the patent of Onions, which to a certain extent anticipated that of Cort for puddling. Onions employed two furnaces—a common smelting furnace, and a furnace of stone and brick, bound with iron work and well annealed, into which the fluid metal was received from the smelting furnace. When the liquid metal had been introduced into the second furnace by an aperture, it was closed up and subjected to the heat of fuel and blast from below, until the metal became less fluid, and thickened into a kind of paste; this the workman, by opening a door, turns and stirs with a bar of iron, and then closes the aperture again, after which blast and fire is applied until there is a *ferment* in the metal; the adherent particles of iron are collected into a mass, reheated to a white heat, and forged into malleable iron. That the process of puddling is here indicated there can be no doubt, but the actual operation was impracticable until Henry Cort invented the *furnace* in which it could be conducted.

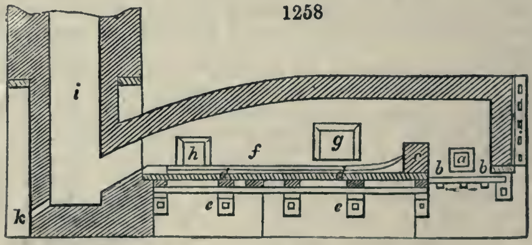
Neither Mr. Cort nor his family appears to have derived much advantage from his important discoveries—discoveries which changed us at once from dependent importers of iron into vast exporters to every country of the world, and which may be considered to have founded the iron industry of Great Britain. So long ago as 1811, the chief representatives of the trade assembled at Gloucester unanimously acknowledged their indebtedness to Mr. Cort for the improvements of which he was the author, and this acknowledgment has been repeated within the last few years by *Robert Stephenson*, *Fairbairn*, *Maudslay and Field*, *Cubitt*, *Rendel*, *Sir Charles Fox*, *Bidder*, *Crawshay*, *Bailey*, and many others. In working out his inventions, Cort is said to have expended a fortune of 20,000*l.*, and when his patents were completed, the leading ironmasters of the country contracted to pay him 10*s.* a ton for their use, so that he would not only have been repaid, but munificently rewarded, had he not unfortunately connected himself with a man named Adam Jellicoe, chief clerk of the Navy Pay Office, who proving to be a defaulter, committed suicide, having previously destroyed the patents and the agreements with ironmasters belonging to his partner, Henry Cort. Upon the death of Jellicoe, the premises, stock, and entire effects of Cort were sold by a summary process obtained by the Navy Pay Office, and the unfortunate man was thus completely ruined.

The *puddling furnace* is of the reverberatory form. It is bound generally with iron, as represented in the side view, *fig.* 1257, by means of horizontal and vertical bars, which are joined together and fixed by wedges, to prevent them from starting asunder. Very frequently, indeed, the reverberatory furnaces are armed with cast-iron plates over their whole surface. These are retained by upright bars of cast iron applied to the side walls, and by horizontal bars of iron, placed across the arch or roof. The furnace itself is divided interiorly into three parts; the *fireplace*, the *hearth*,

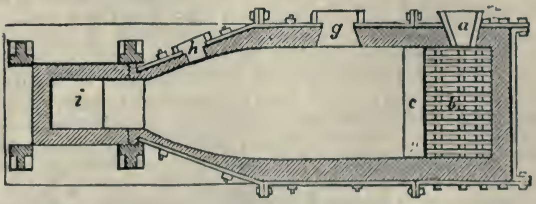
1257



1258



1259

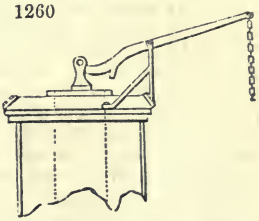


and the *flue*. The *fireplace* varies from 3½ to 4½ feet long, by from 2 feet 8 inches to 3 feet 4 inches wide. The door-way, by which the coke is charged, is 8 inches square, and is bevelled off towards the outside of the furnace. This opening consists entirely of cast iron, and has a quantity of coal gathered round it. The bars of the fire-grate are moveable, to admit of more readily clearing them from ashes.

Fig. 1258 is a longitudinal section referring to the elevation, *fig.* 1257, and *fig.* 1259 is a ground plan. When the furnace is a single one, a square hole is left in the side of the fireplace opposite to the door, through which the rakes are introduced, in order to be heated.

a is the fire-door; *b*, the grate; *c*, the fire-bridge; *d d*, cast-iron hearth-plates, resting upon cast-iron beams *e e*, which are bolted upon both sides to the cast-iron binding plates of the furnace; *f* is the hearth covered with cinders or sand; *g*, is the main working door, which may be opened and shut by means of a lever *g′*, and chain to move it up and down. In this large door there is a hole 5 inches square, through which the iron may be worked with the paddles or rakes; it may also be closed air-tight. There is a second working door *h*, near the flue, for introducing the cast iron, so that it may soften slowly, till it be ready for drawing towards the bridge. *i* is the chimney, from 30 to 50 feet high, which receives commonly the flues of two furnaces, each provided with a damper plate or *register*. *Fig.* 1260, shows the main damper for the top of the common chimney, which may be opened or shut to any degree by means of the lever and chain. *k*, *fig.* 1258, is the tap or floss-hole for running off the slag or cinder.

1260



The sole is sometimes made of bricks, sometimes of cast iron. In the first case it is composed of fire-bricks set on edge, forming a species of flat vault. It rests immediately on a body of brickwork either solid or arched below. When it is made of cast iron, which is now beginning to be the general practice, it may be made either of one piece or of several. It is commonly in a single piece, which, however, causes the inconvenience of reconstructing the furnace entirely when the sole is to be changed. In this case it is a little hollow, as is shown in the preceding vertical section; but if it consists of several pieces, it is usually made flat.

The hearths of cast iron rest upon cast-iron pillars, to the number of four or five; which are supported on pedestals of cast iron placed on large blocks of stone. Such an arrangement is shown in the figure, where also the square hole *a*, *fig.* 1257, for heating the rake irons, may be observed. The length of the hearth is usually 6 feet; and its breadth varies from one part to another. Its greatest breadth, which is opposite the door, is 4 feet. In the furnace, whose horizontal plan is given above, and which produces good results, the sole exhibits in this part a species of ear, which enters into the mouth of the door. At its origin towards the fireplace, it is 2 feet 10 inches wide; from the fire it is separated, moreover, by a low wall of bricks (the fire-bridge) 10 inches thick, and from 3 inches to 5 high. At the other extremity its breadth is 2 feet. The curvature presented by the sides of the sole or hearth is not symmetrical; for sometimes it makes an advancement, as is observable in the plan. At the extremity of the sole furthest from the fire, there is a low rising in the bricks of 2½ inches, called the altar, for preventing the metal from running out at the *floss-hole* when it begins to fuse. Beyond this shelf the sole terminates in an inclined plane, which leads to the *floss*, or outlet of the slag from the furnace. This *floss* is a little below the level of the sole, and hollowed out of the basement of the chimney. The slag is prevented from concreting here, by the flame being made to pass over it, in its way to the sunk entry of the chimney; and there is also a plate of cast iron near this opening, on which a moderate fire is kept up to preserve the fluidity of the scoriæ, and to burn the gases that escape from the furnace, as also to quicken the draught, and to keep the remote end of the furnace warm. On the top of this iron plate, and at the bottom of the inclined plane, the cinder accumulates in a small cavity, whence it afterwards flows away; whenever it tends to congeal, the workman must clear it out with his rake.

The door is a cast-iron frame, filled up inside with fire-bricks; through a small hole in its bottom the workmen can observe the state of the furnace. This hole is at other times shut with a stopper. The chimney has an area of from 14 to 16 inches.

The hearth stands 3 feet above the ground. Its arched roof, only one brick thick, is raised 2 feet above the fire-bridge, and above the level of the sole, taken at the middle of the furnace. At its extreme point near the chimney, its elevation is only 8 inches; and the same height is given to the opening of the chimney. The sole is covered with a layer of finely-pounded cinders from previous workings mixed with mill cinders; formerly the bottoms were of sand, by which great loss of iron was occasioned, and the metal obtained of inferior quality.

The fine metal obtained by the coke is *puddled* by a continuous operation, which calls for much skill and care on the part of the workmen. To charge the puddling furnace, pieces of *fine metal* are successively introduced with a shovel, and laid one over another on the sides of the hearth, in the form of piles rising to the roof; the middle being left open for puddling the metal, as it is successively fused. Indeed, the whole are kept as far separate as possible, to give free circulation to the air round the piles. The working door of the furnace is now closed, fuel is laid on the grate, and the mouth of the fireplace, as well as the side opening of the grate, are both filled up with coal, at the same time that the damper is entirely opened.

The fine metal in about twenty minutes comes to a white-red heat, and its thin-edged fragments begin to melt and fall in drops on the sole of the furnace. At this period the workman opens the small hole of the furnace-door, detaches with a rake the pieces of fine metal that begin to melt, tries to expose new surfaces to the action of the heat, and in order to prevent the metal from running together as it softens, he removes it from the vicinity of the fire-bridge. When the whole of the fine metal has thus got reduced to a pasty condition, he must lower the temperature of the furnace to prevent it from becoming more fluid. He then works about with his paddle the clotty metal which swells up, exhibiting a kind of fermentation occasioned by the discharge of carbonic oxide, burning with a blue flame as if the bath were on fire. The metal becomes finer by degrees and less fusible, or, in the language of the workmen, it begins to *dry*. The disengagement of carbonic oxide diminishes and soon stops. The workman continues meanwhile to puddle the metal till the whole charge is reduced to the state of incoherent sand; the register is then progressively opened. With the return of heat the particles of metal begin to agglutinate, the charge becomes more difficult to raise, or, in the labourer's language, it *works heavy*. The refining is now finished, and nothing remains but to gather the iron into balls. The puddler with his paddle takes now a little lump of metal as a nucleus, and makes it roll about on the surface of the furnace, so as to collect more metal, and form a ball of about 60 or 70 lbs. weight. With a kind of rake called in England a *dolly*, and which he heats beforehand, the workman sets this ball on that side of the furnace most exposed to the action of the heat in order to unite its different particles, which he then squeezes together to force out the scoriæ. When all the balls are fashioned, the small opening of the working door is closed with brick to cause the heat to rise, and to facilitate the welding. Each ball is then lifted out either with the tongs, if roughing rollers are to be used, as in Wales, or with an iron rod welded to the lump as a handle, if the hammer is to be employed, as in Staffordshire. It is usual to introduce a fresh charge when the portion under operation has arrived at the pasty condition; when this is done, the entire process is effected in about 1½ hour.

The charge for each operation is from 4 cwts. to 4¾ cwts. of refined metal, and sometimes the cuttings of bar-ends are introduced, which are puddled apart. The loss of iron is here very variable, according to the degree of skill in the workman, who by negligence may suffer a considerable body of iron to scorify or to flow into the hearth and raise the bottom. Taking the average of 85 furnaces for 21 years' working, Mr. Truran finds the consumption of refined metal to produce one ton of puddle bars to be 21 cwts. 1 qr. 20 lbs. The consumption of coal is likewise subject to variation. With coal of good quality, and suitable for reverberatory furnaces, the ton of puddled bars is produced with a consumption of from 12 to 15 cwts.; but, if the coal be of the anthracitic character, from 18 cwts. to 1 ton will be required. About five puddling furnaces are required for the service of one smelting furnace and one refinery. Each furnace, with good workmen, turns out about 23 tons of puddled bars weekly.

The cast-iron bottom and sides of the puddling furnace are kept cool by currents of air, or, in those portions exposed to the greatest heat, by water. The cinders of the charcoal finery are much esteemed for lining the bottom. When melted into one uniform mass, with the addition of oxide of iron, these scoriæ form a bottom offering great resistance to the action of the melted metal.

Various patents have been taken out within the last four or five years for the employment of chemical agents to assist in the purification of iron in the puddling furnace: some of these have already been alluded to. One of the latest is that of M. Charles Pauvert of Châtellerault, who proposes to employ a cement composed of the following substances:—oxide of iron, 14 parts; highly aluminous clay, 30 parts; carbonate of potash, 1 part; carbonate of soda, 1 part. The iron is to be placed with the cement in layers, and heated in the furnace in the ordinary manner. After cementation it is welded, and then drawn into bars; it is stated to become thus as soft and tenacious as iron made from charcoal. Schafhaeutl's compound, for which a patent was secured in 1835, is said by Overman to furnish very satisfactory results, and where competent workmen are employed, a good furnace is said to make a heat in two hours, producing neither too much nor too little cinder in the furnace. The compound consists of common salt, 5 parts; oxide of manganese, 3 parts; fine white plastic clay, 2 parts. The pig is heated as in common operations. It is melted down by a rapid heat, the damper is closed, and the cinder and metal diligently stirred. In the meantime the above mixture, in small parcels of about half a pound, is introduced in the proportion of 1 per cent. of the iron employed; if, after this, the cinder does not rise, a hammer slag (rolling mill-cinder) may be applied.

Puddling of Iron by Machinery.—The earlier stages at least of the process of puddling a charge of iron involve operations so simple that it is a matter for some surprise that they have not long since been carried out by machinery. The constant stirring of a little pond of molten iron is the thing to be done, and a common bar of iron, with one end bent down at right angles, is the thing to do it with. The necessary motions are in no way complex, and so far very simple machinery should suffice for the operation. The history of attempts at machine-puddling runs back nearly a quarter of a century. But it is only within the last year or two that the practical adoption of puddling-machinery has been attended with success. It is beyond question that the problem presented to the mechanician was formerly invested with difficulties which modern experience proves to have been more or less imaginary. Too much was attempted, and of course little or nothing done. The paramount idea was that the labour of the puddler should be wholly superseded, and the entire process, blooming and all, effected solely by the aid of steam-power. In this lay a great error. There are many processes in the arts which cannot be effected without the very effectual interference of the human arm guided by intelligence, and puddling is pre-eminently one of these. The only available course to adopt is to permit the machine to perform the major part of the hard work, leaving the completion of the process to the man. Mechanism constructed according to this principle has now been at work for some time with excellent results, and the universal adoption of machine-puddling is not, we think, very distant. Mr. Menelaus, of the Dowlais Ironworks, carried out a series of experiments on a very extended scale. The system adopted at Dowlais is that known as Walker's, in which the iron is exposed to the action of flame by the rotation and oscillation of the vessel containing the molten metal, which takes the place of the ordinary hearth. The experiments made at Dowlais were not, however, entirely successful. At the Wombridge Ironworks, Salop, Mr. Henry Bennett, the manager, introduced a system of his own invention. Mr. Bennett read a paper on this machine, and the results obtained from its use, before the Institution of Mechanical Engineers, from which we select the following remarks:—

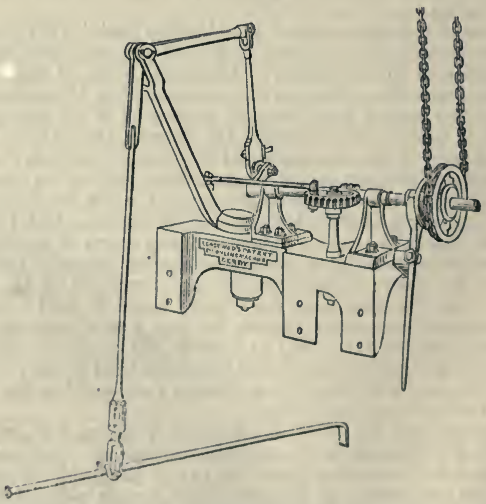
'The importance of the application of machinery to diminish the severe labour of puddling iron, by performing the merely mechanical process of stirring the iron, has led to many attempts in that direction; and, amongst others, it has been attempted to make a rotary furnace for performing the entire operation by machinery. But not till lately has any real success been attained, on account of the practical difficulties that are met with in applying machinery for the purpose, arising from the great heat to which any machinery in the furnace would be exposed, and from the necessity for not interfering with the draught of the furnace, while making the whole machinery simple and strong enough to stand the rough usage of the men employed. The design of the writer in applying machinery to the process of puddling iron has been, therefore, to adhere as closely as possible to the ordinary course of hand-puddling, and to employ the machinery simply to aid the puddler by relieving him of the most laborious part of his work: namely, the stirring or working of the metal in the puddling furnace. At the same time, the objects aimed at have been, by a more rapid and uninterrupted process of stirring the metal, to shorten the time of the puddling, thereby economising the fuel; to improve the quality of the iron, by rendering the process more uniform and perfect than with hand labour; and to increase the work of the furnace, by working larger charges than could be both puddled and balled-up at one heat by hand labour alone.

'With the machine now described, the ordinary puddling tool, or "rabble," is worked backwards and forwards in the puddling furnace by a vertical arm outside the furnace, to which it is connected by a notch in the handle of the rabble, dropped loosely on a pin at the bottom of the arm. The arm is cottered at top into a horizontal slide-bar, working backwards and forwards in a guide-frame overhead; this is driven by a connecting rod from a long iron bar, which extends longitudinally over a whole row of puddling furnaces, and has a longitudinal reciprocating motion given to it by a crank driven by the engine. The guide-frame is centred on a vertical pin immediately over the door of the puddling-furnace, and is moved transversely from side to side with a slow traverse by a crank and worm-wheel, driven by a worm on a longitudinal shaft extending over the series of puddling furnaces, alongside the reciprocating bar. By this means the rabble, instead of moving backwards and forwards always in the same line, is worked successively over every part of the puddling furnace, in lines radiating from the working hole in the door of the furnace, corresponding exactly to the action in hand-puddling. In a double furnace, with a door on each side, one of the machines is fixed over each door, and the two rabbles are made to be always working in different parts of the furnace, by the two traversing cranks of the guide-frames overhead being set at right angles to each other. The whole of the machinery is kept clear above the furnace outside, and completely protected from the heat, and quite out of the way of the men; nothing being exposed to the heat except the rabble or puddling-tool, the same as in hand-puddling. The puddler changes the rabble from time to time as it gets heated, by simply lifting it off the pin on the working arm, and replacing it with a fresh tool, without stopping the machine; and when the iron begins to thicken, or is "coming to nature," he takes the opportunity of each change of tool to make a few strokes by hand, in order to collect the metal from the extreme sides of the furnace into the centre. When the iron is ready for balling-up, the machinery is disconnected, without stopping it, by merely knocking out the cotter which fixes the working arm in the slide-bar; the arm then drops out, leaving the furnace-door entirely free for the puddler to ball up the iron, without his being in any way inconvenienced by the machinery continuing at work overhead.

'By the use of this machine, more work is put into the iron while it is in the boiling state than can be done by hand, the speed of working being one-half greater; and the working is kept up uninterruptedly, without any intervals of rest, such as in hand labour, during which the metal would remain stationary in the furnace. The double furnace, worked from each side, effects a great economy in the consumption of fuel, as compared with a single furnace; and puddles double the quantity of iron in the same time. With the machines at work at the Wombridge Ironworks, the consumption of coal in the double furnace, with a charge of 10 cwts., is only 17 cwts. of coal per ton of puddled bar, as compared with 28 cwts. per ton in the single furnace with a charge of 5 cwts. The number of heats worked by the machine per turn of from nine to ten hours is six heats of 6 cwts. each in the single furnace, and five heats of 10 cwts. each in the double furnace.'

Mr. Eastwood, of Derby, has patented, and is using with much success, a puddling-machine, of which the accompanying woodcut (*fig.* 1261) gives a sufficient example.

1261



This machine is of the simplest and most compact character, while it is efficient in work, giving the same motion to the rabble as is done by manual labour; and working the iron about so thoroughly that the whole is boiled quicker, better, and much cleaner than a man will or can always do it, thus securing a more uniform and better quality of iron, with less percentage of waste: at the same time a larger quantity of iron may be worked with ease in each heat, thus effecting a saving of fuel, time, and labour, and the workmen being relieved, lessens the liability of the underhands absenting themselves from work in hot weather, or when the iron is grey, through which so much loss is sustained in almost every work, and the puddler is still enabled to change his rabble as readily as before, and work in the ordinary way, independently of the machine. The machine, as represented, is made to bolt to the back side of the front furnace-plate, and its action is as follows:—The chain giving motion to the shaft, the crank by the connecting-rod working the lever, and the rabble being attached, is drawn from back to front, and is made to traverse from one jamb to the other, by the worm on the shaft turning the worm-wheel connected to the jib by the connecting-rod; thus every turn of the wheel alters the position of the jib, and the rabble is sent in another direction, but never in the same direction, owing to the wheel having an uneven number of teeth, therefore every part of the furnace bottom is worked over. It is under perfect control, the hand lever throwing in and out of gear the clutch on the side of the chain pulley, thus starting and stopping it at will. It does in no way interfere when the furnace is being rebuilt.

In a future page mechanical contrivances introduced by Dr. Siemens and Mr. Danks will be especially noticed.

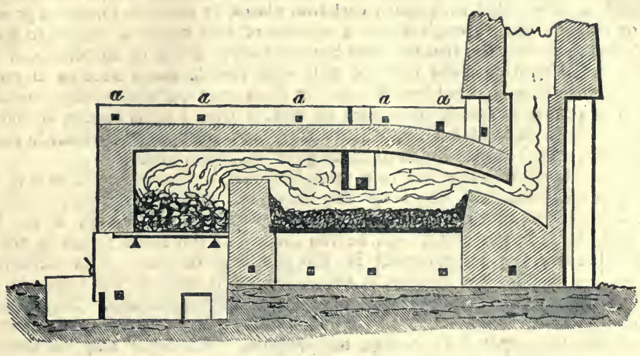
The 'Boiling' Process.—In this operation, which was the invention of Mr. Joseph Hall, pig-iron is converted into malleable iron without the intervention of the refinery, and without any excessive waste: it is, therefore, of great value, especially as it allows of the use of better qualities of pig-iron than those usually employed. The construction of the 'boiling' furnace does not materially differ from that of the 'puddling' furnace, except in the depth of the hearth, that is, in the distance from the work plate below the door to the bottom plate, which, in the former, is double, or nearly so, that of the latter. In the puddling furnace the distance between the bottom and top seldom exceeds twenty inches, while in the boiling furnace it varies from twenty to thirty. In *puddling* the furnace is charged with metal alone, but in boiling *cinder* is charged along with the metal, and the temperature rises much higher. The bottom of the furnace is covered with broken cinders from previous workings, or with the tap cinder from the puddling furnace, which has been subjected to a process of calcination in kilns; this material, which constitutes an admirable protection to the iron plates of the furnace, is called by the workmen 'bull dog;' its preparation was patented by Mr. Hall in 1839. It is made in the following manner: the tap cinder from the puddling furnace is placed in layers in a kiln, and so arranged that a draught shall pass through from the fire-holes on one side to those of the other; the kiln is filled up to the top with broken cinders, and over the whole is laid a layer of coke; about the third or fourth day, the more fusible part of the cinder begins to run out of the bottom holes, leaving in the kiln a fine rich porous silicate of iron, which is the substance used for lining the boiling furnace, the fluid portion being rejected. In 8 or 10 hours the 'bull dog' is melted by the intense heat of the furnace, covering the bottom, and filling up all the interstices in the brickwork; the heat is now somewhat lowered by diminishing the draught, and the charge of pig (from 3½ to 4½ cwts.) introduced in fragments of a convenient and uniform size, together with 30 or 40 lbs. of cinder; the doors of the furnace are now closed, and all access of cold atmospheric air prevented, throwing fine cinder or hammer slag round the crevices, and stopping up the work-hole with a piece of coal. In about a quarter of an hour the iron begins to get red hot; the workman then shifts the pieces so as to bring the whole to a state of uniformity as regards heat. In about half an hour the iron begins to melt; it is constantly turned over, and at intervals of a few minutes cinder is thrown in; the surface of the mass is seen to be covered with a blue flame; it soon begins to rise; a kind of fermentation takes place beneath the surface, and the mass, at first but 2 inches high, rises to a height of 10 or 12 inches, and enters into violent ebullition. During the time that this 'fermentation' is taking place, constant stirring is required to prevent the iron from settling on the bottom. The *boiling* lasts about a quarter of an hour; after which the cinder gradually sinks, and the iron appears in the form of porous spongy masses of irregular size, which are constantly stirred to prevent their adhering together in large lumps, to facilitate the escape of the carbon, and to separate the cinder which, when the operation has been successfully conducted, flows over the bottom apparently as liquid as water. The iron is now 'balled up,' as in the operation of puddling. The objections to the boiling process are: the wear and tear in the furnace which occurs in treating grey pig-iron, particularly that of the more fluid description; the slowness of the operation, and the amount of manual labour which it entails to produce good results. In some works the crude iron is run directly into the boiling furnace from the blast-furnace, by which much saving of coal is effected, and a product of a more uniform quantity obtained; but the labour of the workman becomes more oppressive from the additional heat to which he is subjected from the close proximity of the blast-furnace. Ironmasters are not agreed as to the respective merits of the 'boiling' and 'puddling' systems; some maintain that the former is more economical than the latter, which involves 'refining;' others think that boiling iron has a tendency to communicate to it the 'red short' quality. According to the observations of Mr. Truran, in several works where both methods are employed, the largest quantity of iron is first passed through the refinery.

Mr. Hall, the inventor of the boiling system, in descanting on the merits of his process, describes how, with the same pig, the iron may be made weak and cold short; or tough, ductile, and malleable. For the first proceed thus:—Pass the pig through the refinery, then puddle agreeably to the old plan on the sand bottom; that is, melt it as cold as possible; drop the damper quite close before the iron is all melted, dry the iron as expeditiously as may be, with a large quantity of water; and, lastly, proceed to ball in a proper number of 'young' balls; the result will be a very inferior quality of manufactured iron. On the other hand, to produce a malleable iron of very superior quality, first charge the furnace with good forge pig-iron, adding, if required, a sufficiency of flux, increasing or diminishing the same in proportion to the quality and nature of the pig-iron used. Secondly, melt the iron to a boiling consistency. Thirdly, clear the iron thoroughly before dropping down the hamper. Fourthly, keep a plentiful supply of fire upon the grate. Fifthly, regulate the draught of the furnace by the damper. Sixthly, work the iron into one mass, before it is divided into balls; when thus in balls, take the whole to the hammer as quickly as possible, after which roll the same into bars. The bars being cut into lengths, and piled to the desired weights are then heated in the mill furnace, welded and compressed by passing through the rolls, and thus finished for the market. In this way, from the pig to the finished mill bar, one entire process that of the refinery, is saved. Mr. Hall states that, by his process, he can obtain malleable iron of any character (premising that the ores from which the pig is smelted are of good quality), from the softness of lead to the hardness of steel, and further that he can exhibit different qualities in the same bar, one end being crystalline, nearly as brittle as glass, the other end equal to the best iron that can be produced for fibre and tenacity, while the middle exhibits a character approximating to both; and, as a further illustration of the excellence of the iron that may be made by the 'pig-boiling' process, he refers to a specimen in the Geological Museum, Jermyn Street, London, labelled 'Specimen of two-and-a-quarter inch round iron, tied cold, manufactured at the Bloomfield Ironworks, Tipton, Staffordshire.' This specimen has been called a 'Staffordshire knot'; it was made from a bar 2¼ inches in diameter, and nearly 7 inches in circumference: also to a 'Punched Bar,' ½ inch thick, made at one process for the smithy, commencing with a ½-inch punch, and terminating with one 6½, without exhibiting the slightest fracture.

Mr. Hall was led to the discovery of the 'boiling' principle, by noticing the exceedingly high fusion which took place on subjecting puddling-furnace slag to a high degree of heat, and the excellence of the bloom of iron produced by the operation: it occurred to him, that if such good iron could be made from cinder alone, a very superior product ought to be obtained from good pig-iron, with equally good fluxes, and the result of experiments fully answered his expectation, though for a long time he was unable to make his discovery practically useful, on account of the difficulty of getting furnaces constructed capable of rendering the intense heat required and the corroding action of the fluxes. Puddling furnaces were then made of brick and clay, with sand bottoms. He succeeded at last, by lining the interior of the furnace with iron, and protecting them with a coating of prepared tap cinders.

In America the 'puddling' and 'boiling' processes are both in use. Overman gives preference to the latter as being the most profitable, but it can only be employed to a limited extent for lack of cinder; in a rolling-mill forge, therefore, half the furnaces are employed for boiling, and half for puddling, the latter supplying cinder for the former. In the eastern States, where the fuel is anthracite, double puddling furnaces are employed, and a blast is used, the incombustibility of this variety of coal rendering it impossible to get the requisite heat merely by the draught of the chimney. *Fig.* 1262 represents an anthracite furnace bisected vertically through the grate, hearth, and chimney. It differs from the ordinary puddling furnace chiefly in the greater depth of the grate, which is made to contain from 20 to 24 inches of coal, and in the lesser height of the chimney, which, as a blast is employed, need only be sufficiently high to carry the hot gases out of the furnace; the letters *a*, *a*, *a*, *a*, *a*, indicate the position of the iron cross binders, which serve to bind together the cast-iron plates of the enclosure, and to prevent the sinking of the roof from the expansion and contraction of the brickwork.

1262



The blast machines are fans, the best form of which is shown in *fig.* 1263 (*Overman*). The wings of this fan are encased in a separate box; a wheel is thus formed, which rotates in the outer box; the figure shows a horizontal section through the axis. The wings are thus connected, and form a closed wheel, in which the air is whirled round, and thrown out at the periphery. The inner case, which revolves with the wings, is fitted as closely as possible to the outer case, at the centre near *a*, *a*, *a*, *a*. The speed of the wings is sometimes as much as 1,800 revolutions per minute. The motion of the axis is produced by means of a leather or India-rubber belt and a pulley. This variety of fan is used at the puddling furnaces at Ebbw Vale, where the fuel is small coal.

1263

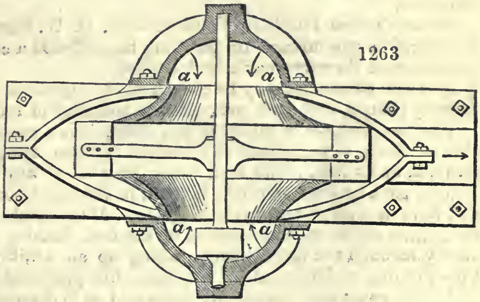


Fig. 1264 is a horizontal section of the double anthracite puddling furnace. The grate measures 3 feet by 5. The width of the furnace externally is from 5½ to 6 feet. The hearth is usually 6 feet in length. It has two work-doors, one directly opposite the other. Two sets of workmen are required, therefore, at the same time; double the quantity of metal is charged, and the yield is twice that of a single furnace; the economy is in the room, fuel, and labour; one good puddler only being required to manage the operation. Double puddling furnaces are also used in several works in England; but as Mr. Truran observes, the economical advantages attending them in point of fuel are lost if the puddlers do not work well to time: they must bring their heats to the respective stages simultaneously, for if one is kept waiting for a short period by the other, the loss of iron more than balances the reduced consumption of coal. The difficulty of obtaining men who will work well in concert has operated against the use of the double furnace, which would otherwise certainly supersede the

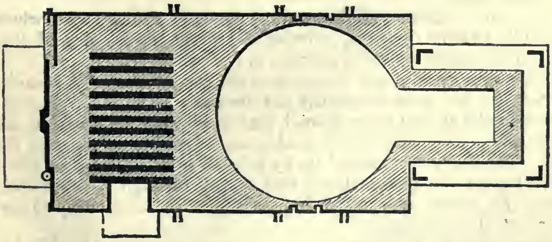
1264



single; as, combined with the process of running the iron in liquid from the blast-furnace, the consumption of fuel is under the one-half of the quantity demanded with single furnaces.

Puddling furnaces are sometimes constructed with what are called 'water boshes.' The hearth is surrounded with heavy cast-iron plates, in which is formed a passage of 1 inch or 1½ inch bore, through which a current of cold water is caused to flow, the object being to protect the furnace from the destructive action of the heat and cinder. Overman found such furnaces to work well with fusible metal such as is produced from a heavy burden on the blast-furnace, or from ores containing phosphorus; but with iron requiring a strong heat, such as results from a light burden on the blast-furnace, or when it contains impurities firmly and intimately combined, puddling furnaces with cooled boshes failed to make good malleable iron.

We do not know whether the iron manufacturers in England will assent to the following proposition, laid down by the American metallurgist, viz:—'That the smaller the amount of coal consumed, or the lower the temperature of the hearth in the blast-furnace, the better will be the quality of the metal; that is, the more fit it will become for improvement in the puddling furnace. The advantage of heavy burden in the blast-furnace is not only that it reduces the first cost of the metal, but makes a far superior article for subsequent operations. The worst cold-short, or sulphurous metal, smelted by a low heat, is quite as good as the best metal from the best ore smelted by a high temperature.' Whatever may be thought of the latter part of this quotation, no iron manufacturer will deny that careful attention to the blast-furnace is the best security of success in the puddling furnace, and that success in the one is in proportion to the economy observed in relation to the other.

Siemens's Gas Puddling Furnace.—Mr. C. W. Siemens in the application of his regenerative gas-furnace to puddling has effected a considerable improvement. His process must therefore be fully described.

It is thought that it may be convenient to reproduce the figure in section of the gas-furnace from p. 599, as it prevents the necessity of referring back to that article.

The gas-producer is shown in *fig.* 1265; it is a rectangular fire-brick chamber, one side of which, B, is inclined at an angle of from 40° to 60°, and is provided with a grate, C, at its foot. The fuel, which may be of any description. such as coal, coke, lignite, peat, or even sawdust, is filled in through a hopper, A, at the top of the incline, and falls in a thick bed upon the grate. Air is admitted at the grate, and in burning, its oxygen unites with the carbon of the fuel, forming carbonic acid gas, which rises slowly through the ignited mass, taking up an additional equivalent of carbon, and thus forming carbonic oxide. The heat thus produced distils off carburetted hydrogen and other gases and vapours from the fuel as it descends gradually towards the grate, and the carbonic oxide already named diluted by the inert nitrogen of the air and by any small quantity of unreduced carbonic acid, and mixed with these gases and vapours distilled from the raw fuel is finally led off by the gas-flue to the furnace. The ashes and clinkers that accumulate in the grate are removed at intervals of one or two days.

E is a pipe for the purpose of supplying a little water to the ashpit, to be decomposed as it evaporates and comes in contact with the incandescent fuel, thus forming some hydrogen and carbonic oxide, which serve to enrich the gas; G is a small plug-hole, by which the state of the fire may be inspected, and the fuel moved by a bar if necessary; and D is a sliding damper by which the gas-producer may be shut off at any time from the flue.

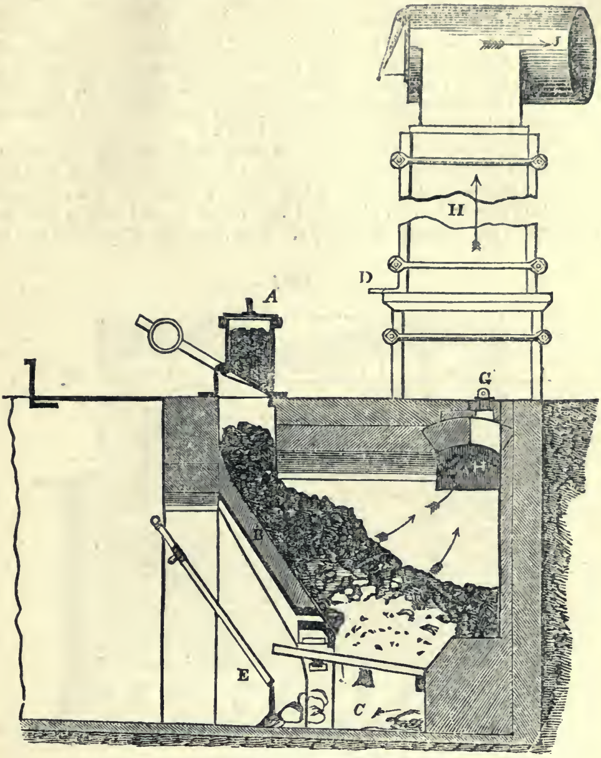
It is necessary to maintain a slight outward pressure through the whole length of the gas-flue leading to the furnaces, in order to prevent the burning of the gas in the flue through the indraught of air at crevices in the brickwork.

Where the furnaces stand much higher than the gas-producers, the required pressure is at once obtained; but more frequently the furnaces and gas-producers are placed nearly on the same level, and some special arrangement is necessary to maintain the pressure in the flue. The most simple contrivance for this purpose is the 'elevated cooling tube.' The hot gas is carried up by a brick stack, H, to a height of 8 or 10 feet above the top of the gas-producer, and is led through a horizontal sheet-iron cooling-tube, J, (*fig.* 1265), from which it passes down either directly to the furnace, or into an underground brick flue.

The gas rising from the producer at a temperature of about 1000° Fahr., is cooled as it passes along the overhead tube, and the descending column is consequently denser and heavier than the ascending column of the same length, and continually overbalances it. The system forms, in fact, a siphon in which the two limbs are of the usual length, but the one is filled with a heavier gaseous fluid than the other.

In erecting a number of gas-producers and furnaces the inventor generally prefers to group the producers together, leading the gas from all into one main flue, from which the several furnaces draw their supplies.

1265



The puddling furnace, proper, is shown in *figs.* 1266, 1267, and 1268.

1266

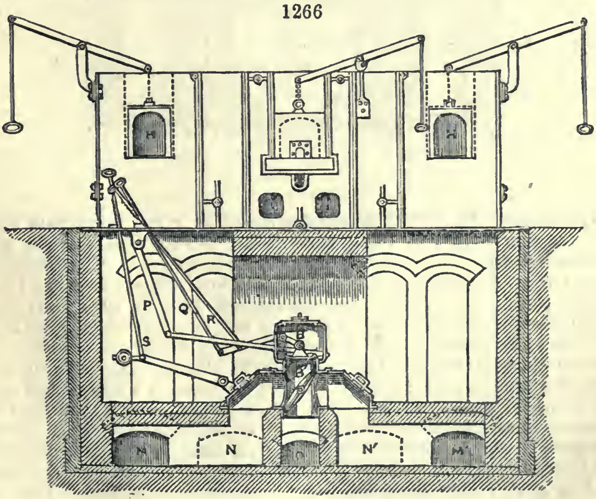


Fig. 1266 is a front elevation of the furnace, showing the gas reversing valve and flues in section.

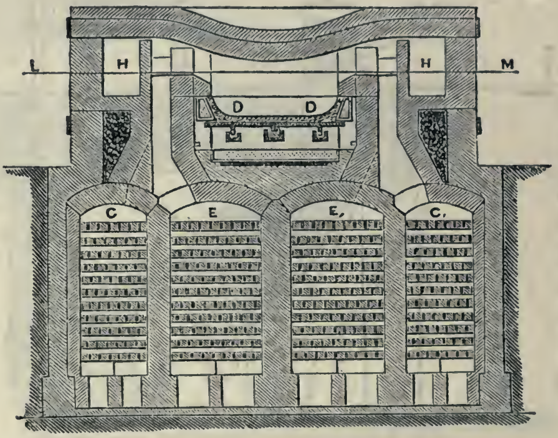
Fig. 1267 is a longitudinal section at A, B, C, D (*fig.* 1268).

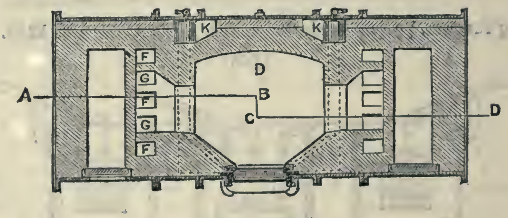
Fig. 1268 is a sectional plan at L, M (*fig.* 1267).

The peculiarity of the regenerative gas-furnace, as applied either to puddling, or to any other process in which a high heat is required, consists in the utilisation *in the furnace* of nearly the whole of the heat of combustion of the fuel, by heating the entering gas and air by means of the waste heat of the products of combustion, after they have left the furnace, and are of no further use for the operation being carried on. The waste heat is, so to speak, intercepted on its passage to the chimney, by means of masses of fire-brick stacked in an open or loose manner in certain chambers, called 'regenerator chambers,' C, E, E^1, C^1 (*fig.* 1267).

On first lighting the furnace the gas passes in through the gas regulating valve, B (*fig.* 1266), and the gas reversing valve, B^1, and is led into the flue, M, and thence into the bottom of the regenerator chamber, C (*fig.* 1267); while the air enters through a corresponding 'air reversing valve,' behind the valve B^1, and passes thence through the flue, N, into the regenerator chamber, E. The currents of gas and air, both quite cold, rise separately through the regenerator chambers, C and E, and pass up through the flues, G, G, and F, F, F (*fig.* 1268), respectively, into the furnace above, where they meet and are lighted, burning and producing a moderate heat. The products of combustion pass away through a similar set of flues at the other end of the furnace into the regenerator chambers, C^1, E^1, and thence through the flues, M^1, N^1, and through the gas and air reversing valves, into the chimney flue, O. The waste heat is thus deposited in the upper courses of open fire-brick work filling the chambers, C^1, E^1, so heating them up, while the lower portion, and the chimney flue, are still quite cool; then, after about an hour, the reversing valves, B^1 (through which the air and gas are admitted to the furnace), are reversed, by means of the levers, P, and the air and gas enter, through those regenerator chambers, E^1, C^1, that have just been heated by the waste products of combustion, and in passing up through the open brickwork they become heated, and *then* on meeting and entering into combustion in the furnace, D, D, they produce a very high temperature, probably 500° Fahr. higher than when admitted cold; the waste heat from such *higher temperature of combustion* heating up

1267





1268

the previously cold regenerator chambers, C, E, to a correspondingly higher heat. After about an hour's work the reversing valves, B^1, are again reversed, and the air and gas enter the first pair of regenerator chambers, C, E, but which are now very hot, and therefore the air and gas become very hot, and enter the furnace in this state, meeting and entering into combustion, and thus producing a still higher temperature, *probably* 500° *higher still,* and again heating the second pair of regenerator chambers, C^1, E^1, *so much higher,* which enables them to again heat the air and gas to a still higher degree, when the valves, B^1, are again reversed. Thus an *accumulation* of heat and an accession of temperature is obtained, step by step, so to speak, until the furnace is as hot as is required; for unless cold materials are put in to be heated, and thus abstract heat, the temperature rises as long as the furnace holds together, and the supply of gas and air is continued. The heat is at the same time so thoroughly abstracted from the products of combustion by the regenerators that the chimney flue remains always quite cool. The command of the temperature of the furnace and of the quality of the flame is rendered complete by means of the gas and air regulating valves shown at B in *fig.* 1266, and by the chimney damper. These are adjusted to any required extent of opening by the notched rods Q, R, and S, (*fig.* 1266) respectively, so that having the power of producing as high a temperature as can be desired, there is also the power of varying it according to the requirements in each case.

The bed of the furnace D D (*fig.* 1267), is of the ordinary construction, formed of iron plates, and is provided with water-bridges at the ends, as shown, to protect the 'fettling' (or oxide of iron used for lining the furnace) from being melted away. The overflow from one of the water-bridges is led into a sheet-iron tank below the bed, and then away. The evaporation from this tank keeps the bottom plates cool and preserves the cinder covering them from melting off, and the steam is carried away by a draught of air entering through two holes, I, I (*fig.* 1266), below the tap-hole, and passing off by small ventilating shafts K, K (*fig.* 1268), at the back of the furnace.

A heating chamber, H (*fig.* 1267), is arranged at each end of the furnace, in which the charge of pig-iron may be heated to redness before it is introduced into the puddling chamber, D, D.

The advantages of this furnace for puddling, are that the heat can be raised to an almost unlimited degree; that the flame can be made at will oxidising, neutral, or reducing, without interfering with the temperature; that indraughts of air and cutting flames are avoided; and that the gas fuel is free from ashes, dust, and other impurities, which are carried into an ordinary puddling furnace from the grate. In this last respect the new furnace presents the same advantages as puddling with wood.

The ordinary furnace received charges of 484 lbs. each, and yielded on an average 426 lbs., representing a loss of 12 per cent., whereas the gas-furnace received charges averaging 424 lbs., and yielded 413 lbs., representing a loss of less than 2·6 per cent.

It is important to observe, moreover, *that the gas-furnace turned out eighteen heats in three shifts per* 24 *hours,* instead of only 12 heats per 24 hours, which was the limit of production in the ordinary furnace.

This rate of working was attained without the employment of any arrangement for heating the pig-iron before charging it into the furnace, the heating chambers at the ends not having been used. The adoption of the plan of heating the metal beforehand, a system already extensively in use both in this country and on the Continent, effects a further saving of 10 to 15 minutes in the time required for working each charge, as well as a considerable economy in fuel.

The quality of the iron produced from the gas-furnace was proved decidedly superior to that from the ordinary furnace, being what is technically called *best best* in the one, and *best* in the other case, from the same pig.

The economy of fuel was greatly in favour of the gas-furnace. The saving of fuel in puddling cannot be less than 40 to 50 per cent. in quantity, while a much cheaper quality may be used.

The composition of 'fettling' was, however, greater in the gas-furnace, and the superior yield was naturally attributed by the forge managers to that cause.

By the use of the water-bridge the amount of 'fettling' required is reduced to an ordinary proportion, the average quantity of red ore used being 92·6 lbs. per charge, besides the usual allowance of bull dog, while the yield per charge of 483·3 lbs. of grey forge pig has been increased to 485 lbs. of puddled bar.

Danks's Revolving Puddling Furnace.—It appears that experiments were first commenced by Mr. Samuel Danks in May 1868, in the Cincinnati Railway Works. In 1869, the first experiments being successful, other revolving furnaces were set to work, and in 1870 they were generally adopted in those works. In a little time several iron producing companies in America being convinced of the advantages of Danks's process, adopted his revolving furnace for puddling. The following description by Mr. Samuel Danks will fully explain the arrangements of his puddling furnace.

The furnace has a fire-grate, in outward appearance like the ordinary puddling furnace, but it differs from this considerably in several particulars. It has a fan blast under the grate to urge the fire and produce gas. It has also jets of fan blast *over* the fire, injected for the purpose of ensuring the more perfect combustion of the fuel. This blast is regulated by a valve, by which the workman has a perfect control of the quantity of gas produced and consumed, and he is thus enabled to make the temperature suit the requirements of the charge in the different stages of the puddling process. The ashpit and fire-hole are closed by doors to prevent the escape of the blast through the fire, and the fire-hole has a coil of wrought-iron water-pipe cast into it, for the purpose of allowing a stream of water to circulate around it to keep it cool. The bridge-plate between the fire and the charge of metal has also a coil of water-pipe cast into it for the same purpose. It has a lining of fire-brick on the side next to the fire, and a covering of fettling on the side next to the charge. It also has a course of fire-brick on the top, and is thus perfectly protected on all sides. Fastened on to the bridge-plate is a ring with a flat surface on one side, which ring has a pipe or pipes cast into it, and is made in one piece or in sections. The pipes are for the purpose of admitting water to keep the ring cool, and the flat face is the part that the end of the revolving furnace rubs against, and forms a butt joint. This face should be cast on a metal chill to harden the part exposed to abrasion from the end of the revolving chamber rubbing against it.

The revolving chamber is made of two end-pieces, so formed as to be banded with wrought-iron bands, and to have detachable rings on the part most exposed to the fire. It rests on carrying rollers, to allow its free rotation. It has also suitable ribs for strengthening it, and holes for rivetting the rings and staveplates upon it. These two ends are connected together by a series of staveplates to form a cylinder, and are of suitable length according to the desired size of the chamber. They have hollow ribs, running longitudinally, which serve the double purposes of holding the fettling and keeping it cool, and when rivetted together, form an open-ended cylinder, one end of which butts against the ring that is fastened to the bridge-plate, where the gases are admitted over the bridge from the grate, and the other open end serves the purpose of a doorway for the reception of the charges of metal, and for their removal; also for the escape of the products of combustion through a moveable head-piece which connects the revolving chamber and the chimney. This moveable piece answers the purpose both of door and flue. It can be moved at pleasure by means of a suitable apparatus overhead, and when in its place for puddling, the escaping gases pass through it into the stationary flue, and from thence to the chimney or boiler. When it is removed for the introduction or removal of the charge, the end of the revolving chamber is open, and balls of great weight can be very readily removed. When the moveable piece is adjusted for puddling, it is held in position by suitable props. It has also an arrangement of water-pipes for keeping it cool, and a stopper-hole in front, so that the operations going on inside can be seen at all times.

The vessel is made to revolve by means of a toothed wheel, fixed longitudinally upon it. A suitable engine is attached to each machine, so that the chamber can be made to revolve at any speed that may be required according to the different stages of the operation.

The chamber is lined in the following manner:—The 'initial' lining is composed of a mixture of pulverised iron ore and pure lime, worked with water into the consistency of a thick paste. About one-third of the inner surface of the chamber is covered with this mortar in a layer projecting about one inch over the hollow ribs. After about four hours, the first part of the lining, as described, will be found hard, and in the same way the remaining parts are filled in and are allowed to set. The furnace is then ready to receive the fettling. About one-fifth of the whole quantity required in the shape of pulverised iron ore is thrown in upon the above-mentioned lining. The furnace is heated up, and is made to revolve slowly until the iron ore is found to be completely melted. The apparatus is then stopped, and that part of the molten iron ore, which has not been consumed by glazing the 'initial' lining surface, runs to the lowest level of the furnace, and there forms a pool, into which there are put a number of small and large lumps of iron ore, of such dimensions as will be required to allow the said lumps to project over the surface of the liquid ore by from two to six inches. This first part of the fettling is allowed to set when a fresh quantity of pulverised ore is thrown in. The furnace is again made to rotate slightly until the newly-added ore is liquefied, when the apparatus is again stopped, and the pool is filled with lumps as before. In this manner the whole of the inner surface is gradually fettled, and care is taken to regulate the position of each pool so that the vessel or apparatus shall at all times find itself properly balanced. From 2 to 2½ tons of iron ore are required to fettle a 700-lb. rotary furnace. Rather more than the ordinary quantity of hammer or rolled cinder is used, and upon that the iron is charged either in a solid or molten condition. When charged in the shape of pig-iron, the melting-down occupies from 30 to 35 minutes, during which a partial rotation is given to the furnace from time to time in order to expose equally all sides of the charge to the flame. When the whole of the charge is thoroughly melted, the furnace is made to revolve once or twice per minute only during the first five or ten minutes, in order to obtain the most perfect action of the cinder upon the molten iron. A stream of water is injected through the stopper-hole along and just above the line of contact between the floating cinder and the inner surface of the vessel on the descending side. A certain portion of uncontaminated cinder is thereby solidified on the metal surface, and is carried down into or below the bath of molten iron in a continuous stream, which, in rising up through the iron, combines with the impurities of the latter in a far more effectual and complete manner than any mode of puddling hitherto known can effect. On the expiration of the said five or ten minutes, the iron begins to thicken, and the motion is stopped. The heat is then raised, so that the cinder shall be perfectly liquefied, and thereby float over the iron. That cinder contains all the impurities which have been liberated from the charge, and it is essential to prevent its further contact with the iron. The vessel is therefore brought into such a position that the tap-hole shall be just over the level of the iron, which by this time has become partly pasty. The puddler gently pushes back the iron, and the cinder is made to run off. The tap-hole, by a slight motion of the vessel, is then brought high enough over the level of the iron, and is stopped up. The heat is again raised, and the furnace is put in motion at a velocity of from six to eight revolutions per minute, by which means the charge is dashed about violently in the furnace. Should a sufficient degree of decarburisation not have been produced at that point of the operation, then the liquidity which the iron will assume under the increased temperature will prove the fact. A high temperature being kept up, and the charge being continually turned over, the particles begin to adhere when the velocity of the apparatus is lowered to from two to three revolutions per minute, upon which the ball then very speedily forms. Should any loose pieces be detected in the furnace, the puddler moves them all to the same side of the ball, and by giving a partial rotation to the furnace he causes the ball to fall upon them, and thereby forms them into one mass. The puddler solidifies the front end of the ball by a few blows from a tool applied through the stopper-hole. The props of the moveable piece are then removed, and the flue hanging from the overhead rail is moved away. A large fork suspended from a crane is moved into the vessel along one side, and the ball, which by a turn of the vessel is rolled on to the fork, is then removed by means of a crane. The ball is then worked in a squeezer. The requisite quantity of cinder and metal is again charged. The flue is replaced, and the process continued. From eight to ten charges are made before any re-fettling is required, when the parts most worn are repaired. The bloom comes from the squeezer in a very solid condition, and is either reheated, or rolled off into puddled bar, &c., at once.

The inventor claims for his revolving furnace the following advantages:—A great saving in the cost of labour, and also in the consumption of coal, varying according to the size of the furnace; a superior and more regular quality of puddled iron from a given quality of pig; a yield of puddled iron much in excess of the charge of pig-metal, instead of the usual loss, the extra yield being obtained by the reduction of the rich fettling used in the machine; eight to ten heats, whether from 5 to 10 cwts. are made in a day of ten hours when suitable metal is used; the refining process is very complete, the whole of the phosphorus and silica and the sulphur, to a large extent, being removed by the chemical action of the lining mixture; the very heavy and exhaustive labour of puddling is performed by steam-power, thereby enabling one skilled man to attend to the working of a large quantity of iron; the bringing to nature and balling of the iron are completed by the rotary action without the use of rabbling, except when the heat has to be divided into smaller balls; and the capacity may be suited for heats of any weight from 5 cwts. upwards. The cost of the furnace, weight of product considered, is about the same as that of the usual hand-puddling furnaces.

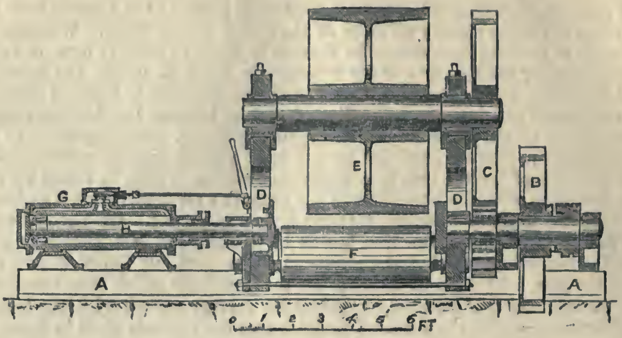
It is almost needless to say that the existing arrangements for hammering and rolling puddled iron would not be suitable where such large masses of metal have to be dealt with. In proportion as the subsidiary appliances are carried out upon a proper scale, so will be the advantageous results obtained from the puddling apparatus.

On this account the drawings of the 'Squeezer,' recommended by Mr. Danks has been introduced into these pages.

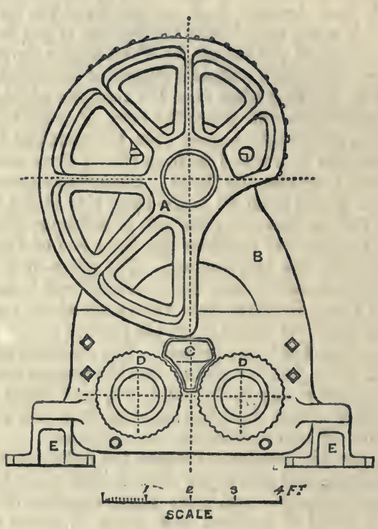
Squeezer.—Fig. 1269 is a front sectional elevation, showing a section of the steam-hammer or ram; a section of the squeezer-cam and roll; housings, bed-plate, and driving gear wheels.

Fig. 1270 is a section of squeezers, showing the squeezer-cam, rolls, the head of

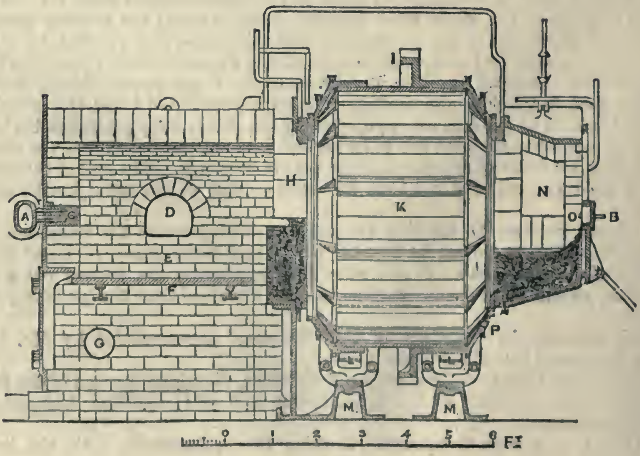
1269



1270



1271



steam-ram, housing, and the ends of bed-plates. A is the squeezer-cam; B, the housing; C, the head of steam-ram; D D, the rolls; and E E, the ends of bed-plates.

The following is a description of the drawings of Danks's improved revolving puddling furnace:—

Fig. 1271 is a sectional elevation of the furnace, showing the fire-grate, E; wind jet pipes G, which convey fan-blast into the fire-chamber over the fire, for the purpose of effecting as perfect a combustion of the gases as is desirable, producing a quick and intense heat; H, is the passage for gases; I, the gear-holder. The bridge is shown, with the plate having water-pipes passing through it, protected on the one side with fire-brick, and on the other with fettling. The revolving chamber, K, is also shown; with the tapping-hole, B; carrying-rollers, L; also the ends of bed-plates, M M; and moveable piece, N; with stopper-hole, B, which latter is suspended from an overhead tract.

Fig. 1272 is an end view, showing the arrangement of bed-plate, C; carrying-rollers and gear-wheels, upon a pillar-block, B; also an end view of the revolving chamber, supported by standard, A, with a section of fettling; a portion of the fire-bridge is also shown.

1272

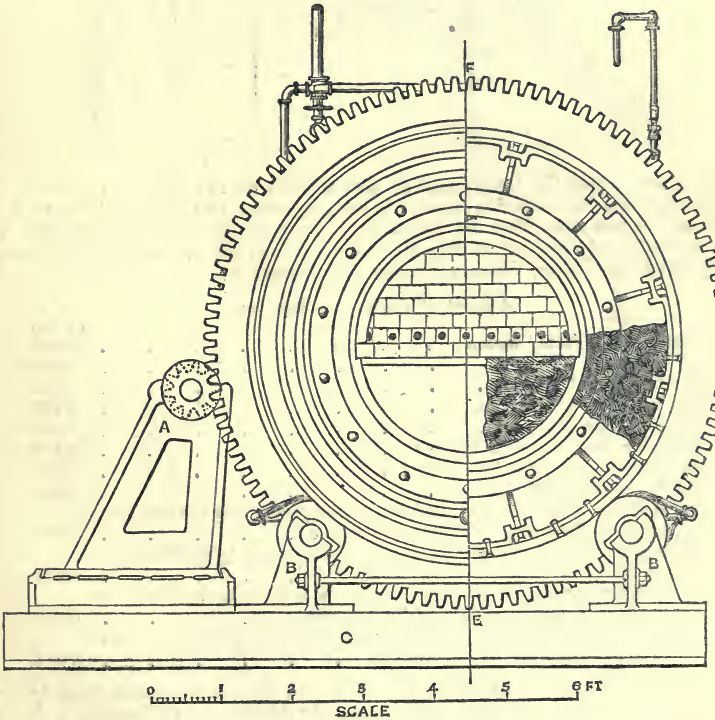


Fig. 1273 presents a front view of the furnace, showing the moveable piece, C; with its stopper-hole, D; props, E E; arrangements and water-pipes, F F; rods and swivels for suspending the moveable piece, G G; stationary flue, B; and chimney-stack, A.

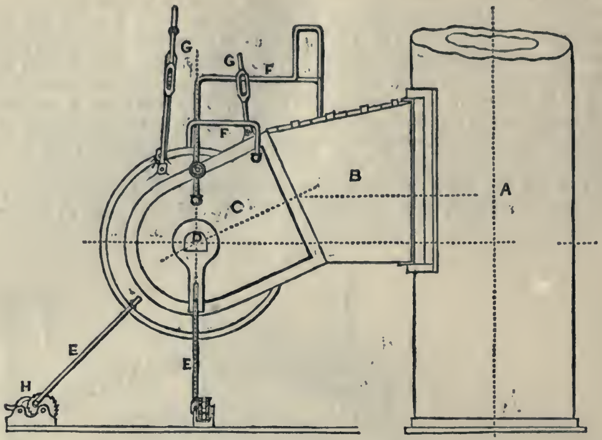
In the autumn of 1856 the attention of ironmasters was powerfully excited by a proposal from Mr. Bessemer to manufacture malleable iron and steel from crude iron, without fuel. The first experiment was only partially successful, but Mr. Bessemer, conscious of the correctness of his principle, pursued his investigations with undiminished zeal, and the result was that he was rewarded by the most decided success. See STEEL.

One of the objections urged against the Bessemer process was, that the high temperature to which the iron was subjected destroyed its fibrous character.

It is more than probable that iron containing only 0·05 per cent. of carbon has almost lost the property of becoming fibrous by any treatment; for, without going so far as to assert that the development of fibre depends on the presence of carbon, or that carbon exercises a specific function in bringing about this molecular condition of the iron, analysis shows that the toughest and most flexible bar-iron contains a far larger quantity of carbon than that above indicated, as will be seen by the following analyses by Gay-Lussac, Willson, Karsten, and Bromeis :—

1273



Amount of Carbon in Bar-Iron.

	Carbon
Best bar-iron from Sweden	0·293
Do. do.	0·240
Bar-iron from Creusot	0·159
Bar-iron from Champagne	0·193
Bar-iron from Berry	0·162
Cold-short bar-iron from Moselle	0·144
Soft bar-iron analysed by Karsten	0·200
Hard bar-iron by Karsten	0·500
Three different varieties produced from white pig-iron by the Swabian method of refining, analysed by Bromeis	0·318

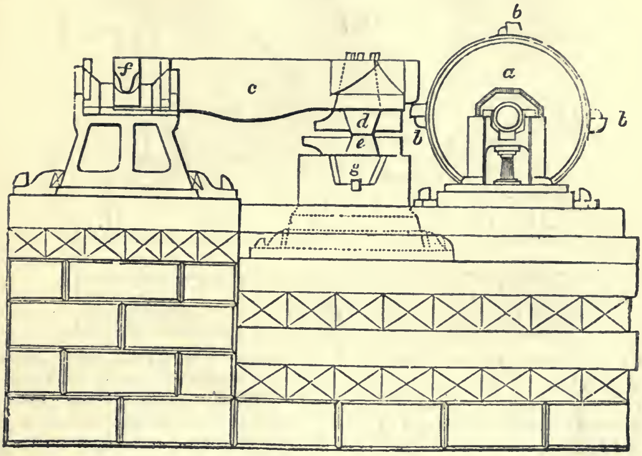
Machines for Forging and Condensing Iron.—To prepare the puddle balls for the rolling mills, they have to undergo the process of 'shingling,' or 'blooming'; this is effected either by the hammer or by the squeezer: the latter has almost entirely superseded the former, as it effects the object at less cost, though, perhaps, with hardly such good results as to quality. These mechanisms are moved either by steam-engines or by water-wheels. We shall offer some details concerning them.

The main driving-shaft usually carries at either end a large toothed wheel, which communicates motion to the different machines through smaller toothed wheels. Of these there are commonly six, four of which drive four different systems of cylinders, and the two others work the hammer and the shears. The different cylinders of an iron work should never be placed on the same arbor, because they are not to move together, and they must have different velocities according to the diameter. In order to economise time and facilitate labour, care is taken to associate on one side of the motive machine the hammer, the shears, and the reducing cylinders, and on the other side to place the several systems of cylinders for drawing out the iron into bars. For the same reason, the puddling furnaces ought to be grouped on the side of the hammer, and the reheating furnaces on the other side of the works.

The hammers, *fig.* 1274, are made entirely of cast iron; they are nearly 10 feet long, and consist usually of two parts, the helve *c*, and the head or pane *d*. The latter enters with friction into the former, and is retained in its place by wedges of iron or wood. The head consists of several faces or planes receding from each other, for the purpose of giving different forms to the ball lumps. A ring of cast iron, *a*, called the *cam-ring bag*, bearing moveable cams, *b b*, drives the hammer, *d*, by lifting it up round its fulcrum, *f*, and then letting it fall alternately. In one iron work this ring was found to be 3 feet in diameter, 18 inches thick, and to weigh 4 tons. The weight of the helve (handle) of the corresponding hammer was 3½ tons, and that of the head of the hammer 8 cwts.

1274



The anvil, *e*, consists also of two parts; the one called the pane of the anvil, is the counterpart of the pane of the hammer; it likewise weighs 8 cwts. The second, *g*, named the stock of the anvil, weighs 4 tons. Its form is a parallelopiped, with the edges rounded. The *bloom* or rough ball, from the puddle-furnace, is laid and turned about upon it, by means of a rod of iron welded to each of them, called a *porter*. Since the weight of these pieces is very great, and the shocks very considerable, the utmost precautions should be taken in setting the hammer and its anvil upon a substantial mass of masonry, as shown in the figure, over which is laid a double, or even quadruple, flooring of wood, formed of beams placed in transverse layers close to each other. Such beams possess an elastic force, and thereby partially destroy the injurious reaction of the shock. In some works a 6-feet cube of cast iron is placed as a pedestal to the anvil.

Forge-hammers are very frequently mounted as levers of the first kind, with the centre of motion about one-third or one-fourth of the length of the helve from the cam-wheel. The principle of this construction will be understood by inspection of *fig.* 1275. The short end of the lever, which is struck down by the tappet, 6, is driven against the end of an elastic beam, *t*, and immediately rebounds, causing the long end to strike a harder blow upon the anvil, *s*.

1275

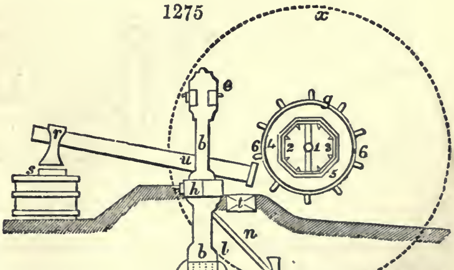


Fig. 1275 is the German forge-hammer; to the left of 1 is the axis of the rotatory cam, 2, 3, consisting of eight sides, each formed of a strong broad bar of cast iron, which are joined together to make the octagon wheel. 4, 5, 6, are cast-iron binding-rings or hoops made fast by wooden wedges; *b*, *b*, are standards of the frame-work, *e*, *l*, *m*, in which the helve of the forge-hammer has its fulcrum near *u*; *h*, the sole-part of the frame;

another cast-iron base or sole is seen at m; n is a strong stay, to strengthen the frame-work; at r two parallel hammers are placed, with cast-iron heads and wooden helves; s is the anvil, a very massive piece of cast iron; t is the end of a vibrating beam, for throwing back the hammer forcibly from it by recoil; x, y, is the outline of the water-wheel which drives the whole. The cams or tappets are shown mounted upon the wheel, 6, g, 6.

Squeezers are machines which condense a ball by pressure. They are either single or double; their construction will be readily understood from *fig.* 1276, which represents a single level-squeezer of the simplest construction: the bed-plate, *a*, is cast in one piece; it is 6 feet long, 16 inches wide, and 12 inches high. The whole is screwed down on a solid foundation of stone, brick, or timber: *b* is the moveable part, which makes from 80 to 90 motions per minute. The motion is imparted by the crank *c*, which in turn is driven by means of a strap and pulley by the elementary power. The diameter of the fly-wheel is from 3 to 4 feet. The anvil *d* is about two feet in length and from 12 to 14 inches in width; it is a moveable plate, at least 3 inches thick, which if injured can be replaced by another; the face of the working part of the lever exactly fits the anvil, and consists of plates attached by means of screws. It is desirable to have all these face plates in small parts of 8 or 10 inches in width, by this means they are secured against breaking by expansion and contraction. The whole machine, including the crank and everything, is made of cast iron, and weighs from 4 to 5 tons. According to Overman this machine is both cheap and durable, and will squeeze 100 tons of iron per week.

1276

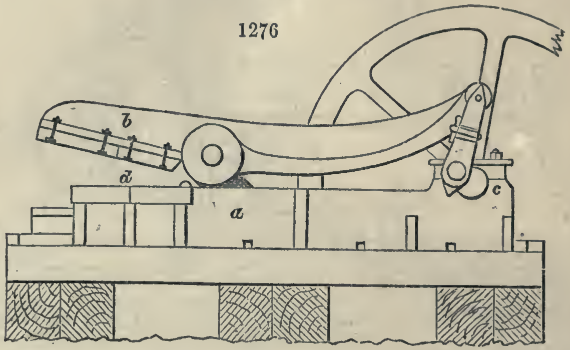

Fig. 1277 represents the double squeezer, employed at many English iron works. The drawing is taken from a machine at the Dowlais Iron Works, figured in Mr. Truran's work. Many other forms are in use.

1277

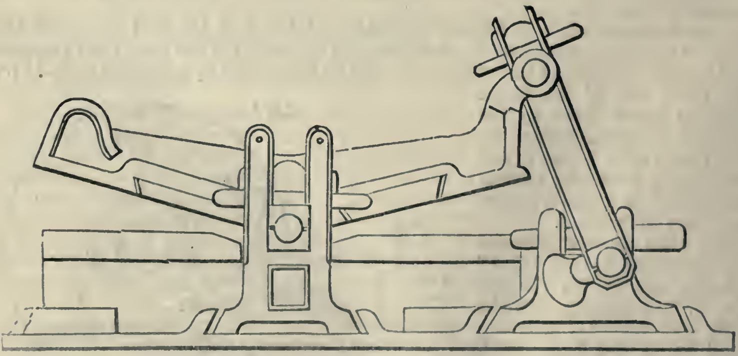

Fig. 1278 represents Brown's patent bloom squeezer. The heated ball of puddled iron K, thrown on the top is gradually pressed between the revolving rollers as it descends, and at last emerges at the bottom, where it is thrown on to a moveable 'Jacob's ladder,' by which it is elevated to the rolls. This machine effects a considerable saving of time, will do the work of 12 or 14 furnaces, and may be constantly going as a feeder to one or two pairs of rolls. There are two distinct forms of this machine; in the one figured the bloom receives only two compressions; in another, which is much more effective it is squeezed four times before it leaves the rolls and falls upon the Jacob's ladder. Another form of squeezer is shown in *fig.* 1279.

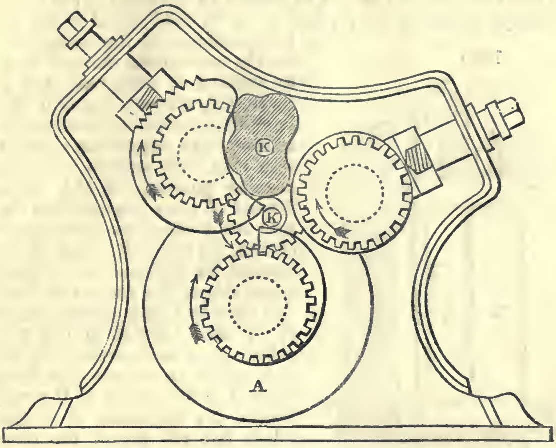
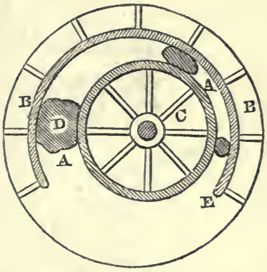
1278



1279



A table A A with a sledge rising up from it to a height of about 2 feet, so as to form an open box, is firmly imbedded in masonry; within this is a revolving box, C, of similar character, much smaller than the last, and placed excentrically in regard to it. The ball or bloom D is placed between the innermost revolving box C and the outer case A A, where the space between them is greatest, and is carried round till it emerges at E, compressed and fit for the rolls.

Cylinders.—The compression between cylinders now effects, in a few seconds, that condensation and distribution of fibres, which 40 years ago could not be accomplished till after many heats in the furnace, and many blows of the hammer. The cylinders may be distinguished into two kinds: 1, those which serve to draw out the ball, called *puddling rolls*, or roughing rolls, and which are, in fact, reducing cylinders; 2, the cylinders of extension, called *rollers*, for drawing into bars the massive iron after it has received a welding, to make it more malleable. This second kind of cylinders is subdivided into several varieties, according to the patterns of bar iron that are required. These may vary from 2 inches square to less than one-sixth of an inch.

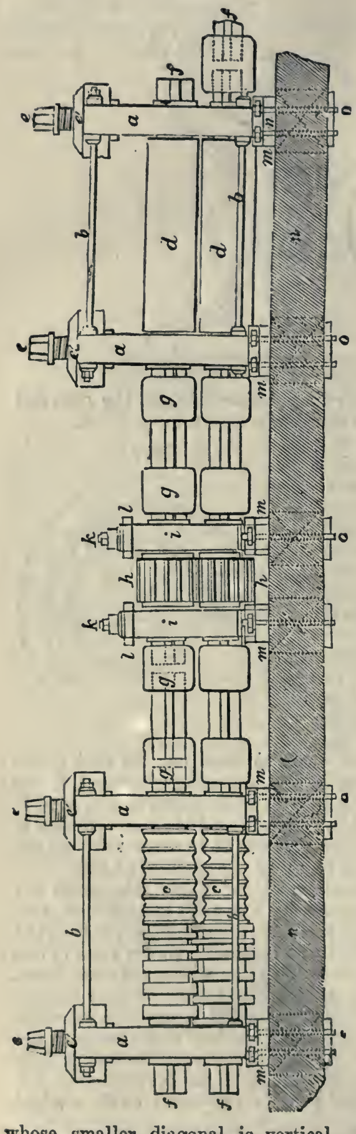
Beneath the cylinders there is usually formed an oblong fosse, into which the scoriæ and the scales fall when the iron is compressed. The sides of this fosse, constructed of stone, are founded on a body of solid masonry, capable of supporting the enormous load of the cylinders. Beams of wood form in some measure the sides of this pit, to which cylinders may be made fast, by securing them with screws and bolts. Massive bars of cast iron are found, however, to answer still better, not only because the uprights and bearers may be more solidly fixed to them, but because the basement of heavy metal is more difficult to shatter or displace, an accident which happens frequently to the wooden beams. A rill of water is supplied by a pipe to each pair of cylinders, to hinder them from getting hot; as also to prevent the hot iron from adhering to the cylinder, by cooling its surface, and perhaps producing on it a slight degree of oxidisement.

The shafts are 1 foot in diameter for the hammer and the roughing rolls; and 6 inches where they communicate motion to the cylinders destined to draw the iron into bars.

The *roughing rolls* are employed either to work out the lump or ball immediately after it leaves the puddling furnace, as in the Welsh forges; or only to draw out the piece, after it has been shaped under the hammer, as is practised in most of the

Staffordshire establishments. These roughing cylinders are generally 7 feet long, including the trunnions, or 5 feet between the bearers, and 18 inches diameter; and weigh in the whole from 4 to 4½ tons. They contain from 5 to 7 grooves, commonly of an elliptical form, one smaller than another in regular progression, as is seen in *fig.* 1280. The small axis of each ellipse, as formed by the union of the upper and under grooves, is always placed in the vertical direction, and is equal to the great axis, or horizontal axis of the succeeding groove; so that in transferring the bar from one groove to another, it must receive a quarter of a revolution, whereby the iron gets elongated in every direction. Sometimes the roughing rolls serve as preparatory cylinders, in which case they bear towards one extremity rectangular grooves, as the figure exhibits. Several of these large grooves are bestudded with small asperities analogous to the teeth of files, for biting the lump of iron, and preventing its sliding. On a level with the under side of the grooves of the lower cylinder, there is a plate of cast iron with notches in its edge adapted to the grooves. This piece, called the apron, rests on iron rods, and serves to support the balls and bars exposed to the action of the rollers, and to receive the fragments of ill-welded metal, which fall off during the drawing. The *housing frames* in which the rollers are supported and revolve, are made of great strength. Their height is 5 feet; their thickness is 1 foot in the side perpendicular to the axis of the cylinders, and 10 inches in the other. Each pair of bearers is connected at their upper ends by two iron rods, on which the workmen rest their tongs or pincers for passing the lump or bar from one side of the cylinders to the other.

1280

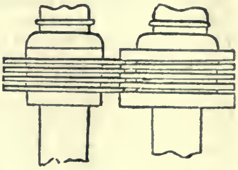


The cods or bushes are each composed of two pieces; the one of hard brass, which presents a cylindrical notch, is framed into the other which is made of cast iron, as is clearly seen in *fig.* 1280.

The iron bar delivered from the square grooves, is cut by the shears into short lengths, which are collected in a bundle in order to be welded together. When this bundle of bars has become hot enough in the furnace, it is conveyed to the rollers, which differ in their arrangement according as they are meant to draw iron from a large or small piece. The first, *fig.* 1280, possess both elliptical and rectangular grooves; are 1 foot in diameter and 3 feet long between the bearers. The bar is not finished under these cylinders, but is transferred to another pair, whose grooves have the dimensions proper for the bar, with a round, triangular, rectangular, or fillet form. The triangular grooves made use of for square iron have for their profile an isosceles triangle slightly obtuse, so that the space left by the two grooves together may be a rhombus, differing little from a square, and whose smaller diagonal is vertical. When the bar is to be passed successively through several grooves of this kind, the larger or horizontal diagonal of each following groove is made equal to the smaller or upright of the preceding one, whereby the iron must be turned one fourth round at each successive draught, and thus receive pressure in opposite directions. Indeed, the bar is often turned in succession through the triangular and rectangular grooves, that its fibres may be more accurately worked together. The decrement in the capacity of the grooves follows the proportion of 15 to 11.

When it is intended to reduce the iron to a small rod, the cylinders have such a diameter, that three may be set in the same housing frame. The lower and middle cylinders are employed as roughing rollers, while the upper and middle ones are made to draw out the rod. When a rod or bar is to be drawn with a channel or gutter in its face, the grooves of the rollers are suitably formed.

1281



To draw out square rods of a very small size, as nail-rods, a system of small rollers is employed, called *slitters.* Their ridges are sharp-edged, and enter into the opposite grooves 2½ inches deep; so that the flat bar in passing between such rollers is instantaneously divided into several slips. For this purpose the rollers represented in *fig.* 1281, may be put on and removed from the shaft at pleasure.

The velocity of the cinders varies with their dimensions. In one work, cylinders for drawing out iron of from one-third to two-thirds of an inch thick, make 140 revolutions per minute; while those for iron of from two-thirds of an inch to 3 inches, make only 65. In another work, the cylinders for two-inch iron, make 95 revolutions per minute; those for iron from two-thirds of an inch to an inch and a third, make 128; and those for bars from one-third to two-thirds of an inch, 150. The *roughing rollers* move with only one-third the velocity of the drawing cylinders.

The shingling and plate-rolling mill is represented in *fig.* 1280. The shingling mill, for converting the blooms from the balling furnace into bars, consists of two sets of grooved cylinders, the first being called *puddling rolls* or *roughing rolls*; the second are for reducing or drawing the iron into mill-bars, and are called simply *rolls.*

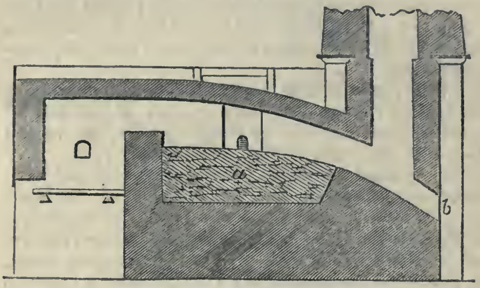
a, a, a, a, are the powerful uprights or standards called *housing frames,* of cast iron, in which the gudgeons of the rolls are set to revolve; *b, b, b, b,* are bolt rods for binding these frames together at top and bottom; *c,* are the roughing rolls, having each a series of triangular grooves, such that between those of the upper and under cylinders, rectangular concavities are formed in the circumference with slightly sloping sides. The end groove to the right of *c,* should be channelled like a rough file, in order to take the better hold of the blooms, or to bite the metal as the workmen say; and give it the preparatory elongation for entering into and passing through the remaining grooves till it comes to the square ones, where it becomes a mill-bar. *d, d,* are the smooth cylinders, hardened upon the surface, or *chilled,* as it is called, by being cast in iron moulds for rolling iron into plates or hoops. *e, e, e, e,* are strong screws with rectangular threads, which work by means of a wrench or key, into the nuts *e′ e′ e′ e′,* fixed in the standards; they serve to regulate the height of the plummer blocks or bearers of the gudgeons, and thereby the distance between the upper and under cylinders. *f* is a junction shaft; *g, g, g,* are solid coupling boxes, which embrace the two separate ends of the shafts, and make them turn together. *h, h,* are junction pinions, whereby motion is communicated from the driving shaft *f,* through the under pinion to the upper one, and thus to both upper and under rolls at once. *i, i,* are the pinion standards in which their shafts run; they are smaller than the uprights of the rolls. *k, k,* are screws for fastening the head pieces *l* to the top of the pinion standards. All the standards are provided with sole plates *m,* whereby they are screwed to the foundation beams *n* of wood, or preferably iron, as shown by the dotted lines; *o, o,* are the binding screw bolts. Each pair of rolls at work is kept cool by a small stream of water let down upon it from a pipe and stop-cock.

In the cylinder drawing, the workman who holds the ball in tongs passes it into the first of the elliptical grooves, and a second workman, on the other side of the cylinders, receives this lump and hands it over to the first, who repasses it between the rollers after bringing them somewhat closer to each other by giving a turn to the adjusting pressure screws. After the lump has passed five or six times through the same groove it has got an elliptical form, and is called in England a *bloom.* It is next passed through a second groove of less size, which stretches the iron bar. In this state it is subjected to a second pair of cylinders, by which the iron is drawn into flat bars four inches broad and half an inch thick. Fragments of the ball or bloom fall round about the cylinders, which are afterwards added to the puddling charge. In a minute and a half the rude lump is transformed into bars with a neatness and rapidity which the inexperienced eye can hardly follow. A steam-engine of thirty horse-power can rough down in a week 200 tons of coarse iron.

This iron, called mill-bar iron, is however of too inferior a quality to be employed in any machinery, and it is subjected to another operation, which consists in welding several pieces together, and working them into a mass of the desired quality. The iron bars, while still hot, are cut by the shears into a length proportional to the size of the iron bar that is wanted, and four rows of these are usually laid over each other into a heap or pile which is placed in the *re-heating* furnace, and exposed to a free circulation of heat, one pile being set crosswise over another. In a half or three quarters of an hour the iron is hot enough, and the pieces now sticking together are carried in successive piles to the bar drawing cylinders to be converted into strong bars, which are reckoned of middle quality. When a very tough iron is wanted, as for anchors, another welding and rolling must be given. In the re-heating ovens the loss is from 8 to 10 per cent. on the large bar, and from 10 to 12 in smaller work. The consumption of coals in heating the large piles averages 7 cwts. to the ton of iron charged; in the smaller sizes 10 cwts.; and in heating the guide rolled iron 10 cwts.

The re-heating furnace is shown in section in *fig.* 1282: it differs but little from a puddling furnace. The whole interior, with the exception of the hearth *a*, is made of fire-brick; the hearth is made of sand. For this purpose a pure siliceous sand is required; the coarser the better. The hearth slopes considerably towards the flue, the object of which is to keep the hearth dry and hard. The iron wasted in re-heating combines with the silica of the sand, forming a very fusible cinder, which flows off through the opening at *b*, at which there is a small fire to keep the cinder liquid. The thickness of the sand bottom is from 6 to 12 inches, resting on fire-brick; it generally requires re-making after two or three heats. The height of the fire-brick arch, or its distance from the sand bottom, is from 8 to 12 inches. The area of the fireplace averages 12 feet, and the width of the furnace varies from 5 to 8 feet. When the piles are charged into the furnace, the door is shut, and fine coal is dusted around its edges to exclude the cold air; the temperature is raised to the highest intensity as quickly as possible, and the workman turns the piles over from time to time that they may be brought to an uniform welding heat in the shortest possible time.

1282



It is thought by many that a purer iron is obtained by subjecting the balls as they come out of the puddling furnace to the action of the hammer at first rather than to the roughing rollers, as by the latter process vitrified specks remain in the metal, which the hammer expels. Hence in some works the balls are first worked under the forge-hammer, and these *stampings* being afterwards heated in the form of pies or cakes, piled over each other, are passed through the roughing mills.

Bars intended for boiler or tin plates are made from the best cold-blast mine iron. The raw pig is refined in the usual manner with coke, the loss amounting to from 2½ to 3 cwts. per ton. It is then refined a second time with charcoal, the loss amounting again to from 2½ to 3 cwts. per ton. After this second refining, it is beaten into flat plates white hot by the tilt hammer and thrown into cold water; the sudden chilling makes it more easily broken into small slabs. The slabs are piled in heaps and welded in the *hollow* fire, coke being the fuel; the slabs are laid across the fire, and do not come into contact with the fuel; the blast is thrown under the fuel, and the heat is immense; when the piles are nearly at the fusing point, they are withdrawn and passed under the rollers; they are again heated in the hollow fire, then again rolled and heated a third time in the ordinary reverberatory furnace, after which they are drawn out into flat bars for boiler-plates, or for tin plate: the loss in these operations amounts to from 3½ to 4 cwts. per ton. About 9 heats are accomplished in 12 hours, each heat consisting of 2¼ cwts. of refined metal, and consuming 5 baskets of charcoal.

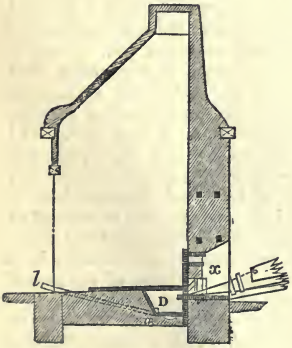
The bars intended for tin plates are repeatedly heated and rolled until of the requisite thinness, the plates are then cut into squares, and annealed by exposing them for several hours to heat in covered iron boxes, being allowed to cool very slowly; this gives the plates the proper degree of pliancy. The next operation is that of *pickling*; the plates are immersed in dilute sulphuric acid for the purpose of removing from their surfaces all oxide and dirt; after remaining in the acid for the requisite time, they are thoroughly washed in successive troughs of water, and then dried in sawdust; finally, the surfaces of the metal are prepared for the reception of the tin, by rubbing them with leather upon cushions of sheepskin. The spent sulphuric acid is run out into evaporating pans, and the sulphate of iron crystallised out. In order to tin the plates, they are immersed in a bath of melted tin, the surface of which is covered with tallow or palm-oil; when sufficiently covered, they are transferred to the *brusher* on the left-hand side of the tinner; he passes a rough brush rapidly over each side of the plate, whereby the superfluous tin is removed; he then plunges the plate again into the tin-bath, and passes it on to his left hand neighbour, who gives it a washing. The plate passes through several hands before it is dried. Great skill is required in the tinning process; nevertheless, in a well-conducted work the *wasters* do not amount to more than 10 per cent.; a small percentage of which are so bad as to require to be re-worked. Great care is taken to avoid waste, tin being worth about 150*l.* per ton. A box of 225 sheets of tin plates, 10 inches by 14, consumes about 8½ lbs. of tin. See TIN PLATE.

On the Continent, iron is frequently refined from the cast metal of the blast-furnaces by three operations, in three different ways. In one, the pig being melted, with aspersion of water, a cake is obtained, which is again melted in order to form a second cake. This being treated in the refinery fire, is then worked into a *bloom.* In another system, the pig-iron is melted and cast into plates: these are melted anew in order to obtain crude balls, which are finally worked into blooms. In a third mode of manufacture, the pig-iron is melted and cast into plates, which are roasted, and then strongly heated, to form a bloom.

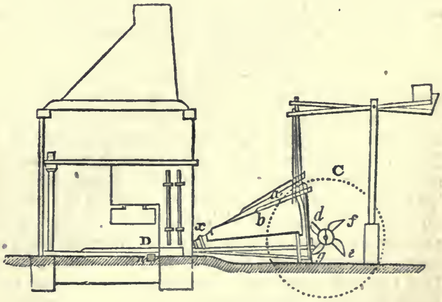
The French fusible ores, such as the silicates of iron, are very apt to smelt into white cast iron. An excess of fluxes, light charcoals, or too strong a blast, produce the same results. A surcharge of ores which deranges the furnace and affords impure slags mixed with much iron, too rapid a slope in the boshes, too low a degree of heat, and too great condensation of the materials in the upper part of the furnace; all tend also to produce a white cast iron. In its state of perfection, white cast iron has a silver colour, and a bright metallic lustre. It is employed frequently in Germany for the manufacture of steel, and is then called *steel floss*, or *lamellar floss*, a title which it still retains, though it be hardly silver-white, and has ceased to be foliated. When its colour takes a bluish grey tinge, and its fracture appears striated or splintery, or when it exhibits grey spots, it is then styled *flower floss.* In a third species of white cast iron we observe still much lustre, but its colour verges upon grey, and its texture is variable. Its fracture has been sometimes compared to that of a broken cheese. This variety occurs very frequently. It is a white cast iron, made by a surcharge of ore in the furnace. If the white colour becomes less clear and turns bluish, if its fracture be contorted, and contains a great many empty spaces or air-cells, the metal takes the name of *cavernous floss* or *tender floss.* The whitest metal cannot be employed for casting. When the white is mixed with the grey cast iron, it becomes *riband* or *trout* cast iron.

The German Refining Forge.—*Figs.* 1283, 1284, represent one of the numerous refinery furnaces once common in the Hartz. The example is taken from the Mandelholz works, in the neighbourhood of Elbingerode. *Fig.* 1284 is an elevation of this forge. D is the refinery hearth, provided with two pair of bellows. *Fig.* 1283 is a vertical section, showing particularly the construction of the crucible or hearth in the refinery forge D. C is an overshot water-wheel, which gives an alternate impulsion to the two bellows *a b* by means of the revolving shaft *c*, and the cams or tappets *d f e g*.

1283



1284



D, the hearth, is lined with cast-iron plates. Through the pipe *l*, cold water may be introduced, under the bottom plate *m*, in order to keep down, when necessary, the temperature of the crucible, and facilitate the solidification of the *loupe* or bloom. An orifice *n*, *figs.* 1283, 1284, called the *chio* (floss-hole), allows the melted slag or cinder to flow off from the surface of the melted metal. A copper pipe or nose piece conducts the blast of both bellows into the hearth, as shown at *b x*, *fig.* 1284.

The substance subjected to this mode of refinery is a grey carbonaceous cast iron, from the works of Rothehütte. The hearth D, being filled and heaped over with live charcoal, upon the side opposite to the tuyère *x*, *figs.* 1283, 1284, long pigs of cast iron are laid with their ends sloping downwards, and are drawn forwards successively into the hearth by a hooked bar, so that the extremity of each may be plunged into the middle of the fire, at a distance of 6 or 8 inches from the mouth of the tuyère. The workman proceeds in this way till he has melted enough of metal to form a *loupe*. The cast iron, on melting, falls down in drops to the bottom of the hearth; being covered by the fused slags, or vitreous matters more or less loaded with oxide of iron. After running them off by the orifice *n*, he then works the cast iron by powerful stirring with a rabble, till it is converted into a mass of a pasty consistence.

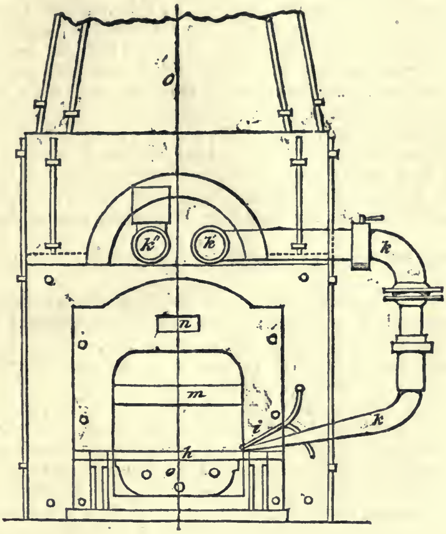
During this operation, a portion of the carbon contained in the cast iron combines with the atmospherical oxygen supplied by the bellows, and passes off in the form of carbonic oxide and carbonic acid. When the lump is coagulated sufficiently, the workman turns it over in the hearth, then increases the heat so as to melt it afresh, meanwhile exposing it all round to the blast, in order to consume the remainder of the carbon, that is, till the iron has become ductile, or refined. If one fusion should prove inadequate to this effect, two are given. Before the conclusion, the workman runs off a second stratum of vitreous slag, but at a higher level, so that some of it may remain upon the metal.

The weight of such a *loupe* or *bloom* is about 2 cwts., being the product of 2 cwts. and $\frac{7}{10}$ths of pig-iron; the loss of weight is therefore about 26 per cent. 149 pounds of charcoal are consumed for every 100 pounds of bar iron obtained. The whole operation lasts about 5 hours. The bellows are stopped as soon as the bloom is ready; this is immediately transferred to a forge-hammer, the cast-iron head of which weighs 8 or 9 cwts. The bloom is greatly condensed thereby, and discharges a considerable quantity of semi-fluid cinder. The lump is then divided by the hammer and a chisel into 4 or 6 pieces, which are re-heated, one after another, in the same refinery fire, in order to be forged into bars, whilst another pig of cast iron is laid in its place, to prepare for the formation of a new bloom. The above process is called by the Germans *Klump-frischen*, or lump refining. It differs from the *Durchbrech-frischen*, because in the latter the lump is not turned over in mass, but is broken, and exposed in separate places successively to the refining power of the blast near the tuyère. The French call this *affinage par portions*; it is much lighter work than the other.

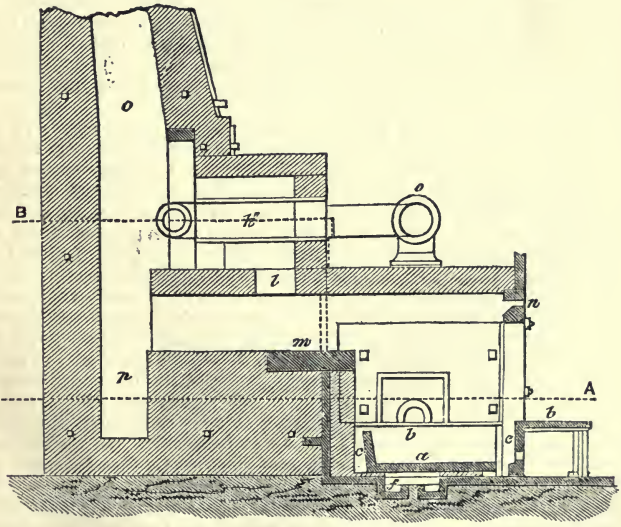
Charcoal Finery or Lancashire Hearth.—We are indebted for the following accurate account of this important finery to Dr. Percy, who gives it in his work on iron and steel:—

The furnace (*figs.* 1285 and 1286) consists essentially of a shallow quadrangular hearth, formed of cast-iron plates *a*, *b*, *c*, *d*, and *e*. The hearth-bottom *a*, is horizontal; the tuyère side *b*, slightly inclined inwards; the opposite side *n*, and the back *c*, inclined outwards; the front *e* is vertical, and in it there are three round holes for tapping off the cinder. Under the hearth-bottom is an open shallow cast-iron box, having a gutter on one side *f*, and a round hole in the centre of the bottom *f*, surrounded with a border not quite so high as the box is deep. The box and gutter are cast in one piece. During the working of the furnace cold water is continually flowing through *f*, and running out at *f*; by this arrangement the hearth-bottom is kept cool. The side walls above the hearth are protected within by cast-iron plates, (*figs.* 1285 and 1286). Hot blast is used, and there is one iron water tuyère *i*, nearly semicircular in section, which passes through a thick cast-iron plate set in one of the side plates *g*. The narrow end projects over the side of the hearth $\frac{3}{4}$ inch, and the axis is inclined at an angle of about 10° with the horizon. As the charcoal is confined round and above the tuyère, the plate *g* is exposed to great heat, and consequently destruction; it is made very thick, and may be readily replaced when required. In front of the hearth is a table or platform of cast iron *h*, resting on the ends of cast-iron standards. This table is essential for the necessary manipulations. The arrangement for heating and conveying the blast to the tuyère is represented at *k*, *k'* *k''*. The heating apparatus consists merely of a siphon-pipe of cast iron, set horizontally and exposed to the waste gases of the furnace. There is a throttle valve at *k* for stopping and regulating the blast; the nozzle end of the blast-pipe may be raised or lowered at will by a telescope sliding piece, and may be turned in any direction by means of the union joint below *k* (*fig.* 1286). The waste gases escape partially through the square opening *l*; at *m* is a cast-iron plate, on which pigs or blooms are laid so as to become heated; at *n* is an opening through which an iron bar may be introduced to move the objects on the plate *m*, or clean the arched passage leading from this part to the stack *o*, to which, at the

1285



1286



bottom, is often attached a large chamber destined to intercept sparks. There is an ash-pit *p*, from which the ashes may be removed through an opening at p^1, which is closed with a cast-iron door.

All being in working order, and the ball obtained in the previous heat removed, charcoal-dust is put on the fore-side, and the hearth is spread with clean charcoal. The pig-iron, which is in plates 2 inches or 3 inches thick, and has been previously heated on the plate in the flue, is transferred to the hearth, the charge being 200 lbs. Fresh charcoal is added and the blast turned on, when, in about half an hour, the metal will have completely melted down, and in dropping through the blast from the tuyère, have become partially oxidised; by the action of the oxide of iron thus formed, and of the basic silicate of protoxide of iron remaining in the hearth at the close of the last operation upon the molten pig-iron, the latter is decarburized to a considerable extent, and, in consequence, becomes less fusible and more pasty. After perfect fusion of the metal, the refining process begins; this consists in incessantly breaking up the metal with an iron bar, and carrying towards the tuyère the raw portions, which being more highly carburised and more fusible than the rest, always run down to the bottom and there harden. The metal, which has thus more or less solidified, is broken up and submitted to the action of the blast, until all is sufficiently refined; this operation lasts about half an hour. Subsequently, all the metal is brought up to the top of the hearth, and again melted down with a lively heat to form the ball, fresh charges being thrown into the hearth, and the unmelted portions being kept up at intervals with an iron bar to prevent their adhering to the ball before having been melted. The ball is then taken out and hammered into a prismatic shape, which is cut into pieces to be welded in another fire. The whole process lasts from 1¼ to 1½ hour.

The blast is frequently used at a temperature of 100° C., and at a pressure of 2½ inches of mercury.

The cut-up pieces to be drawn out under the hammer are welded and heated in hearths much resembling in size and construction the charcoal finery itself, or in an Ekman's furnace, now extensively used for this purpose.

The quality of the iron is tried in various ways: as, first, by raising a bar by one end, with the two hands over one's head, and bringing it forcibly down to strike across a narrow anvil at its centre of percussion, or one-third from the outer extremity of the bar; after which it may be bent backwards and forwards at the place of percussion several times; 2, a heavy bar may be laid obliquely over props near its end, and struck strongly with a hammer with a narrow pane, so as to curve it in opposite directions; or while heated to redness, they may be kneaded backwards and forwards at the same spot, on the edge of the anvil. This is a severe trial, which the hoop L, Swedish iron, bears surprisingly, emitting as it is hammered a phosphoric odour, peculiar to it and to the bar iron of Ulverstone, which also resembles it in furnishing a good steel. The forging of a horse-shoe is reckoned a good criterion of the quality of iron. Its freedom from flaws is detected by the above modes; and its linear strength may be determined by suspending a scale to the lower end of a hard-drawn wire, of a given size, and adding weights till the wire breaks. The treatises of Barlow, Tredgold, Hodgkinson, and Fairbairn may be consulted with advantage on the methods of proving the strength of different kinds of iron in a great variety of circumstances.

Dry Assay of Iron-ores.—The object of a *dry assay* of an iron ore is to ascertain by an experiment on a small scale the amount of iron which the ore should yield when smelted on the large scale in the blast-furnace. For this purpose the metal must be deoxidised, and such a temperature produced to melt the metal and the earths associated with it in the ore, so that the former may be obtained in a dense button at the bottom of the crucible, and the latter in a lighter glass or slag above it. Such a temperature can only be obtained in a wind furnace connected with a chimney at least 30 feet in height, and when made expressly for assaying the furnace, is generally built of such a size that four assays may be made at the same time, viz., about 14 inches square, and 2 feet in depth from the under side of the cover to the moveable bars of iron which form the grate. In order that the substances associated with the iron in the ore should form a fusible compound, it is usually requisite to add a flux, the nature of which will depend upon the character of the ore under examination. Berthier divides iron-ore into five classes: 1. The almost pure oxides, such as the *magnetic oxide, oligistic iron,* and the *hæmatites*; 2. Ores containing silica, but free or nearly so from any other admixture; 3. Ores containing silica and various bases, but little or no lime; 4. Ores containing one or more bases, such as *lime, magnesia, alumina, oxide of manganese, oxide of titanium, oxide of tantalum, oxide of chromium,* or *oxide of tungsten,* but *little* or no *silica;* 5. Ores containing *silica, lime,* and *another base,* and which are fusible alone. Ores of the first class may be reduced without any flux, but it is always better to employ one, as it greatly facilitates the formation of the button; borax may be used, or better, a fusible earthy silicate, such as ordinary flint-glass. Ores of the second class require some base to serve as a flux, such as carbonate of soda, a mixture of carbonate of lime and clay, or of carbonate of lime and dolomite. Ores of the third class are mixed with carbonate of lime in the proportion of from one half to three-fourths of the weight of the foreign matter present in the ore. Ores of the fourth class require a flux of silica in the form of pounded quartz, and generally also some lime; the manganesian spathic ores which belong to this class may be assayed with the adddition of silica alone, but the magnesian spathic ores require lime. Ores of the fifth class require no flux.

Method of conducting the assay.—One hundred grains of the ore finely pulverised and passed through a silk sieve are well mixed with the flux, and the mixture introduced into the smooth concavity made in the centre of a crucible that has been lined with charcoal; the lining of the crucible is effected by partially filling it with coarsely-powdered and slightly-damped charcoal or *brasque*, which is then rammed into a solid form by the use of a light wooden pestle. The mingled ore and flux must be covered with charcoal. The crucible thus filled is closed with an earthen lid luted on with fire-clay; and it is then set on its base in the air-furnace. The heat should be very slowly raised, the damper remaining closed during the first half-hour. In this way the water of the damp charcoal exhales slowly, and the deoxidation of the ore is completed before the fusion begins; if the heat were too high at first the luting would probably split, and moreover, the slag formed would dissolve some oxide of iron, which would be lost to the button, and thus give an erroneous result. After half an hour the damper is gradually opened, and the furnace being filled with fresh coke, the temperature is raised progressively to a white heat, at which pitch it must be maintained for a quarter of an hour; the damper is then closed, and the furnace is allowed to cool. As soon as the temperature is sufficiently reduced, the crucible is removed and opened over a sheet of brown paper; the *brasque* is carefully removed, and the button of cast iron taken out and weighed. If the experiment has been entirely successful the iron will be found at the bottom of the crucible in a small rounded button, and the slag will be entirely free from any adhering metallic globules, and will resemble in appearance green bottle-glass; should, however, the slag contain small metallic particles, the experiment is not necessarily a failure, as they may generally be removed by washing and the magnet. But if on breaking the crucible, the reduced metal should be found in a partially melted state, and not collected into a distinct mass, it indicates either too low a temperature or an improper selection of fluxes, and the experiment must be repeated. The iron obtained is not chemically pure, but contains carbon, and if the ore is manganiferous, manganese; the result is therefore somewhat too high, though indicating with sufficient exactness for all manufacturing purposes the richness of the ore assayed.

Humid Assay of Iron-ores.—The quantitative determination of the various substances that occur in iron-ores, demands on the part of the operator a considerable amount of skill and patience, and can only be profitably undertaken by those who have acquired in the laboratory a thorough acquaintance with analytical operations. As, however, much attention has of late years been bestowed on the composition of iron-ores, and as certain elements, viz. *manganese*, *sulphur*, and *phosphorus*, are frequently present, which very considerably affect their commercial value, we deem it right to give a detailed account of the operations to be performed in order to arrive at an accurate knowledge of the composition of an ore.

Taking for illustration a specimen of the most complicated composition, the substances besides iron to be looked for, and estimated, are *water* (*hygroscopic* and *combined*), *organic matter*, *sulphur* (as *sulphuric acid*, and as *bisulphide of iron*), *phosphoric acid*, *carbonic acid*, *silicic acid*, *oxide of manganese*, *alumina*, *lime*, and *alkalis; lead*, *tin*, *copper*, and *arsenic*, are also occasionally met with; these metals are sought for when a suspicion of their presence is entertained, by a special operation on a large quantity of ore.

Too great care cannot be bestowed on the *sampling* of ores intended for analysis; to expend so much time and labour on an isolated specimen (unless for a special object) is worse than useless; the sample operated upon should be selected from a large heap, which should be thoroughly gone over, and several dozen pieces taken from different parts; these should be coarsely powdered and mixed, and about half a pound taken from the mass should be preserved in a well-corked bottle for examition.

1. *Determination of water* (*hygroscopic* and *combined*).—About 50 grains of the ore are dried in the water-oven till no further loss of weight is experienced; the loss indicates the hygroscopic water; the residue is introduced into a tube of hard glass, to which is adapted a weighed tube containing chloride of calcium; the powder is then gradually raised to a low red heat; the combined water is thereby expelled, and its amount determined by the increase in weight of the chloride of calcium tube. Some ores (the hydrated hæmatites) contain as much as 12 per cent. of combined water.

2. *Sulphuric acid and sulphur.*—From 30 to 50 grains of the ore are digested with hydrochloric acid, filtered and washed. The filtrate, concentrated if necessary by evaporation, is precipitated by great excess of chloride of barium. Every 100 parts of the sulphate of baryta produced indicate 34·37 parts of sulphuric acid. The insoluble residue on the filter is fused in a gold crucible with nitre and carbonate of

soda, the fused mass is dissolved in hydrochloric acid, evaporated to dryness, moistened with strong acid, diluted and filtered; from the filtrate the sulphuric acid is precipitated as sulphate of baryta, every 100 parts of which indicate 13·748 parts of sulphur, and 25·48 parts of bisulphide of iron.

In the analysis of hæmatites it is necessary to bear in mind that perchloride of iron is partially reduced when boiled with finely-divided iron pyrites and hydrochloric acid, sulphuric acid being formed.—*Dick.*

3. *Phosphoric acid.*—From 50 to 75 grains of the ore are digested with hydrochloric acid and filtered; the clear solution, which should not be too acid, is boiled with *sulphite of ammonia*, added gradually in small quantities till it either becomes colourless or acquires a pale green colour, indicating that the peroxide of iron originally present has been reduced to protoxide; the solution is nearly neutralised with carbonate of ammonia, excess of acetate of ammonia added, and the liquid boiled; strong solution of perchloride of iron is then added drop by drop, until the precipitate which forms has a distinct red colour; this precipitate, which contains all the phosphoric acid originally present in the ore, is collected on a filter, washed, and redissolved in hydrochloric acid, tartaric acid added, and then ammonia. From this ammoniacal solution, the phosphoric acid is finally precipitated as ammonio-phosphate of magnesia, by the addition of chloride of ammonium, sulphate of magnesia, and ammonia. The precipitate is allowed 24 hours to subside; it is then collected on a filter, and if it has a yellow colour, which is almost invariably the case, it is redissolved in hydrochloric acid, and more tartaric acid being added, it is again precipitated by ammonia: 100 parts of the ignited pyrophosphate of magnesia correspond to 64·3 parts of phosphoric acid.

Alkalis.—It was ascertained by Mr. Dick, that nearly the whole of the alkali present in an iron ore is contained in that portion which is insoluble in hydrochloric acid. The residue from about 50 grains of the ore is placed in a platinum capsule, moistened with ammonia, and exposed for several hours to the action of hydrofluoric acid gas in a closed leaden dish; it may be necessary to repeat the operation if much silica is present; it is then slowly heated to dull redness, and dissolved in dilute hydrochloric acid; the solution is mixed with excess of baryta-water and filtered; the excess of baryta is removed by carbonate of ammonia, and the solution is evaporated to dryness and ignited; the residue is redissolved in a little hot water, and a few drops of oxalate of ammonia added. If no precipitate or cloudiness occurs, it may be once more evaporated to dryness and gently ignited: the residue is chloride of potassium, 100 parts of which indicate 63 parts of potash. Should oxalate of ammonia have occasioned a precipitate, it must be filtered off, and the clear liquid evaporated. The search for potash is troublesome and lengthy; it may be altogether omitted in a technical analysis.

Determination of the remaining constituents.—25 or 30 grains of the finely-powdered ore are digested for about half an hour with strong hydrochloric acid, diluted with boiling distilled water and filtered. The residue on the filter being thoroughly washed, the solution is peroxidised, if necessary, by the addition of chlorate of potash, nearly neutralised by ammonia, boiled with excess of acetate of ammonia, and rapidly filtered while hot; the filtrate (which should be colourless) together with the washings, is received in a flask, ammonia is added, and then a few drops of bromine, and the flask closed with a cork. In a few minutes, if manganese be present, the liquid acquires a dark colour; it is allowed to remain at rest for 24 hours, then warmed, and rapidly filtered and washed; the brown substance on the filter is hydrated oxide of manganese: it loses its water by ignition, and then becomes $Mn^3 O^4$, 100 parts of which correspond to 93 parts of protoxide.

The liquid filtered from the manganese contains the *lime* and *magnesia*; the former is precipitated by oxalate of ammonia, and the oxalate of lime formed converted by ignition into carbonate, in which state it is either weighed, having been previously evaporated with carbonate of ammonia, or it is converted into sulphate by the addition of a few drops of sulphuric acid, evaporation and ignition. The lime being separated, the magnesia is thrown down as ammonio-magnesian phosphate by phosphate of soda and ammonia, and after standing for 24 hours it is collected on a filter, washed with cold ammonia-water, dried, ignited, and weighed; 100 parts of carbonate of lime correspond to 56·0 of lime; 100 parts of sulphate of lime to 40·1 of lime, and 100 parts of pyrophosphate of magnesia to 35·7 of magnesia.

The red precipitate collected on the filter after the boiling with acetate of ammonia, consists of the basic acetates of *iron* and *alumina*, together with the *phosphoric acid.* It is dissolved in a small quantity of hydrochloric acid, and then boiled in a silver or platinum basin with considerable excess of pure caustic potash; the alumina (with the phosphoric acid) is hereby dissolved, the insoluble portion is allowed to subside, and the clearer liquor is then decanted, after which the residue is thrown on a filter and washed; the filtrate and washings are supersaturated with hydrochloric acid, nearly neutralised with ammonia, and the alumina finally precipitated by carbonate of ammonia. From the weight of the ignited precipitate, the corresponding amount of phosphoric acid determined by a separate operation is to be deducted, and the remainder is calculated as *alumina.* The residue left after digesting the ore with hydrochloric acid, consists principally of *silica*, but it may also contain *alumina*, *peroxide of iron*, *lime*, *magnesia*, and *potash*. For practical purposes it is rarely necessary to submit it to minute examination; should such be desired, it must be dried, ignited, and weighed, then fused in a platinum crucible with four times its weight of mixed alkaline carbonates, the fused mass dissolved in dilute hydrochloric acid, and evaporated to dryness, the residue moistened with strong hydrochloric acid, and after standing at rest for some hours, digested with hot water, filtered, and the *silica* on the filter ignited and weighed. The *alumina*, *lime*, *oxide of iron*, and *magnesia* in the filtrate are separated from each other according to the instructions given above; the *potash* is estimated by a distinct process.

Carbonic acid.—This acid, which constitutes a considerable part of the weight of that large and important class of ores the *clay ironstones*, is estimated by noting the loss sustained after adding to a weighed portion of the ore sulphuric acid, and thus evolving the gas; or more roughly, by the loss sustained in the entire analysis. Another method is to fuse 20 or 25 grains of the ore with 60 or 80 grains of dry borax, and noting the loss, which consists of water and carbonic acid; by deducting the water obtained in a previous experiment, the quantity of carbonic acid is obtained. This method, however, can scarcely be recommended, on account of the corrosion of the crucible, though the results are very accurate.

Determination of the iron.—This is performed on a separate portion of the ore, either by the volumetric method of Marguerite, or by that of Dr. Penny: both give very exact results. Marguerite's method is based on the reciprocal action of the salts of protoxide of iron and permanganate of potash, whereby a quantity of the latter is decomposed exactly proportionate to the quantity of iron. The ore (about 10 or 15 grains) is dissolved in hydrochloric acid, and the metal brought to the minimum of oxidation by treating the solution with *sulphite of soda* (or better, *sulphite of ammonia*), and boiling to expel the excess of sulphurous acid; the solution of permanganate of potash is then cautiously added drop by drop, until the pink colour appears, and the number of divisions of the burette required for the purpose accurately noted. The solution should be considerably diluted, and there must be a sufficient quantity of free acid present to keep in solution the peroxide of iron formed and also the oxide of manganese. The whole of the iron must be at the *minimum* of oxidation, and the excess of sulphurous acid must be completely expelled; if the latter precaution be neglected an erroneous result will be obtained, as the sulphurous acid will itself take oxygen from the permanganic acid, and thus react in the same manner as iron.

To prepare the permanganate of potash, 7 parts of chlorate of potassa, 10 parts of hydrate of potassa, and 8 parts of peroxide of manganese are intimately mixed. The manganese must be in the finest possible powder, and the potash having been dissolved in water, is mixed with the other substances, dried, and the whole heated to very dull redness for an hour. The fused mass is digested with water, so as to obtain as concentrated a solution as possible, and dilute nitric acid added till the colour becomes of a beautiful violet; it is afterwards filtered through asbestos. The solution must be defended from the contact of organic matter, and kept in a glass-stoppered bottle. If the solution be evaporated, it yields beautiful red acicular crystals: it is better to employ the crystals in the preparation of the test-liquor, as the solution keeps much better when no *manganate* is present. To prepare the normal or test-liquor, a certain quantity, say 15 grains, of pianoforte wire are dissolved in pure hydrochloric acid; after the disengagement of hydrogen has ceased, and the solution is complete, the liquor is diluted with about a pint of water, and accurately divided by measurement into two equal parts, the number of burette divisions of the solution of permanganate required to produce in each the pink colour is accurately noted; and this number is then employed to reduce into weight the result of the analysis of an ore. A useful normal liquor is made by dissolving 100 grains of the crystallised permanganate in 10,000 grains of water.

Penny's method is based on the reciprocal action of chromic acid and protoxide of iron, whereby a transference of oxygen takes place, the protoxide of iron becoming converted into peroxide, and the chromic acid into sesquioxide of chromium. The process is conducted as follows:—A convenient quantity of the specimen is reduced to coarse powder, and one half at least of this is still further pulverised until it is no longer gritty between the fingers. The test solution of bichromate of potash is next prepared: 44·4 grains of this salt in fine powder are weighed out, and put into a burette graduated into 100 equal parts, and warm distilled water is afterwards poured in until the instrument is filled to 0. The palm of the hand is then securely placed on the top, and the contents agitated by repeatedly inverting the instrument until the salt is dissolved and the solution rendered of uniform density throughout. Each division of the solution thus prepared contains 0·444 grain of bichromate, which Dr. Penny ascertained to correspond to half a grain of metallic iron. The bichromate must be pure, and should be thoroughly dried by being heated to incipient fusion. 100 grains of the pulverised iron-stone are now introduced into a Florence flask with 1½ oz. by measure of strong hydrochloric acid and ½ oz. of distilled water. Heat is cautiously applied and the mixture occasionally agitated until the effervescence caused by the escape of carbonic acid ceases, the heat is then increased, and the mixture made to boil, and kept at moderate ebullition for ten minutes or a quarter of an hour. About 6 oz. of water are next added and mixed with the contents of the flask, and the whole filtered into an evaporating basin. The flask is rinsed several times with water, to remove all adhering solution, and the residue on the filter is well washed. Several small portions of a weak solution of *red* prussiate of potash (containing 1 part of salt to 40 water) are now dropped upon a white porcelain slab, which is conveniently placed for testing the solution in the basin during the next operation. The prepared solution of bichromate of potash in the burette is then added very cautiously to the solution of iron, which must be repeatedly stirred, and as soon as it assumes a dark greenish shade it should be occasionally tested with the red prussiate of potash. This may be easily done by taking out a small quantity on the end of a glass rod, and mixing it with a drop of the solution on the porcelain slab. When it is noticed that the last drop communicates a distinct blue tinge, the operation is terminated; the burette is allowed to drain for a few minutes, and the number of divisions of the test-liquor consumed read off. This number multiplied by 2 gives the amount of iron per cent. The necessary calculation for ascertaining the corresponding quantity of protoxide is obvious. If the specimen should contain iron in the form of peroxide, the hydrochloric solution is deoxidised as before by sulphite of ammonia. The presence of peroxide of iron in an ore is easily detected by dissolving 30 or 40 grains in hydrochloric acid, diluting with water, and testing a portion of the solution with *sulphocyanide of potassium.* If a decided blood-red colour is produced, peroxide of iron is present. If it be desired to ascertain the relative proportions of peroxide and protoxide of iron in an ore, two operations must be performed: one on a quantity of the ore that has been dissolved in hydrochloric acid in a stout stoppered bottle; and another on a second quantity that has been dissolved as usual, and then deoxidised by sulphite of ammonia or by metallic zinc. It is advisable to employ the solution of bichromate much weaker than proposed by Dr. Penny, and to employ a burette graduated to cubic millimeters. A good strength is 1 grain of metallic iron = 10 cubic centimeters of bichromate-solution.

Metals precipitable by sulphuretted hydrogen from the hydrochloric solution.—A weighed portion of the ore, varying from 200 to 2,000 grains, is digested for a considerable time in hydrochloric acid: the solution is filtered off; the iron in the filtrate reduced when necessary by sulphite of ammonia, and a current of sulphuretted hydrogen passed through it. A small quantity of sulphur which is always suspended is collected on a filter and thoroughly washed; it is then incinerated at as low a temperature as possible. The residue (if any) is mixed with carbonate of soda, and heated upon charcoal before the blowpipe: any globules of metal that may be obtained are dissolved and tested.

Analysis of Pig-iron.—The most important constituents to be determined are *carbon* (combined and uncombined), *silicon*, *sulphur*, *phosphorus*; those of less consequence, or of more rare occurrence, are *manganese*, *arsenic*, *copper*, *zinc*, *chromium*, *titanium*, *cobalt*, *nickel*, *tin*, *aluminium*, *calcium*, *magnesium*, and the *metals of the alkalis.*

1. *Determination of the total amount of carbon.*—About 100 grains of the iron in small pieces are digested, at a moderate temperature, in 6-oz. measure of a solution formed by dissolving 6 oz. of crystallised sulphate of copper, and 4 oz. of common salt in 20 oz. of water and 2 oz. of concentrated hydrochloric acid. The action is allowed to proceed until all, or nearly all the iron is dissolved. *Carbon* and *copper* are left insoluble; these are collected on a filter, and washed first with dilute hydrochloric acid (to prevent the precipitation of subchloride of copper), then with water, then with dilute caustic potash, and finally with boiling water. The mixed carbon and copper are dried on the filter, from which they are easily removed by a knife-blade, and are mixed with oxide of copper, and burned in a combustion tube in the usual way, with a current of air, or, still better, of oxygen. The carbonic acid is collected in Liebig's apparatus, from which the amount of carbon is calculated.

2. *Graphite*, or *uncombined carbon.*—A weighed portion of the finely-divided iron (filings or borings may be used) is digested with moderately strong hydrochloric acid, the combined carbon is evolved with combination with hydrogen, while the graphite is left undissolved. It is collected on a filter, washed, and then boiled with a solu-

tion of caustic potash, specific gravity 1·27, in a silver dish; the silica which existed in the iron in the form of silicon is hereby dissolved; the clear caustic solution is drawn off by a pipe or siphon, and the black residue repeatedly washed; it is dried at as high a temperature as it will bear, and weighed; it is then heated to redness in a current of air, until the whole of the carbon is burnt off. A reddish residue generally remains, which is weighed, and the weight deducted from that of original black residue, the difference gives the amount of graphite.

3. *Silicon.*—The amount of this element is determined by evaporating to dryness a hydrochloric solution of a weighed quantity of the metal: the dry residue is redigested with hydrochloric acid, diluted with water, boiled and filtered; the insoluble matter on the filter is washed, dried, and ignited, until the whole of the carbon is boiled off; it is then weighed, after which it is digested with solution of potash, and the residue, if any, washed, dried, ignited, and weighed: the difference between the two weights gives the amount of silicic acid, 100 parts of which indicate 47 parts of *silicon.*

4. *Phosphorus.*—A weighed portion of the metal is digested in nitro-hydrochloric acid, evaporated to dryness, and the residue redigested with hydrochloric acid. The solution is treated precisely as recommended for the determination of phosphoric acid in ores; every 100 parts of pyrophosphate of magnesia indicate 28·56 parts of phosphorus.

5. *Sulphur.*—In *grey* iron this element is very conveniently and accurately estimated by allowing the gas evolved by the action of hydrochloric acid on a weighed quantity (about 100 grains) of the metal, in filings or borings, to pass slowly through a solution of acetate of lead acidified by acetic acid: the sulphur, the whole of which takes the form of sulphuretted hydrogen, enters into combination with the lead, forming a black precipitate of sulphide of lead, which is collected, washed, and converted into sulphate of lead by digesting it with nitric acid, evaporating to dryness, and gently igniting: 100 parts sulphate of lead = 10·55 sulphur. The most minute quantity of sulphur in iron is detected by this process. If, however, crude *white* iron is under examination, this method does not give satisfactory results, on account of the difficulty with which it is acted upon by hydrochloric acid; it is better, therefore, to treat the metal with nitro-hydrochloric acid, evaporate to dryness, re-digest with hydrochloric acid, and then precipitate the filtered solution with great excess of chloride of barium; or the finely-divided metal may be fused in a gold crucible, with an equal weight of pure nitrate of soda, and twice its weight of pure alkaline carbonates; the fused mass is extracted with water acidified with hydrochloric acid, and finally precipitated by chloride of barium.

Manganese.—This metal is determined by the process described for its estimation in ores; the iron must exist in the solution in the form of sesquioxide.

Arsenic and Copper.—The nitro-hydrochloric solution of the metal is evaporated to dryness, re-digested with hydrochloric acid, and filtered. The iron in the clear solution is reduced to protochloride by boiling with a sufficient quantity of sulphite of ammonia, the solution is boiled till it has lost all smell of sulphurous acid. It is then saturated with sulphuretted hydrogen, and allowed to stand for 24 hours in a closed vessel, the excess of gas is boiled off, and the precipitate, if any, collected on a small filter and well washed; it is digested with monosulphide of potassium, which dissolves the sulphide of arsenic, leaving the sulphide of copper untouched; the latter is decomposed by heating with nitric acid, and the presence of copper evinced by the addition of ammonia, which produces a fine blue colour; the sulphide of arsenic is precipitated from its solution in sulphide of potassium by dilute sulphuric acid; it may be redissolved in *aqua regia*, and the nitric acid having been expelled by evaporation, the arsenic may be reduced in Marsh's apparatus.

Nickel and Cobalt.—These metals, if present, will be found in the solution from which the copper and arsenic have been precipitated by sulphuretted hydrogen. The solution is peroxidised, and the sesquioxide of iron precipitated by slight excess of carbonate of baryta, after which the nickel and cobalt are precipitated by sulphide of ammonium.

Chromium and Vanadium.—These metals, which should be looked for in the carbonaceous residue obtained by dissolving a large quantity of the iron in dilute hydrochloric or sulphuric acid, are detected as follows (*Wöhler*):—The ignited residue is intimately mixed with one-third of its weight of nitre, and exposed for an hour in a crucible to a gentle ignition. When cool, the mass is powdered and boiled with water. The filtered solution is gradually mixed, and well stirred with nitric acid, taking care that it may still remain slightly alkaline, and that no nitrous acid is liberated which would reduce the vanadic and chromic acids. The solution is then mixed with an excess of solution of chloride of barium as long as any precipitate is produced. The precipitate, which consists of vanadate and chromate of baryta, is decomposed with slight excess of dilute sulphuric acid, and filtered. The filtrate is neutralised with ammonia, concentrated by evaporation, and a fragment of chloride of ammonium placed in it. In proportion as the solution becomes saturated with chloride of ammonium, *vanadate* of ammonia is deposited as a white or yellow crystalline powder. To test for chromium only, the mass after fusion with nitre is extracted with water, and then boiled with carbonate of ammonia; the solution is neutralised with acetic acid, and then acetate of lead added; the production of a yellow precipitate indicates *chromic* acid.

Aluminium.—This metal is best separated from iron, by first reducing the latter to the state of protoxide by sulphite of ammonia, then neutralising with carbonate of soda, and afterwards boiling with excess of caustic potash, until the precipitate is black and pulverulent. The solution is then filtered off, slightly acidulated with hydrochloric acid, and the alumina precipitated by sulphide of ammonium.

Calcium and Magnesium.—These metals are found in the solution from which the iron and aluminium have been separated; they both exist probably (together with the aluminium) in the cast iron in the form of *slag*, and are best detected in the black residue which is left on dissolving the iron in dilute sulphuric or hydrochloric acid. After digesting this residue with caustic potash, and burning away the graphite, a small quantity of a red powder is left, which is composed of silicic acid, oxide of iron, alumina, lime, and magnesia; if 500 grains of cast iron are operated upon, a sufficient quantity of insoluble residue will be obtained for a quantitative determination of its constituents.

Eggertz's Methods.—Eggertz's method of determining combined carbon in iron or steel depends upon the discoloration produced by carbon in solution of pernitrate of iron, which, under ordinary circumstances, is colourless, or at most of a greenish tint. The standard series of colours is made by dissolving quantities weighing 1 diagramme of steel of known composition in nitric acid at low temperature, and diluting with water to a standard volume. The solutions which give different shades of brown are preserved in glass tubes.

A similar weight of the steel to be examined is dissolved in pure nitric acid under the conditions observed in making the standard series. The solution is decanted from the residue, poured into a burette of the same diameter as the tubes containing the standard series, and diluted with water until it matches one of the tints. The amount of carbon is then found by calculation from the relative volumes of the solutions of steel, with a medium amount of carbon, say 0·8 per cent., gives a yellowish green solution; a very hard variety, with 1·5 per cent. brownish red; and the softest, with 0·40 per cent., only a slight greenish tinge.

The Swedish classification of Bessemer steel by numbers, based upon the percentage of carbon determined by the above process, is as follows:—

No. 1 contains 2 per cent.; No. 1·5, 1·75; No. 2, 1·5; and so on, up to No. 4·5, with only 0·25 per cent., below which point the scale is not extended.

The following determinations of carbon in various kinds of iron and steel made in Sweden are by Eggertz:—

Softest Swedish Bessemer iron contains	0·08	per cent. of carbon
Soft steel	0·75	„ „
Best quality of cast steel	1·4 to 1·5	„
Natural forge steel	0·99 „ 2·44	„
Cement steel	0·5 „ 1·90	„
Cast steel	0·36 „ 1·9	„
Hardest welding cast steel	1·80	„
Malleable cast iron	0·88 „ 1·52	„
Draw plate steel	3·30	„

The following modification of this process is adopted at Seraing, in Belgium, for the determination of carbon in mild Bessemer steel. Two samples, each weighing 0·2 gramme, of the ingot to be tested are taken; one being in the state of filings, and the other of borings. These are treated with 20 cubic centimeters of nitric acid, of specific gravity 1·2; the solution being effected in a water-bath at 80°. For the test-standard the same weight of two different samples, of the hardest steel made in the works, whose carbon has been already determined and containing 0·61 and 0·63 per cent. respectively, are dissolved up in the same manner. The whole of the four solutions are then brought down to one tint by adding water to the darker ones, care being taken to conduct the operation in tubes of exactly the same diameter. The amount of carbon can then be computed from the volume of the solutions. If the difference in the results given by the two samples does not exceed 4·03 per cent., the arithmetical mean between them is adopted as the true amount; but should it be larger, the operation is repeated.

In order to obviate the necessity of making standard solutions for every set of determinations, different coloured liquids have been employed with a view of obtaining a permanent scale of colours. Among these may be mentioned caramel, or burnt sugar, which gives various shades of yellow and brown, but alters very quickly; and partially decomposed solution of indigo in sulphuric acid, which is said to keep its characteristic colour without alteration for a considerable time. Another recommended by Hetman consists of a mixture of bichromate of potash and nitrate of cobalt. In most cases, however, the direct system of comparison with solutions obtained of steel of known composition is preferred.

Silicon.—The determination of silicon in iron and steel is a matter of some difficulty, as the mere weighing of the ignited insoluble residue from the hydrochloric acid solution and calculation of the silica found, as silicon, depends upon the assumption that the iron is free from silicates, which is often contrary to the fact, especially in malleable iron, which may contain a notable amount of intermingled slag that has not been perfectly expelled in the welding, and exists as a mechanical impurity, having no relation whatever to the real composition of the metal. This defective interpretation of the ultimate analyses is probably the cause of the contradictory statements current as to the amount of silicon that may be present beneficially in metallic iron. Eggertz has introduced a method of determining silicon in the presence of slags, which is based upon the fact that when iron is slowly acted on by bromine, or a solution of iodine, it dissolves, and the silicon set free is converted into silica, which is completely soluble in a boiling solution of carbonate of soda, while that in combination in the slag, if any be present, is not acted upon. The same method may be employed with cast iron, as blast-furnace slag, which sometimes occurs in it as a mechanical impurity is not sensibly acted upon either by iodine, bromine, or carbonate of soda.

The process is conducted as follows:—Three grammes or ·45 grain of iron in the state of filings or borings sufficiently small to pass through a sieve with meshes $\frac{1}{70}$th of an inch in diameter, is treated with five times its weight of iodine, in a volume of fifteen cubic centimeters of water contained in a beaker of about six or seven times that capacity. Water that has been boiled to free it from air is used, and the operation must be performed at as low a temperature as possible, in order to permit oxidation of the iron by the air; it is usual, therefore, to keep the beaker cool by the use of ice. When the iron is completely dissolved, the solution is increased to three times the original volume by the addition of very cold water, in order to prevent the separation of basic salts of iron, and is well stirred and left to settle. The lighter scales of graphitic carbon remain in suspension, but are poured off with the bulk of the liquid into a filter 2 inches in diameter, with only about one-tenth of the original quantity of the insoluble residue which forms a heavy powder at the bottom of the beaker. A few drops of hydrochloric acid are added, and the liquid stirred with a glass rod; if this produces a disengagement of gas, the whole of the iron is not dissolved, and a little iodine and carbonate of soda are added in order to complete the solution. The acidified water must be poured quickly on the filter in order to prevent the decomposition of the slag. When the whole of the residue is transferred to the filter it is washed with cold water until the whole of the iron is found to be completely removed when tested by a solution of ferrocyanide of potassium. The filtrate is evaporated to dryness with the addition of hydrochloric acid in order to recover any small amount of silica that may have gone into solution with the iron. The original residue, which may contain graphite silica and slag, is transferred without drying into a large platinum crucible, and after concentrating the waste water to 6 cubic centimeters, a saturated solution of carbonate of soda is added, and the crucible is heated for one hour in a water-bath, the liquid being stirred from time to time with a platinum spatula in order to dissolve any lumps in the insoluble residue. The solution is then carefully poured from the insoluble mass in the crucible on to a small filter, and a fresh quantity of carbonate-of-soda solution is added and boiled for another hour when the whole contents of the crucible are thrown upon the filter and washed. The alkaline solution of silica is acidified with hydrochloric acid added to that containing the iron, and evaporated to dryness in a water-bath. This operation is repeated with the addition of fresh acid until the silica is perfectly freed from iron, when it is filtered, dried, ignited, and weighed, as often as may be necessary to ensure its complete purity which must be further tested by heating it with hydrochloric acid. When 3 grammes of iron are treated 0·016 gramme of silica corresponds to 0·001 gramme of silicon. The insoluble residue from the carbonate-of-soda solution may contain graphite, slag, oxide of iron, and titanic acid. There is no way of distinguishing the amount of oxide of iron present as such, in addition to that in combination with silica, except by assuming the composition of the slag to be constant, which is not the case.

Eggertz found by the use of this process that the amount of silicon in good bar iron may vary from 0·01 to 0·10 per cent.; but in two samples of Krupp's cast steel it was as high as 0·30 per cent. Slag has been found usually in mere traces in cast steel, but in one instance it mounted to 0·2 per cent. Malleable iron, however, contained much more. In wire iron from a charcoal hearth 0·38 p. c. was found, in armour-plates from 0·75 to 3·00 p. c., and in a rail as much as from 4·00 to 5·00 p. c.—H.B.

The following Statistics of some of the principal iron-producing countries will be of interest and use :—

IRON-BARK TREES. Certain species of *Eucalyptus*, valued for their wood, are so called in Australia.

IRON LIQUOR. A solution of acetate of iron, used as a mordant by calico-printers.

IRON, METEORIC. See Aerolites.

IRON MINERALS *not used as Ores:—*

1. *Iron-Alum* or *Halotrichite.*—A sulphate of alumina and sulphate of iron, with 43 per cent. of water. Occurs in fibrous silky masses of a yellow colour. It is found in the exhausted beds of Hurlet and Campsie, near Paisley. It occurs in Persia, where it is used for making ink; and in Rhenish Bavaria.

2. *Iron-Apatite* or *Zwieselite.*—A phosphate of iron and manganese. See Zwieselite.

3. *Iron, Arsenate of; Pharmacosiderite; Würfelerz.*—This mineral, which is rather rare, occurs in great beauty associated with copper-ores in Cornwall; it has an olive-green colour, and is rather brittle. Its composition, according to the analysis of Berzelius, is: arsenic acid, 40·4; peroxide of iron, 28·1; protoxide of iron, 12·6; water, 18·9.

4. *Iron, Chromate of; Octohedral Chrome-ore; Chromite.*—This mineral occurs in serpentine, or in crystalline limestone, near this rock. It was first discovered at Gassin, in the Var department in France, and is found in Saxony, Silesia, Bohemia, and Styria; also in Norway; and in large masses in the Ural, near Katharinenberg. It has been found also in great abundance in Unst and Fetlar, in the Zetlands; the mineral is opaque, with a semi-metallic lustre; colour, iron or brownish-black, streak yellowish to reddish-brown. A specimen from Norway, analysed by Von Kobell, gave protoxide of iron, 25·66; sesquioxide of chromium, 54·08; alumina, 9·02; magnesia, 5·36; and silica, 4·83: another specimen, from Chester in Pennsylvania, yielded to Sebert protoxide of iron, 36·00; oxide of chromium, 39·61; alumina, 13·0; and silica, 10·60. It is used in the preparation of various pigments. For the treatment and use of the ore, see Chrome.

5. *Iron-Chrysolite* or *Fayalite.*—An anhydrous silicate of iron, in which iron is replaced by manganese. It is found in the Mourne mountains.

6. *Iron-Flint.*—A quartz containing 5 per cent. of oxide of iron. It is found in St. Just and Marazion in Cornwall.

7. *Iron-Natrolite.*—A variety of natrolite, in which one-fourth of the alumina is replaced by peroxide of iron. See Natrolite.

8. *Iron, Oxalate of; Oxalite; Humboldtine.*—This mineral, which occurs in the form of capillary crystals in the brown coal at Kolosoruk, near Bilin, in Bohemia, and at Gross Almerode in Hessia, is composed, according to the analysis of Rammelsberg, of oxalic acid, 42·40; protoxide of iron, 41·13; and water, 16·47.

9. *Iron, Phosphate of; Blue Iron; Vivianite.*—The colour of this mineral varies from indigo-blue to blackish green; the earthy variety is white in the beds, but changes blue on exposure to the air; heated in a closed tube it yields much water, intumesces, and becomes spotted with grey and red; before the blowpipe on charcoal, it fuses to a grey, shining, metallic granule. Transparent indigo-coloured crystals of phosphate of iron, sometimes an inch in diameter and two inches long, occur, with iron and copper pyrites, in the tin and copper veins at St. Agnes in Cornwall. It was first found in the auriferous veins at Vöröspatak in Transylvania; the earthy varieties are very common in Cornwall, Styria, North America, Greenland, and New Zealand. A specimen from St. Agnes, Cornwall, gave Stromeyer—phosphoric acid, 31·18; protoxide of iron, 41·23; water, 27·48: and another from New Jersey yielded to Rammelsberg—phosphoric acid, 28·40; protoxide of iron, 33·91; peroxide of iron, 12·06. It is sometimes used as a pigment, but is of no use as a smelting ore.

10. *Iron, Pitchy Hydrate of; Pitticite; Eisensinter.*—This mineral occurs in many old mines, especially those near Freiberg; and also at Schneeberg in Saxony, Pleiss in Silesia, and Bleistadt in Bohemia. It is probably a product of the decomposition of mispickel: its composition, according to the analysis by Stromeyer, being $Fe^{2}O^{3}$, $AsO^{5} + Fe^{2}O^{3},SO^{3} + 15HO = 35$ peroxide of iron, 26 arsenic acid, 9 sulphuric acid, and 30 water. According to *Freiesleben*, it is first fluid, and gradually separates in a solid

form. In external characters it agrees with *Diadochite*, which is $Fe^2O^3,2PO^5 + 4Fe^2O^3,SO^3 + 32HO$, according to Gmelin from Plattner's analysis, viz. peroxide of iron, 36·69; phosphoric acid, 14·81; sulphuric acid, 15·15; water, 30·35.

11. *Iron, Sulphate of; Native Green Vitriol.*—This is formed by the oxidation of sulphide of iron.

12. *Iron, Tungstate of; Wolfram,*—occurs, with tin ore, forming fine crystals, at Altenberg in Saxony; at Schlackenwald in Bohemia; and in France, in quartz veins. In Cornwall, especially near Redruth, it renders the tin ore valueless until it is removed. An analysis of a specimen from Cumberland gave Berzelius, tungstic acid, 78·77; protoxide of iron, 18·32; protoxide of manganese, 6·22; and silica, 1·25. See Wolfram.

13. *Yenite or Lievrite; Hisingerite or Thraulite; Nontronite; Pinguite;* and *Chloropal*, are rather rare minerals, composed of peroxide of iron and silica. The first may contain about 12 per cent. of lime; the others are destitute of this earth, but contain from 10 to 20 per cent. of water: the amount of silica in these minerals ranges between 30 and 40 per cent.

14. *Iserite.*—A variety of titaniferous iron-ore.

IRON PYRITES. Native bisulphide of iron. See Pyrites.

IRON, TELLURIC. A name given to native iron, of which there is no proof of meteoric origin. See Iron.

IRON WOOD. A name given to several of the hard, heavy, and close-grained woods. The *Metrosideros vera*, or true iron-wood, is a native of Java and Amboyna. The Chinese use it for making anchors. The *Metrosideros polymorpha* is the wood of which the Sandwich Islanders make their clubs. *Metrosideros buxifolia* is a New Zealand shrub, the wood of which is called in the country *Aki* or *Lignum vitæ.* Other varieties of these woods are produced by the *Sideroxylon*, found in many tropical countries. In North America the timber of the *Ostrya virginica* is known as iron-wood.

ISINGLASS (*Colle de Poisson*, Fr.; *Hausenblase*, Ger.) Ichthyocolla, ἰχθυόκολλα, from ἰχθὺς, a fish, and κόλλα, glue, or Fish-glue, is a whitish, dry, tough, semi-transparent substance, twisted into different shapes, often in the form of a lyre, and consisting of membranes rolled together. Good isinglass is unchangeable in the air, has a leathery aspect, and a mawkish taste, nearly insipid; when steeped in cold water it swells, softens, and separates in membranous laminæ. At the boiling heat it dissolves in water, and the solution, on cooling, forms a white jelly, which is semi-transparent, soluble in weak acids, but is precipitated from them by alkalis. It is gelatine, nearly pure; and if not brittle, like other glue, this depends on its fibrous and elastic texture. The whitest and finest is preferred in commerce. Isinglass is prepared from the air-bladders of sturgeons, and especially the great sturgeon, the *Accipenser huso*, which is fished on the shores of the Caspian Sea, and in the rivers flowing into it, for the sake chiefly of its swimming-bladder. It is also obtained from the *A. stellatus* and the *A. Güldenstadtii.* At Hamburg, German isinglass is made from the swimming-bladder of the common sturgeon (*A. sturio*). We are informed that in Russia the *Siluris glanis* is also caught for the purpose of obtaining isinglass.

The preparations of isinglass in Russia, and particularly at Astracan, consists in steeping the swimming-bladders in water, removing carefully their external coat, and the blood which often covers them, putting them into a hempen bag, squeezing them, softening them between the hands, and twisting them into small cylinders. They are ready for the market immediately after being dried in the sun, and whitened with the fumes of burning sulphur.

In some districts of Moldavia another process is followed. The skin, the stomach, the intestines, and the swimming-bladder of the sturgeon are cut in small pieces, steeped in cold water, and then gently boiled. The jelly thus obtained is spread in thin layers to dry, when it assumes the appearance of parchment. This being softened in a little water, then rolled into cylinders, or extended into plates, constitutes an inferior article.

The swimming-bladder of the cod, and many other fishes, also furnishes a species of isinglass, but it is much more membranous, and less soluble than that of the sturgeon.

The properties of isinglass are the same as those of gelatine or pure glue; and its uses are very numerous. It is employed in considerable quantities to clarify ale, wine, liqueurs, and coffee. As an article of food to the luxurious in the preparation of creams and jellies, it is in great request. Four parts of it convert 100 of water into a tremulous jelly, which is employed to enrich many soups and sauces. It is used along with gum as a dressing to give lustre to ribbons and other silk articles.

It is by covering thin silk with a coat of isinglass that court-plaster is made. A solution of isinglass covered with carmine forms an excellent injection-liquor to the anatomist. M. Rochen has made another pretty application of isinglass. He plunges into a limpid solution of it, made by means of a water-bath, sheets of wire-gauze set in window- or lamp-frames, which, when cold, have the appearance of glass, and answer instead of it for shades and other purposes. If one dip be not sufficient to make a proper transparent plate of isinglass, several may be given in succession, allowing each film to harden in the interval between the dips. The outer surface should be varnished to protect it from damp air. These panes of gelatine are now generally used for lamps instead of horn, in the maritime arsenals of France. See GELATINE.

Isinglass is known commercially as *Leaf Isinglass, Long and Short Staple,* and *Book Isinglass.* Dr. Royle speaks of the *Samovey leaf, book,* and *long and short staple,* in his paper *On the Production of Isinglass along the coasts of India, with a Notice of its Fisheries.* We receive from the Brazils, *Pipe, Lump,* and *Honeycomb Isinglass.*

Our *Importations* of isinglass in 1871 and 1872 were :—

ISOMERISM, from ἴσος, equal, and μέρος, part. Identity of elements and proportions with variations in physical properties. Thus, oil of turpentine and oil of citron are isomeric, each having the composition $C^{20}H^{16}$ ($\mathbf{C^{10}H^{16}}$). The study of the laws of atomic constitution is one of the most important within the range of physico-chemical science, and, beyomd all others, it demands the highest powers of the philosopher, united with the mechanical care of the microscopic analyst. The tendency of science leads to the conviction that many of the bodies which we now regard as distinct elements are only isomeric; and such groups as chlorine, iodine, bromine, and fluorine, as sulphur, selenium, and boron, and as carbon and silicon, may, with the advance of our knowledge, be shown to be modified conditions of one form of matter.

Several groups of isomeric bodies may be recognised, namely: *isomeric,* properly so called, when compounds have the same percentage composition, and exhibit analogous decompositions; *metameric,* when compounds have the same percentage composition, but do not exhibit analogous decompositions under similar circumstances; and *polymeric,* when compounds have the same percentage composition, but different molecular weights.

The subject of Isomerism is fully treated in Watts's 'Dictionary of Chemistry.'

ISOMORPHISM. Mitscherlich was the first to observe that many groups of substances, simple or compound, having an *analogous* constitution, crystallise in forms of the same crystalline character, or differ but little in their angles. Thus, *alumina, red oxide of iron,* and *sesquioxide of chrome* crystallise in forms of the rhombohedral system.

Carbonate of lime, carbonate of magnesia, carbonate of iron, and *carbonate of manganese,* are also isomorphous forms, belonging to the rhombohedral system.

Sulphate of baryta, sulphate of strontia, and *sulphate of lead,* crystallise in isomorphic forms of the prismatic system.

For a development of this law, consult Brooke and Miller's 'Mineralogy,' Dana's 'System of Mineralogy,' and 'Watts's Dictionary of Chemistry.'

ISOPURPURATE OF AMMONIUM. See MUREXIDE.

ITABIRITE. A rock composed of specular iron ore (micaceous iron) and quartz. It takes its name from Itabira, in Brazil, where it often accompanies the occurrence of gold.

ITACOLUMITE. A fine-grained schistose rock, composed mainly of quartz, with more or less mica, talc, or chlorite. Some varieties are flexible when in thin slabs. By many geologists it is regarded as a metamorphic sandstone. It derives its name from Mount Itacolumi, in Brazil. Diamonds have occasionally been found imbedded in itacolumite; and it has been supposed that some connection exists between the distribution of this rock and the occurrence of diamonds.

IVORY. (*Ivoire*, Fr.; *Elfenbein*, Ger.) The osseous matter of the tusks and teeth of the elephant, and of the tusks of the hippopotamus, and the horn of the narwhal.

Formerly, the name ivory was given to the main substance of the teeth of all animals; but it is now, by the best anatomists and physiologists, restricted to that modification of *dentine*, or tooth-substance, which, in transverse sections or fractures, shows lines of different colours, or striæ, proceeding in the arc of a circle, and forming by their decussation minute or curvilinear lozenge-shaped spaces. By this character, which is presented by even the smallest portion of an elephant's tusk, in transverse section or fracture, true ivory may be distinguished from every other kind of tooth-substance, and from every counterfeit, whether derived from tooth or bone. It is a character—this engine-turned decussatory appearance—which is as characteristic of fossil as of recent ivory. Although, however, no other teeth except those of the elephant present the characteristics of true ivory, there are teeth in many other species of animals which, from their large size, and the density of their principal substance, are useful in the arts for purposes analogous to those for which true ivory is used; and some of those dental tissues, such as those of the large tusks of the hippopotamus, are more serviceable for certain purposes, especially in the manufacture of artificial teeth by the dentist, than any other kind of tooth-substance. The utility of teeth in commerce and in the arts, depends chiefly on a peculiar modification in their laws of growth. For the most part teeth, as in our own frames, having attained a certain size and shape, cease to grow. They are incapable of renewing the waste to which they are liable through daily use, and when worn away, or affected by decay, they perish. Teeth of this kind are said to be of limited growth; but there are other teeth, such as the front teeth of the rat, rabbit, and all the rodent tribe, the tusks of the boar and hippopotamus, the long descending canine tusks of the walrus, the still longer spiral horn-like tusk of the narwhal, and the ivory tusks of the elephant, which are endowed with the property of perpetual growth; that is, they grow as long as the animal lives.

'In teeth of unlimited growth, fresh pulp, fresh capsule, and in some instances also fresh enamel organs are formed, and added to the pre-existing constituents of the tooth matrix, in proportion as those are calcified or converted into tooth-substance; and as fast as the ivory and enamel may be worn away from the summit of such a tooth, will ivory and enamel be formed at its base, and thus the growth of the tooth is uninterrupted. The ratio of the addition of the formative principles is at first greater than the ratio of abrasion, and the tooth not only grows, but increases in size. When, however, the animal has attained its full growth, the tooth, for the most part, is reproduced without increase of size, or, at most, augments only in length, and that in cases where its summit is not perpetually worn down by being opposed to that of an opposite tooth.'

With respect to the distribution of the elephant, the same authority (*Professor Owen*) has the following remarks:—

'In the present creation, elephants are restricted to the African and Asiatic continents. The African elephant, as is well known, is a distinct species from the Asiatic one; and some of the Asiatic elephants of the larger islands of the Indian Archipelago, as those of Sumatra, if not specifically distinct from the elephants of Continental Asia, form, at all events, a strongly marked variety. With reference, however, to the commercial relations of ivory, it is chiefly worthy of notice that in the Asiatic elephants, tusks of a size which gives them the value of ivory in commerce are peculiar to the males, whilst in the African elephants both males and females afford good-sized tusks, although there is a sexual difference of size in this species, those of the males being the largest. In former times, and, as it would seem, before man existed to avail himself of this beautiful animal substance for use or ornament, the large animals furnishing true ivory, proboscidian quadrupeds, as they are termed, from their peculiar prehensile nasal appendage, were much more widely spread over the globe, and existed in far greater numbers than in the present day, more numerous in individuals, more numerous in species, manifesting so great diversities in the conformation of their grinding teeth, as to have led the naturalist and the palæontologist to divide them into two genera, called *Elephas* and *Mastodon*. A true elephant roamed in countless herds over the temperate and northern parts of Europe, Asia, and America. This was the creature called by the Russians Mammoth; it was warmly clad with both hair and fur, as became an animal deriving sustenance from the leaves and branches of trees, which grow as high as the 65th degree of north latitude. Some of the ivory of commerce is, or used to be, derived from the tusks of this extinct species.'

The ivory of the tusks of the African elephant is most esteemed by the manufacturer for its density and whiteness.

The outside of the tusk of the elephant is covered by the cortical part, which is softer and less compact than the interior substance, with the exception of the brown plate that sometimes lines the interior cavity. The hardest, toughest, whitest, and most translucent ivory has the preference in the market; for many purposes the horn of the narwhal being considered the best. The horn of the narwhal is sometimes 10 feet long.

The ivory of the hippopotamus is preferred by dentists; it is much harder than that of the elephant, its colour is a purer white, and it is almost free from grain. The teeth of the walrus, sometimes called the sea-cow, which hang perpendicularly from the upper jaw, are also used for the same purpose. The masticating teeth of some of the large animals are occasionally used as ivory; those of the spermaceti whale are of a flattened oval section, and resemble ivory in section, but they are dark coloured towards the centre, and surrounded by an oval band of white ivory.

Ivory has been used for ornamental works from the earliest periods. Phidias is stated to have been famous for his works made in ivory combined with gold, and described as the *Torentic Art*. The ivory statues of the ancients appear to have been formed upon centres, or cores of wood covered with plates of ivory.

In our days ivory has been extensively employed by the miniature painter; it is used by the turner in the manufacture of numberless useful and ornamental articles; the cutler makes his best knife-handles from it; and the philosophical-instrument maker constructs his scales from this material.

When ivory shows cracks or fissures in its substance, and when a splinter broken off has a dull aspect, it is reckoned of inferior value. Ivory is distinguishable from bone by its peculiar semi-transparent rhombohedral net-work, which may be readily seen in slips of ivory cut transversely.

Ivory is very apt to take a yellow-brown tint by exposure to air. It may be whitened or bleached by rubbing it first with pounded pumice-stone and water, then placing it moist under a glass shade luted to the sole at the bottom, and exposing it to sunshine. The sunbeams without the shade would be apt to occasion fissures in the ivory. The moist rubbing and exposure may be repeated several times.

For etching ivory a ground made by the following recipe is to be applied to the polished surface:—Take of pure white wax, and transparent tears of mastic, each 1 oz.; asphalt, ½ oz. The mastic and asphalt having been separately reduced to fine powder, and the wax being melted in an earthenware vessel over the fire, the mastic is to be first slowly strewed in and dissolved by stirring; and then the asphalt in like manner. This compound is to be poured out into lukewarm water, well kneaded, as it cools, by the hand, into rolls or balls about 1 inch in diameter. These should be kept wrapped round with taffety. If white resin be substituted for the mastic, cheaper composition will be obtained, which answers nearly as well; 2 oz. asphalt, 1 oz. resin, ½ oz. white wax, being good proportions. Callot's etching ground is made by dissolving with heat 4 oz. of mastic in 4 oz. of very fine linseed oil; filtering the varnish through a rag, and bottling it for use.

Either of these grounds being applied to the ivory, the figured design is to be traced through it in the usual way, a ledge of wax is to be applied, and the surface is to be then covered with strong sulphuric acid. The effect comes better out with the aid of a little heat; and by replacing the acid, as it becomes dilute by absorption of moisture, with concentrated oil of vitriol. Simple wax may be employed, instead of the copperplate engraver's ground; and strong muriatic acid, instead of sulphuric. If an acid solution of silver or gold be used for etching, the design will become purple or black on exposure to sunshine. The wax may be washed away oil of turpentine. Acid nitrate of silver affords the easiest means of tracing permanent black lines upon ivory.

Ivory may be dyed by using the following prescriptions:—

1. *Black dye.*—If the ivory be laid for several hours in a dilute solution of neutral nitrate of pure silver, with access of light, it will assume a black colour, having a slightly green cast. A still finer and deeper black may be obtained by boiling the ivory for some time in a strained decoction of logwood, and then steeping it in a solution of red sulphate or red acetate of iron.

2. *Blue dye.*—When ivory is kept immersed for a longer or shorter time in a dilute solution of sulphate of indigo (partly saturated with potash), it assumes a blue tint of greater or less intensity.

3. *Green dye.*—This is given by dipping blued ivory for a little while in solution of nitro-muriate of tin, and then in a hot decoction of fustic.

4. *Yellow dye*—is given by impregnating the ivory first with the above tin mordant, and then digesting it with heat in a strained decoction of fustic. The colour passes into orange, if some Brazil wood has been mixed with the fustic. A very fine unchangeable yellow may be communicated to ivory by steeping it 18 or 24 hours in a strong solution of the neutral chromate of potash, and then plunging it for some time in a boiling hot solution of acetate of lead.

5. *Red dye*—may be given by imbuing the ivory first with the tin mordant, then plunging it in a bath of Brazil wood, cochineal, or a mixture of the two. Lac-dye may be used with still more advantage, to produce a scarlet tint. If the scarlet ivory be plunged for a little in a solution of potash, it will become cherry-red.

6. *Violet dye*—is given in the logwood-bath, to ivory previously mordanted for a short time with solution of tin. When the bath becomes exhausted, it imparts a lilac hue. Violet ivory is changed to purple-red by steeping it a little while in water containing a few drops of nitro-muriatic acid.

With regard to dyeing ivory, it may in general be observed that the colours penetrate better before the surface is polished than afterwards. Should any dark spots appear, they may be cleared up by rubbing them with chalk; after which the ivory should be dyed once more to produce perfect uniformity of shade. On taking it out of the boiling hot dye-bath, it out to be immediately plunged into cold water, to prevent the chance of fissures being caused by the heat.

Aniline dyes.—Any of these colours give a fine and permanent colour to ivory.

If the borings and chips of the ivory-turner, called ivory dust, be boiled in water, a kind of fine size is obtained.

Ivory made flexible.—Ivory articles may be made flexible and semi-transparent, by immersing them in a solution of pure phosphoric acid of sp. gr. 1·130, and leaving them there till they lose their opacity; they are then to be taken out, washed with water, and dried with a soft cloth; it thus becomes as flexible as leather. It hardens on exposure to dry air, but resumes its pliancy when immersed in hot water. Necks of children's sucking-bottles are thus made.

The following account of the methods of preparing this material, we extract from Holtzapffel's 'Mechanical Manipulation':—

'On account of the great value of ivory, it requires considerable judgment to be employed in its preparation, from three conditions observable in the form of the tusk: first, its being curved in the direction of its length; secondly, hollow for about half that extent, and gradually taper from the solid state to the thin feather edge at the root; and thirdly, elliptical or irregular in section. These three peculiarities give economy, as the only waste should be that arising from the passage of the thin blade of the saw: even the outside strips of the rind, called spills, are employed for the handles of penknives, and many other little objects; the scraps are burned in retorts for the manufacture of ivory black, employed for making ink for copper-plate printers, and other uses, and the clean sawdust and shavings are sometimes used for making jelly.

'The methods of dividing the tooth, either into rectangular pieces or those of a circular figure required for turning, are alike in their early stages, until the lathe is resorted to. The ivory saw is stretched in a steel frame to keep it very tense; the blade generally measures from fifteen to thirty inches long, from one and a half to three inches wide, and about the fortieth of an inch thick; the teeth are rather coarse, namely, about five or six to the inch, and they are sloped a little forward, that is, between the angle of the common hand-saw tooth and the cross-cut saw. The instrument should be very sharp, and but slightly set; it requires to be guided very correctly in entering, and with no more pressure than the weight of its own frame, and is commonly lubricated with a little lard, tallow, or other solid fat.

'The cutter begins generally at the hollow, and having fixed that extremity parallel with the vice, with the curvature upwards, he saws off that piece which is too thin for his purpose, and then two or three parallel pieces to the lengths of some particular works, for which the thickness of the tooth at that part is most suitable; he will then saw off one very wedge-form piece, and afterwards two or three more parallel blocks.

'In setting out the length of every section, he is guided by the gradually-increasing thickness of the tooth; having before him the patterns or images of his various works, he will in all cases employ the hollow for the thickest work it will make. As the tooth approaches the solid form, the consideration upon this score gradually ceases, and then the blocks are cut off to any required measure, with only a general reference to the distribution of the *heel*, or the excess arising from the curved nature of the tooth, the cuts being in general directed as nearly as may be to the imaginary centre of curvature. The greater waste occurs in cutting up very long pieces, owing to the difference between the straight line and the curve of the tooth, on which account the blocks are rarely cut more than five or six inches long, unless for some specific object.'

Mr. P. L. Simmonds has given the following as the weights of large elephants' tusks :—

	lbs.
Mr. Gordon Cumming had one weighing	173
Mr. Cawood, of Graham's Town, had a pair weighing . . .	330
From Camaroon, shipped to Liverpool	164
A tusk imported at Bristol	147
At the Great Exhibition of 1851, tusk	162

IVORY BLACK (*Noir d'ivoire*, Fr.; *Kohle von Elfenbein*, Ger.) is prepared from ivory-dust, by calcination, in the very same way as is described under Bone Black. The calcined matter being ground and levigated on a porphyry slab affords a beautiful velvety black, much used in copperplate printing.

IVORY, FICTILE, is plaster-of-Paris which has been made to absorb, after drying, melted spermaceti, by capillary action; or it may be prepared according to Mr. Franchi's process as follows :—Plaster and colouring matter are employed in the proportions of a pound of superfine plaster-of-Paris to half an ounce of Italian yellow ochre. They are intimately mixed by passing them through a fine silk sieve, and a plaster cast is made in the usual way. It is first allowed to dry in the open air, and is then carefully heated in an oven; the plaster cast, when thoroughly dry, is soaked for a quarter of an hour in a bath containing equal parts of white wax, spermaceti, and stearine, heated just a little beyond the melting-point. The cast on removal is set on edge, that the superfluous composition may drain off; and before it cools, the surface is brushed, with a brush like that known by house-painters as a sash tool, to remove any wax which may have settled in the crevices; and finally when the plaster is quite cold, its surface is polished by rubbing it with a tuft of cotton wool.

IVORY NUT or *Vegetable Ivory*. This substance is the hardened albumen of the seeds of a species of palm known as the *Phytelephas macrocarpa*. The palm grows in the low valleys of the Peruvian Andes. The seeds are known in commerce as *Corosso nuts*, and are enclosed in large capsular fruit, somewhat resembling a negro's head, and hence locally termed *Cabeza de Negro*. The albumen has a structure somewhat resembling that of ivory; but it more nearly resembles white wax. The ivory nut is occasionally used by the turner for small ornamental objects, but not for any important work.
