the use of metallic oxides;' and in another he writes, 'A decoction of *Thlaspi* (Shepherd's purse), fumes of phosphorus, and particularly of sulphur, as acting on silver in the *same way as iodine*, and caloric, produce the same effect by oxidising the metal, for from this cause proceeded in all these instances their extreme *sensibility to light*.' Niepce died in July 1833. Daguerre proceeded with his experiments for nearly six years, before he succeeded in producing the desired results. The Daguerreotype process depends on the production of a very delicate chemical compound of iodine and silver on the surface of a carefully-prepared silver plate. The image is developed by the action of mercurial vapour, and lastly rendered permanent, so far as the action of light is concerned, by dissolving off the iodide of silver by hyposulphite of soda. According to the first published description by Daguerre, the process is divided into five operations. The first consists in polishing and cleaning the silver surface, by friction, with cotton fleece imbued with olive-oil, upon the plate previously dusted over with very finely-ground dry pumice-stone out of a muslin bag. The hand of the operator should be moved round in circles of various dimensions. The plates should be laid upon a sheet of paper solidly supported. The pumice must be ground to an impalpable powder upon a porphyry slab with water, and then dried. The surface is next to be rubbed with a dossil of cotton, slightly moistened with nitric acid, diluted with sixteen parts of water, by applying the tuft to the mouth of the phial of acid, and inverting it for a moment. Two or three such dossils should be used in succession. The plate is lastly to be sprinkled with pumice-powder or Venetian tripoli, and rubbed clean with cotton.

The plate is then placed in a wire frame, with the silver surface uppermost, over a spirit-lamp, meanwhile moving it so as to act equally on every part of the plate. In about five minutes a whitish coating will indicate that this operation is completed. The plate must now be laid upon a flat metal or marble slab to cool it quickly. The white surface is to be brightened by rubbing it with cotton and pumice-powder. It must be once more rubbed with the cotton imbued with acid, and afterwards dried by

D

DAGUERREOTYPE. Although this beautiful photographic process is entirely superseded by other processes, a description of it is preserved, on account of the interesting conditions involved in the production of the picture. It was discovered by M. Daguerre, a celebrated French dioramic painter, with whom was associated M. Nicéphore Niepce, and published in July 1839; the French Government having secured a pension for life of 6,000 francs on M. Daguerre, and of 4,000 francs on M. Isidore Niepce, the son of M. Nicéphore Niepce.

It is rendered clear from some of Niepce's letters, that he had abandoned all hope of succeeding by his methods (named by him Heliography), and in a letter to Daguerre, he says, 'I repeat it, sir, I do not see that we can hope to derive any advantage from this process—the use of iodine—more than from any other method which depends on the use of metallic oxides;' and in another he writes, 'A decoction of *Thlaspi* (Shepherd's purse), fumes of phosphorus, and particularly of sulphur, as acting on silver in the *same way as iodine*, and caloric, produce the same effect by oxidising the metal, for from this cause proceeded in all these instances their extreme *sensibility to light*.' Niepce died in July 1833. Daguerre proceeded with his experiments for nearly six years, before he succeeded in producing the desired results. The Daguerreotype process depends on the production of a very delicate chemical compound of iodine and silver on the surface of a carefully-prepared silver plate. The image is developed by the action of mercurial vapour, and lastly rendered permanent, so far as the action of light is concerned, by dissolving off the iodide of silver by hyposulphite of soda. According to the first published description by Daguerre, the process is divided into five operations. The first consists in polishing and cleaning the silver surface, by friction, with cotton fleece imbued with olive-oil, upon the plate previously dusted over with very finely-ground dry pumice-stone out of a muslin bag. The hand of the operator should be moved round in circles of various dimensions. The plates should be laid upon a sheet of paper solidly supported. The pumice must be ground to an impalpable powder upon a porphyry slab with water, and then dried. The surface is next to be rubbed with a dossil of cotton, slightly moistened with nitric acid, diluted with sixteen parts of water, by applying the tuft to the mouth of the phial of acid, and inverting it for a moment. Two or three such dossils should be used in succession. The plate is lastly to be sprinkled with pumice-powder or Venetian tripoli, and rubbed clean with cotton.

The plate is then placed in a wire frame, with the silver surface uppermost, over a spirit-lamp, meanwhile moving it so as to act equally on every part of the plate. In about five minutes a whitish coating will indicate that this operation is completed. The plate must now be laid upon a flat metal or marble slab to cool it quickly. The white surface is to be brightened by rubbing it with cotton and pumice-powder. It must be once more rubbed with the cotton imbued with acid, and afterwards dried by friction with cotton and pumice; avoiding to touch the plate with the fingers, or with the part of the cotton held in them, or to breathe upon the plate, since spots would thereby be produced. After cleaning with cotton alone, the plate is ready for the next operation.

The second stage is that of iodising the plate. A box is prepared, having iodine strewed over its bottom, and the silver plate, face downwards, is placed a few inches above the iodine, and the lid of the box being closed, all is left at rest for a short time. The plate must be left in this position till the surface of the silver acquires a fine golden hue, caused by the vapours of the iodine rising and condensing upon it; but it should not be allowed to assume a violet tint. The room should be darkened, and no heat should be employed. When the box is in constant use it gets impregnated with iodine, and acts more uniformly and rapidly; but in general states of the atmospheric temperature this operation will be effected in about twenty minutes. If the purple colour be produced, the plate must be repolished, and the whole process repeated.

The plate with its golden hue is to be introduced, with its frame, to the camera obscura. During this transfer the light must not be suffered to strike upon the surface of the plate; on which account, the camera obscura may be lighted briefly with a small wax taper.

The plate is now submitted to the third operation, that of the camera obscura, and with the least possible delay. The action of the solar radiations is obviously quicker the brighter the radiations which act upon it; and the more correct, according as the focus of the camera is previously accurately adjusted to the place of the plate, by moving backwards and forwards a roughened pane of glass, till the focal point be found; and the plate is to be inserted precisely there. This silver plate exactly replaces the ground glass. While the prepared plate is being fastened, the camera must be closed. The plate is now in a proper position to receive and retain the impression of the image of the objects presented the moment that the camera is opened. Experience alone can teach the proper length of time for submitting the plate to the concentrated rays of light; because that time varies with the climate, the seasons, and the time of day. More time should not be allowed to pass than what is necessary for fixing a distinct impression, because the parts meant to be clear would be apt to become clouded. The impression of the image of nature is now actually made upon the plate; but it is as yet invisible; and it is only after a lapse of several minutes, during which it is exposed to mercurial vapour, that faint tracings of the objects begin to be seen.

The fourth is the operation with quicksilver, which must follow as soon as possible the completion of the third. Here a phial of quicksilver, a spirit-lamp, and a glass funnel with a long neck, are required. The funnel is used for pouring the mercury into a cup, placed in the bottom of an apparatus which will allow of the application of heat. No daylight must be admitted to the mercury box, a small taper only being used to examine, from time to time, the effects. The plate with the dormant image is placed some distance above the mercury, which vaporising, evokes in a truly magical manner, the delicate lines which the solar pencil has traced.

After each operation, the interior of the apparatus and the black board or frame should be carefully wiped, in order to remove every particle of mercury. The picture may now be inspected in a feeble light, to see how far the process has succeeded. The plate, freed from the metallic bands, is to be placed in a box, provided with a cover and grooves, to exclude the light, till it is made to undergo the last operation. For the fifth and last operation the following articles are now required:—strong brine, or a weak solution of hyposulphite of soda; two troughs of tin plate, and a jug of distilled water. The object of this process is to fix the photographic picture. One of the troughs is to be filled with brine to the depth of an inch, and the other with pure water, both liquids being heated somewhat under the boiling point. The solution of hyposulphite of soda is preferable, and does not need to be warm. The plate is to be first immersed in the pure water for a moment, and transferred immediately to the saline solution, and moved to and fro in it to equalise the action of the liquor. Whenever the yellow tint of the iodine is removed, the plate is to be lifted out by the edges, and dipped straightway in the water-trough. The plate, when lifted out of the water-trough, is to be placed immediately on an inclined plane; and without allowing it time to dry, is to be floated over with hot distilled water from the top, so as to carry off all the saline matter. As the quicksilver which traces the images will not bear touching, the silvered plate should be secured by a cover of glass, made tight at the edges by pasting paper round them.

The Daguerreotype process as thus published, although even then an exceedingly beautiful process, was not sufficiently sensitive to enable the operator to obtain portraits from the life. A period of twenty minutes was required, even with the most favourable light, to produce the desired effect. Numerous modifications were speedily introduced, and many of them were patented.

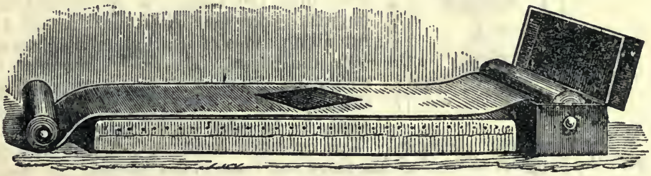
The progressive advance of this branch of the photographic art, though of great interest, cannot be dwelt on in this place. Those who are interested in the inquiry will find the information fully detailed in Hunt's 'Manual of Photography,' last edition, and more recent works. It will be sufficient here to name the more important improvements which have become generally adopted. The first advance of real importance was made by Mr. Towson, of Devonport, who has since that time distinguished himself by the introduction of his system of Great Circle Sailing. Mr. Towson suggested the use of enlarged lenses; and by acting with such Dr. Draper, of New York, was the first to procure a portrait from the life. Still this was a tedious process; but in 1840, Mr. Goddard proposed the use of bromide of iodine, by which infinitely increased sensibility was obtained. From that time the Daguerreotype was generally employed for portraiture, until the facilities of the Collodion process drove it from the field.

The improved manipulation now resolves itself into:—

Carefully polishing the silver plate after some of the methods previously described, and the application finally of the highest polish by the use of a buffer, the best form being that employed by M. Claudet.

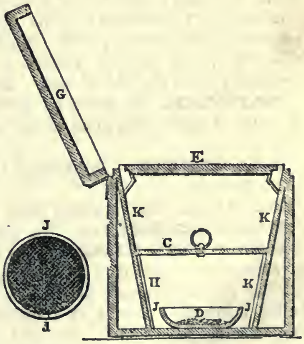
In a box on a roller, to which there is a handle, *fig.* 596, is placed a long piece of drab-coloured velvet, which can be drawn out and extended, by means of a second roller, upon a perfectly flat table. The first foot or two, for example, is drawn out; the plate which has already received its preliminary polishing is placed face downwards, and being pressed close with the fingers, a rapid circular motion is given to it, and in a few minutes it receives its highest lustre. As the velvet becomes blackened by use, it is rolled off, the portion remaining in the box being always perfectly clean and ready for use.

596



The iodising process follows: and for this purpose a box similar to that represented will be found to be very convenient (*fig.* 597). This iodising apparatus consists of a square box, with a closely-fitting square cover G: false sides are placed at an angle with this box; a cup D at the bottom contains the iodine, which is covered with a thin gauze screen J J. C is a cover which confines the iodine when it is not required for the plate; this dividing the box into two parts, H H and K K, the former being always full of iodine vapour. When it is desired to iodise a plate, the cover C is removed, the silver plate is placed at E, and the cover G closed.

597

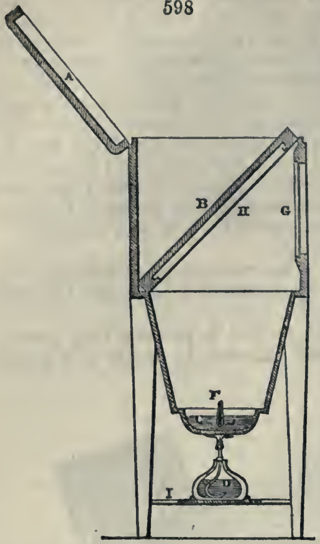


The plate is thus placed in the iodine box until it acquires a fine straw-yellow colour. In another box is placed either bromine or some of the many accelerating fluids. If bromine, or any bromide is employed, the plate should remain until it is of a rose colour. As a general rule, if the yellow colour produced by iodine be pale, the red should be pale also; if deep, the red must incline to violet. The proper time for exposing a plate to any of those chemical substances which are destined to produce the sensitive film must vary with the temperature, and it can only be determined by experience. The sensitive plate is now removed to the camera obscura, for a description of which see PHOTOGRAPHY. It is scarcely necessary to say, that the plate must be preserved in perfect darkness until exposed to the image in the camera.

A few seconds when the plate is properly prepared will be found amply sufficient to produce the best effect.

The impression must be developed in the mercury box (*fig.* 598) in the manner described by Daguerre. This mercurial box consists of a box mounted on legs, having a close-fitting cover A, and an iron bottom in which is placed the mercury C, with a small thermometer F to indicate the proper temperature. G is a piece of glass let into the side of the box through which the Daguerreotype plate H, fixed in the frame B, can be seen. D is a spirit-lamp, and I the platform on which it stands. The subject is eventually fixed by the use of hyposulphite of soda, which removes the bromo-iodide of silver and leaves a picture produced by the contrast between a combination of the silver and mercury, and the surface of the unchanged polished silver.

598



The application of chloride of gold to the finished picture was introduced by M. Fizeau.

Chloride of gold applied to the picture has the effect of fixing and enlivening the tints. A small grate being fixed by a clamp to the edge of a table, the plate is laid upon it with the image uppermost, and overspread evenly with solution of chloride of gold, by means of a fine broad camel-hair brush, without letting any drop over the edge. A spirit-lamp is now brought under the plate, and moved to and fro till a number of small steam bubbles appear upon the image. The spirit-lamp must be immediately withdrawn. The remainder of the chloride solution must be poured back into the phial, to be used on another occasion. It is lastly to be washed and examined. This operation has been repeated three or four times with the happiest effect of giving fixity and force to the picture. It may then be wiped with cotton without injury. The process of colouring these pictures is a purely artificial one, which, while it destroys the beauty of the photograph, does not in any way improve it as a picture.

Daguerreotype Engraving.—Several processes for etching the Daguerreotype plate were introduced with more or less success. Professor Grove produced a few good engravings by the action of voltaic electricity. Berard and Becquerel were also enabled to produce some promising results by a similar process. The following process by M. Claudet was carried out to some extent with every prospect of success:

A mixed acid, consisting of water, nitric acid, nitrate of potash, and common salt, in certain proportions, being poured upon a Daguerreotype picture, attacks the pure silver, forming a chloride of that metal, but does not affect the white parts, which are produced by the mercury of the picture. This action does not last long. Water of ammonia, containing a little chloride of silver in solution, dissolves the rest of that chloride, which is then washed away, leaving the naked metal to be again attacked, especially with the aid of heat. See Collodion; Heliography; Photography.

DAHLINE, the same as Inuline. The fecula obtained from elecampane and from the dahlia, analogous in many respects to starch. It has not been employed in the arts.

DALARNITE. Breithaupt's name for a Swedish variety of mispickel or arsonical pyrites.

DAMAR. See Dammar Gum.

DAMASCEENING. See Damaskeening.

DAMASCUS BLADES are swords or scimitars, presenting upon their surface a variegated appearance of *watering*, as white, silvery, or black veins, in fine lines, or fillets; fibrous, crossed, interlaced, or parallel, &c. They are brought from the East, being fabricated chiefly at Damascus, whence their name. Their excellent quality has become proverbial; for which reason these blades are much sought after by military men, and are high priced. The oriental processes have never been satisfactorily described; but of late years methods have been devised in Europe to imitate the fabric very well.

Clouet and Hachette pointed out the three following processes for producing Damascus blades: 1, that of *parallel fillets*; 2, that by *torsion*; 3, the *mosaic*. The first, which is still pursued by some French cutlers, consists in scooping out with a graving tool the faces of a piece of stuff composed of thin plates of different kinds of steel. These hollows are by a subsequent operation filled up, and brought to a level with the external faces, upon which they subsequently form tress-like figures. 2. The method of torsion, which is more generally employed at present, consists in forming a bundle of rods or slips of steel, which are welded together into a well-wrought bar, twisted several times round its axis. It is repeatedly forged, and twisted alternately; after which it is slit in the line of its axis, and the two halves are welded with their outsides in contact; by which means their faces will exhibit very various configurations. 3. The mosaic method consists in preparing a bar, as by the torsion plan, and cutting this bar into short pieces of nearly equal length, with which a faggot is formed and welded together; taking care to preserve the sections of each piece at the surface of the blade. In this way, all the variety of the design is displayed, corresponding to each fragment of the cut bar.

The blades of Clouet, independently of their excellent quality, their flexibility, and extreme elasticity, have this advantage over the oriental blades, that they exhibit in the very substance of the metal, designs, letters, inscriptions, and, generally speaking, all kinds of figures which had been delineated beforehand.

Notwithstanding these successful results of Clouet, it was pretty clear that the watered designs of the true Damascus scimitar were essentially different. M. Bréant has attempted a solution of this problem. He supposes that the substance of the oriental blades is a cast steel more highly charged with carbon than our European steel, and in which, by means of a cooling suitably conducted, a crystallisation takes place of two distinct combinations of carbon and iron. This separation is, he thinks, the essential condition; for if the melted steel be suddenly cooled in a small crucible or ingot, there is no damascene appearance.

If an excess of carbon be mixed with iron, the whole of the metal will be converted into steel; and the residuary carbon will combine in a new proportion with a portion of the steel so formed. There will be two distinct compounds; namely, pure steel, and carburetted steel or cast iron. These at first being imperfectly mixed, will tend to separate if while still fluid they be left in a state of repose; and form a crystallisation in which the particles of the two compounds will place themselves in the crucible in an order determined by their affinity and density conjoined. If a blade forged out of steel so prepared be immersed in acidulous water, it will display a very distinct Damascus appearance; the portions of pure steel becoming black, and those of carburetted steel remaining white, because the acids with difficulty disengage its carbon. The slower such a compound is cooled, the larger the Damascus veins will be. Tavernier relates that the steel crucible ingots, like those of wootz, for making the true oriental Damascus, come from Golconda, that they are the size of a halfpenny roll, and when cut in two, form two swords.

Steel combined with manganese displays the Damascus appearance very strongly.

A mixture of 100 parts of soft iron and 2 of lamp-black melts as readily as ordinary steel. Several of the best blades which M. Bréant presented to the Société d'Encouragement are the product of this combination. This is an easy way of making cast steel without previous cementation of the iron. 100 parts of filings of very grey cast iron, and 100 parts of like filings previously oxidised, produced, by their fusion together, a beautiful damascene steel, fit for forging into white arms, sabres, swords, &c. This compound is remarkable for its elasticity, an essential quality, not possessed by the old Indian steel. The greater the proportion of the oxidised cast iron the tougher is the steel. Care should be taken to stir the materials during their fusion, before they are allowed to cool; otherwise they will not afford a homogeneous damask. If the steel contains much carbon it is difficult to forge, and cannot be drawn out except within a narrow range of temperature. When heated to a red-white it crumbles under the hammer; at a cherry-red it becomes hard and brittle; and as it progressively cools it becomes still more unmalleable. It resembles completely Indian steel, which European blacksmiths cannot forge, because they are ignorant of the suitable temperature for working it. M. Bréant, by studying this point, succeeded in forging fine blades.

Experience has proved that the orbicular veins, called by the workmen *knots* or *thorns* (*ronces*), which are seen upon the finest Eastern scimitars, are the result of the manner of forging them, as well as the method of twisting the Damascus bars. If these be drawn in length, the veins will be longitudinal; if they be spread equally in all directions, the stuff will have a crystalline aspect; if they be made wavy in the two directions, undulated veins will be produced like those in the oriental Damascus.

The characteristics ascribed to the real Damascus blades are extraordinary keenness of edge, great flexibility of substance, a singular grain of fleckiness always observable on the surface, and *a peculiar musky odour* given out by any friction of the blade, either by bending or otherwise. The author of 'Manufactures in Metals' remarks:

'A gentleman who purchased one of these blades in the East Indies for a thousand piastres, remarked to the writer of this volume that, although the instrument was very flexible, and bore a very keen edge, it could not with safety be bent to more than 45° from the straight shape, and it was not nearly so sharp as a razor, yet, wielded by a skilful hand it would cut through a thick roll of sail-cloth without any apparent difficulty; a feat which could not be performed with an ordinary sword, nor, it should be observed, by the sabre itself in an ordinary hand, though the swordsman who tried it could, it appears, do nearly the same thing with a good European blade.'

Emerson, in his letters from the Ægean, says: 'I have seen some blades (scimitars) which were valued at 200 or 300 dollars; many are said to be worth triple that sum, and all retain the name of *Damascus*, though it is by no means likely that they have been manufactured there. The twisting and interwisting of the fibres of the metal are considered as the tests of excellence, but I have never seen any possessed of the perfume said to be incorporated with the steel in the real Damascus blade.'

Steel helmets and cuirasses were formed of cast and damascened steel, intermixed with pure iron, a mixture supposed to combine toughness and hardness in the greatest possible degree.

The production and use of damask steel received much attention from the late General Anossoff, of the Corps of Engineers of the Imperial Russian army, and Master of the Fabric of Arms at Zlatoust, in Siberia. His researches and successful practice have become matters of history.

At different periods these works at Zlatoust have been visited, by two English travellers, Major Abbott of the Bengal Artillery, and Mr. Atkinson, who have recorded the results of observation, experiment, and conversational intercourse, and they state severally their conviction that the damask steel produced by Anossoff rivalled in beauty and excellence any works they had ever seen in other lands. They accord to Anossoff the honour of being the reviver of the art of making damask steel in Europe, while they declare the Russian natural damask steel is not approached by the fabrics of any Eastern nation now existing. These works were also visited by the late Sir R. I. Murchison.

The Siberian swords and daggers were compared and tried with the choicest specimens, and found equal to the blades of Damascus and the sabres of Khorassan; and while these valued articles might have been selected from numbers manufactured by chances of skill and material, Anossoff united chemical analyses of ores and steel, and records of observations on progressive stages, to give a true history of the means to explain and insure success.

Major Abbott gives the following description of the damask as produced at Zlatoust. He defines it to be a modification of cast steel, by which it is impressed with a peculiar character in its crystallisation, which character betrays itself when the corrosion of acids, by acting more violently between the interstices of the structure than elsewhere, traces out the arrangement of the crystals. This property is communicated to the damask of Zlatoust by a process tending to perfect the quality of the steel, and to impress upon the cast steel the elastic properties of a softer material. The general fault of European blades is, that being forged of shear steel for the sake of elasticity, they are scarcely susceptible of the keen edge which cast steel will assume. The genius of Anossoff has triumphed over this objection, not by hardening the soft steel, but by giving elasticity to the hard; the result has been the production of weapons combining, in the very highest degree, elasticity with keenness of edge. We believe that the manufacture of damask steel is no longer carried on at Zlatoust.

Colonel Anossoff has published, in Russia, a treatise on the art of damasking steel. The following remarks are extracted and condensed from it:—

'In Russia, we understand, by *damask*, a metal harder, and supplying a material for arms of a keener edge, than ordinary steel. All the researches of chemists have, until now, failed in discovering any essential difference between the damask and ordinary steel, which, nevertheless, proves only that the analysis has been imperfect, and that it is only want of means that prevents success. Although the chemists of the present day presume that the natural damask is the effect of crystallisation, produced by retarded cooling of the heated metal, yet, not having been able to produce a damask by this means equal to the ancient work of Asia, they cannot establish this ground. If crystallisation generally is but the result of the structure of bodies under certain physical conditions, the question results, Why in the damask is it not the result of a similar cause; and since common steel acquires no visible damask by gradual refrigeration, is not this a convincing proof that the composition of damask differs from that of ordinary steel? Thus, on the one hand, the imperfection of our chemical knowledge, and on the other, the difficulty of fabricating the damask, leave Europeans still in uncertainty as to its merits.

'All steel which exhibits a surface figured with dark lines is called damask. In some of the various kinds of steel these figures appear after burnishing, whilst in others dilute acid is necessary to bring them out.

"The mere appearance of this damascene does not confer upon the steel the title of damask. On ordinary steel, similar figures may be brought out by subjecting it to corrosion, after having designed on it the figures required. This is called false damask.'

A second kind of damask, called artificial damask, is peculiar to the metal itself, so that however often it is repolished the same figures will reappear whenever it is subject to corrosion. It is composed of several sorts of steel, interlaced with iron. The beauty of such damask consists partly in the quantity of the several materials, and partly in the skill with which they are worked together. These artificial damasks are chiefly wrought in Asia, viz. in India, Turkey, and Georgia, whilst those of Europe have as yet obtained no great reputation, because the European workmen are more intent on producing elegant figures on the steel than on improving the steel itself.

The Orientals judge of the goodness of the damask in the following manner:—The first and most essential sign of the beauty of the damask or water is its being thick, defined, and fantastic. They further give us three rules whereby the quality of the damask may be judged:

1. By the form of the damask, which may be either in points, right lines, or curved, the right lines being the lowest quality, and advancing by stages into curves and points. forming, in the best damask, figures resembling grapes or network.
2. By the line of its ground: the deeper the tint the more perfect the metal.
3. By the play of colour on the metal in an oblique light. Some show no variation of tint, whilst others take on a crimson or golden hue. The more perceptible the play of colour the finer the quality of the damask.

The qualifications claimed for the most perfect damask are extreme malleability and ductility, the hardest possible substance after tempering, the keenest and firmest edge, and elasticity when properly tempered.

DAMASCUS GUN-BARRELS. See GUN-BARREL.

DAMASK is a variegated textile fabric, richly ornamented with figures of flowers, fruits, landscapes, animals, &c., woven in the loom, and is by far the most rich, elegant, and expensive species of ornamental weaving, tapestry alone excepted. The name is said to be derived from Damascus, where it was anciently made.

Damask belongs to that species of texture which is distinguished by practical men by the name of tweeling, of which it is the richest pattern. The tweel of damask is usually half that of full *satin*, and consequently consists of eight leaves moved either in regular succession or by regular intervals, eight leaves being the smallest number which will admit of alternate tweeling at equal intervals.

The generic difference of tweeling, when compared with common cloth, consists in the intersections, although uniform and equidistant, being at determinate intervals, and not between the alternate threads. Hence we have the specimens of tweeled cloth, where the intersections take place at the third, fourth, fifth, sixth, seventh, eighth, or sixteenth interval only. The threads thus deflecting only from a straight line at intervals, preserve more of their original direction, and a much greater quality of materials can be combined in an equal space, than in the alternate intersection, where the tortuous deflection, at every interval, keeps them more asunder. On this principle tweeled cloths of three and four leaves are woven with facility of combination alone. The coarser species of ornamental cloths, known by the names of dornock and diaper, usually intersect at the fifth, or half satin interval. The sixth and seventh are rarely used, and the intersection at the eighth is distinguished by the name of satin in common, and of damask in ornamental tweeling. It will further be very obvious, that where the warp and woof cross only at every eighth interval, the two sides of the cloth will present a diversity of appearance; for on one side the longitudinal or warp threads will run parallel from one end of a web to the other, and, on the other, the threads of woof will run also parallel, but in a transverse direction across the cloth, or at right angles to the former. The points of intersection being only at every eighth interval, appear only like points; and in regular tweeling these form the appearance of diagonal lines, inclined at an angle of 45° (or nearly so) to each of the former.

The appearance, therefore, of a piece of cotton tweeled cloth is very similar to that of two thin boards glued together, with the grain of the upper piece at right angles to that of the under one. That of an ornamental piece of damask may, in the same manner, be very properly assimilated to a piece of veneering, where all the wood is of the same substance and colour, and where the figures assume a diversity of appearance from the ground, merely by the grain of the one being disposed perpendicularly to that of the other.

From this statement of the principle, it results that the most unlimited variety of figures will be produced by constructing a loom by which every individual thread of warp may be placed either above or below the woof at every intersection; and to effect this, in boundless variety, is the object of the Jacquard mounting. See LOOM, JACQUARD.

The chief seat of this manufacture is the town and neighbourhood of Dunfermline, in Fifeshire, and Lisburn and Ardoyne, near Belfast, where it is considered as the staple, having proved a very profitable branch of traffic to the manufacturer, and given employment to many industrious people.

The material used there is chiefly linen, but many have been recently woven of cotton, since the introduction of that article into the manufacture of cloth has become so prevalent. The cotton damasks are considerably cheaper than those of linen, but are not considered either so elegant or durable. The cotton, also, unless frequently bleached, does not preserve the purity of the white colour nearly so well as the linen.

DAMASKEENING. The art of ornamenting iron, steel, &c., by making incisions upon its surface, and filling them up with gold or silver wire. It is chiefly used in enchasing sword-blades, guards, and grips, locks of pistols, &c.

Its name shows the place of its origin, or, at least, the place where it has been practised in the greatest perfection, viz., the city of Damascus, in Syria; though M. Félibien attributes the perfection of the art to his countryman, Cursinet, who wrought under the reign of Henry IV.

Damaskeening is partly mosaic work, partly engraving, and partly carving. As mosaic work, it consists of pieces inlaid; as engraving the metal is indented, or cut in *intaglio*; and as carving, gold and silver are wrought into it in *rilievo*.

There are two ways of damaskeening: in the first, which is the most beautiful, the artists cut into the metal with a graver, and other tools proper for engraving upon steel, and afterwards fill up the incisions, or notches, with a pretty thick silver or gold wire. In the other, which is only superficial, they content themselves to make hatches, or strokes across the iron, &c., with a cutting knife, such as is used in making small files. As to the first, it is necessary for the gravings or incisions to be made in dove-tail form, that the gold or silver wire, which is thrust forcibly into them, may adhere the more strongly. As to the second, which is the more usual, the method is this: having heated the steel till it changes to a violet, or blue colour, they hatch it over and across with a knife, then draw the ensign or ornament intended upon this hatching with a fine brass point or bodkin. This done they take fine gold wire, and conducting or chasing it according to the figures already designed, they sink it carefully into the hatches of the metal with a copper tool.

An inferior description of damaskeen work has been introduced since the discovery of the electrotype processes. The pattern has been etched on the steel, and then gold or silver deposited into the etched lines.

DAMASSIN. A kind of damask, with gold and silver flowers woven in the warp and woof, or occasionally with silk organzine.

DAMBONITE. A crystallisable saccharine substance obtained by M. Aimé Girard from a peculiar kind of caoutchouc from the Gaboon on the West coast of Africa. The botanical source of this caoutchouc is not known. Dambonite, when isolated, crystallises in white needles, which contain $C^8H^8O^6$ ($\mathbf{C^4H^8O^3}$). It is readily soluble in water and in ordinary alcohol; it melts at 374° F., (190° C.) and sublimes between 392° and 410° F., (200° and 210° C.). Dambonite is decomposed by hydriodic or by hydrochloric acid, yielding iodide or chloride of methyl, together with a sugar isomeric with glucose, containing $C^6H^6O^6$ ($\mathbf{C^3H^6O^3}$). This sugar is called *Dambose*.

DAMMAR GUM or **DAMMARA RESIN.** A pale yellow resin, somewhat resembling copal, and used like it in the manufacture of varnishes. Dammara resin is the produce of the *Dammara australis*, or Kawrie-pine of New Zealand. Large masses of the gum-resin are found in the ground at the base of the pines. Another kind of dammar is obtained from the *Dammara alba* of India, where it is usually called *Dammar Pute*, or *Cat's-eye resin*. A substance called Dammar is used in the East Indies for caulking ships. It is composed of this resin, mixed with the powdered bark of the bamboo, and a little chalk. Some Indian dammar is said to come from the *D. orientalis*,, and the Indian *Piney Dammar* is yielded by the *Vaterica Indica*.

Dammar is largely employed in the preparation of certain varnishes. 'Damar is easily dissolved in oil of turpentine, and when carefully selected is almost colourless; it makes a softer varnish than mastic; the two combined, however, form an almost colourless varnish, moderately hard and flexible, and well suited for maps and similar purposes.'—*Holtzapffel.*

Dammar varnish has been lately recommended for mounting microscopic objects in the stead of Canada balsam. The following recipe for its preparation has been given by Dr. Klein: Dissolve half an ounce of gum-dammar, in powder, in one or two ounces of turpentine, and dissolve half an ounce of gum-mastic in two ounces of chloroform;

the two solutions are then separately filtered, and mixed together. The varnish thus obtained is clear, and if exposed in a thin layer on a plate of glass it rapidly solidifies.

DAMMAR PITCH. A balsamic resin employed in India for incense, and obtained from the Sál tree, the *Shea robusta*.

DAMOURITE. A hydrated potash-mica, named after the French chemist, M. Damour.

DAMP, *in mining*, a term applied to dangerous exhalations, or rather gases,—so called from the German *Dampf*, vapour—escaping from the mineral formations, or accumulating in the workings.

Fire-Damp, which occurs in coal-mines, is *carburetted hydrogen gas*.

Choke-Damp, *After-Damp*, and *Black-Damp*, may be regarded as carbonic acid. See MINES, VENTILATION OF.

DANAITE. A cobaltiferous mispickel. It has been proposed to unite under this name all varieties of mispickel which contain cobalt. The name is complimentary to Mr. J. F. Dana.

DANALITE. A silicate of the protoxides of iron, manganese, and beryllium, with sulphide of zinc. It occurs in octahedral crystals, in granite, at Rockport, and near Gloucester, in the State of Massachusetts. The mineral takes its name from the American mineralogist, Prof. J. D. Dana, of Yale College.

DANBURITE. A silico-borate of lime, containing, when pure, silica, 48·9; boric acid, 28·4; and lime, 22·7. It is found at Danbury, Connecticut, U.S.

DANDELION. The *Taraxacum Dens Leonis*, a common British weed, belonging to the *Compositæ*. It has a milky juice, which contains a bitter principle called *Taraxacine*. Preparations of dandelion are employed in medicine as diuretics and alteratives; and dandelion root, when roasted, is sometimes used like chicory, as an addition to coffee.

DANK or **DAWK.** (*A mining term.*) Bands and beds of tough sandy clay, more or less compact and homogeneous. It is probably derived from *dough*.

DANNEMORITE. An iron- and manganese-hornblende, from the iron-mines of Dannemora, in Sweden.

DAPHNE CANNABINA. The bark of this shrub, a native of Nepaul, has been used for paper-making.

DAPHNINE. The bitter principle of the *Daphne alpina*.

DAPICHO. A spongy kind of caoutchouc, which exudes from the roots of the *Siphonia elastica*. It is used in South America for making stoppers. See CAOUTCHOUC.

DARWINITE. A mineral consisting, according to David Forbes, of copper, 88·07; silver, 0·24; and arsenic, 11·69. It is found at Potrero Grande, south-east of Copiapo, in Northern Chili.

DASH WHEELS. These are revolving wheels having dash-boards, which are much used in the washing-processes necessary in calico-printing. See BLEACHING.

DATES. (*Tamr*, a date, Arabic.) The fruit of the *Date Palm*. The date tree, *Phœnix dactylifera*, grows to the height of sixty feet. The dates are pulled before they are ripe, and are then dried in the sun. These form one of the chief parts of the usual food of the Arabs, while the seeds softened and ground down form the nourishment for their camels. The leaves are employed for making mats. The threads of the web-like integument at the basis of the leaves are twisted into ropes, while the stems, when old, are used in the construction of houses. Tadmor, in the Desert, built by Solomon, is supposed to derive its name from those trees, which grew abundantly around it.

DATHOLITE, or **DATOLITE.** A boro-silicate of lime, containing silica, 37·30; boric acid, 21·32; lime, 35·67; water, 5·71. It is found in fine glassy crystals, of complex form, at Bergen Hill, New Jersey.

DATISCA, YELLOW. A yellow dye obtained by treating the aqueous decoction of the leaves of the *Datisca cannabina*, a bastard hemp, growing in the Levant and in India, with salts of lead. This yellow is obtained in a translucent mass, soluble in water. Stuffs mordanted with alum are dyed a permanent yellow.

DATURINE. A poisonous alkaloïd found in the Thorn-apple (*Datura Stramonium*). Daturine closely resembles Atropine and Hyoscyamine.

DAUCUS CAROTA. The common carrot.

DAVIDSONITE. A greenish-yellow beryl, from Rubislaw, near Aberdeen, in Scotland.

DAVY LAMP. See SAFETY LAMP.

DAVYNE. A Vesuvian mineral, consisting of silicate of alumina, soda, potash, and lime. It is regarded as a variety of nepheline.

DEADS. Waste on or in a mine. Rubbish. Mine-stuff too poor in ore to pay for working.

DEAD DIPPING. The process of producing an agreeable pale yellow dead surface on ornamental brass work is so called. The brass work, after the final stamping with its adhering black scale from the annealing oven, is placed in dilute nitric acid, and left in it until the scale may be easily detached; it is then taken out and washed with water. Again it is plunged in dilute acid somewhat stronger than before, until the surface is covered with minute bubbles, after which it is washed in a solution of argol, and dried in hot sawdust. Dead dipping is also used in the manufacture of the ornamental parts of stoves, especially such as are intended for drawing-rooms. The brass portions of these are treated in the manner described, but the iron or steel after being polished, or ornamented by engraving, is treated with dilute sulphuric acid.

DEAD OIL. The oil which is obtained from the fractional distillation of coal-tar, after the light oil or naphtha has passed over. See NAPHTHA.

DEAD WELLS. Wells which are made to carry off refuse waters. See ARTESIAN WELLS, *Negative.*

DEADLY NIGHTSHADE. The *Atropa belladonna.* It owes its poisonous character to the alkaloïd called *atropine.* See ATROPINE; BELLADONNA.

DEAL WOOD. See PINES.

DEBRIS. A term signifying wreck or waste. It has been adopted from the French to express any accumulation of loose materials arising from the waste of rock. It is also applied to drifted accumulations of all kinds.

DECANTATION. (Eng. and Fr.; *Abgiessen,* Ger.) The act of pouring off the clear liquor from any sediment or deposit. It is much employed in the chemical arts, and is frequently effected by means of a siphon, there being less risk of disturbing the precipitate.

DECARBONISATION. Articles made of cast iron, and, consequently brittle, are decarbonised and rendered tough by being exposed to heat in contact with some peroxide of iron, as the finely-divided hematite ore. Most of the iron articles used in saddlery or harness making are now manufactured by this process.

DECHENITE. A vanadate of lead, and perhaps also of zinc. It occurs in Rhenish Bavaria, and is named after the German geologist Von Dechen.

DECIMAL. A tenth part. A *Decimal Fraction* is one whose denominator is 10 or some power of 10. It is not usual, however, to express this denominator, but a period, called a *decimal-point,* is placed between the unit and the first fractional number. Thus, 1·5 is the same as $1+\frac{5}{10}$, or one and five-tenths; in like manner 1·05 means one and five-hundredths; 1·842 signifies one unit and eight-tenths, four-hundredths, and two-thousandths of the unit; and so on.

DECIMAL COINAGE is a proposed system in which the unit is divided and subdivided decimally. The coinage of the English florin was a step towards the decimal system; the value of the florin, or two-shilling piece, being one-tenth of the sovereign. The metrical system of weights and measures is based on the decimal system; the multiplication and division of the unit always proceeding by some power of 10. See METRICAL SYSTEM.

DECKLE. A name given by the paper-maker to a thin frame of wood fitting on the shallow mould in which the paper-pulp is placed.

DECOCTION. The process of boiling a liquid with some organic body, or the liquid compound resulting from the process of boiling.

DECOMPOSITION. (Eng. and Fr.; *Zersetzung,* Ger.) The separation of bodies from each other. The methods employed are almost innumerable, and usually depend on the special reactions of the matters under examination. We shall consider a few of the most striking cases in both the grand divisions of the science, viz. inorganic and organic chemistry. In each instance we shall, for the sake of convenience, subdivide into the three classes of acids, alkalis, and neutral bodies. Previous, however, to this, we must glance at some of the reactions of which chemists avail themselves in separating the elements. The decomposition of ordinary metallic salts, with the view of making a qualitative analysis of a more or less complex mixture, is a problem, in general, of extreme simplicity, and directions for the purpose are to be found in all the numerous works on qualitative analysis. The principle on which the modern methods of qualitative analysis are founded is the separation of the metals in the first place into large groups by certain reagents, and then, by means of others, to subdivide into smaller groups, in which the individual metals can be determined by special tests. For the sake of simplicity, we shall only consider the more commonly occurring metals. The general reagents, by which the first subdivision is effected. are hydrochloric acid, sulphuretted hydrogen, sulphide of ammonium, carbonate of ammonia mixed with chloride of ammonium, and finally phosphate of soda. The substance in solution is treated with hydrochloric acid, by which mercury, silver, and lead are removed. The mercury will only be perfectly removed if it exists entirely in the state of a subsalt. Lead is only partially precipitated, and will be subsequently found in the next group. The precipitate by hydrochloric acid is to be boiled with water, which will remove the chloride of lead, and leave the chlorides of mercury and silver. The latter may be separated by means of ammonia, which will dissolve the chloride of silver and convert the mercury into a black powder, in which the metal can be detected by special tests. The fluid filtered from the precipitate by hydrochloric acid is to have a stream of hydrosulphuric acid gas (sulphuretted hydrogen) passed through it for a considerable time, or until no more precipitation occurs. By this means antimony, arsenic, tin, cadmium, gold, mercury, silver, lead, bismuth, and copper are thrown down, and must be separated from each other by special processes. The filtrate from the precipitate by hydrosulphuric acid is to have ammonia added in slight excess, and then a solution of sulphide of ammonium as long as any precipitation takes place. By this means nickel, cobalt, iron, manganese, zinc, alumina, and chromium, are thrown down; also baryta, strontia, and lime, if they happen to be in combination with phosphoric, oxalic, or boracic acids, or if united to fluorine. From the filtrate, carbonate of ammonia mixed with chloride of ammonium, precipitates baryta, strontia, and lime. The filtrate from the last precipitate can only contain magnesia, or the alkalis. The above brief description of the mode of dividing the above metals into groups will be sufficient to give an idea of the processes employed for decomposing complex mixtures into simple ones.

Inorganic acids are usually removed from metals by converting the latter into an insoluble compound, while the acid remains in solution either in the free state or combined with a body of such a nature as not to mask the reactions of the acid with reagents. This is often done in the laboratory by boiling the metallic salt with an alkaline carbonate. The metals are, consequently, either converted into oxides or carbonates insoluble in water, while the acid unites with the alkali to form a soluble salt capable of being obtained by filtration in such a condition as to permit the nature of the acid to be made known by means of appropriate tests. It is usually necessary to neutralise the solution carefully before testing for the acid.

It is seldom necessary in researches to reduce inorganic alkalis to their elements, their constitution being usually ascertained by converting their constituents into new forms capable of being weighed or measured with accuracy. If, for instance, it was necessary to ascertain the constitution of sulphuric acid, it would be sufficient to determine the quantity of baryta contained in the sulphate. On the other hand, acids susceptible of assuming, when pure, the gaseous condition may have their constitution determined by decomposing a known volume with a substance capable of combining with one ingredient and liberating the other in the gaseous state. Thus hydrosulphuric acid may be analysed by heating it with potassium, which will remove the sulphur and liberate the hydrogen.

In decomposing inorganic alkalis with the view of separating the metals contained in them, we usually have to avail ourselves of very powerful affinities. This arises from the fact, that the substances in question are, generally, produced by the union of a metal with oxygen, the metal having so strong a tendency to combine with that element, that mere exposure to the air is sufficient to determine their union into a compound of great stability. In order, therefore, to decompose the alkalis of this class, it is necessary to find some substance having a powerful tendency to combine with oxygen under certain conditions. Now it has been found that carbon, if raised to an exceedingly high temperature, and employed in great excess, is capable of removing the oxygen, even from such bodies as potassium and sodium, the affinity of which for oxygen is very great.

Inorganic neutral bodies are generally decomposed either by the ordinary processes of analysis, or, where the neutrality arises from the substance under examination being a compound of an acid and a base, by separating the two by treatment with a reagent capable of combining with one to the exclusion of the other. This is a process frequently available in quantitative analysis. As an illustration, we may take the decomposition of the carbonates by a mineral acid in an apparatus which permits the carbonic acid set free to be accurately estimated by weighing. See CARBONATES.

Another instance of the decomposition of a neutral body, by treating it with a substance capable of combining with one of the constituents and separating the other in a free state, is the decomposition of sulphate of potash by baryta. If a solution of the salt be boiled with excess of solution of baryta, sulphate of baryta is produced, and caustic potash set free. The excess of baryta is removed by boiling in the air until the whole of the latter base is converted into the insoluble carbonate. A precisely analogous process is the ordinary mode of preparing caustic potash by boiling its carbonate with quicklime.

Neutral bodies are frequently, however, so constituted, that the neutrality does not arise from the circumstance of an acid being saturated with a base, but from the energies of two elements being, to some extent, satisfied by the fact of their being in combination. Thus, water is a neutral substance, nevertheless it may be decomposed by a variety of processes, several of which are susceptible of quantitative precision. In the first place, it may be decomposed by passing steam over a metal capable of uniting with its oxygen with liberation of the hydrogen. It may also be electrolysed, and the two gases separately obtained.

Organic or inorganic neutral salts may, at times, be very completely and simply decomposed by means of the battery. Not only are the various processes in electro-metallurgy founded on this principle, but it has even been practically applied to the quantitative estimation of the metals in ores. The electrolysis of the neutral salts of the great series of organic acids of the general formula $C^nH^nO^4$ has thrown great light on some previously obscure points in the radical theory.

The decompositions undergone by organic substances in contact with reagents are so manifold, that the limits of this work preclude the possibility of doing more than glancing at a few of the most general and interesting. Perhaps of all the modes of inducing the breaking up of more complex into simpler substances, the application of heat is the most remarkable for its power and the varied and opposite character of the substances produced. It has been shown that, as a decomposing agent, heat possesses no special function. From complex organic molecules all classes of substances are formed. Individual substances belonging to every chemical type are, therefore, found among products of destructive distillation. Acids, alkalis, and neutral bodies of every kind are formed, and some of the most interesting and beautiful bodies known to chemists are found in the uninviting-looking tar of coal. Let us illustrate this by a glance at a few of the coal-tar products. Among the acids are the oxyphenic, carbolic, and cresylic. The alkaloïds represented are methylamine, ethylamine, propylamine, butylamine, amylamine, pyridine, picoline, lutidine, collidine, parvoline, chinoline, lepidine, cryptidine and aniline. Among hydrocarbons, benzole, toluole, xylole, cumole, cymole, propyle, butyle, amyle, caproyle, caproylene, œnanthylene, naphthaline, anthracene, chrysene, pyrene, acetylene, &c. This list, probably, does not include one half of the substances produced from coal by the decomposing and recomposing influence of heat.

Mineral acids exercise a powerful decomposing influence on organic substances. Of these the nitric and sulphuric are the most commonly used. Nitric acid is especially active, owing to its twofold action. By virtue of its oxidising tendencies, it breaks up great numbers of substances into more simple and less carburetted derivatives, and the hyponitric acid produced by the removal of one of the atoms of the oxygen of the acid frequently enters into the resulting compound, a substitution-product being the final result. In the latter bodies produced in this manner the hyponitric acid (NO^4) generally replaces hydrogen, the original type remaining unaltered. The production of oxalic acid from sugar; succinic, lipic, adipic, pimelic, suberic, &c., acids from oily and fatty matters by the action of nitric acid, are examples of its oxidising power; while the formation of nitrobenzole, and bodies of more or less analogous character, present instances of the replacement of hydrogen by hyponitric acid.

Sulphuric acid owes its decomposing power to its extreme tendency to combine with water. Many of the less stable organic bodies are, by this means, absolutely broken up, so that the resulting products are of a character too indefinite to allow of the changes being expressed by an equation which shall render a true account of all the substances directly or indirectly formed. On the other hand, the action may be so controlled by the careful regulation of the temperature and strength of the acid that products may be eliminated which are themselves totally broken up and destroyed by an acid of greater strength. The production of grape-sugar by the action of sulphuric acid on starch, or lignine, may be taken as an example. It not unfrequently happens, that the sulphuric acid unites with the substance acted on to form a conjugated compound. Benzole, and many other hydrocarbons, as well as oxidised bodies, behave in this manner with concentrated sulphuric acid.

Chlorine and the other halogens are powerful decomposing agents, acting chiefly by virtue of their affinity for hydrogen. The principal effects produced by them are oxidation and substitution. The oxidising action of the halogens arises from the decomposition of water; the hydrogen combining with the chlorine, &c., to form an hydracid, and the free oxygen uniting with the other substances present.

The above sketch will sufficiently indicate some of the most usual methods by which the decomposition of organic and inorganic bodies is effected; but hundreds of other decomposing agencies are at the call of the chemist, when any phenomena involving the disruptions of compounds are to be investigated.—C. G. W.

DECREPITATION (Eng. and Fr.; *Verknistern*, Ger.) is the crackling noise, attended with the flying asunder of their parts, made by several minerals and salts when heated. Sulphate of baryta, chloride of sodium, calcareous spar, nitrate of baryta, and several other bodies which contain no water, decrepitate most violently, separating at the natural joints of their crystalline structure.

DEFECATION. (Eng. and Fr.; *Klaren*, Ger.) The freeing from dregs or impurities.

DEFLAGRATION. (Eng. and Fr.; *Verpuffung*, Ger.) A rapid combustion, attended with much evolution of flame and vapour. When metals are burnt by electricity, they are said to undergo deflagration.

DEFLAGRATOR. A galvanic instrument for producing a rapid and powerful combustion, introduced by Professor Hare.

DE LAINES. Properly, fine worsted fabrics. They are indeed figured muslins, which should always be made of wool, but they are frequently made of mixed material.

DELAWARITE. A cleavable potash felspar, from Delaware County, Pennsylvania.

DELESSITE. A ferruginous chlorite, usually occurring as a dark greenish coating in the interior of amygdaloidal cavities in trap-rocks.

DELF or **DELFT.** A coarse species of pottery originally manufactured at Delft in Holland, covered with a white stanniferous enamel or glaze. See POTTERY.

DELIQUESCENT. (*Zerfliessen*, Ger.) Any solid which absorbs moisture from the air spontaneously and becomes soft or liquid, such as potash, and chloride of calcium is said to be deliquescent.

DELPHINIA. The poisonous principle of the Stavesacre (*Delphinium Staphysagria*).

DELVAUXITE. A variety of Dufrenite, or hydrous phosphate of iron.

DEMIDOFFITE or **DEMIDOVITE.** A mineral mixed with malachite, found at Nischne-Tagilsk in Russia. It contains oxide of copper 33·14, silica 31·53, magnesia 3,15, phosphoric acid 10·22, and water.

DENDRITES. Arborescent or shrub-like markings on rocks, commonly produced by oxide of manganese; thus, the ramified patterns in Mocha-stones are dendrites.—*Dendritic*, a term applied to the branching forms of certain minerals, such as native copper and native silver.

DEMY. Paper of a particular size is so called. Drawing demy is 15 inches by 20, printing demy is 17¾ inches by 22½.

DENMARK SATIN. A stout worsted stuff used for ladies' shoes.

DENSITY, the property of compactness in bodies, the closeness of their component particles. The specific gravity of bodies is taken as a measure of their densities. See SPECIFIC GRAVITY.

DENTIFRICE. Tooth-powder for the purpose of cleansing the teeth. A variety of preparations are recommended. The object being to remove acid incrustations from the teeth, and to cleanse them from feculent matter, simple preparations of chalk or magnesia are undoubtedly to be preferred. Occasionally charcoal may be used with advantage, but the particles are usually too hard, and consequently they tend to abrade the fine enamel-surface of the teeth.

DENUDATION. (*Denudo*, to lay bare.) The carrying away by the action of running water or other agent, of the superficial solid materials of the land, by which the character of the surface is altered, and the lower rocks often laid bare.

DEODORISERS. Bodies which have the power of depriving fetid and offensive effluvia of their odours. There appears to exist a general idea that these substances are, all of them, equally disinfectants. No greater mistake can be made than to suppose that because a preparation has the power of removing a disagreeable smell, that therefore it has removed all the elements of infection or disease. See DISINFECTANT.

To disguise unpleasant odours, fumigation is employed, many of the fragrant gums are burnt and fumigating pastiles employed. It is also a common practice to burn lavender and brown paper, but these merely overpower or disguise the smell; they do not in any way act upon the noxious effluvia. See PASTILES; FUMIGATION.

DEOXIDATION. The act of removing oxygen; thus, when oxide of iron is heated with carbonaceous matter the oxide is deoxidised, and metallic iron reduced.

DEPHLEGMATION. The process by which liquids are deprived of their watery particles. It is applied chiefly to spirituous liquors, but is now obsolete, as involving the alchemistical notion of a peculiar principle called *phlegm*.

DEPHLOGISTICATED, deprived of *phlogiston*, which was for a long period after the time of Stähl regarded as the principle of *levity* and of *combustion*. It may be regarded as synonymous with oxygenated. 'Others believe that *Earth* and *Phlogiston* are those principles which are the constituent parts of all corporeal substances.'

'It appears from all those experiments, that in each of them *phlogiston*, the simple inflammable principle, is present.' 'Thus much I see from the above-mentioned experiments; the air is composed of two different fluids, the one of which attracts not the *phlogiston*, and the other has the quality of attracting it.'—Scheele: *Experiments on Air and Fire.*

DEPILATORIES. Preparations for removing hair from the skin. These are said to have been much used by the ancients. In modern times they have been used as cosmetics to remove superfluous hair from the face. Lime and the tersulphuret of arsenic (orpiment) are the constituents of most of the ancient and modern depilatories; but the use of orpiment is dangerous, especially if there is any abrasion of the skin.

The best and safest depilatory is said, in Gray's 'Supplement to the Pharmacopœia,' edited by Redwood, to be a strong solution of sulphuret (sulphide) of barium made into a paste with powdered starch. It should be applied to the hair immediately after it is mixed, and allowed to remain there for five or ten minutes.

DEPOSITION OF METALS. See Electro-Metallurgy.

DERBYSHIRE SPAR. Fluor-spar, or fluoride of calcium. See Fluor-Spar.

DERMATIN. A variety of serpentine found in reniform masses, in thin coatings on the serpentine of Waldheim in Saxony.

DERRICK CRANE. The term Derrick is applied to a temporary crane, consisting of a spar supported by stays and guys, carrying a purchase for loading or unloading goods on shipboard. The Derrick crane is somewhat similar in its plan, the projecting iron beam, or derrick, of which, can be raised or lowered to any desired angle.

DESCLOIZITE. A South American vanadate of lead, named after the French crystallographer Des Cloiseaux.

DESICCATION. The act of drying.

Davison and Symington patented a process for drying or seasoning timber, by currents of heated air. Even after wood has been dried in the ordinary manner, it contains much moisture, which it is still necessary to remove. The patentees have given some curious results of this desiccating process:—

Temperature of air 214°.

Violin wood	Original weight	Weight after seasoning	Moisture removed
6 pieces small and thin . . .	3·38	2·87	8· per cent.
2 ,, larger	10·56	9·5	10·1 do.
2 ,, larger	25·25	22·93	9·25 do.

	Original weight	100° after 6 hours	120° after 10 hours	150° after 20 hours	180° after 30 hours	230° after 38 hours	Per cent.
Oak	1·84	1·76	1·71	1·59	1·56	1·51	18·1
Red pine . . .	1·5	1·4	1·38	1·33	1·28	1·25	16·6
Birch	1·2	1·09	1·05	1·01	·99	·97	19·2
Mahogany . . .	1·21	1·14	1·09	1·03	1·0	·98	19·2

White wood, lime tree.

	Original weight	170° after 6 hours	Part 140°, and part 212° after 15 hours	After 24 hours	After 34 hours	After 84 hours[1]	Per cent.
1	23·5	20·45	18·7	18·22	17·4	17·4	26·
2	25·19	21·33	19·37	18·9	18·07	18·0	28·5
3	23·67	19·7	17·83	17·6	16·82	16·75	29·2
4	20·08	17·07	15·8	15·6	15·13	15·05	25·

---

[1] It will be observed, on referring to the last column of lime, that the wood, although kept in the chamber exposed to heated currents for 50 hours, weighed nothing less after the first 34 hours.—(*Whishaw.*) One application of the desiccating process for timber is to expose it for some hours to the heated currents of air, and then, in its heated state, immersing it suddenly in any of the approved antiseptics, creosote or coal-tar. The result is, that the air-vessels of the wood, if not entirely empty, contain air at so very high a temperature that a vacuum is instantly formed, and every pore is immediately charged with the cold antiseptic in which the wood is immersed.

No. 3 exposed to the atmosphere for three weeks, weighed at the end of that time 17·8, or had taken in 4·2 per cent. of moisture.

Feathers.—Feather beds, mattresses, blankets, and clothing, are not only dried, but purified by this process. A feather bed of sixty pounds weight will have no less than 100,000 cubic feet of air passed through it; and at the same time beaters are made use of, for the purpose of removing the dust. Feathers treated in this manner have their bulk and elasticity so much increased, that a second tick is found almost invariably necessary to put the feathers into.

A practical proof of the extreme powers of currents of dry heated air was given in Syria, by exposing to them sixty suits of clothes, which had belonged to persons who died of the plague. These clothes were subjected to the process alluded to, at a temperature of about 240°, and afterwards worn by sixty living persons, not one of whom ever gave the slightest symptom of being affected by the malady.—(*Whishaw.*) It has been proposed to dry coffee by currents of heated air, and subsequently to roast it by the same process.

Thick card-board, used for tea-trays and papier-maché, is now frequently dried by heated air. By the plan adopted at one establishment, previously to the introduction of Davison and Symington's method, it invariably occupied from eighteen to twenty hours to dry a room full of paper by a heating surface equal to 330 feet; whereas by the new method, the same amount of work is accomplished in four hours, and with a heating surface of only 46 feet, or one-seventh the area required by the former.

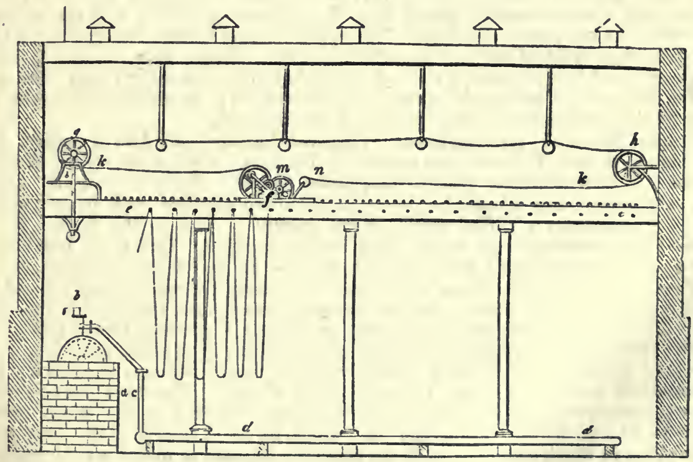
Silk.—For the purpose of drying silk, it has been usual to heat the drying chambers by large cast-iron globular stoves, the heat obtained thus was equal to 120° F., but excessively distressing to any stranger entering these apartments.

In one arrangement 7,000 cubic feet per minute are admitted at the above temperature through small perforated iron plates, let into the stone floor. As many as 3,000 pieces of silk are sometimes suspended at one time: and as each piece of silk, when wet, contains about seven ounces of water, and as the operation of drying the whole occupies but one hour, it follows that about 130 gallons of water are evaporated in that time.

Yarns.—In Scotland and other places they now dry yarns by modified applications of this process; and it is indeed extensively used in bleaching establishments, in calico-printing works, &c. See *Transactions of the Society of Arts for* 1847-8.

A DRYING HOUSE is an apartment fitted up in a peculiar manner for drying calicoes, and other textile fabrics. Mr. Southworth, of Sharples, a Lancashire bleacher, obtained a patent in 1823, for the following ingenious arrangement, which has been since generally adopted, with certain modifications, in most of our extensive bleaching and printing works. *Fig.* 599 is a section of the drying-house, where *a* is a furnace and boiler for the purpose of generating steam; it is furnished with a safety valve in the tube *b*, at top, and from this tube the steam-main *c* passes down to the floor of the basement story. From this main, a series of steam-pipes, as *d d*, extends over the surface of the floor, and from them heat is intended to be diffused for the purpose of warming the drying-house.

599



Along the middle of the building a strong beam of timber *e e* extends, and is supported by cast-iron pillars; from this beam, to bearings on the side walls, a series of rails are carried in a cross direction, over which rails the wet cloth is to be hung in folds, and the steam or vapour emitted in drying is allowed to escape through apertures or ventilators in the roof.

The mode in which the cloth is delivered on to the rails, on either side of the beam will be best understood by reference to the delivering carriage, which is shown, with its rollers partly in section.

The wet cloth is first to be coiled upon a roller, and then placed in the carriage, as at *f*, with its pivots bearing upon inclined planes. The carriage is to be placed at the commencement of the rails, running upon the middle beam, and also upon the side-bearings or railways extending along the side walls of the building, parallel to and upon a level with the same beam. It is made to travel by means of an endless band passing over two riggers *g* and *h*, in *fig.* 599, and over pulleys and a band-wheel attached to the carriage, as will be explained. The rigger *g*, which moves this endless band, is actuated by bevel gear, seen at *b*, which is put in motion by a pinion at the end of a revolving shaft leading from a steam-engine.

In the same *fig.*, *k k*, is the endless band passing over a pulley under the band-wheel, and over the pulley *n*, by which it will be perceived that the traversing of the band, as described, would cause these pulleys and wheels to revolve. On the action of the band-wheel *m*, there is a drum against which the roll of wet cloth *f* presses, and as this drum revolves, the roll of wet cloth is, by its friction, made to turn in a contrary direction, and to deliver off the cloth on to the periphery of the drum, whence it passes over a roller and descends to the rails. Upon the end of the axle of the band wheel *m*, there is a pinion which takes into the teeth of the large wheel, and upon the axle of this large wheel there is a pinion that actuates the intermediate wheel which turns another toothed wheel. This last-mentioned toothed wheel takes into cogs upon the side railway, and hence, as the train of wheels moves round, the carriage to which the wheels are attached is slowly impelled forward.

As soon as the wheels begin to move, and the carriage to advance, the wet cloth begins to uncoil, and to pass down over the first roller; a small roller attached to the carriage, as it passes over the rail in succession, holds the cloth against each rail for a short space of time, and prevents it from slipping, by which means the cloth descends in folds or loops between the rails, and is thereby made to hang in a series of folds or loops, as shown in the figure.

It will be perceived that as the pivots of the cloth roller *f* bear upon inclined planes, the roller will continually slide down as the cloth diminishes in bulk, keeping in contact with the drum, and delivering the cloth from the roller on to the several rails, as described.

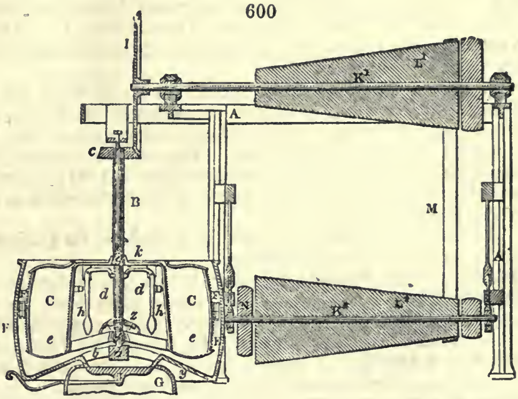
In order to stop the carriage in any part of its course, or to adjust any of the folds of the cloth, a man is usually placed upon the platform travelling with the carriage, over which he has perfect command. This apparatus may be also employed for taking the cloth when dried off the rails; in which case the carriage must be made to travel backwards, and by first guiding the end of the cloth on to the roller *f*, and then putting the wheels in a retrograde motion, the cloth will be progressively coiled upon the roller *f*, in a similar way to that by which it was uncoiled.

Drying Machine (centrifugal). (*Hydro-extracteur*; *Machine à essorer*, Fr.) By this contrivance, Pentzoldt was enabled to deprive all kinds of wet clothes in a few minutes of their moisture, without compression or heat. Kelly, a dyer, and Alliott a bleacher, have since obtained a patent for the above machine with improvements. *Fig.* 600 represents a partial section of the machine. A, A, is the frame; B, the vertical shaft turning in the step *a*, fixed on the bridge *b*. This shaft bears on its upper part a friction cone *c*, from which it receives its movement of rotation, as will be presently shown; C is a drum containing two concentric compartments *d e*, of the form represented in the figure; this drum moves freely upon the shaft B, and rests when it is not in motion upon two conical projections *f*, *g*, which form a part of the shaft. These two compartments are each composed mainly of metal, and their sides consist of tinned iron wire coiled circularly at very small distances from each other, and soldered together crosswise by small strips of metal. The top which covers the inner compartment *d*, is secured by bolts and screws to a circle of iron which retains the wire sides of the same metal, but that which serves as a cover to the little compartment *e*, in which alone the goods are placed, is disposed so that it may be removed with ease, when these are to be introduced or withdrawn. It is furnished with an outer and inner border, disposed so that when the top is fixed the inner border presses upon the convex circumference of the central compartment, while the exterior border falls outside of the edges of the other compartment. While the machine is at work, the second plate is maintained in its place by pins or bolts, not shown in the figure.

The sides of the outer compartment *d*, are connected with the bottom by means of a prolongation of cross bands of metal, which unite the wires and are riveted or soldered to the two outer plates. The wires of the interior compartment are attached by an iron hoop, to which they are riveted and soldered, and are united to the bottom plate by means of a rim upon this plate; a rim somewhat flattened upon the sides, which are riveted and soldered.

D, is a regulator suspended in the inner compartment *d*, and whose two branches *h*, *h*, are loaded. These two branches having room to play around the bolts which serve as points of attachment, and which are fixed to the upper plate, terminate in kneed branches whose extremities rest upon a rope *g*, which projects from the shaft. E, is an exterior envelope secured to the frame A, A. It encloses the whole drum except at top, and serves to catch the water thrown out of the goods. At *y* there is a stop-cock for the discharge of this water, and the bottom contains besides the end of a pipe by which hot air is introduced.

600



The vertical shaft B receives a movement of rotation and carries with it the drum. The more rapid this movement is the more does the centrifugal force tend to expel the water contained in the clothes or yarn to be dried. But as this force might also displace the central shaft, if the weight was not rightly distributed in the drum, and cause the dislocation of the machine when the great velocity requisite for quick drying is given to it, the regulator D is tested to prevent accident. The branches of this regulator spread wider the more the velocity is increased, and raise consequently the drum C above the conical enlargements, which permits the drum to be somewhat misplaced and to rectify its position conformably to the inequalities of its load, so that its centre of gravity may always coincide with its centre of rotation. The drum is connected with the shaft, as is shown in *z*, leaving it free to take the requisite adjustment. To hinder it from rising too suddenly, a spiral spring *k* is fixed over the shaft immediately above the conical enlargement *g*. In order to maintain the equilibrium more certainly, the apparatus is surrounded with a hollow crown F, half filled with water, and if during the revolution of the machine the weight of the goods predominates on one side, that of the water which accumulates on the other side serves the more to counterbalance it. The effect of this crown may be increased by dividing it into two compartments or more. G is a large pipe by which steam or hot air is introduced into the belly of the drum, which is pierced in this place with a great number of small holes to receive it.

The rotatory movement is transmitted to the drum in the following way:—

I, is a conical disc mounted upon the extremity of a shaft K^1 which actuates the cone C and the shaft B by means of friction; L^1 is a cone fixed upon the extremity of the shaft. K^2 L^2 'is another cone of the same dimension, but whose base fronts the top of the other, and which is placed on the shaft K^2' commanded by the prime mover. M is the belt which embraces the two cones, and whose lateral displacement, effected by means of a fork, permits the velocity of the machine to be regulated at pleasure. N is the pulley which directly receives the movement. In place of a single friction disc I, another may be employed, if judged necessary, and placed between the two, an additional friction pole, in order better to equalise the friction. In this case the disc and additional cone should turn freely upon their own shafts. We may also adopt another arrangement for the bottom of the vertical shaft. The shaft immediately above the step is surrounded by a loose rim, around which a certain quantity of lead shot, or other granular matter, is contained in the rim in the box which serves for the step. The top of this box is pierced with an opening, into which, when the machine is at rest, a cord connected with the shaft sinks, controlled by the shaft, and when the drum is raised by the action of the regulator D, this cord quits its place, which allows the shaft to displace the shot a little, and to take a position conformably to the point of the centre of gravity,

But after all, great attention should be paid to the proper working of the machine. There are many other drying machines used, some of which are described in the articles devoted to special manufactures.

DETERMA. A wood used in Guiana for masts, booms, and planking. It is very durable, insects will not attack it, and it will square from 14 to 16 feet.

DETONATION. For the mode of preparing detonating-powder for the percussion-caps of fire-arms, see FULMINATES.

DETRITUS. (*De*, from, *tero*, to rub.) Matter worn off rocks, and re-deposited.

DEUTOXIDE, literally means the second oxide, but is usually employed to denote a compound containing two atoms of oxygen to one or more of a metal. Thus we say, deutoxide of copper and deutoxide of mercury. Berzelius abbreviated this expression by adopting the principles of the French nomenclature of 1787; according to which the higher state of oxidisement is characterised by the termination *ic*, and the lower by *ous*. It is now rarely employed.

DEVIL. The name of a spiked mill, used in Yorkshire, for tearing woollen rags into fragments for the manufacture of SHODDY.

DEVILLINE. A basic sulphate of copper, known also as *Lyellite.*

DEVITRIFICATION. A process by which glass loses its characteristic vitreous properties, and becomes opaque. This change may be induced by very slow cooling, or by the prolonged heating of glass. See RÉAUMUR'S PORCELAIN.

DEVONSHIRE BATTS. A porous fine-grained sandstone, from the quarries of Black Down Cliffs, near Collumpton, in repute as a grindstone.

DEVONSHIRE OIL-STONE. This stone occurs near Huel Friendship Mine, about three miles from Tavistock, in the Devonian slates of that district. It has considerable local repute for sharpening all kinds of thin-edged broad instruments; it has not, however, become an article of commerce.—*Knight, Trans. Society of Arts.*

DEWEYLITE. A hydrous silicate of magnesia, occurring in several localities in the United States, and named after Prof. Chester Dewey.

DEW-RETTING. See FLAX.

DEXTRIN. Starch gum. There are three modes of obtaining this from starch, viz., by torrefaction, by the action of dilute acids, and by the action of *diastase.* The impure dextrin obtained by roasting is termed *roasted starch* or *leicomme.* British gum is prepared by carefully roasting wheat-starch, at a temperature of 300° Fahr. Another method of preparing dextrin consists in moistening 1,000 parts of potato-starch with 300 parts of water, to which 2 parts of nitric acid have been added. The mixture is allowed to dry spontaneously, and is afterwards heated for two or three hours in a stove, at 212° Fahr. Dextrin in many of its characters resembles ordinary gum, but it is distinguishable from it by its *right-handed rotation of a ray of plane polarised light,*—hence its name *dextrin,*—and by its yielding oxalic acid, but not mucic acid, when heated with nitric acid.

DEXTROSE, or **DEXTRO-GLUCOSE.** Names applied to ordinary glucose or grape sugar, in consequence of the power which a solution of such sugar possesses of turning the plane of polarisation of a ray of light towards the right hand. This rotation is often distinguished by the symbol +. See GRAPE-SUGAR.

DHIL MASTIC. A mixture of massicot (protoxide of lead) and eight or ten times as much brick-dust, made into a paste with linseed-oil. It is used for repairing defects in stone facings.

DHOONA PITCH. A name for Dammar Pitch. See DAMMAR GUM.

DIABASE. A fine-grained igneous rock, composed of a crystalline-granular mixture of triclinic felspar, with augite and chlorite. The felspar is generally either oligoclase or labradorite, and the augitic constituent is frequently hypersthene. The presence of chlorite gives a green colour to the rock; hence diabase is often included under the general name of *greenstone.*

DIACTINIC LENS. A name proposed to be given to the best construction of lens for the photographic camera obscura. It should be transparent to all the chemical rays, or rather, it should be a lens which unites the chemical and luminous focus in one point. The name has not been generally adopted.

DIAL. The compass used in underground surveying is called a miner's dial, and is essentially the same instrument as the circumferentor used by the land-surveyor. Improved forms of dial have been brought out by Wilton, Philipps, and others. It is beyond the purpose of this Dictionary to enter into detailed descriptions of surveying instruments, but the art of dialling will be explained. The miner may be referred to Budge's 'Practical Miners' Guide,' and to Rickard's 'Miners' Manual of Arithmetic and Surveying.' See Mine Surveying.

DIALLAGE. *Bronzite*, *Hypersthene*, and *Schiller-spar* are often confounded under this name. The name is derived from διαλλαγή, difference, alluding to dissimilar cleavage. It is thin, foliated, and easily cleavable; laminæ brittle; colour, various shades of green, grey, and brown, sometimes bronze and pearly metallic. Diallage is now included by most mineralogists under the head of pyroxene.

Of diallage-rock fine examples will be found near the Lizard Point, and beautiful crystals of diallage are to be discovered in the Serpentine rocks near Cadgwith, in the same locality.

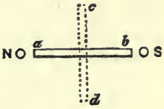
DIALLOGITE. Carbonate of manganese, a mineral usually occurring in rose-red or pinkish rhombohedral crystals. See Manganese.

DIALYSIS. The late Professor Graham applied this term to the separation of certain substances by liquid diffusion. For example, if a mixture of gum and sugar is placed in a dialyser, which is a piece of 'paper parchment' stretched upon a hoop, and this floated in water, three-fourths of the sugar will pass through the membrane in twenty-four hours, without a trace of the gum. See Watts's 'Dictionary of Chemistry.'

DIAMAGNETISM. As this term is now generally used in our scientific language, it appears necessary to give a definition of it, although it is not our purpose to enter on the consideration of any purely physical subject.

The term was introduced by the late Dr. Faraday to express those bodies which did not act as magnetic bodies do. If N and S (*fig.* 601) represent the poles of a horse-shoe magnet, any bar of a magnetic character, as iron, cobalt, or nickel, hung up between them and free to move, will by virtue of the attracting and repelling polar forces, place itself along the line joining the two poles *a b*, which is called the magnetic axis. If, instead of a bar of iron, we suspend in the same manner a rod of glass, of bismuth, or of silver, it will arrange itself equatorially, or across the line *a b*, as shown by the dotted lines, *c d*. All bodies in nature appear to exist in one of those two conditions. The prefix *dia* is used here in the same sense as in dia-meter. For a full explanation of all the diamagnetic phenomena, see De La Rive's 'Electricity,' and 'Researches on Diamagnetism and Magne-crystallic Action,' by Dr. Tyndall. (Longmans, 1870.)

601



DIAMOND. (*Diamant*, Fr.; *Diamant*, *Demant*, Ger.) Experiment has determined that this beautiful gem is a peculiar (*allotropic*) condition of carbon. By burning the diamond in oxygen-gas we produce carbonic acid; and by enclosing the gem in a mass of iron, and subjecting it to a strong heat, the metal is converted into steel, when the diamond has disappeared. It has been shown that we can, by the agency of the heat of the voltaic arc, convert the diamond into excellent coke, and into graphite; but although portions of coke are found to be sufficiently hard to cut glass, we have not yet succeeded in making diamonds from coke. Sir Humphry Davy noticed that the charcoal of one of the poles of Mr. Children's great voltaic battery was considerably hardened, and he regarded this as an advance towards the production of that gem. Recently some experiments made by a French philosopher have advanced the discovery another step: one of the poles of a voltaic battery being of charcoal and the other of platinum, it was found that the fine charcoal escaping from the carbon pole and depositing itself on the platinum pole was sufficiently hard to be used in the place of diamond dust for polishing gems. The formation of the diamond in nature is one of the problems which 'our philosophy' has not yet enabled us to solve. Time is an element which enters largely into Nature's works; she occupies a thousand, or even thousands of years to produce a result, while man in his experiments is confined to a few days, or a few years at most.

Although diamonds have been occasionally found in various parts of the globe, there are only three places which can be strictly named as diamond districts, namely, a portion of the Indian Peninsula, Brazil, and South Africa. India has been celebrated from the most remote antiquity as the country of diamonds. Its principal mines are in the kingdoms of Golconda and Visapur, extending from Cape Comorin to Bengal, at the foot of a chain of mountains called the Orixa, which appear to belong to the trap-rock formation. In all the Indian diamond-soils these gems are so dispersed that they are rarely found directly, even in searching the richest spots, because they are enveloped in an earthy crust, which must be removed before they can be seen. The stony matter is therefore broken into pieces, and is then, as well as the looser earth, washed in basins scooped out for the purpose. The gravel thus washed is collected, spread out on a smooth piece of ground, and left to dry. The diamonds are now recognised by their sparkling in the sun, and are picked out from the stone.

Diamonds are also said to come from the interior of the island of Borneo, on the banks of the river Succadan, and from the peninsula of Malacca. It is said the principal spots where diamonds are found are recognised by certain small flints, generally of a black colour, which lie upon the surface, and also by the yellow colour of the stony soil. The ground is dug in the presence of an overseer: all stones above 5 carats are claimed for the sovereign. Diamonds are found occasionally in the rivers, seldom, however, of any size.

The diamond-mines of Brazil were discovered in 1728, in the district of Serro-do-Frio. The ground in which they are embedded has the most perfect resemblance to that of the East Indies where the diamonds occur. It is a solid or friable conglomerate, consisting chiefly of a ferruginous sand, which encloses fragments of various magnitude of yellow and bluish quartz, of schist, jasper, and grains of gold, disseminated with specular iron ore: all mineral matters different from those that constitute the neighbouring mountains. This conglomerate, or species of pudding-stone, almost always superficial, occurs sometimes at a considerable height on the mountainous table-land. The most celebrated diamond-mine is that of Mandanga, on the Jigitonhonha, in the district of Serro-do-Frio to the north of Rio Janeiro. The river Jigitonhonha, three times broader than the Seine at Paris, and from 3 to 9 feet deep, is made nearly dry, by drawing the water off with sluices at a certain season; and the *cascalho*, or diamond-gravel, is removed from the channel by various mechanical means, to be washed elsewhere at leisure. This cascalho, the same as the matrix of the gold-mines, is collected in the dry season, to be searched into during the rainy; for which purpose it is formed into little mounds of 15 or 16 tons weight each. The washing is carried on beneath an oblong shed, by means of a stream of water admitted in determinate quantities into boxes containing the cascalho. A negro-washer is attached to each box; inspectors are placed at regular distances on elevated stools, and whenever a negro has found a diamond, he rises up and exhibits it. If it weighs 17½ carats, he receives his liberty. Many precautions are taken to prevent the negroes from secreting the diamonds. Each squad of workmen consists of 200 negroes, with a surgeon and an almoner or priest.

The flat lands on either side of the river are equally rich in diamonds over their whole surface, so that it becomes very easy to estimate what a piece of ground not yet washed may produce.

It is said that the diamonds surrounded by a greenish crust are of the *first* water, or are the most limpid when cut. The diamonds received in the different mines of the district are deposited once a month in the treasury of Tejuco; and the amount thus delivered, was estimated at about 18 or 19 thousand carats per annum. It appears that few of the Brazilian diamond-fields are now worked (1874).

On the banks of the torrent called Rio Pardo there is another mine of diamonds. The ground presents a great many friable rocks of pudding-stone, distributed in irregular strata. It is chiefly in the bed of this stream that masses of cascalho occur, peculiarly rich in diamonds. They are much esteemed, particularly those of a greenish-blue colour. The ores that accompany the diamonds at Rio Pardo differ somewhat from those of the washing-grounds of Mandanga, for they contain no pisiform iron ore; but a great many pebbles of slaty jasper. This table-land seems to be very high, probably not less than 5,500 feet above the level of the sea.

Tocaya, a principal village of Minas-Novas, is 34 leagues to the north-east of Tejuco, in an acute angle of the confluence of the Jigitonhonha and the Rio Grande. In the bed of the streamlets which fall westward into the Jigitonhonha, those rolled white topazes are found which are known under the name of *minas novas* with *blue topazes*, and aquamarine-beryls. In the same country are found the beautiful cymophanes or chrysoberyls so much prized in Brazil. And it is from the cantons of Indaia and Abaïte that the largest diamonds of Brazil come; yet they have not so pure a water as those of the district of Serro-do-Frio, but incline a little to the lemon-yellow.

It appears to be well established that the Brazilian diamonds occur in a quartzose rock, sometimes flexible, called *itacolumite;* and it is notable that a similar rock has been found associated with the diamond in other localities.

Within the last few years, unparalleled discoveries of diamonds have been made in South Africa. The earliest discovery dates only from 1867. Schalk van Niekerk, a Dutch farmer in the Colesberg district, having observed the children of a neighbouring boer playing with some pebbles picked up on the farm, was attracted by one of these stones different from the rest, and secured it. Having been transmitted to Dr. Atherstone, of Graham's Town, the stone was determined to be a diamond, and was then sent to the Paris Exhibition of 1867. At the close of the Exhibition it was sold for 500*l.* to Sir Philip Wodehouse, the governor of the colony. The occurrence of diamonds once known, search was extended in various directions, and other diamonds were soon detected. Although at first received with some suspicion, the truth gradually became established that South Africa contained diamond-fields rivalling those of Brazil. Numbers of adventurers were soon attracted to the chief diamond-bearing localities, and vast numbers of stones, including many of unusual size, have been brought to light. It is estimated that the total shipments of diamonds from Port Elizabeth, Table Bay, and Natal, during the year 1870 represented a value of 220,000*l.*

The South African diamonds occur chiefly in the valleys of the Vaal and Orange Rivers; the principal localities being Pniel, Hebron, Klipdrift, Du Toit's Pan, Old De Boer's Farm, and the New Rush or Colesberg Koppie. The workings are of two kinds, known as the 'river-diggings' and the 'dry-diggings.' The former are in deposits of gravel and drift, rich in pebbles of jasper, chalcedony, carnelian, agate, lydian stone, garnets, ilmenite, &c.; the diamonds are sparsely disseminated through these gravels, and are separated by simple washing. But, in addition to these drift-workings, mining has been very successfully prosecuted in dry diggings at a distance from the river. These diggings are generally opened in deposits of detrital matter, occupying circular areas, surrounded by Karoo (Trias) shales. Each of these diamond-bearing areas represents a 'pipe,' containing intrusive rocks more or less altered and frequently broken up so as to form a breccia. The diamonds are associated with garnets, green bronzite, vermiculite, and a few other minerals; a calcareous deposit, or tufa, is also commonly present in the upper part of the pipes; and fragments of schist, dolerite, and steatitic minerals are generally found in company with the diamonds. The crystals of diamond are occasionally embedded in the tufa, and are disseminated through the altered rocks which form the chief contents of the pipes; but it may be doubted whether in either case the gem occurs in its original matrix.

It unfortunately happens that by far the greater number of the Cape diamonds are 'off coloured,' that is to say, they are not of pure water, but exhibit more or less colour, a pale straw tint being especially characteristic. The crystals are commonly well formed, and often of large size; indeed the great number of unusually large diamonds is one of the most notable features in the occurrence of the South African diamonds. Thus the 'Star of South Africa' weighed 83 carats, and yielded a fine brilliant of 46½ carats. But the largest diamond hitherto discovered at the Cape is a stone now known as the 'Stewart,' which was found at Waldeck's plant in November 1872.

The Stewart is a fine octahedral crystal of pale straw colour, weighing in the rough 288⅜ carats. It is believed that this diamond is exceeded in weight by only three others in the world, namely, the Nizam, the Great Mogul, and the diamond of the Rajah of Mattan. It seems likely that a brilliant may be cut from the Stewart, which will weigh half as much again as our Koh-i-noor.[1]

Diamonds take precedence of every gem for the purpose of dress and decoration; and hence the price attached to those of pure water increases in so rapid a proportion, that, beyond a certain term, there is no rule of commercial valuation. One of the largest diamonds known seems to be that of the Rajah of Mattan in Borneo. It is of the purest water and weighs 367 carats, or at the rate of 4 grains to a carat, upwards of 3 ounces troy. It is shaped like an egg, with an indented hollow near the smaller end; it was discovered at Landak about 100 years ago; and though the possession of it has cost several wars, it remained in the Mattan family for 90 years. A governor of Batavia, after ascertaining the qualities of the gem, wished to be the purchaser, and offered 150,000 dollars for it, besides two war brigs with their guns and ammunition, together with a certain number of great guns, and a quantity of powder and shot. But this diamond possessed such celebrity in Borneo, being regarded as a talisman involving the fortunes of the Rajah and his family, that he refused to part with it at any price.

The Mogul diamond passed into the possession of the ruling family of Kabul, as has been invariably affirmed by the members of that family, and by the jewellers of Delhi and Kabul. It has been by both parties identified with the great diamond now known under the name of the *Koh-i-noor*, or *Mountain of Light*—which was displayed by its present proprietor, Her Majesty the Queen, at the Great Exhibition in 1851.

The diamond denominated the Koh-i-noor (or Mountain, *koh*, of Light, *noor*), called Kuh-i-nur by Mr. E. B. Eastlake (p. 23), has long enjoyed both Indian and European celebrity, and has accordingly been the subject of traditional fable, as well as of historical record.

According to Hindu legend, it was found in the mines of the south of India, in the days of the Great War, the subject of the heroic poem, the *Mahâbhârata*, and was worn by one of the warriors who was slain on that occasion, Karna, king of Anga:

---

[1] For further information on the occurrence of diamonds in South Africa, see a lecture by Professor Tennant, 'Journal of the Society of Arts,' November 25, 1870; an article by Professor Rupert Jones, in the 'Geological Magazine,' February 1871; and a paper by Mr. E. J. Dunn, in the Quart. Journ. Geological Soc., Feb. 1874.

this would place it about 4,000 years ago, or 2100 B.C. A long interval next makes it the property of Vikramaditya, the rajah of Mjayin, 56 B.C., from whom it descended to his successors, the Rajahs of Malwa, until the principality was subverted by Mohammedan conquerors, into whose hands it fell, with other spoils of infinite value.

Whatever may be thought of the legend which gives so high an antiquity to the Koh-i-noor, we might expect some more trustworthy information when we come down so low as the beginning of the fourteenth century; Malwa having been invaded and overrun by the armies of Ala-ad-din, the sultan of Delhi, in 1306, who, according to the autobiography of the sultan Baber, acquired the jewel. That it did become the property of the sultans of Delhi is little doubtful, but when or how is matter of some uncertainty; although the grounds of the difficulty have not hitherto been investigated.

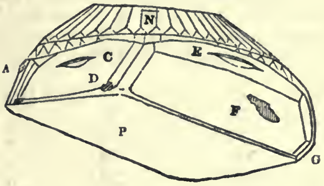
In 1665 M. Jean Baptiste Tavernier, an enterprising and intelligent traveller, and an eminent jeweller, although Ecuyer, Baron d'Aubonne, visited India especially to purchase diamonds. His profession and his personal character seem to have recommended him to the favourable attention of the nobles of the court of Delhi, and bigot as he was, of Aurungzebe himself, by whose commands M. Tavernier was permitted to inspect, handle, and weigh the jewels of the imperial cabinet. Amongst them was one which far surpassed all the rest in size and value. Tavernier describes it as rose-cut, of the shape of an egg cut in two, of good water, and weighing 319½ *ratis*, which, he says, is equal to 280 of our carats.

There is but little doubt that the diamond examined by Tavernier in the Delhi cabinet was the Koh-i-noor. Baber, the Mogul emperor, obtained a diamond, corresponding exactly with this, and it passed eventually into the possession of the ruling family of Kabul. Nadir Shah, on his occupation of Delhi in 1739, compelled Mohammed Shah, the great-grandson of Aurungzebe, to give up to him everything of value that the imperial treasury possessed, and his biographer and secretary specifies a *peshkash*, or present, by Mohammed Shah to his conqueror of several magnificent diamonds. According to the family and popular tradition, Mohammed Shah wore the Koh-i-noor in front of his turban at his interview with his conquerer, who insisted on exchanging turbans in proof of his regard. However this might have been, we need have little doubt that the great diamond of Aurungzebe was in the possession of Mohammed Shah at the time of the Persian invasion; and if it was, it most certainly changed masters, and became, as is universally asserted, the property of Nadir Shah, who is also said to have bestowed upon it the name of Koh-i-noor. After his death, the diamond which he had wrested from the unfortunate representative of the house of Timur, became the property of Ahmed Shah, the founder of the Abdali dynasty of Kabul, having been given to him, or more probably taken by him, from Shahrikh, the young son of Nadir. The jewel descended to the successors of Ahmed Shah, and when Mr. Elphinstone was at Peshawur, was worn by Shah Shuja on his arm. When Shah Shuja was driven from Kabul, he became the nominal guest and actual prisoner of Runjet Sing, who spared neither importunity nor menace, until, in 1813, he compelled the fugitive monarch to resign the precious gem, presenting him on the occasion, it is said, with a lakh and 25,000 rupees, or about 12,000*l.* sterling, According to Shah Shuja's own account, however, he assigned to him the revenues of three villages, not one rupee of which he ever realised. Runjet was highly elated by the acquisition of the diamond, and wore it as an armlet at all great festivals. When he was dying, an attempt was made by persons about him to persuade him to make the diamond a present to Jagannuth, and it is said that he intimated assent by an inclination of his head. The treasurer, however, in whose charge it was, refused to give it up without better warrant, and Runjet dying before a written order could be signed by him, the Koh-i-noor was preserved for a while for his successors. It was occasionally worn by Rhurreuk Sing and Shu Sing. After the murder of the latter, it remained in the Lahore treasury until the supercession of Dhulip Sing, and the annexation of the Punjaub by the British Government, when the civil authorities took possession of the Lahore treasury, under the stipulations previously made, that all the property of the state should be confiscated to the East India Company, in part payment of the debt due by the Lahore government and of the expenses of the war; it was at the same time stipulated that the Koh-i-noor should be presented to the Queen of England. Such is the strange history of certainly one of the most extraordinary diamonds in the world. After the Company became possessed of the gem, it was taken in charge by Lord Dalhousie, and sent by him to England in custody of two officers.—*Hunt's Handbook of the Great Exhibition of* 1851.

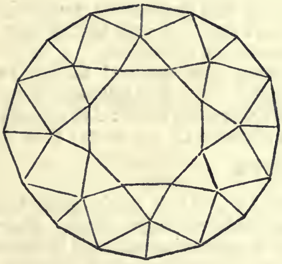
As exhibited at the Great Exhibition of 1851 in Hyde Park, the Koh-i-noor weighed $186\frac{1}{16}$ carats.

The form of the Koh-i-noor is given in *fig.* 602. P is a large plane at the base of the diamond which is a cleavage-plane. F, also a large cleavage-plane, produced by a fracture; this had not been polished, and being inclined to the plane P at an angle of 109° 28′, affords a satisfactory means for determining the direction of the cleavage-planes of the stone. A shows a flaw running parallel to the cleavage-plane F. This constituted the principal danger to be apprehended in cutting the stone, and was most skilfully ground nearly out before any of the facets were cut. This flaw seemed to proceed from a fracture marked B. C and E were little notches cut in the stone for the purpose of holding the diamond in its original setting; N, a small flaw, which almost required a glass to see it, evidently parallel to the plane P; D, a fracture from a blow or fall, showing at its base a cleavage-plane.—*Tennant.*

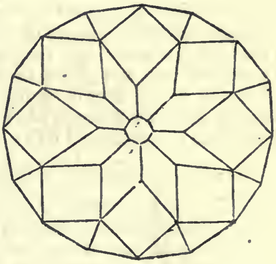
602



603



604



This fine diamond did not possess the high degree of brilliancy which was expected from its great reputation; it was consequently submitted to Messrs. Garrard to be re-cut. In the operation the weight was reduced more than one-third, but its brilliancy was greatly improved. The present state of the Koh-i-noor is shown in *figs.* 603 and 604. In this state it weighs 102½ carats. It is stated by Mr. E. B. Eastlake who has inspected the jewels of the Shah of Persia, and described them in his 'Journal of a Diplomat,' that according to Persian tradition the Daryá-i-nur, the sister jewel to the Kuh-i-nur was with it in the hilt of Afrásiab's sword, according to some, 3000 years B. C. Timúr carried it away from Persia, it having been brought there by Rustam, and Nadir brought it back. It alone is valued at two millions, and altogether the jewels cannot be worth less than six millions.

After this gem, the next in size are:—1. That of the Emperor of Russia, bought by the late empress Catherine, which weighs 193 carats. It is said to be of the size of a pigeon's egg, and to have been bought for 90,000*l.*, besides an annuity to the Greek merchant of 4,000*l.* It is reported that the above diamond formed one of the eyes of the famous statue of Sherigan, in the temple of Brama, and that a French grenadier, who had deserted into the Malabar service, found the means of robbing the pagoda of this precious gem, and escaped with it to Madras, where he disposed of it to a ship captain for 2,000*l.*, who resold it to a Jew for 12,000*l.* From him it was transferred for a large sum to the Greek merchant, 2. That of the Emperor of Austria, which weighs 139 carats, and has a slightly yellowish hue. It has, however, been valued at 100,000*l.* 3. That of the French State, called the Regent or Pitt diamond, remarkable for its form and its perfect limpidity. Although it weighs only 136 carats, its fine qualities have caused it to be valued at 160,000*l.*, though it cost only 100,000*l.*

A large diamond furnished by Brazil, now in possession of the Crown of Portugal, weighs, according to the highest estimates, 120 carats. It was found in the streamlet of Abaïte, in a clay-slate district. The largest Brazilian diamond yet found was discovered in 1853 at Bogagem, in the province of Minas Geraes. It presented the form of a distorted rhombic dodecahedron, and weighed in the rough 254½ carats. On cutting, it yielded a splendid brilliant of 125 carats. The gem was exhibited in the International Exhibition of 1862, and is known as 'The Star of the South.'

Diamonds possessed of no extraordinary magnitude, but of a good form and a pure water, may be valued by a certain standard rule. In a brilliant, or rose diamond of regular proportions, so much is cut away that the weight of the polished gem does not exceed one-half the weight of the diamond in the rough state; whence the value of a cut diamond is esteemed equal to that of a similar rough diamond of double weight exclusive of the cost of workmanship. The weight and value of diamonds are reckoned by carats of 4 grains each; and the comparative value of two diamonds of equal quality, but different weights, is as the squares of these weights respectively. The average price of rough diamonds that are worth working, is about 2*l.* for one of a single carat; but as a polished diamond of one carat must have taken one of two carats, its price in the rough state is double the square of 2*l.*, or 8*l.* Therefore to estimate the value of a wrought diamond, ascertain its weight in carats, double that weight, and multiply the square of this product by 2*l.* Hence, a wrought diamond of

1	carat is worth	£8	7	carats is worth	£392
2	,,	32	8	,,	512
3	,,	72	9	,,	612
4	,,	128	10	,,	800
5	,,	200	20	,,	3,200;
6	,,	288			

beyond which weight the price can no longer rise in this geometrical progression, from the small number of purchasers of such expensive toys. A very trifling spot or flaw of any kind lowers exceedingly the commercial value of a diamond.

The preceding rule was given by Jefferies many years ago, and though no doubt correct enough in its day, is of little or no value now. The following formula has been recently given by Schrauf, of Vienna (*Edelsteinkunde*, 1869): Let a be the weight of a given stone in carats, and b the value of a diamond of one carat; then the value of the stone of a carats is approximately $\frac{a}{2}(a+2)\,b$.

After all, it may be doubted whether any really useful rule can be given to connect weight with value; certainly there is none applicable to large stones. The market value is often capricious; at one time, stones of a particular size will be fashionable, and will therefore fetch unusually high prices. Moreover, much depends on the quality or 'water' of the gem; if the stone be 'off-coloured,' or if it contain cloudy imperfections known in the trade as 'milk' or 'salt,' its value is very greatly diminished. On the other hand, brilliantly-coloured diamonds are prized as 'fancy stones,' and are eagerly purchased at high prices.

Diamonds are used not only as decorative gems, but for more useful purposes, as for cutting glass by the glazier, and all kinds of hard stones by the lapidary.

On the structure of the glaziers' diamond we possess some very interesting observations and reflections by Dr. Wollaston. He remarks, that the hardest substances brought to a sharp point scratch glass, indeed, but do not cut it, and that diamonds alone possess that property; which he ascribes to the peculiarity of its crystallisation in rounded faces, and curvilinear edges. For glass-cutting, those rough diamonds are always selected which are sharply crystallised, hence called diamond sparks; but cut diamonds are never used. The inclination to be given to a set diamond in cutting glass is comprised within very narrow limits; and it ought, moreover, to be moved in the direction of one of its angles. The curvilinear edge adjoining the curved faces, entering as a wedge into the furrow opened up by itself, thus tends to separate the parts of the glass; and in order that the crack which causes the separation of the vitreous particles may take place, the diamond must be held almost perpendicular to the surface of the glass. The Doctor proved this theory by an experiment. If, by suitable cutting with the wheel, we make the edges of a spinel, ruby, or corundum-telesie (sapphire), curvilinear, and the adjacent faces curved, these stones will cut glass as well as a glaziers' diamond, but being less hard than it, they will not preserve this property so long. He found that upon giving the surface of even a fragment of flint the same shape as that of the cutting diamond, it acquired the same property; but, from its relative softness, was of little duration. The depth to which the fissure caused by the glaziers' diamond penetrates does not seem to exceed the two-hundredth of an inch.

The following remarks by Mr. Tennant cannot fail to be of interest, and, as pointing out the errors which have been frequently committed through ignorance, are of great value:—

'By attending to the forms of the crystal, we are quite sure that we shall not find the emerald, sapphire, zircon, or topaz in the form of a cube, octahedron, tetrahedron, or rhombic dodecahedron; nor the *diamond*, spinel, or garnet in that of a six-sided prism, and so on with other gems. For want of a knowledge of the crystalline form of the diamond a gentleman in California offered 200*l.* for a small specimen of quartz. He knew nothing of the substance, except that it was a bright, shining mineral, excessively hard, not to be scratched by the file, and which would scratch glass. Presuming that these qualities belonged only to the diamond, he conceived that he was offering a fair price for the gem; but the owner declined the offer. Had he known that the diamond was never found as a six-sided prism, terminated at each end by a six-sided pyramid, he would have been able to detect the fact that what he was offered 200*l.* for, was really not worth more than half-a-crown.'—*Tennant's Lecture on Gems.*

The accompanying forms (*figs.* 605 and 606) may serve to guide those who are ignorant of crystallography:—

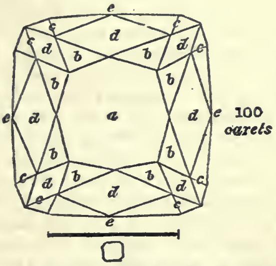
605

Quartz.

606

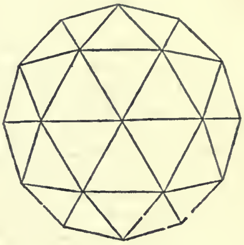
Diamond.

607 Brilliant (upper side).



a, table; *b*, star-facets; *c*, skill-facets; *d*, lozenges; *e*, girdle.

608 Rose.



The following technical terms are applied to the different faces of diamonds:—

Bezils: the upper sides and corners of the *brilliant*, lying between the edge of the table and the girdle.

Collet: the small horizontal plane or face, at the bottom of the *brilliant.*

Crown: the upper work of the rose, which all centres in the point at the top, and is bounded by the horizontal ribs.

Facets: small triangular faces or planes, both in *brilliants* and *roses.* In *brilliants* there are two sorts, *skew-* or *skill*-facets, and *star*-facets. Skill-facets are divided into *upper* and *under.* Upper skill-facets are wrought on the lower part of the bezil, and terminate in the girdle; under skill-facets are wrought on the pavilions, and terminate in the girdle; star-facets are wrought on the upper part of the bezil, and terminate in the table.

Girdle: the line which encompasses the stone parallel to the horizon; or, which determines the greatest horizontal expansion of the stone.

Lozenges: are common to *brilliants* and *roses.* In *brilliants* they are formed by the meeting of the skill- and star-facets on the bezil. In *roses* by the meeting of the facets in the horizontal ribs of the crown.

Pavilions: the under sides and corners of *brilliants*, lying between the girdle and the collet.

Ribs: the lines or ridges, which distinguish the several parts of the work, both in *brilliants* and *roses.*

Table: the large horizontal plane, or face, at the top of the *brilliant.*

Fig. 607 represents a brilliant, and *fig.* 608 a rose-cut diamond.

The rose-diamond is flat beneath, like all weak stones, while the upper face rises into a dome and is cut into facets. Most usually six facets are put on the central region which are in the form of triangles, and unite at their summits; their bases abut upon another range of triangles, which being set in an inverse position to the preceding, present their bases to them, while their summits terminate at the sharp margin of the stone. The latter triangles leave spaces between them which are likewise cut each into two facets. By this distribution the rose-diamond is cut into 24 facets; the surface of the diamond being divided into two portions, of which the upper is called the crown, and that forming the contour, beneath the former, is called *dentelle* (lace) by the French artists.

According to Mr. Jefferies, in his 'Treatise on Diamonds,' the regular rose-diamond is formed by inscribing a regular octagon in the centre of the table side of the stone, and bordering it by eight right-angled triangles, the bases of which correspond with the sides of the octagon; beyond these is a chain of 8 trapeziums, and another of 16 triangles. The collet side also consists of a minute central octagon, from every angle of which proceeds a ray to the edge of the girdle, forming the whole surface into 8 trapeziums, each of which is again subdivided by a salient angle (whose apex touches the girdle) into one irregular pentagon and two triangles.

To fashion a rough diamond into a brilliant the first step is to modify the faces of the original octahedron, so that the plane formed by the junction of the two pyramids shall be an exact square, and the axis of the crystal precisely twice the length of one of the sides of the square. The octahedron being thus rectified, a section is to be made parallel to the common base or *girdle*, so as to cut off $\frac{5}{18}$ths of the whole height from the upper pyramid and $\frac{1}{18}$th from the lower one. The superior and larger plane thus produced is called the *table*, and the inferior and smaller one is called the *collet*; in this state it is termed a *complete square table diamond.* To convert it into a brilliant, two triangular facets are placed on each side of the table, thus changing it from a square to an octagon; a lozenge-shaped facet is also placed at each of the four corners of the table, and another lozenge extending lengthwise along the whole of each side of the original square of the table, which, with two triangular facets set on the base of each lozenge, completes the whole number of facets on the table side of the diamond: viz. 8 lozenges and 24 triangles. On the collet side are formed 4 irregular pentagons, alternating with as many irregular lozenges radiating from the collet as a centre, and bordered by 16 triangular facets adjoining the girdle. The brilliant being thus completed, is set with the table side uppermost, and the collet side implanted in the cavity made to receive the diamond. The brilliant is always three times as thick as the rose diamond. In France, the thickness of the brilliant is set off into two unequal portions; one third is reserved for the upper part or table of the diamond, and the remaining two-thirds for the lower part or collet (*culasse*). The table has eight planes, and its circumference is cut into facets, of which some are triangles and other lozenges. The collet is also cut into facets called *pavillons.* It is of consequence that the pavillons lie in the same order as the upper facets, and that they correspond to each other, so that the symmetry be perfect, for otherwise the play of the light would be false.

Although the rose diamond often projects bright beams of light in more extensive proportion than the brilliant, yet the latter shows an incomparably greater play, from the difference of its cutting. In executing this, there are formed 32 faces of different figures, and inclined at different angles all round the table, on the upper side of the stone. On the collet (*culasse*) 24 other faces are made round a small table, which converts the culasse into a truncated pyramid. These 24 facets, like the 32 above, are differently inclined and present different figures. It is essential that the faces of the top and the bottom correspond together in sufficiently exact proportions to multiply the reflections and refractions, so as to produce the colours of the prismatic spectrum.

Diamonds, cutting of. Although the diamond is the hardest of all known substances, yet it may be split by a steel tool, provided a blow be applied; but this requires a perfect knowledge of the structure, because it will only yield to such means in certain directions. This circumstance prevents the workman from forming facets or planes generally, by the process of splitting; he is therefore obliged to resort to the process of abrasion, which is technically called cutting. The process of cutting is effected by fixing the diamond to be cut on the end of a stick, or handle, in a small ball of cement, that part which is to be reduced being left to project. Another diamond is also fixed in a similar manner; and the two stones being rubbed against each other with considerable force, they are mutually abraded, flat surfaces, or facets, being thereby produced. Other facets are formed by shifting the diamonds into fresh positions in the cement, and when a sufficient number are produced they are fit for polishing. The stones, when cut, are fixed for this purpose by imbedding them in soft solder, contained in a small copper cup, the part or facet to be polished being left to protrude.

A flat circular plate of cast iron is then charged with the powder produced during the abrasion of the diamonds; and by this means a tool is formed which is capable of producing the exquisite lustre so much admired on a finely-polished gem. Those diamonds that are unfit for working on account of the imperfection of their lustre or colour, are sold, for various purposes, under the technical name of Bort. Stones of this kind are frequently broken in a steel mortar, by repeated blows, until they are reduced to a fine powder, which is used to charge metal plates of various kinds, for the use of jewellers, lapidaries, and others. Bort, in this state of preparation, is incapable of polishing any gems; but it is used to produce flat surfaces on rubies and other precious stones.

Fine drills are made of small splinters of bort, which are used for drilling small holes in rubies, and other hard stones, for the use of watch-jewellers, gold and silver wire-drawers, and others who require very fine holes drilled in such substances. These drills are also used to pierce holes in china, where rivets are to be inserted;

also for piercing holes in artificial enamel teeth, or any vitreous substances, however hard.

The following description furnished to Mr. Tennant, by Messrs. Garrard, of the cutting of the Koh-i-noor will fully explain the peculiar conditions of the process, and also show that there are some remarkable differences in the physical condition of the gem in its different planes. The letters refer to the cut of the Koh-i-noor, *fig.* 602, (p. 23):—

'In cutting diamonds from the rough, the process is so uncertain that the cutters think themselves fortunate in retaining one-half the original weight. The Koh-i-noor, on its arrival in England, was merely surface cut, no attempt having been made to produce the regular form of a brilliant by which alone lustre is obtained. By reference to the figures, which are the exact size of the Koh-i-noor, it will be clearly understood that it was necessary to remove a large portion of the stone in order to obtain the desired effect, by which means the apparent surface was increased rather than diminished, and the flaws and yellow tinge were removed.

'The process of diamond cutting is effected by a horizontal iron plate of about ten inches diameter, called a *schyf* or *mill* which revolves from two thousand to three thousand times per minute. The diamond is fixed in a ball of pewter at the end of an arm, resting upon the table in which the plate revolves; the other end, at which the ball containing the diamond is fixed, is pressed upon the wheel by moveable weights at the discretion of the workmen. The weight applied varies from 2 to 30 lbs. according to the size of the facets intended to be cut. The recutting of the Koh-i-noor was commenced on July 16, 1852, His Grace the late Duke of Wellington being the first person to place it on the mill. The portion first worked upon was that at which the planes P and F meet, as it was necessary to reduce the stone at that part, and so to level the set of the stone before the table could be formed; the intention being to turn the stone rather on one side, and take the incision or flaw at E, and a fracture on the other side of the stone, not shown in the engraving, as the boundaries or sides of the girdle. The next important step was the attempt to remove an incision or flaw at C, described by Professor Tennant and the Rev. W. Mitchell as having been made for the purpose of holding the stone more firmly in its setting, but pronounced by the cutters (after having cut into and examined it) to be a natural flaw of a yellow tinge, a defect often met with in small stones. The next step was cutting a facet on the top of the stone immediately above the last-mentioned flaw. Here the difference in the hardness of the stone first manifested itself; for while cutting this facet, the lapidary noticing that the work did not proceed so fast as hitherto, allowed the diamond to remain on the mill rather longer than usual, without taking it off to cool; the consequence was, that the diamond became so hot from the continual friction and greater weight applied, that it melted the pewter in which it was imbedded. Again, while cutting the same facet, the mill became so hot from the extreme hardness of the stone, that particles of iron mixed with diamond powder and oil ignited. The probable cause of the diamond proving so hard at this part is, that the lapidary was obliged to cut directly upon the angle at which two cleavage planes meet, cutting across the grain of the stone. Another step that was thus considered to be important by the cutters was removing a flaw at G. This flaw was not thought by Professor Tennant and Mr. Mitchell to be dangerous, because if it were allowed to run according to the cleavage, it would only take off a small piece, which it was necessary to remove in order to acquire the present shape. The cutters, however, had an idea that it might not take the desired direction, and, therefore, began to cut into it from both sides, and afterwards directly upon it, and thus they succeeded in getting rid of it. While cutting, the stone appeared to become harder and harder the further it was cut into, especially just above the flaw at A, which part became so hard, that, after working the mill at the medium rate of 2,400 times per minute, for six hours, little impression had been made; the speed was therefore increased to more than 3,000, at which rate the work gradually proceeded. When the back (or former top) of the stone was cut, it proved to be much softer, so that a facet was made in three hours, which would have occupied more than a day, if the hardness had been equal to that on the other side; nevertheless, the stone afterwards became gradually harder, especially underneath the flaw at A, which part was nearly as hard as that directly above it. The flaw at N did not interfere at all with the cutting. An attempt was made to cut out the flaw at A, but it was found not desirable on account of its length. The diamond was finished on September 7th, having taken thirty-eight days to cut, working twelve hours per day without cessation.' The weight of the Koh-i-noor since cutting is 102½ carats.

DIAMOND BORER. See BORING.

DIAMOND BORON. See BORON.

DIAMOND DUST. The use of diamond dust within a few years has increased very materially, on account of the increased demand for all articles that are wrought by it, such as cameos, intaglios, &c. There has been a discovery made of the peculiar power of diamond dust upon steel; it gives the finest edge to all kinds of cutlery, and threatened at one time to displace the hone of Hungary. Finely-powdered corundum, however, now occupies its place. It is well known that in cutting a diamond, the dust is placed on the teeth of the saw, to which it adheres. To this dust is to be attributed solely the power of man to make brilliant from rough diamonds.

Diamond dust can be made by voltaic electricity but not economically.

DIAMOND MICROSCOPES were first suggested by Dr. Goring, and have been well executed by Mr. Pritchard. Among the different crystalline forms of the diamond, probably the octahedron and the cube are the only ones that will give a single vision. It will, in many cases, be advisable to grind diamond lenses plano-convex, both because this figure gives a low spherical aberration, and because it saves the trouble of grinding one side of the gem. A concave tool of cast iron, paved with diamond powder, hammered into it by a hardened steel punch, was employed by Mr. Pritchard. This ingenious artist succeeded in completing a double convex of equal radii, of about $\frac{1}{25}$th of an inch focus, bearing an aperture of $\frac{1}{30}$th of an inch with distinctness upon opaque objects, and its entire diameter upon transparent ones.

DIAMOND SPAR. A name given to corundum, as it is next to the diamond the hardest known mineral. See Corundum.

DIAMOND TOOLS. 1. *The Glaziers' diamond* is the natural diamond, so set that one of its edges is brought to bear on the glass.

The extreme point of any diamond will *scratch* glass, making a white streak; but when the rounded edge of a diamond is slid over a sheet of glass with but slight pressure, it produces *a cut*, which is scarcely visible, but which readily extends through the mass.

Dr. Wollaston succeeded in giving to the ruby, topaz, and rock crystal forms similar to those of the diamond, and with those he succeeded in *cutting* glass; proving that this useful property of the diamond depended on its form. Although the primitive form of the diamond is that of a regular octahedron, the Duke de Bournon published upwards of one hundred forms of crystallisation of the diamond. The irregular octahedrons with round facets are those proper for glaziers' diamonds.

Notwithstanding the hardness of the diamond, yet, in large glass works, as many as one and two dozens are worn out every week: from being convex, they become rapidly concave, and the cutting power is lost.

2. *Diamond drills* are made of various shapes; these are either found amongst imperfect diamonds, or, selected from fragments split off from good stones in their manufacture for jewelling.

For description of the diamond-mounted borers, used for rock-drilling, see Boring.

DIAPER is the name of a kind of cloth, used chiefly for table-linen. It is known among the French by the name of *Toile fourré*, and is ornamented with the most extensive figures of any kind of tweeled cloth, excepting damask. The mounting of a loom for working diaper is, in principle, much the same as a draw-loom, but the figures being less extensive, the mounting is more simple, and is wrought entirely by the weaver, without the aid of any other person. As tweeled cloths, of any number of leaves, are only interwoven at those intervals when one of the leaves is raised, the woof above and the warp below are kept floating or flushed, until the intersection takes place. Of consequence the floating yarn above appears across the fabric, and that below longitudinally. This property of tweeled cloths is applied to form the ornamental figures of all kinds of tweeled goods, merely by reversing the floating yarn when necessary. In the simpler patterns this is effected by a few additional leaves of treddles; but when the range of pattern becomes too great to render this convenient, an apparatus called a *black harness* is employed, and the cloth woven with this mounting is called diaper. Diapers are generally five-leaf tweels, that is to say, every warp floats under four threads of woof, and is raised, and of course interwoven with the fifth. This is done either successively, forming diagonals at 45° upon the cloth, or by intervals of two threads, which is called the broken tweel. The latter is generally, if not universally, adopted in the manufacture of diaper. The reason of preferring the broken to the regular tweel, where ornaments are to be formed, is very obvious. The whole depending upon reversed flushing, to give the appearance of oblique or diagonal lines through either, would destroy much of the effect, and materially injure the beauty of the fabric. The broken tweel, on the contrary, restores to the tweeled cloth a great similarity of appearance to plain or alternately interwoven fabrics, and at the same time preserves the facility of producing ornaments by reversing the flushing.

DIAPHANOUS. Transparent to light.

DIASPORE. A native hydrate of alumina, frequently found with emery and corundum. It occurs in Asia Minor; in the Grecian Archipelago; at Schemnitz, in Hungary; and in Chester Co., Pennsylvania.

DIASTASE. A white and tasteless nitrogenous substance, obtained by moistening pounded malt, and squeezing the water through a bag. Albumen is precipitated from the turbid fluid by alcohol, and filtered. Then the diastase is precipitated by an additional quantity of alcohol, and purified by re-solution and re-precipitation.

Diastase has the property of acting like a ferment on starch, and converting it into dextrine or into sugar, thus reducing the starch to a soluble form. One part of diastase will convert 2,000 parts of starch into dextrine, and 1,000 parts into sugar.

DIATHERMANOUS. Transparent to radiant heat, as rock-salt.

DICHROISCOPE. An instrument invented by Haidinger for examining the dichroism, or pleochroism, of crystals. It consists of a rhombohedron of Iceland spar, having a glass prism of 18° cemented to each end. This is enclosed in a brass tube, one end of which carries a convex lens, whilst the other end is furnished with a screen having a square aperture. On looking through this crystal two images of the aperture are seen, and if a transparent dichroic crystal be held in front of the aperture the two images appear of different tints. The dichroiscope may be used with advantage for the discrimination of certain gems. If, for example, a stone be found to give two differently-coloured images, we know at once that it cannot belong to the cubic system. Thus, Oriental ruby may be distinguished from spinel-ruby, the former being doubly refracting and dichroic, whilst the latter crystallises in the cubic system, and is therefore not dichroic. See Gems.

DICHROISM. The property of exhibiting two colours. Many of the phenomena belong to the conditions producing fluorescence. Some of the phenomena have been referred to polarisation, but this requires examination. See Fluorescence.

DICHROITE. A mineral otherwise known as *Iolite* or *Cordierite.* It is called *Dichroite* in allusion to its marked dichroism, or decided difference of colour observable in its crystals when viewed in different directions. Chemically, it is a silicate of alumina, magnesia, and protoxide of iron.

DIDYMIUM. One of the rarer metals. It is found in connection with *Lanthanum* and *Cerium.*

Solutions of salts of didymium give a characteristic absorption-spectrum containing two black lines enclosing a very bright space. Mr. Greville Williams has detected didymium in churchite by means of spectrum analysis, and has called attention to the presence of this metal in some varieties of apatite.

DIE-EARTH. A local term—used in Coalbrookdale for the Wenlock Shale—because it lies below all the mining ground.

DIES FOR STAMPING. (*Coins,* Fr.; *Münzstämpeln,* Ger.) The first circumstance that claims particular attention in the manufacture of dies is the selection of the best kind of steel for the purpose, and this must in some measure be left to the experience of the die-forger, who, if well skilled in his art, will be able to form a tolerably correct judgment of the fitness of the metal for the purpose, by the manner in which it works upon the anvil. It should be rather fine-grained than otherwise, and above all things perfectly even and uniform in its texture, and free from spots and patches finer or coarser than the general mass. But the very fine and uniform steel with a silky fracture, which is so much esteemed for some of the purposes of cutlery, is unfit for our present purpose, from the extreme facility with which it acquires great hardness by pressure, and its liability to cracks and flaws. The very cross-grained, or highly crystalline steel, is also equally objectionable; it acquires fissures under the die-press, and seldom admits of being equally and properly hardened. The object, therefore, is to select a steel of a medium quality as to fineness of texture, not easily acted upon by dilute sulphuric acid, and exhibiting an uniform texture when its surface is washed over with a little aquafortis, by which its freedom from pins of iron, and other irregularities of composition, is sufficiently indicated.

The best kind of steel being thus selected, and properly forged at a high heat into the rough die, it is softened by very careful annealing, and in that state, having been smoothed externally, and brought to a table in the turning lathe, it is delivered to the engraver.

The process of annealing the die consists in heating it to a bright cherry red, and suffering it to cool gradually, which is best effected by bedding it in a crucible or iron pot of coarsely-powdered charcoal. In this operation it is sometimes supposed that the die, or at least its superficial part, becomes super-carbonised or highly-converted steel, as it is sometimes called; but experience does not justify such an opinion, and probably the composition of the die is scarcely, certainly not materially, affected by the process, for it does not remain long enough in the fire for the purpose.

The engraver usually commences his labours by working out the device with small steel tools *in intaglio*; he rarely begins in relief (though this is sometimes done); and having ultimately completed his design, and satisfied himself of its general effect and correctness, by impressions in clay, and dabs, or casts in type-metal, the die is ready for the important operation of hardening, which, from various causes, a few of which will be enumerated, is a process of much risk and difficulty; for should any accident now occur, the labour of many months may be seriously injured, or even rendered quite useless.

The process of hardening soft steel is in itself very simple, though not very easily explained upon mechanical or chemical principles. We know by experience that it is a property of this highly valuable substance to become excessively hard, if heated and suddenly cooled; if, therefore, we heat a bar of soft malleable and ductile steel red hot, and then suddenly quench it in a large quantity of cold water, it not only becomes hard, but fragile and brittle. But as a die is a mass of steel of considerable dimensions, this hardening is an operation attended by many and peculiar difficulties, more especially as we have at the same time to attend to the careful preservation of the engraving. This is effected by covering the engraved face of the die with a protecting face, composed of fixed oil of any kind, thickened with animal charcoal: some persons add pipe-clay, others use a pulp of garlic, but pure lamp-black and linseed-oil answer the purpose perfectly. This is thinly spread upon the work of the die, which, if requisite, may be further defended by an iron ring; the die is then placed with its face downwards in a crucible, and completely surrounded by animal charcoal. It is heated to a suitable temperature, that is, about cherry red, and in that state is taken out with proper tongs, and plunged into a body of cold water, of such magnitude as not to become materially increased in temperature; here it is rapidly moved about, until all noise ceases, and then left in the water till quite cool. In this process it should produce a bubbling and hissing noise; if it pipes and sings, we may generally apprehend a crack or fissure.

No process has been found to answer better than the above simple and common mode of hardening dies, though others have had repeated and fair trials. It has been proposed to keep up currents and eddies of cold water in the hardening cistern, by means of delivery-pipes coming from a height; and to subject the hot die, with its face uppermost, to a sudden and copious current of water, let fall upon it from a large pipe, supplied from a high reservoir; but these means have not in any way proved more successful, either in saving the die, or in giving it any good qualities. It will be recollected, from the form of the die, that it is necessarily only, as it were, case-hardened, the hardest strata being outside, and the softer ones within, which envelope a core, something in the manner of the successive coats of an onion; an arrangement which we sometimes have an opportunity of seeing displayed in dies which have been smashed by a violent blow.

The hardening having been effected, and the die being for the time safe, some further steps may be taken for its protection; one of these consists in a very mild kind of tempering, produced by putting it into water, gradually raised to the boiling point, till heated throughout, and then suffering it gradually to cool. This operation renders the die less apt to crack in very cold weather. A great safeguard is also obtained by thrusting the cold die into a red-hot iron ring, which just fits it in that state, and which, by contracting as it cools, keeps its parts together under considerable pressure, preventing the spreading of external cracks and fissures, and often enabling us to employ a split or die for obtaining punches, which would break to pieces without the protecting ring.

If the die has been successfully hardened, and the protecting paste has done its duty by preserving the face from all injury and oxidisement, or burning, as it is usually called, it is now to be cleaned and polished, and in this state constitutes what is technically called a *matrix*; it may of course be used as a multiplier of medals, coins, or impressions, but it is not generally thus employed, for fear of accidents happening to it in the coining press, and because the artist has seldom perfected his work upon it in this state. It is therefore resorted to for the purpose of furnishing a *punch*, or steel impression for relief. For this purpose a proper block of steel is selected, of the same quality, and with the same precautions as before, and being carefully annealed, or softened, is turned like the matrix, perfectly true and flat at the bottom, and obtusely conical at top. In this state, its conical surface is carefully compressed by powerful and proper machinery upon the matrix, which, being very hard, soon allows it to receive the commencement of an impression; but in thus receiving the impression, it becomes itself so hard by condensation of texture as to require during the operation to be repeatedly annealed, or softened, otherwise it would split into small superficial fissures, or would injure the matrix; much practical skill is therefore required in taking the impression, and the punch, at each annealing, must be carefully protected, so that the work may not be injured.

Thus, after repeated blows in the die-press, and frequent annealing, the impression from the matrix is at length perfected, or brought completely up, and having been retouched by the engraver, is turned, hardened, and collared, like the matrix, of which it is now a complete impression in relief, and, as we have before said, is called a punch.

This punch becomes an inexhaustible parent of dies, without further reference to the original matrix; for now by impressing upon it plugs of soft steel, and by pursuing with them an exactly similar operation to that by which the punch itself was obtained, we procure impressions from it to any amount, which, of course are fac-similes of the matrix, and these dies being turned, hardened, polished, and, if necessary, tempered, are employed for the purposes of coinage.

The distinction between striking medals and common coin is very essential, and the work upon the dies is accordingly adjusted to each. Medals are usually in very high relief, and the effect is produced by a succession of blows; and as the metal in which they are struck, be it gold, silver, or copper, acquires considerable hardness at each stroke of the press, they are repeatedly annealed during the process of bringing them up. In a beautiful medal, which Mr. Wyon executed for the Royal Naval College, the obverse represents the head of the King, in very bold relief; it required thirty blows of a very powerful press to complete the impression, and it was necessary to anneal each medal after every third blow, so that they went ten times into the fire for that purpose. In striking a coin or medal, the lateral spread of the metal, which otherwise would ooze out as it were from between the dies, is prevented by the application of a steel collar, accurately turned to the dimensions of the dies, and which, when left plain, gives to the edge of the piece a finished and polished appearance; it is sometimes grooved, or milled, or otherwise ornamented, and occasionally lettered, in which case it is made in three separate and moveable pieces, confined by a ring, into which they are most accurately fitted, and so adjusted that the metal may be forced into the letters by its lateral spread, at the same time that the coin receives the blow of the screw-press.

Coins are generally completed by one blow of the coining-press. These presses are worked in the Royal Mint by machinery, so contrived that they shall strike, upon an average, sixty blows in a minute; the blank piece, previously properly prepared and annealed, being placed between the dies by part of the same mechanism.

The number of pieces which may be struck by a pair of dies of good steel, properly hardened and duly tempered, not unfrequently amounts at the Mint to between one and two hundred thousand; but the average consumption of dies is of course much greater, owing to the variable qualities of steel, and to the casualties to which the dies are liable; thus, the upper and lower die are sometimes struck together, owing to an error in the layer-on, or in that part of the machinery which ought to put the blank into its place, but which now and then fails so to do. This accident very commonly arises from the boy who superintends the press neglecting to feed the hopper of the layer-on with blank pieces. If a die is too hard, it is apt to break or split, and is especially subject to fissures, which run from letter to letter upon the edge. If too soft, it swells, and the collar will not rise and fall upon it, or it sinks in the centre, and the work becomes distorted and faulty. He, therefore, who supplies the dies for an extensive coinage, has many accidents and difficulties to encounter. There are eight presses at the Mint, frequently at work for ten hours each day, and the destruction of eight pair of dies per day (one pair for each press) may be considered a fair average result, though they much more frequently fall short of, than exceed this proportion. It must be remembered, that each press produces 3,600 pieces per hour; but making allowance for occasional stoppages, we may reckon the daily produce of each press at 30,000 pieces; the eight presses, therefore, will furnish a diurnal average of 240,000 pieces.

DIES, hardening of. See STEEL, HARDENING OF.

DIFFUSION. As the principles of diffusion are sometimes involved in processes of manufacture, a short notice of the phenomena appears to properly find its place in this Dictonary. To no one do we owe so much for elucidating this subject as to the late Prof. Graham, and from his 'Elements of Chemistry' the following notices have been selected. When light and heavy gases are mixed together, they do not exhibit any tendency to separate again on standing at rest, differing in this respect from mixed liquids, many of which speedily separate and arrange themselves according to their densities, the lightest uppermost, the heaviest undermost, as in the familiar example of oil and water, unless they have combined together. This peculiar property of gases has repeatedly been made the subject of careful experiment. Common air, for instance, is essentially a mixture of two gases, differing in weight in the proportion of 971 to 1,105; but the air in a tall close tube of glass, several feet in length, kept upright in a still place, has been found sensibly the same in composition at the top and bottom of the tube after a lapse of months. Hence, there is no reason to imagine that the upper stratum of air differs in composition from the lower, or that a light gas, such as hydrogen, escaping into the atmosphere, will rise and ultimately possess the higher regions; suppositions which have been the groundwork of meteorological theories at different times.

The earliest observations we possess on this subject are those of Dr. Priestley, to whom pneumatic chemistry stands so much indebted. Having repeated occasion to transmit a gas through stoneware tubes, surrounded by burning fuel, he perceived that the tubes were porous, and that gas escaped outwards into the fire, while, at the same time, the gases of the fire penetrated into the tube, although the gas within the tube was in a compressed state.

'In entering upon this inquiry, I found, first: that gases diffuse into the atmosphere, and into each other, with different degrees of ease and rapidity. This was observed by allowing each gas to diffuse from a bottle into the air through a narrow tube, taking care, when the gas was lighter than the air, that it was allowed to escape from the lower part of the vessel, and when heavier from the upper, so that it had on no occasion any disposition to flow out, but was constrained to diffuse in opposition to the effect of gravity. The result was, that the same volume of different gases escapes in times which are exceedingly unequal, but have a relation to the specific gravity of the gas. The light gases diffuse or escape most rapidly; thus, hydrogen escapes five times quicker than carbonic acid, which is twenty-two times heavier than that gas. Secondly, in an intimate mixture of two gases, the most diffusive gas separates from the other, and leaves in the receiver the greater proportion. Hence, by availing ourselves of the tendency of mixed gases to diffuse with different degrees of rapidity, a sort of mechanical separation of gases may be effected. The mixture must be allowed to diffuse for a certain time into a confined gaseous or vaporous atmosphere, of such a kind as may be afterwards condensed or absorbed with facility.

'But the nature of the process of diffusion is best illustrated when the gases communicate with each other through minute pores or apertures of insensible magnitude.

'A singular observation belonging to this subject was made by Professor Döbereiner, of Jena, on the escape of hydrogen gas by a fissure or crack in glass receivers. Having occasion to collect large quantities of that light gas, he had accidentally made use of a jar with a slight fissure in it. He was surprised that the water in the pneumatic trough rose into this jar one and a half inches in twelve hours; and that after twenty-four hours the height of the water was two inches two-thirds above the level of that in the trough. During the experiment, neither the height of the barometer nor the temperature of the place had sensibly altered. He ascribed the phenomenon to capillary action, and supposed that hydrogen only is attracted by the fissures, and escapes through them on account of the extreme smallness of its atoms. It is unnecessary to examine this explanation, as Döbereiner did not observe the whole phenomenon. On repeating the experiment, and varying the circumstances, it appeared to me that hydrogen never escapes outwards by the fissure without a certain portion of air penetrating at the same time inwards, amounting to between one-fourth and one-fifth of the volume of the hydrogen which leaves the receiver. It was found, by an instrument which admits of much greater precision than a fissured jar, that when hydrogen gas communicates with the air through such a chink, the air and hydrogen exhibit a powerful disposition to exchange places with each other; a particle of air, however. does not exchange with a particle of hydrogen of the same magnitude, but of 3·83 times its magnitude. We may adopt the word *diffusion-volume* to express this diversity of disposition in gases to interchange particles, and say that the diffusion-volume of air being 1, that of hydrogen gas is 3·83. Now, every gas has a diffusion-volume peculiar to itself, and depending upon its specific gravity. Of those gases which are lighter than air, the diffusion-volume is greater than 1; and of those which are heavier, the diffusion-volume is less than 1. The diffusion-volumes are, indeed, inversely as the square root of the densities of the gases. Hence, the times of the effusion and diffusion of gases follow the same law.' See Watts's 'Dictionary of Chemistry;' Graham's 'Elements of Chemistry;' and papers in 'Philosophical Transactions of the Royal Society.'

DIGESTER is the name of a kettle or pot of small dimensions, made very strong, and mounted with a safety valve in its top. Papin, the contriver of this apparatus, used it for subjecting bones, cartilage, &c., to the solvent action of high-pressure steam, or highly-heated water, whereby he proposed to facilitate their digestion in the stomach. This contrivance is the origin of the French cookery pans, called *autoclaves*, because the lid is self-keyed, or becomes steam-tight by turning it round under clamps or ears at the sides, having been previously ground with emery to fit the edge of the pot exactly. In some autoclaves the lid is merely laid on with a fillet of linen as a lute, and then secured in its place by means of a screw bearing down upon its centre from an arch bar above. The safety valve is loaded either by a weight placed vertically upon it, or by a lever of the second kind pressing near its fulcrum, and acted upon by a weight which may be made to bear upon any point of its graduated arm.

Chevreul made a useful application of the digester to vegetable analysis. His instrument consists of a strong copper cylinder, into which enters a tight cylinder of silver, having its edge turned over at right angles to the axis of the cylinder, so as to form the rim of the digester. A segment of a copper sphere, also lined with silver, stops the aperture of the silver cylinder, being applied closely to its rim. It has a conical valve pressed with a spiral spring, of any desired force, estimated by a steelyard. This spring is enclosed within a brass box, perforated with four holes, which may be screwed into a tapped orifice in the top of the digester. A tube screwed into another hole serves to conduct away the condensible vapours at pleasure into a Woulfe's apparatus.

DIKA-BREAD. A food made from the fruit of the *Mangifera Gabonensis*, a tree indigenous to the country from Sierra Leone to the Gaboon. It is one of the *Anacardiaceæ*. White almond kernels are found in the fruit; these are bruised and pressed to form the Dika-bread.

DIKE. See Dyke.

DILATATION. The increase of size produced in bodies by the agency of heat. See Expansion.

DILL. The *Anethum graveolens*, an umbelliferous plant, containing an essential oil.

DILLNITE. A hydrous silicate of alumina, occurring with diaspore at Dilln, near Schemnitz, in Hungary.

DILUVIUM. Those accumulations of gravel and loose materials, which, by some geologists, are said to have been produced by the action of a diluvian wave or deluge sweeping over the surface of the earth.—*Lyell.*

The term was formerly applied to the superficial deposits, now commonly called 'drift,' and was used to distinguish them from the still more recent accumulations known as *alluvium.*

DIMITY is a kind of cotton cloth originally imported from India, and now manufactured in great quantities in various parts of Britain, especially in Lancashire. Dr. Johnson calls it *dimmity*, and describes it as a kind of fustian. The distinction between fustian and dimity seems to be, that the former designates a common tweeled cotton cloth of a stout fabric, which receives no ornament in the loom, but is most frequently dyed after being woven, Dimity is also a stout cotton cloth, but not usually of so thick a texture; and is ornamented in the loom, either with raised stripes or fancy figures: it is seldom dyed, but usually employed white, as for bed and bed-room furniture. The striped dimities are the most common; they require less labour in weaving than the others; and the mounting of the loom being more simple, and consequently less expensive, they can be sold at much lower rates.

DIMORPHISM. (*dis*, two; *morphe*, form.) This name is applied to bodies which will crystallise in two forms. Sulphur, for example, will usually crystallise in the rhombic system; but will when melted under certain conditions form monoclinohedric crystals. Carbon appears in nature as the diamond and graphite, and carbonate of lime as calc-spar and aragonite. Many chemical compounds of the same compositions are susceptible of crystallisation in two essentially distinct forms.

In Biology, the tendency of some organisms to exhibit two distinct forms in their essential organs is called dimorphism. Thus Mr. Darwin has shown that some species of *Primula* are dimorphic, one form having a long style and short stamens, and the other form having a short style and long stamens. A check is thus given to self-fertilisation; perfect fertilisation occurring only when the two dimorphic forms are crossed, the pollen of the short-stamened variety being applied to the stigma of the short-styled form, and conversely the pollen of the long-stamened variety to the stigma of the long-styled form.

DIMORPHITE. A sulphide of arsenic, containing As^2S^3 ($\mathbf{As^4S^3}$). It occurs at the Solfatara, near Naples.

DINAS BRICKS. Fire-bricks made of Dinas sand, and much used in the construction of the copper-smelting furnaces of South Wales. The rock known as 'Dinas sand' is found in the Vale of Neath in Glamorganshire, and consists almost wholly of silica. Having been ground, the material is mixed with water, with addition of about one per cent. of lime, and is pressed into the shape of bricks, which are then fired. The granules of quartz are cemented together by a slightly-fusible compound formed by the action of the lime.

DIOPSIDE. A name applied to a clear green crystalline variety of pyroxene or augite. It has occasionally been cut as a gem-stone, but is too soft to be of much value.

DIOPTASE, or *Emerald Copper*, occurs in fine emerald green transparent crystals. It is a silicate of protoxide of copper, and is found in veins in limestone in the Kirghis Steppes. See Copper.

DIOPTRIC LIGHTHOUSES. See Lighthouses.

DIORITE. An igneous rock composed of a crystalline-granular mixture of a triclinic felspar and hornblende. It is often so fine-grained in texture that it is difficult to determine the component minerals. Diorite generally presents a dark green colour, and is one of the rocks commonly included under the general name of 'greenstone.'

DIP. When any stratum, mineral vein, or dyke, does not lie horizontally it is said to dip E. W. N. or S., as the case may be. The angle which it makes with the horizon is called the angle of the dip.

DIPPEL'S ANIMAL OIL. A fetid volatile oil obtained when animal substances, such as bone, are subjected to distillation. That which is found in commerce is obtained in the manufacture of bone-black.

DIPPING. Ornamental works in brass are usually brightened by a process called *dipping*. After the work has been properly fitted together and the grease removed, either by the action of heat, or by boiling in a pearlash-lye, it is *pickled* in a bath of dilute aqua fortis. It is then scoured bright with sand and water, and being well washed is plunged into the dipping bath, which consists of pure nitric acid, commonly known as *dipping aqua fortis*, for an instant only, and is then well washed with cold and hot water to remove every trace of acid from the surface, after which the work is put into dry beech or box wood sawdust, &c., well rubbed until it is quite dry, and then burnished and lacquered. See Dead-Dipping.

DISCRASE or **DISCRASITE.** An antimonial silver ore, of rare occurrence.

DISINFECTANT. A substance which removes the putrid or infected condition of bodies. It is well not to confound it with antiseptic, which applies to those bodies which prevent putrefaction. The word 'disinfectant' has lately become somewhat uncertain in its meaning, on account of a word being used as its equivalent, viz. deodoriser. This latter means a substance which removes odours. In reality, however, there are no such substances known to us as a class. There are, of course, some substances which destroy certain others having an odour, but in all cases the removal of the smell and the destruction or neutralisation of the vapour or gas causing the smell must be simultaneous. There is, however, a large class of substances that destroy putrefaction, and the name 'disinfectant' is therefore distinctly needed. The gases which rise from putrefying bodies are not all capable of being perceived by the senses in their ordinary condition, but sometimes they are perceived. A disinfectant puts a stop to them and deodorises simultaneously. If any substance were to remove the smell of these gases, it would remove the gases too, as they are inseparable from their property of affecting the nose. A deodoriser would therefore be, and is, a disinfectant of that gas the smell of which it removes. But it has been suggested that it may remove those gases which smell, and allow the most deleterious to pass, they having no smell. Whenever we find such a class of substances, it will be well to give them the name of 'deodorisers.' There may be some truth in the hypothesis that metallic salts remove the sulphur, and by preventing the escape of sulphuretted hydrogen cause less odour, without complete disinfection. So far as we know, however, there is a disinfecting action along with the deodorising. Any solution having the effect here supposed would at the least be a partial disinfectant, inasmuch as the decomposition would be so far put a stop to, as to prevent at least one obnoxious gas. To prevent the formation of one gas is to arrest decomposition or to alter the whole character of the change which is producing the gases. The most deleterious of emanations have no smell at all to the ordinary senses, and we can only judge of the evil by its ulterior effects, or the fact that the substances capable of producing it are near, or by the analysis of the air. The cases where sulphuretted hydrogen accompanies the offensive matter are chiefly connected with fecal decomposition. This gas is a useful indication of the presence of other substances. So far as is known, the destruction of the one causes the destruction of the other. But the presence of sulphuretted hydrogen is no proof of the presence of infectious matter, nor is its absence a proof of the absence of infectious matter, it being only an occasional accompaniment. When the infectious matter and the odoriferous matter are one, then to deodorise is to disinfect. We can find no line of duty to be performed by deodorisers, and no class of bodies that can bear the name, although there may be a few cases where the word may be found convenient. If, for example, we destroy one smell by superadding a greater, that might in one sense be deodorising. If we added an acid metallic salt, and removed the sulphuretted hydrogen, letting loose those organic vapours which for awhile accompany this act, we might, to those who were not very near, completely destroy smell, and still send a substance into the air by no means wholesome; but in such a case decomposition is stopped, at least for awhile. The word 'deodorisers' may be used for such substances as remove the odour and the putrefaction of the moment but allow them to begin again. Even in this case deodorisers become temporary disinfectants, which character all removers of smell must more or less have.

Antiseptics, or colytic agents. Substances which prevent decomposition. The words *colysis* and *colytic* come from *κωλύω, to arrest, restrain, cut short.* This word was proposed by the writer to apply to cases such as are included under antiseptics, antiferments, and similar words. There was needed a word for the general idea. A colytic force manifests itself towards living persons in anæsthetics, anodynes, and narcotics, as well probably, as in other ways. Colytics may probably act from different causes, but these causes not being separately distinguished, a name for the whole class can alone be given. The action of *colysis* is entirely opposed to *catalysis,* which is a loosening up of a compound. *Colysis* arrests *catalysis,* as well also as other processes of decomposition, ordinary oxidation for example. Disinfectants, in their character of restraining further decomposition, are included under *colytics.* One of the most remarkable substances for arresting decomposition is creosote. It has been used in some condition or mixture from the earliest times, The ancient oil of cedar has been called with good reason turpentine, which has strong disinfecting properties, but the word has evidently been used in many senses, as there are many liquids to be obtained from cedar. It is used for the first liquid from the distillation of wood; and Berzelius for that reason says that the Egyptians used the pyroligneous acid, which, containing some creosote, was a great antiseptic. But addition of this acid to soda would be of little value in embalming, nor is it probable that they would add a volatile liquid like turpentine along with caustic soda. It is expressly said (in Pliny) that pitch was reboiled, or in other words, the tar was boiled and distilled, the product being collected in the wool of fleeces, from which again it was removed by pressure. In doing this the light oils or naphtha would be evaporated, and the heavy oil of tar, containing the carbolic acid, or creosote, would remain. It was called picenum, as if made of pitch or pissenum, and pisselæum or pitch-oil, a more appropriate name than that of Runge's carbolic acid or coal-oil, and still more appropriate than the most recent, which by following up a theory, has converted it into phenic acid. The distillation was made in copper vessels, and must have been carried very far, as they obtained 'a reddish pitch, very clammy, and much fatter than other pitch.' This was the *anthracene, chrysene,* and *pyrene* of modern chemistry. The remaining hard pitch was called *palimpissa,* or second pitch, which we call pitch in contradistinction to tar. By the second pitch, however, was sometimes meant the product of distillation instead of what was left in the still. Some confusion, therefore, exists in the names, but not more than with us. The pitch oil was resinous fat, and of yellow colour, according to some. This oil, containing creosote, was used for toothache—a colytic action applied to living bodies—and for skin diseases of cattle, for which it is found valuable. They also used it for preserving hams.—*Disinfectants, by the Writer. Jour. Soc. of Arts,* 1857, *and separate volume* 1869.

It is quite possible that creosote may be the chief agent in most empyreumatic substances which act as antiseptics. But it is not the only agent. Hydrocarbons of various kinds act as antiseptics, as well as alcohol and methylic alcohol, which contain little oxygen. To this class belong essential oils and substances termed perfumes, which are used for fumigation, and have also a colytic action. It is exceedingly probable that the true theory of this action is connected with the want of oxygen. These substances do not rapidly oxidise, but, on the contrary, only very slowly, and that chiefly by the aid of other bodies. Their atoms are, therefore, in a state of tension, ready to unite when assisted. As an example, carbolic acid and creosote unite with oxygen when a base is present, and form rosolic acid. We can scarcely suppose that an explanation, commonly resorted to by some to explain the action of sulphurous acid, would suit them; viz., that it takes up the oxygen, and so keeps it from the putrescible substance. It is supposible that the molecular condition acts on the putrescible body. For, as the state of motion of a putrefying substance is transferred to another, so may the state of immobility.

In 1750 Sir John Pringle wrote his 'Experiments on Septic and Antiseptic Substances, with remarks relating to their Use in the Theory of Medicine.' He recommended salts of various kinds, and astringent and gummy parts of vegetables and fermenting liquors. Dr. Macbride followed him with numerous experiments. He speaks of acids being the long-prescribed agents as antiseptics. He found them antiseptic even when diluted to a great extent. Alkalis also he found antiseptic, and salts in general. Also 'gum-resins, such as myrrh, assafœtida, aloes, and terra japonica,' besides 'decoctions of Virginia snake-root, pepper, ginger, saffron, contrayerva root, sage, valerian root, and rhubarb, with mint, angelica, senna, and common wormwood.' Many of the common vegetables also were included as to some extent antiseptic; such as horse-radish, mustard, carrots, turnips, garlic, onions, celery, cabbage, colewort. Lime was found to prevent, but not to remove putrefaction. We are inclined at present very much to qualify some of these observations. Animal fluids, he observes, will remain for a long time without putridity if kept from the air. He says that astringent mineral acids and ardent spirits 'not only absorb the matter from the putrescent substances, but likewise crisp up its fibres, and thereby render it so hard and durable that no change of combination will take place for many years.' He adds also molasses to the antiseptics. In 1767 the Academy of Dijon gave a prize for the use of nitrate of potash in ventilation, driving off the oxygen by heat. This may have given the first idea to Carmichael Smyth using the nitrous fumes. Guyton-Morveau came later with a volume of valuable experiments on acids chiefly muriatic.

An *antiseptic* preserves from putrefaction, but does not necessarily remove the odour caused by that which has previously putrefied. Many of the substances described as disinfectants here might equally be called antiseptics. When they remove the putrid matter, they are disinfectants; when they prevent decomposition, they are antiseptics. But when the smell is removed by a substance which is known to destroy putrefactive decomposition, and to preserve organic matter entire, then we have the most thorough disinfection; then we know that the removal of the smell is merely an indication of the removal of the evil.

Disinfectants are of various kinds. Nature seems to use soil as one of the most active. All the dejecta of the animals on the surface of the earth fall on the soil, and are rapidly made perfectly innoxious. Absorption distinguishes porous bodies, and the soil has peculiar facilities for the purpose. But if saturated, it could disinfect no longer. This is not allowed to occur; the soil absorbs air also, and oxidises the organic matter which it has received into its pores, and the offensive matter is either converted into food for plants and absorbed by them, or is made an innocent ingredient of the air, or, if the weather be moist, of the water. The air is, therefore, in conjunction with the soil, one of the greatest disinfectants, but it acts also quite alone and independent of the soil. Its power of oxidising must be very great. The amount of organic effluvium sent into large towns is remarkable, and yet it seldom accumulates so as to be strongly perceptible to the senses. The air begins to oxidise it almost as rapidly as it rises; this is hastened apparently by the peculiar agent in the air, ozone, which has a greater capacity of oxidation than the common air; when this is exhausted, it is highly probable that the oxidisation will be much slower, and this exhaustion does take place in a very short time in our large and smoky towns. So rapid is the oxidation, that the wind, even blowing at the rate of fifteen to twenty miles an hour, is entirely deprived of its ozone by passing over less than a mile of Manchester. In London this does not take place so rapidly, at least near the Thames. But when the ozone is removed, it is probable that the rate of increase of the organic matter will be much greater. We may by this means, then, readily gauge the condition of a town up to a certain point by the removal of the ozone: but it requires another agent to gauge it afterwards or thoroughly.

It is in connection with each other that the air and the soil best disinfect. When manure is thrown upon land without mixing with the soil, it may require a very long period to obtain thorough disinfection, but when the atmosphere is moist, or rain falls, then the air is rapidly transferred into every portion of the porous earth, and the organic matter becomes rapidly oxidised. To prevent a smell of manure, and with it also the loss of ammonia, it is then needful that as soon as possible the manure should be mixed with the soil. The same power of oxidation is common to all porous bodies, to charcoal, and especially, as Dr. Stenhouse has shown, to platinised charcoal. Disinfection by the use of porous bodies is at first a process of preservation, but soon it may change to that of slow destruction. It has been shown by the last-mentioned chemist that charcoal produces an oxidation in which all the escaping gases are so thoroughly oxidised, that none of them have any smell or any offensive property. But being so, the body disinfected must necessarily decay, and in reality the process of decay is remarkably increased. All such bodies must therefore be avoided when manures are to be disinfected, and when they are not to be put on the land immediately. Stenhouse has employed charcoal for disinfecting the air. The air is passed through the charcoal either on a large scale for a hospital or on a small scale as a respirator for the mouth. Care must be taken, however, to keep the charcoal dry: wet charcoal is not capable of absorbing air until that air is dissolved in the water. This absorption takes places less rapidly in water. Wet charcoal is therefore a filter for fluids chiefly, and dry charcoal for vapours. Its destructive action on manures will, however, always prevent charcoal from being much used as a disinfectant for such purposes, or, indeed, any other substance which acts principally by its porosity or by oxidation. This the soil does only partially, as it has another power, viz. that of retaining organic substances fit to be the food of plants. Although air acts partly in conjunction with the soil and the rain to cause disinfection, and partly by its own power, it also acts mechanically as a means of removing all noxious vapours. The wind and other currents of the air are continually ventilating the ground, and when these movements are not sufficiently rapid, or when they are interrupted by our mode of building, we are compelled to cause them artificially, and thus we arrive at the art of ventilation. The addition of one-tenth per cent. of carbonic acid to the air may be perceived, at least if accompanied with the amount of organic matter usually given out at the same time in the breath, and as we exhale in a day 12–16 cubic feet of that gas, we can injure the quality of 16,000 cubic feet of air in that time. The great value of a constant change of air is therefore readily proved, and the instinctive love which we have of fresh air is a sufficient corroboration.

Cold is a great natural disinfectant. The flesh of animals may be preserved as far as we know for thousands of years in ice; putrefying emanations are completely arrested by freezing, but the mobility of the particles, or chemical action, is also retarded by a degree of cold much less than freezing, and beginning at 54° Fahr.

Heat is also a disinfectant, when it rises to about 140° of Fahrenheit, according to Dr. Henry. But as a means of producing dryness it is a disinfectant at various temperatures. Nothing which is perfectly dry can undergo putrefaction. On the other hand heat with moisture below 140° is a condition very highly productive of decomposition and all its resulting evils. Disinfection by heat is used at quarantine stations. Light is undoubtedly a great disinfectant; so far as we know, it acts by hastening chemical decomposition. In all cases of ventilation, it is essential to allow the rays of light to enter as well as the currents of air. Its effect on the vitality of the human being is abundantly proved, and is continually asserting itself in vegetation. The true disinfecting property of light exists in all probability in the chemical rays which cause compositions and decompositions. Water is scarcely to be called a disinfectant itself except indirectly, for it increases putrefaction, but as a mechanical agent of purity the most remarkable, and there is no other capable of taking its place actively. Wherever animals, even human beings, live, there are emanations of organic matter, even from the purest. The whole surface of the house, furniture, floor, and walls, becomes coated by degrees with a thin covering, and this gradually decomposes, and gives off unpleasant vapours. Sometimes it becomes planted with fungi, and so feeds plants of this kind. But long before this occurs a small amount of vapour is given off sufficiently disagreeable to affect the senses, and sometimes affecting the spirits and the health before the senses distinctly perceive it. This must be removed. In most cases this film is removed by water, and we have the ordinary result of household cleanliness; but in other cases when the furniture is such as will be injured by water, the removal is made by friction or by oil or turpentine, and other substances used to polish. Water as a disinfectant is used also in washing of clothes; for this purpose nothing whatever can supply its place, although it requires the assistance both of soap and friction, or agitation and heat. Water is also used as a mechanical agent for removing filth generally, and the method which Hercules devised of using a river to wash away filth is now adopted in all the most advanced plans of cleansing towns. It is only by means of water that the refuse of towns can be conveyed away in covered and impervious passages, whilst none whatever is allowed to remain in the town itself. In cases where this cannot be done, it is much to be desired that some disinfecting agent should be used to prevent decomposition. Where water is not used, as in water-closets, there is generally a great amount of matter stored up in middens, and the town is of course continually exposed to the effluvia. Beside these methods of acting, water disinfects partly by preventing effluvia from arising from bodies, simply because it keeps them in solution. This action is not a perfect one, but one of great value. The water gives off the impurity slowly, sometimes so slowly as to be of no injury, or it keeps it so long that complete oxidation takes place. The oxygen for this purpose is supplied by the air, which the water absorbs without ceasing. To act in this way, water must be delivered in abundance. Bodies decompose rapidly under water, and it acts also as a great opponent to disinfection by rising up in vapour loaded with the products of decomposition.

Mere drying is known to arrest decay, as the mobility of the particles in decomposition is stayed by the want of water. We are told in Andersson's Travels in S. Africa, that the Damaras cut their meat into strips, and dry it in the sun, by which means it is preserved fresh. A similar custom is found in S. America. Certain days prevent this, and decomposition sets in rapidly. A little overclouding of the sky, or a little more moisture in the air, quickly stops the process.

The above may be called natural disinfectants, or imitations of natural processes, charcoal being introduced as an example of a more decided character of porous action.

They show both mechanical and chemical action. The mechanical, when water or air removes, dilutes, or covers the septic bodies: the chemical, when porous bodies act as conveyers of oxygen: or an union of both, when cold and heat prevent the mobility of the particles. The action by oxidation causes a destruction of the offensive material. The other method is antiseptic. It is much to be desired that all impurities should be got rid of by some of these methods, but especially by the air, the water, and the soil. There are, however, conditions in which difficulties interfere with the action. Large towns may be purified by water, but what is to be done with the water which contains all the impurity? If put upon land, capable of absorbing it, it is very soon disinfected, but on its way to the land it may do much mischief. It has been proposed to disinfect it on its passage, and even in the sewers themselves; by this means the town itself is freed from the nuisance, and the water may be used where it is needed without fear. This introduces artificial disinfectants. There are other cases where such are required; when the refuse matter of a town is allowed to lie either in exposed or in underground receptacles; in this case a town is exposed to an immense surface of impurity, and disinfectants would greatly diminish the evil, if not entirely remove it. There are besides, special cases without end continually occurring, where impurities cannot be at once removed, and where treatment with artificial disinfectants is required.

Artificial disinfectants which destroy the compound are of various kinds. *Heat* is one of the most powerful. A putrid body, when heated so as to be deprived of all volatile particles, cannot any longer decompose. It is however possible that the vapours may become putrid, and if not carefully treated, this will happen. It was the custom of some of the wealthy among the ancients to burn the dead, and it is still the custom in India; but although the form is kept up amongst all classes, the expense is too great for the poor. The bodies are singed, or even less touched by fire, and thrown if possible into the river. This process has been recommended here, but the quality of the gaseous matter rising from a dead body is most disgusting to our physical, and still more to our moral senses, and the amount is enormous. It is of course possible so to burn it, that only pure carbonic acid, water, and nitrogen, shall escape, but the probability of preventing all escape is small enough to be deemed an impossibility, and the escape of one per cent. would cause a rising of the whole neighbourhood. To effect the combustion of the dead of a great city, such a large work, furnished with great and powerful furnaces, would be required, that it would add one of the most frightful blots to modern civilisation, instead of the calm and peaceful churchyard where our bones are preserved as long at least as those who care for us live, and then gradually return to the earth. In burning the dead some prefer to burn the whole body to pure ash. This was the ancient method; but it is highly probable that the ashes which they obtained were a delusion in most cases. The amount of ash found in the urns is often extremely small. The body cannot be reduced to an infinitesimal ash, as is supposed; eight to twelve pounds of matter remain from an average man when all is over. A second plan, is to drive off all volatile matter, and leave a cinder. This disgusting plan leaves the body black and incorruptible. It can never, in any time known to us, mix with its mother earth, and yet it ceases at once to resemble humanity in the slightest degree; it will not even for a long time assist us by adding its composition to the fertility of the soil. The burning of bodies never could have been general, and never can be general. Fire has only a limited use as a disinfectant. It cannot at present be economically used in the daily disinfection of the dejecta of animals, and is applied only occasionally, where the most rapid destruction is the most desirable, either because the substance has no value, or it is too disgusting to exist, or the products after burning are not offensive. There are two methods of using fire, charring or burning to ashes. The second is an act of—

Oxidation.—This is effected either by rapid combustion called fire; by slow combustion, the natural action of the air; or by chemical agency, assisted by mechanical, as in porous bodies. Slow oxidation in the soil is a process which is desirable for most offensive matters, and it would be well if we could bring it all into this condition; the ammonia is preserved, or it is in part oxidised into nitric acid and water, both the ammonia and nitric acid being food for plants. Sometimes this process is hastened by mixing up the manure with alkaline substances, raising it in heaps, and watering, by this means forming nitrates, a process performed abundantly in warm countries upon the materials of plants and animals, and imitated even in temperate regions with success. This amount of oxidation destroys a good deal of the carbonaceous substances, and leaves less for the land. It is only valuable when saltpetre is to be prepared.

One of the most thorough methods of oxidation, is by the use of the manganates or permanganates. They transfer their oxygen to organic substances with great rapidity, and completely destroy them. They are therefore complete disinfectants. They destroy the odour of putrid matter rapidly, and oxidise sulphuretted hydrogen, and phosphuretted hydrogen, as well as many purely organic substances having offensive smells. As they do this by oxidation at a low temperature, they are the mildest form of the destructive disinfectants, and their application to putrid liquids of every kind gives most satisfactory results. The quantities treated at a time should not be great, and the amount of material used must be only to the point of stopping the smell, or at least not much more, because both pure and impure matter act on the manganates, and an enormous amount of the material may be used in destroying that which is not all offensive. The manganates do not prevent decay from beginning again. Their use has been patented by Mr. Condy. A similar action takes place with various high oxides and other oxides which are not high. Sometimes, however, a deleterious gas is produced as a secondary result by oxidation, as when sulphuric acid in the sulphates oxidises organic matter, allowing sulphuretted hydrogen to escape. In this case it is highly probable that a true disinfection takes place, or a destruction of the putrid substance, and all offensive purely organic substances; still the amount of sulphuretted hydrogen given off is of itself sufficiently offensive and deleterious, but not properly speaking an infectious or putrid gas, although an occasional accompaniment.

Nitric acid is another agent of destruction or oxidation, although it has qualities which might cause it to be ranked amongst those which prevent the decomposition by entering into new combinations. But properly speaking, it is not nitric acid which is the disinfectant of Carmichael Smyth, but nitric oxide, which is a powerful oxidiser, and most rapidly destroys organic matter. For very bad cases, in which gaseous fumigation is applicable, nothing can be more rapid and effective in its action than this gas. Care must be taken that there is no one present to breathe it, as it has a powerful action on the lungs, killing without due warning, and care must be taken that metallic surfaces which are to be preserved clean, be well covered with a coating of varnish. This was used with great effect in ships and hospitals for some years, beginning with 1780, and so much good did it do, that the Parliament in 1802 voted Dr. C. Smyth a pension for it. Guyton-Morveau was vexed at this, and wrote an interesting volume concerning his mode of fumigating by acids; but in reality acids alone are insufficient, and his favourite muriatic acid has no such effect as nitrous fumes, which so readily part with their oxygen. On the whole, nitrous fumes are too dangerous for general use.

Chlorine is another destructive agent, and its peculiar action may be called an oxidation. When used as a gas, it has a great power of penetration, like nitrous fumes, and stops all putrefaction. It has a more actively destructive power than oxygen alone, even when its action is that of oxidation only. It decomposes compounds of ammonia and organic substances containing nitrogen into water and nitrogen, and as putrefactive matter is united with, or composed partly of nitrogen, it destroys the very germ of the evil. By the same power it destroys the most expensive part of a manure, the ammonia. It cannot therefore be used where the offensive matter is to be retained for manure. When chlorine is united with lime or soda, it may be used either as a solution or a powder. This latter acts as the gaseous chlorine, but the power of destroying ammonia is greater. As a liquid, it acts too rapidly; as a solid, the chloride of lime soon attracts moisture and soon loses its power. Some people use the chloride of lime as a source of chlorine; they pour sulphuric acid on it, and so cause it to give out chlorine, which escapes as a gas, and acts as aforesaid. Too much is given out at first, too little at last. It is said to have increased the lung diseases at hospitals, where it was much used in Paris. When only a minute quantity of gas is given out, as at bleach works, it certainly causes a peculiar freshness of feeling, and the appearance of the people is much in its favour, nor has it ever there been known to affect the lungs. For violent action, in cases of great impurity, it is a great disinfectant, and to be preferred to nitrous fumes, probably causing a less powerful action on the lungs: at least, it gives good warning. Mixed with alum, without ammonia, it gives off chlorine slowly. *Eau de javelle* is a chloride of potash used in Paris. Mr. Daniel Stone uses muriatic acid with a small crystal of chlorate of potash to give out a slight chlorine vapour slowly.

Sometimes oxygen, or at least air, is used alone, to remove both colour and smell, oils having it pumped into them. Sometimes acids alone are used for disinfection. As putrid compounds contain ammonia or organic bases, they may be removed, or at least they may be retained in combination, and in this way restrained from further evaporation. This seems to be the way in which muriatic acid acts, and all other merely acid agents. This acid, so much valued at one time, is now entirely disused, as it ought to be, because it is exceedingly disagreeable to breathe, and destructive of nearly all useful substances which it touches, being at the same time a very indirect disinfectant. Acids poured on putrid matters, no doubt destroy the true putrefaction, but they cause the evolution of gases exceedingly nauseous, and of course unwholesome, This evolution does not last long, but long enough to make them useless as disinfectants when used so strong. Vinegar is the best of the purely acid disinfectants; wood vinegar the best of the vinegars, because it unites to the acidity a little creosote. Vinegar is a very old and well-established agent; it has been used in the case of the plague and various pestilences from time immemorial. It is used to preserve eatables of various kinds. For fumigation no acid vapour used is pleasant except vinegar, and in cases where the impurity is not of the most violent kind, it may be used with great advantage. Even this, however, acts on some bright surfaces, a disadvantage attending most fumigations.

Sulphurous acid, or the fumes of burning sulphur, may be treated under this head, although in reality it does not act as a mere acid combining with a base and doing no more. It certainly unites with bases so that it has the advantage of an acid, but it also decomposes by precipitating its sulphur, as when it meets sulphuretted hydrogen. It therefore acts as an oxidiser in some cases, but it is generally believed, from its desire to obtain oxygen, that it acts by being oxidised, thus showing the peculiar characteristics of a deoxidiser. We can certainly believe that bodies may be disinfected both by oxidation and deoxidation. The solutions of sulphurous acid act as a restraint on oxidation, and preserve like vinegar. Its compounds with bases, such as its salts of soda, potash, &c., preserve also like vinegar, saltpetre, &c.; probably from their affinity for oxygen, taking what comes into the liquid before the organic matter can obtain it. But it is not probable that this rivalry exists to a great extent; the presence of the sulphurous acid in all probability puts some of the particles of oxygen in the organic matter in a state of tension or inclination to combine with it, so that the tension of the particles which are inclined to combine with the oxygen of the air is removed.

Sulphur fumes are amongst the most ancient disinfectants held sacred in early times from their wonderful efficacy, and still surpassed by none. With sulphur the shepherd purified or disinfected his flocks, and with sulphur Ulysses disinfected the suitors which he had slain in his house. No acid fumigation is less injurious generally, vinegar excepted, to the lungs or furniture, and its great efficiency marks it out as the most desirable, although much laid aside in modern times. The amount arising from burning coal must have a great effect in disinfecting the putrid air of our streets, and rendering coal-burning towns in some respects less unpleasant; this is one of the advantages which that substance brings along with it, besides, it must be confessed, greater evils. It is curious that this compound of sulphur should be one of the most efficient agents in destroying sulphuretted hydrogen, another compound of sulphur. Sulphurous acid prevents decomposition, and also preserves the valuable principle of a manure, so that it belongs partly to the class of disinfectants, and partly to antiseptics.

The peculiar actions of sulphites and carbolic acid have been united in that called 'Mc Dougall's Disinfecting Powder'; where it is desirable not to use liquids, these two have been united into a powder, which assists also in removing moisture, as water is often a great cause of discomfort and disease in stables and cowhouses. When they are used in this manner the acids are united with lime and magnesia. The cattle are, it is said, freed from a great amount of illness, not only because the air of the stable is purified, but that it is dried at the same time. It does not seem well to use excess of water in our climate, and it is then that a disinfecting powder becomes so valuable, and where our towns are so badly supplied with water-closets that disinfectants are wanted for the middens.

It has been proposed to disinfect sewers, as well as sewage, by the same substances; not, however, in the state of a powder. The acids are applied to the sewage water in the sewers themselves, and so cause the impure water to pass disinfected through the town; by this means the towns and sewers are to be purified together. Besides the above-mentioned powder, there are Calvert's disinfecting powder containing carbolic acid, and Mudie's disinfecting powder with metallic salts.

Lime is used for precipitating sewage water, and acts as a disinfectant as far as the removal of the precipitate extends, and also by absorbing sulphuretted hydrogen, which, however, it allows again to pass off gradually. The other substances proposed for sewers have chiefly relation to the precipitation, and do not so readily come under this article. Charcoal has been mentioned. Alum has been proposed, and it certainly does act as a disinfectant and precipitant. None of these substances have been tried on a great scale, excepting lime, and carbolic acid or tar products, the first at Leicester, the second at Carlisle.

Absence of air is an antiseptic of great value. The process of preserving meat, called Appert's process, is by putting it in tin vessels with water, boiling off a good deal of steam, to drive out the air, and then closing the aperture with solder. Schroeder and De Dusch prevented putrefaction for months by allowing no air to approach the meat without passing through cotton; so also veils are found to be a protection against some miasmas. *Salts*, or compounds of acids with bases, are valuable antiseptics; some of them are also disinfectants, that is, they remove the state of putrefaction after it has begun. An antiseptic prevents it, but does not necessarily remove it. Common salt is well known as a preserver of flesh; nitrate of potash, or saltpetre, is a still more powerful one. Some of these salts act by removing the water. Meat, treated with these salts, gives out its moisture, and a strong solution of brine is formed. Chloride of calcium prevents, to some extent, the putrefaction of wood. Alum, or the sulphate of alumina, is not a very efficient preserver; but chloride of aluminium seems to have been found more valuable. It is sometimes injected into animals by the carotid artery and jugular vein. Meat, usually keeps a fortnight: if well packed, cleaned, and washed with a solution of chloride of aluminium, it will keep three months. This salt is sold as *chloralum*.

But in reality the salts of the heavier metals are of more activity as disinfectants. It has been supposed that their efficiency arose from their inclination to unite with sulphur and phosphorus, and there is no doubt that this is one of their valuable properties, by which they are capable of removing a large portion of the impure smell of bodies; but they have also an inclination to combine with organic substances, and by this means they prevent them from undergoing the changes to which they are most prone. The actual relative value of solutions it is not easy to tell. Most experiments have been made on solutions not sufficiently definite in quantity. Salts of mercury have been found highly antiseptic. Such a salt is used for preserving wood; the process is known as that of Kyan's, or kyanising. A solution of corrosive sublimate, containing about 1½ per cent. of the salt, is pressed into the wood either by a forcing pump or by means of a vacuum. The albumen is the substance most apt to go into putrefaction, and when in that condition it conveys the action to the wood. It is no doubt by its action on the albumen that the mercury chiefly acts. Thin pieces of pine wood, saturated for four weeks in a solution of 1 to 25 water, with the following salts, were found, after two years, to be preserved in this order:—1. Wood alone, brown and crumbling. 2. Alum, like No. 1. 3. Sulphate of manganese, like 1. 4. Chloride of zinc, like 1. 5. Nitrate of lead, somewhat firmer. 6. Sulphate of copper, less brown, firm. 7. Corrosive sublimate, reddish yellow and still firmer. In an experiment, in which linen was buried with similar salts, the linen was quite consumed, even the specimen with corrosive sublimate. Other experiments showed salts of copper and mercury to protect best.—*Gmelin*.

Nevertheless, all these metallic salts are found true preservers under other conditions. Chloride of manganese, a substance frequently thrown away, may be used, as Gay-Lussac and Mr. Young have shown, with great advantage, and Mr. Boucherie has shown the value of the acetate of iron. Mr. Boucherie's process is very peculiar. He feeds the tree, when living, with the acetate of iron, by pouring it into a trough dug around the root. The tree, when cut down, has its pores filled with the salt, and the albumen in the sap is prevented from decomposing. For preservation of vegetable and animal substances, see PUTREFACTION, PREVENTION OF.

The chloride of zinc of Sir William Burnett is also a valuable disinfectant, and has more power than it would seem to possess from the experiments quoted above. Wood, cords, and canvas have been preserved by it under water for many years. It has the advantage also of being so soluble as to take up less room than most other salts, although liquids generally are inconvenient as disinfectants in many places.

Nitrate of lead is a disinfectant of a similar kind; it lays hold of sulphur and organic compounds. All these metals are too expensive for general use, and can only be applied to the preservation of valuable materials. Even iron is expensive as a disinfectant for materials to be thrown on the fields as manure. All are apt to be very acid, a state to be avoided in a disinfectant, unless when it is applied to substances in a very dilute state, or in an active putrid state, and giving out ammonia.—R.A.S. See Dr. Angus Smith's Tables, pp. 45 to 47.

This subject is further developed by the writer in his report to the Cattle Plague Commission, 1866; and in 'Disinfectants:' Edmondston and Douglas, 1869.

The importance of this subject appears to give considerable prominence to the report made to Her Majesty's Commissioners on the Cattle Plague by Mr. Wm. Crookes, F.R.S. We therefore select the more important portions. Referring especially to the Cattle Plague, Mr. Crookes says:—

'The specific disease-producing particles must, moreover, be organised, and possess vitality; they must partake of the nature of *virus* rather than of *poison*.[1] No poison yet known to chemists can approach, even in a faint degree, the tremendous energy of the active agent of infectious diseases. A poison may be organic, but it is not organised. It may kill with far greater rapidity than the virus of infection, but,

---

[1] The words *virus* and *poison* are generally regarded as synonymous. It would be more convenient, and would tend to promote accuracy of thought, were the distinction here made generally adopted.

unlike this virus, it cannot multiply itself in the animal economy to such an extent as to endow within a few hours every portion of its juices with the power of producing similar results. A virus, on the contrary, renders the liquids of an infected animal as virulent as the original germ. Strychnine may be regarded as the type of a poison, and vaccine matter as the type of a virus.

'Many considerations tend to show that the virus of cattle plague is a body similar to vaccine lymph, and consists of germinal matter, or living cells, possessing physiological individuality, which, if not exposed to extremes of heat, cold, or dryness, are capable of preserving their activity for a certain time outside the living organism, of adhering to material objects, and of being carried from one place to another by currents of air; each, when introduced into the blood, requires a certain time (known as the period of incubation) during which the septic germs develope and multiply, until they have so far poisoned the blood that the ordinary symptoms of disease become manifest.

'The blood poisoning thus set up may legitimately be called "fermentation"; it is a decomposition caused by the act of nutrition of the living cell, whereby it reproduces in incalculable numbers the specific septic germs which have given it birth. These gradually infest the blood and other animal liquids, and as the disease progresses are discharged from the skin, throat, glands, &c.; the breath, perspiration, and excreta of the animals forming vehicles for the distribution of the virus. By "living" cells, is not meant living, in the sense in which an animal, or even a low form of infusoria, lives; but living as a seed, or as vaccine matter, even when dried, may be living, inasmuch as it still possesses reproductive vitality.

'It is by no means certain that the multiplication of these individual cells is the immediate cause of the blood poisoning. The analogy of the action of virus on the blood, to that of yeast on sugar, renders it more probable that this is not the fact. In the case of the best-known ferment—yeast—its cells multiply by feeding upon the sugar in the liquid; alcohol and carbonic acid being their excretions. It is therefore probable that during the multiplication of the virus cells, they, in a similar manner, impoverish and weaken the blood, by feeding upon some element in it, whilst at the same time they excrete a poison to which the symptoms of the disease may be immediately due.'

Passing over that portion of the report which deals with the usual disinfectants which have been already dealt with by Dr. Angus Smith, the passages, which especially relate to the Tar acids are selected on account of the value of the experimental evidence they give.

'*The Tar Acids* (*Carbolic and Cresylic Acids*).—These two bodies are so commonly known under the name of acids, that I shall continue so to designate them, although by chemists they are more generally classed with the alcohols. They have great similarity, and only within the last few months have they been met with separately in commerce, having hitherto been both called carbolic acid. Creosote, (*κρέας σώζειν*, to preserve flesh), prepared from coal-tar, one of the most powerful antiseptics known, was thought to be impure carbolic acid, until 1854, when Professor Williamson and Mr. Fairlie, in an investigation of it, discovered that it was a mixture of carbolic and cresylic acids. It was then taken for granted that Reichenbach's creosote, from wood-tar, had a similar composition, until Hlasiwetz, in 1858, showed that this creosote was a different body from carbolic or cresylic acids. Finally, Dr. Hugo Müller, in 1864, discovered that true creosote, and its analogue guaiacol, belonged to a different class of bodies, and consisted of methyl-oxy-phenic and methyl-oxy-cresylic acids. No experiments on the large scale have yet been tried with true creosote, as I have only been aware within the last few weeks that this compound could be obtained in quantity.

'Pure carbolic acid is a white crystalline solid, melting at 34° C., and distilling at 180° C.; a trace of water or oily impurity renders it liquid, and for disinfecting purposes it is always supplied in this form, to avoid the extra expense and trouble needed for the separation of the last traces of impurity; cresylic acid is liquid, it boils at 203° C., and closely resembles carbolic acid in odour and other properties. Before the commencement of these inquiries it was thought to be of little or no value as a disinfectant, but Dr. Angus Smith has lately shown that it rivals, if it does not surpass, carbolic acid in antiseptic properties. For the present purpose of cattle-plague disinfection it is immaterial which acid is used, and to avoid unnecessary repetition I shall use the term "carbolic acid" to express either acid, or the commercial mixture of the two acids.

'From time immemorial carbolic acid, creosote, or bodies containing them, have been used as antiseptics. Passages in Pliny, read by the light of chemical science, show that the Egyptians used for embalming their mummies a compound made from pitch, which must have contained large quantities of creosote. Carbolic acid is the active agent in tar, which, either in its ordinary state or burnt as a fumigator, has always held high rank amongst disinfectants. Pitch and tar were the most popular medicines in use against the cattle plague when it visited this island in the last century; the animals being preserved against contagion by having their noses and jaws rubbed with tar, whilst the cowhouses were disinfected by burning pitch and tar in them (in which process a certain quantity of the vapours of carbolic acid would escape combustion). The almost universal custom of burning gum resins and odoriferous woods in connection with religious ceremonies may have originally arisen from the disinfecting powers of the creosote in the smoke. The well-known efficacy of smoke in preserving meat is entirely due to the presence in it of this agent.

'Pitch oil, oil of tar, and similar products owe their value entirely to carbolic acid. This body may, in fact, be called the active principle of tar, just as quinine is the active principle of bark, or morphia of opium, and it has the great advantage of being easily prepared in any country where coal or wood can be obtained.'

After describing some experiments with sulphurous acid, Mr. Crookes proceeds to describe some made by himself with carbolic acid:—

'A piece of fresh meat was soaked in a one-per-cent. aqueous solution of carbolic acid for one hour; it was then wrapped in paper and hung up in a sitting-room in which there was a fire almost daily; at the end of ten weeks it was examined. It had dried up to about one-fourth of its original size, but looked and smelt perfectly good and fresh, a very faint odour of carbolic acid being all that was perceptible. It was soaked for twenty-four hours in water, and then stewed with appropriate condiments and eaten; it was perfectly sweet, and scarcely distinguishable from fresh meat, except by possessing a very faint flavour of carbolic acid, not strong enough to be unpleasant.

'Animal membranes in the forms of gut, skin, and bladder, were perfectly preserved if immersed direct in aqueous solution containing 1 per cent. of carbolic acid; but if previously moistened with water, and then immersed in dilute carbolic acid, the preservation of the skins was not so complete.

'Animal size and glue, mixed, in the form of solution, with small quantities of carbolic acid, were perfectly preserved from change even in hot weather.

'These are important experiments. They point out in a striking manner the difference between mere deodorisers and antiseptics. Hitherto attention has been almost entirely confined to the deodorisation of gases arising from putrescence. The effect has been combated, whilst the removal of the cause has received scarcely any attention. Chloride of lime, one of the strongest of the class of deodorisers, acts, as has been shown, only on the gases of existing putrefaction, but it has no influence over the future. Carbolic acid, on the other hand, has scarcely any action on the fœtid gases; but it attacks the cause which produces them, and, at the same time, puts the organic matter in such a state that it never re-acquires its tendency to putrefy.

'It became now a matter of considerable interest to ascertain in what way carbolic acid acted in arresting decomposition, and the following experiments were made, with the object of clearing up this point:—

'Albumen was mixed with four times its bulk of water, and a one-per-cent. solution of pure carbolic acid was added to it. No change took place for the first few minutes, but after a little time a white cloudiness was formed, which gradually collected together into a coagulum. On separating this, and exposing it freely to the air, it entirely resisted putrefactive decomposition. The solution strained from the coagulum still contained carbolic acid and uncoagulated albumen.

'The same experiment was repeated with pure cresylic acid. This acid had still less affinity for albumen, the mixed solutions remaining clear for nearly half-an hour.

'It is evident, therefore, that the tar acids do not owe their special action to their coagulating powers on albumen, for the last two experiments show, contrary to the generally received opinion, that their affinity for this body is but slight.

'A few drops of carbolic acid, added to half a pint of sugar syrup, and yeast in full action, immediately put a stop to the fermentation.

Fresh brewers' yeast was washed with a solution of one per cent. of carbolic acid, and then with water. Its power of inducing fermentation in a solution of sugar was entirely destroyed, although no perceptible change in the appearance of the yeast-cells could be detected under the microscope. This experiment was repeated several times, and always with the same result, although when the yeast was simply washed in water it readily induced fermentation.

'The odour of carbolic acid adhered most pertinaciously to the yeast, and by no ordinary amount of washing and exposure to the air could it be removed.

'Strychnine was added to a mixture of yeast and sugar solution in full fermentation. No visible effect was produced, the evolution of carbonic acid continuing as brisk as before.

'The above experiments, some of which were performed by my friend Mr. Spiller, prove conclusively that carbolic acid has a special action on the fermentation induced by organised matter; it not only arrests it instantly when in progress, but it prevents the development of future fermentation.

'The action of the tar acids was now examined on certain chemical bodies, which are supposed to act by fermentation, in order to see if they were influenced in the same manner.

'A solution of diastase (infusion of malt) was mixed with thick starch paste, and a one-per-cent. solution of carbolic acid. On gently heating for a short time, the starch was converted into dextrine, as completely as if no carbolic acid had been present.

'Amygdalin was mixed with synaptase (emulsion of sweet almonds) in the presence of carbolic acid. The formation of the essential oil took place with apparently the same readiness as if carbolic acid had been absent.[1]

'The foregoing results show that carbolic acid has no action on purely chemical ferments. These consist of definite nitrogenous compounds acting simply by chemical affinity, and therefore ought not to be classed with true ferments, which are living bodies. It therefore appears that carbolic acid acts by attacking vitality in some mysterious way, and where an effect is merely due to so-called catalytic force, it exerts no interfering action.

'The action of carbolic acid on vitality was then tested in other ways:—

'Cheese mites were immersed in water, where they lived for several hours. A few drops of a solution of carbolic acid containing one per cent. added to the liquid, killed them instantly.

'An aqueous solution of carbolic acid was added to water in which a small fish was swimming. It proved fatal in a few minutes.

'A very minute quantity of a weak solution of carbolic acid was added, under the microscope, to water containing various infusoria, such as bacteria, vibrios, spirilla, amœbæa, monads, euglenæa, paramecia, rotifera, and vorticellæ. The acid proved instantly fatal, arresting the movements of the animalcules at once.

'These animalcules are the almost invariable accompaniments of putrefactive fermentation. The above experiment has been tried with putrid blood, sour paste, and decayed cheese, and in every instance the destruction of vitality and the arrest of putrefaction has been simultaneous.

'Caterpillars, beetles, crickets, fleas, moths, and gnats were covered with a glass, the inside of which was smeared with carbolic acid. The vapour proved quickly fatal. It allays the pain caused by the stings of bees, wasps, hornets, and gnats, if applied pure, or in strong solution, to the wounded part.

'I find it recorded by Dr. Lemaire and other observers that carbolic acid vapour will also kill flies, ants and their eggs, lice, bugs, tics, acari, mosquitoes, aphides, butterflies, earwigs, wood-lice, cockchafers, centipedes, and other insects of this size; its vapour, however, does not appear to be strong enough to act injuriously on animals larger than mice. When such animals are killed with it, their bodies dry up in the air, and resist putrefaction for some time.

'From the intense aversion shown by all insects to the odour of carbolic acid, it is probable that the plentiful use of this agent would effectually preserve cattle from those terrible scourges met with in certain parts of Africa, the zimb and tsetse-fly. The effects following the bite of the latter have been described to me as being almost identical with the symptoms of cattle plague.

'M. Lucien Biard, in speaking of the invasions of the large ants of Mexico, says that when one of their battalions threatens his house, he sprinkles a little carbolic acid in front of it. The army immediatety makes a detour to avoid the obstacle.

'When an animal is killed by the injection of a saturated aqueous solution of carbolic acid into its veins, circulation is instantly arrested, the blood is not coagulated, and no alteration, either in the shape or the appearance of the globules, is detected under the microscope. The only apparent change consists in the immobility of the globules.

'In the 'Annales de Chemie et de Physique' for October 1865, there is a letter from M. Béchamp to M. Dumas, in which it is said that creosote appears to be the agent which most strongly opposes the development of organic ferments, but that it does not interfere with the living ferments or animacules when they are once developed. This assertion is in direct opposition to all my experiments, about the accuracy of which I have no doubt whatever, having submitted them to repeated tests. The powerful action which carbolic acid exerts on the phenomena of life is the most remarkable property which it possesses. It may be looked upon as the test proper for distinguishing vital from purely physical phenomena, and in most cases its action is characterised by the certainty and definiteness of a chemical re-agent. In the

---

[1] These last two experiments are confirmatory of a statement in Dr. Lemaire's work, 'Sur l'Acide phénique.'

presence of carbolic acid the development of embryotic life is impossible, and before its powerful influence all minute forms of animal life must inevitably perish.

'It may be considered as definitely proved that the vapour of carbolic acid, in the atmosphere, exerts a special selective power on all minute organisms possessing life. If the contagious matter of cattle plague is possessed of organic vitality, as must be now admitted, it will be destroyed, beyond the possibility of revival, when brought into contact with the vapour. French experimentalists have repeatedly tested the influence of carbolic acid on vaccine lymph. They have employed lymph both pure and mixed with a trace of carbolic acid. The vaccination with pure lymph was followed by the usual results, but in no single instance was any effect produced by the lymph containing carbolic acid.

'*On the Adulterations of Carbolic Acid, and their Detection.*

'The official recommendations have naturally brought into the market many substitutions for carbolic acid, in which the valuable agent is diluted with cheap inert bodies, while the price charged, in some cases, is higher than that of the genuine article. Specimens of two such substitutions, called cresyline and carboline, were forwarded to the Royal Cattle Plague Commission for approval, "as being more certain disinfectants than most of the carbolic acids now being sold to the public, many of which contain but a very small percentage of that acid." It was stated that the preparations contained over 60 per cent. of carbolic acid, and were miscible with water. As it was possible from these and other reputed advantages that the prepara-

tions might be of considerable value, they were forwarded to me for examination. Cresyline consists of alkaline water, and tar oils boiling above 370° C., therefore containing little or no carbolic or cresylic acids. Carboline is a dilute solution of caustic soda, containing 4·1 per cent. of carbolic acid. The price of these preparations is higher than that ordinarily charged for good commercial carbolic and cresylic acids.

'Other creosote samples from different makers were found to contain, respectively 4·5, 2·6, 5·9 and 4·2, per cent. of carbolic acid, the rest being tar oils. In other instances, articles have been sold as commercially pure carbolic acid, which were found to contain from 30 to 50 per cent. Frequently a very fœtid sulphur compound is allowed to remain. This should be avoided, as although the antiseptic powers of the liquid are great, the offensive odour which it diffuses round the neighbourhood is excessively nauseous.

'It is by no means difficult to detect the adulterations referred to above. Commercial carbolic acid is soluble in from 20 to 70 parts of water, or in twice its bulk of

a solution of caustic soda, while oil of tar is nearly insoluble; but if the amount of carbolic acid be increased some remains undissolved.

'To apply the tests: 1. Put a teaspoonful of the carbolic acid in a bottle, pour on it half a pint of warm water, and shake the bottle at intervals for half an hour, when the amount of oily residue will show the impurity. Or, dissolve one part of caustic soda in ten parts of warm water, and shake it up with five parts of the carbolic acid. As before, the residue will indicate the amount of impurity.

'These tests will show whether tar oils have been used as adulterants; but to ascertain whether the liquid consists of a mere solution of carbolic acid in water or alkali, or whether it contains sulpho-carbolic or sulpho-cresylic acids, another test must be

used, based upon the solubility of these, and the insolubility of carbolic acid, in a small quantity of water. In this case proceed as follows:—2. Put a wine-glassful of the liquid to be tested in a bottle, and pour on it half a pint of warm water. If the greater part dissolves, it is an adulterated article. Test the liquid in the bottle with litmus-paper; if strongly acid, it will show the probable presence of sulpho-acids, whilst if alkaline it will show that caustic soda has been probably used as a solvent.'

DISINTEGRATION. The mechanical breaking up of rock under the action of atmospheric influences. It is distinguished from decomposition, which always refers to some chemical action.

DISTHENE. A name given to *Cyanite*, in allusion to the unequal degree of hardness which crystals of this mineral exhibit in different directions. See Cyanite.

DISTILLATION. Distillation consists in the conversion of any substance into vapour, in a vessel so arranged that the vapours are condensed again and collected in a vessel apart.

The word is derived from the Latin *dis* and *stillo*, I drop, meaning originally to drop or fall in drops, and is very applicable to the process, since the condensation generally takes place dropwise.

It is distinguished from *sublimation* by the confinement of the latter term to cases of distillation in which the product is solid, or, in fact, where a solid is vaporised and condensed without visible liquefaction.

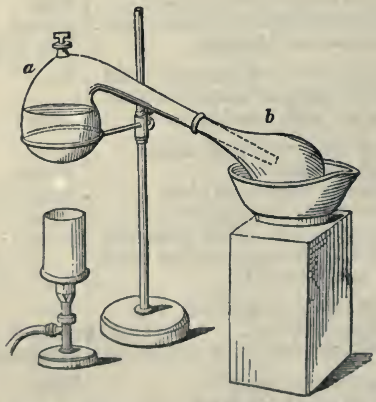
The operation may simply consist in raising the temperature of a mixture sufficiently to evaporate the volatile ingredients; or it may involve the decomposition of the substance heated, and the condensation of the products of decomposition, when it is termed *destructive distillation*; in most cases of destructive distillation the bodies operated upon are *solid*, and the products liquid or gaseous; it is then called *dry distillation.*

In consequence of the diversity of temperatures at which various bodies pass into vapour, and also according to the scale on which the operation has to be carried out, an almost endless variety of apparatus may be employed.

Whatever be the variety of form, it consists essentially of three parts: the *retort* or *still*, the *condenser*, and the *receiver*.

On the small scale, in the chemical laboratory, distillation is performed in the simplest way by means of the common glass retort *a*, and receiver *b*, as in *fig.* 609. The great advantages of the glass retort are that it admits of constant observation of the materials within, that it is acted upon or injured by but a few substances, and may be cleaned generally with facility. Its great disadvantage is its brittleness.

609



610

The retort may be either simple, as in *fig.* 610, or tubulated, as in *fig.* 611.

Retorts should generally be chosen sufficiently convex in all parts, the degree of curvature of one part passing gradually into that of the neighbouring portions, as is represented in the figure; the part to be heated should, moreover, be as uniform in point of thickness as possible. The tubulated retort is more liable to crack than the plain one, on account of the necessarily greater thickness of the glass in the neighbourhood of the tubulature; nevertheless, it is very convenient on account of the facility which it offers for the introduction of the materials.

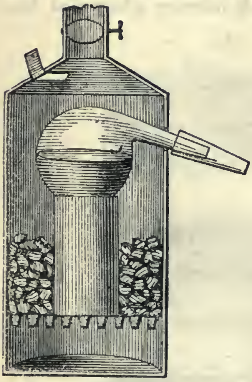
In charging retorts if plain, a funnel with a long stem should be employed, to avoid soiling the neck with the liquid to be distilled; when a solid has to be introduced, it is preferable to employ a tubulated retort; and if a powdered solid is to be mixed with a fluid, it is preferable to introduce the fluid first.

Heat may be applied to the retort either by the argand gas flame, as in *fig.* 609, or a water-, oil-, or sand-bath may be employed.

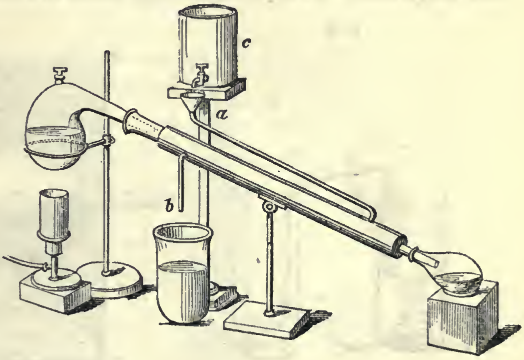
In distilling various substances, *e. g.*, sulphuric acid, great inconvenience is experienced, and even danger incurred, by the phenomenon termed 'bumping.' This consists in the accumulation of large bubbles of vapour at the bottom of the liquid, which bursting cause a forcible expulsion of the liquid from the retort. It is prevented by the introduction of a few angular fragments of solid matter of such a nature as not to be acted upon by the liquid which is to be distilled. Nothing answers this purpose better than a piece of platinum foil cut into a fringe, or even a coil of platinum wire introduced into the cold liquid before the distillation is commenced. Even with this precaution the distillation of sulphuric acid, which it is often desirable to perform for the purpose of its purification, is not unattended with difficulty and danger.

Dr. Mohr suggests the following method:—A glass retort of about two pounds capacity, is placed on a cylinder of sheet iron in the centre of a small iron furnace, while its neck protrudes through an opening in the side of the furnace (*fig.* 611). Ignited charcoal is placed round the cylinder, without being allowed to come in contact with the glass, and a current of hot air is thus made to play on all parts of the retort, excepting the bottom, which is protected by its support. There is a valve in the flue of the furnace for regulating the draught, and three small doors in the cupola or head, for supplying fresh fuel on every side, and for observing the progress of the distillation.

611



612



Instead of the sheet-iron cylinder a Hessian crucible may be employed, and this, if requisite, elevated by placing it on a brick. If the vapour be very readily condensed, nothing more is necessary than to insert the extremity of the retort into a glass receiver as in *fig.* 609.

If a more efficient condensing arrangement be requisite, nothing is more convenient for use on the small scale than a Liebig's condenser, shown in *fig.* 612. It consists simply of a long glass tube into which the neck of the retort is fitted, and the opposite extremity of which passes into the mouth of the receiver; round this tube is fitted another either of glass or metal, and between the two a current of water is made to flow, entering at *a* and passing out at *b*. The temperature of this water may be lowered to any required degree by putting ice into the reservoir *c*, or by dissolving salt in it. (See Freezing.)

Even on the small scale it is sometimes necessary to employ distillatory apparatus constructed of other materials besides glass.

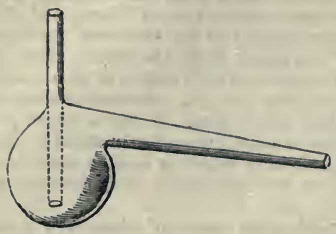
Earthenware retorts are now constructed of very convenient sizes and shapes. There is one kind—which is very useful when it is required to pass a gas into the retort at the same time that the distillation is going on, as in the preparation of chloride of aluminium, &c.—which has a tube passing down into it also made of earthenware, as in *fig.* 613. The closest are of Wedgwood ware, but a common clay retort may be made impermeable to gases, by washing the surface with a solution of borax, then carefully drying and heating it.

---

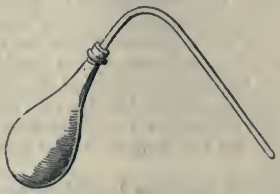
[1] Mohr and Redwood's 'Practical Pharmacy.'

Retorts, or flasks with bent tubes, which screw in thus (*fig.* 614), of copper, are employed when it is requisite to produce high temperatures, as for the preparation of benzole from benzoic acid and baryta, or in making marsh gas from an acetate, &c.

613



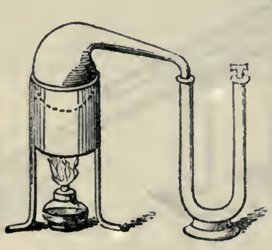
614



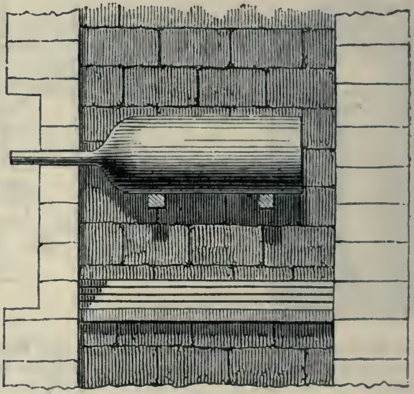
In distilling hydrofluoric acid the whole apparatus should be constructed in lead; the receiver consisting of a U-shaped tube of lead, which is fitted with leaden stoppers so as to serve for keeping the acid when prepared; or a receiver of gutta percha may be employed with a stopper of the same material. (*Fig.* 615.)

For many purposes in the laboratory as, for instance, the preparation of oxygen by heating binoxide of manganese,—in the manufacture of potassium, &c. &c.; where high temperatures are required, the iron bottles in which mercury is imported from Spain may be employed, a common gun-barrel being screwed into them to act as a delivery tube or condenser. (*Fig.* 616.)

615



616



On a large scale an almost endless variety of stills have been and are still employed, which are constructed of different materials.

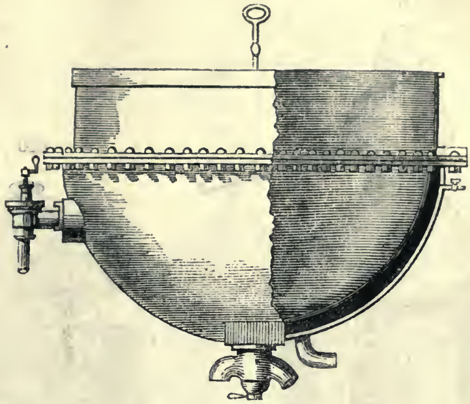
The common 'still' consists of a retort or still proper, in which the substance is heated; and a condenser commonly called a 'worm' on account of its having frequently a spiral shape. The retort or still is generally made in two parts: the *pan* or *copper*, which is the part to which heat is applied, and is commonly set in a furnace of brickwork, and the '*head*,' which is generally removed after each operation, and refixed and luted upon the pan when again used. The condenser or worm is commonly placed in a tube or other vessel of water. (See *fig.* 619.)

The still may be either constructed of earthenware, or, as is very commonly the case, of copper, either plain or electro-plated with silver, according to circumstances; less frequently platinum is employed.

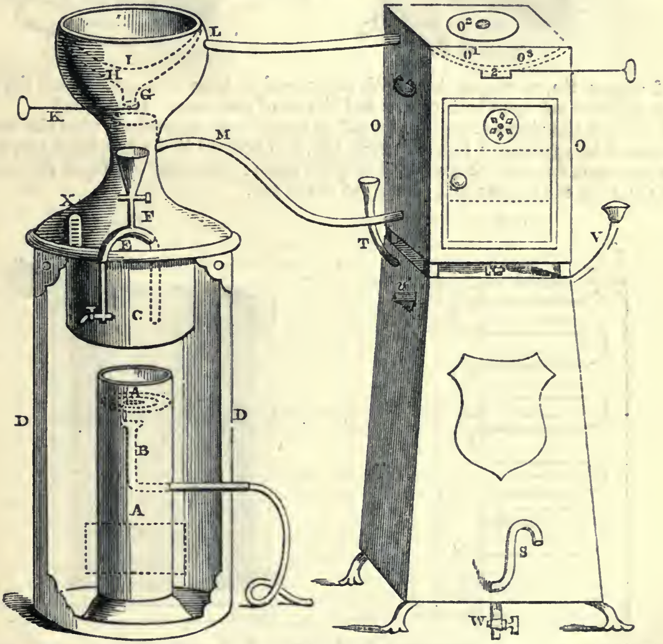
The still is either heated by an open fire, as in *fig.* 615, or, as is now very commonly the case, by steam. The still-pan (*fig.* 617) is surrounded by an outer copper jacket, and steam is admitted between them from a steam-boiler under any required pressure. In this way the temperature may be regulated with the greatest nicety.

Various adaptations for heating by steam have been appropriately arranged in a very convenient form by Mr. Coffey, of Bunhill Row, Finsbury, in his so-called Esculapian Still. It is, in fact, a veritable *multum in parvo*, being intended to afford to the pharmaceutical chemist the means of conducting the processes of ebullition, distillation, evaporation, desiccation, &c., on the small scale, by the heat of a gas-furnace. *Fig.* 618 represents this apparatus.

617



618

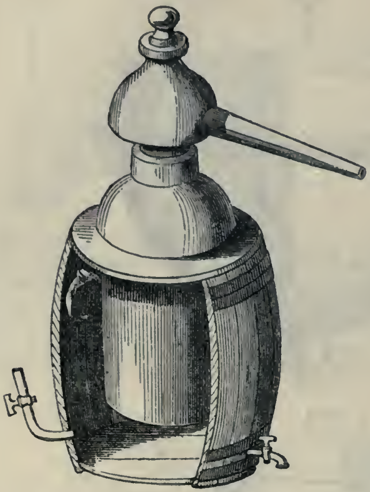


B, a burner supplied with gas by a flexible tube. C, the boiler or still. I, an evaporating pan, fixed over the boiler and forming the top of the still-head. K, a valve for shutting off the steam from I, when it passes through the tube M, otherwise it would pass through L, and communicate heat to the drying-closet O O, and from thence to the condenser T T. O is a second evaporating pan over the drying-closet. Another arrangement for distilling by steam is shown in *fig.* 619.

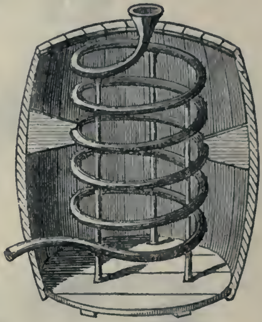
Sometimes also distillation is effected by passing hot steam through a worm contained *within* the still, instead of, or in addition to, the application of heat from without.

The worm or condenser is frequently constructed of earthenware, and set in an earthenware vessel; these are very convenient when the operation is not to be conducted on a very large scale, and only at a moderate temperature. They are now to be obtained of all manufacturers of stone-ware articles. More commonly the worm is of copper, tin, or copper lined with silver, and in some rare cases where the liquids to be distilled act upon both copper and silver, of platinum. (*Fig.* 620.)

619

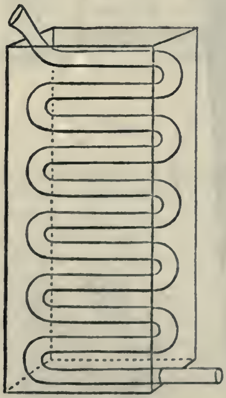


620

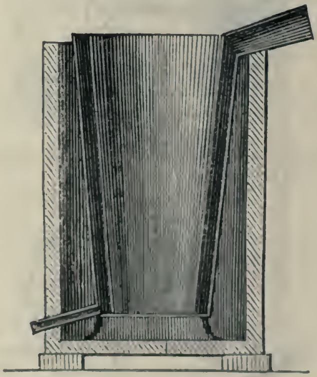


A tube of the shape shown in *fig.* 621 is found more convenient than the worm, on account of its exposing a larger surface, and also because it can be placed into a vessel of a prismatic form which occupies but little space: the water employed for condensation enters at the bottom and passes out at the top.

621



622



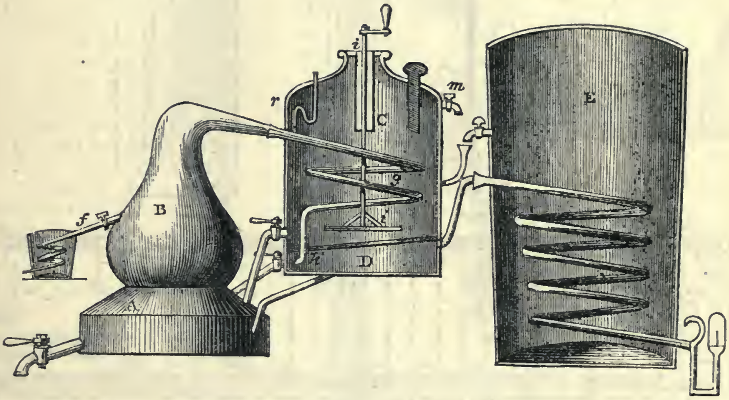
Gadda's condenser is represented in *fig.* 622. It consists of two conical vessels of metal, of unequal size, the smaller being fixed within the other, and the space between them closed at the bottom. These are placed in a tub filled with cold water, which comes in contact with the inner and outer surfaces of the cones, while the space between is occupied by the vapour to be condensed. This condenser is subject to the objection which applies to the common worm, that it cannot be easily and efficiently cleaned.

To obviate this, Professor Mitscherlich has proposed a very simple modification in its form, in which the inner cone is moveable, so that, when taken out, the intervening space between it and the outer cone can be cleaned, and then the inner cone replaced previously to commencing an operation.

Distillation of Spirits.—In the manufacture of *ardent spirits*, the alcoholic liquor obtained by fermentation of a saccharine solution is submitted to distillation; the alcohol being more volatile than the water passes over first, but invariably a considerable proportion of water is evaporated and condensed with the alcohol. To separate this water to the required extent it is necessary either to submit the product to redistillation, or to contrive an apparatus such that the product of this first distillation is returned to the still until a spirit of the required strength is obtained.

One of the earliest and simplest contrivances for effecting the latter object is the still invented by Dorn, which is employed up to the present time in Germany (*fig.* 623). A is the still, heated by the direct action of the fire; B the head, from which

623



r conveys vapour to a small refrigerator, for the purpose of testing the strength of the distillate; E is an ordinary condenser, containing worm, &c. The intermediate copper vessel answers two purposes: the upper part C forming a heater for the wash, while the lower compartment D acts as a rectifier. The heater C, when filled up to the level of the cock *m*, contains the exact measure of wash for charging the still; the contents can be constantly agitated by the rouser *i*. The still and heater being both charged, the vapour will at first be completely condensed in passing through the worm *g*, and flowing into D will close the aperture. When the contents of C become so hot that no more condensation occurs, the vapour will escape by bubbling through the liquid in D, which latter rapidly becomes heated to the boiling point, and evolves vapours richer in alcohol, which in their turn are condensed in E.

In this manner, by one operation, spirit containing about 60 per cent. of alcohol is obtained.

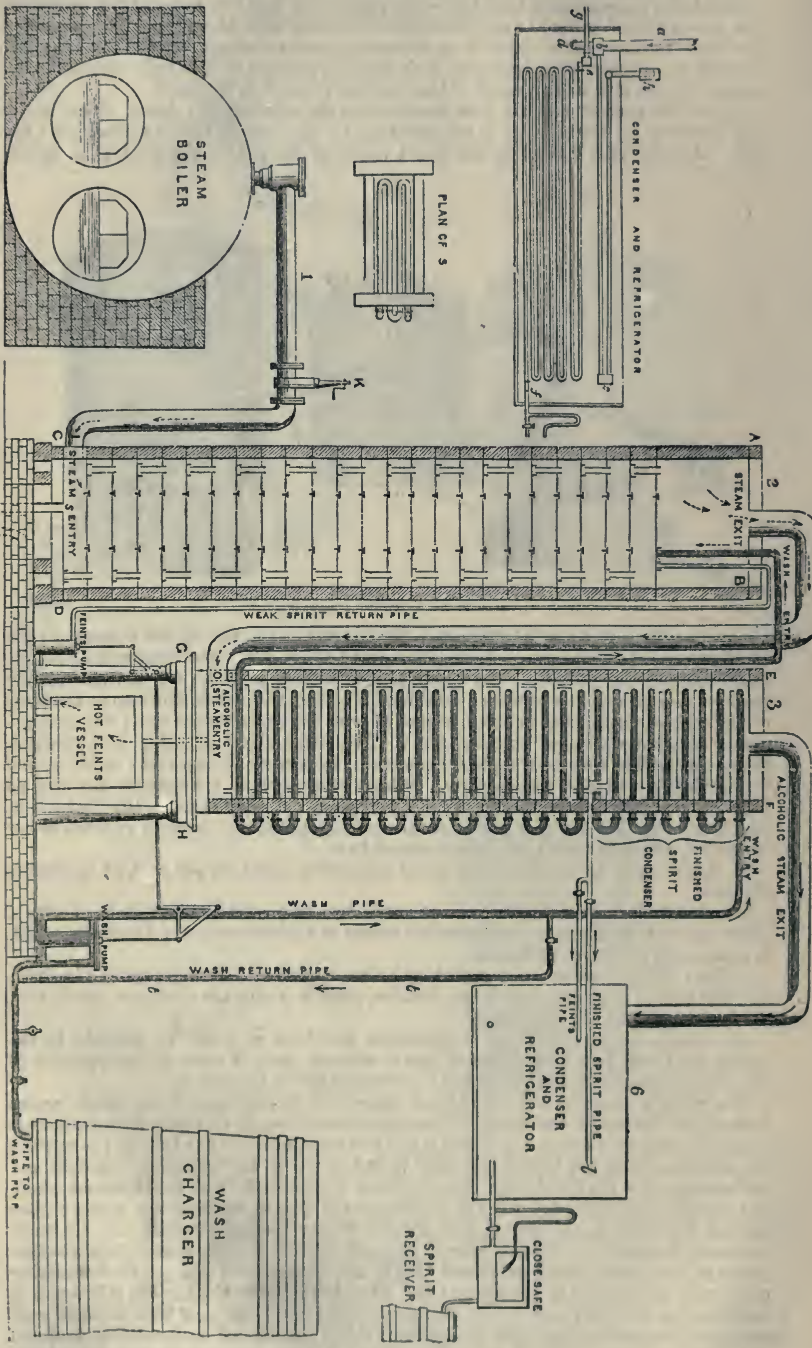
Of the recent improvements on Dorn's still two only need be described: Coffey's, which has in a great measure replaced all others in this country; and Derosne's, which is extensively employed in France.

Coffey's Still far surpasses any of those before described. It was patented in 1832, and has proved most valuable to the distiller, since it yields the strongest spirit that can be obtained on the large scale.

Its objects are twofold: 1st, to economise the heat, as much as possible, by exposing the liquid to a very extended heated surface; 2nd, to cause the evaporation of the alcohol from the wash by passing a current of steam through it.

The wash is pumped from the 'wash charger' into the worm tube, which passes from top to bottom of the rectifier. In circulating through this tube its temperature is raised to a certain extent. Arrived at the last convolution of the tube in the rectifier the wash passes by the tube M (*fig.* 624) in at the top of the 'analyser.' It falls and collects upon the top shelf until this overflows, whence it falls on to the second shelf, and so on to the bottom. All the while steam is passed up from the steam boiler through fine holes in the shelves, and through valves opening upwards. As the wash gradually descends in the analyser it becomes rapidly weaker, partly from condensation of the steam which is passed into it, and partly from loss of alcohol, either evaporated or expelled by the steam; till, when it arrives at the bottom, it has parted with the last traces of spirit. At the same time the vapour, as it rises through each shelf of the analyser, becomes continuously richer in alcohol, and contains less and less water in consequence of its condensation; it then passes from the top of the

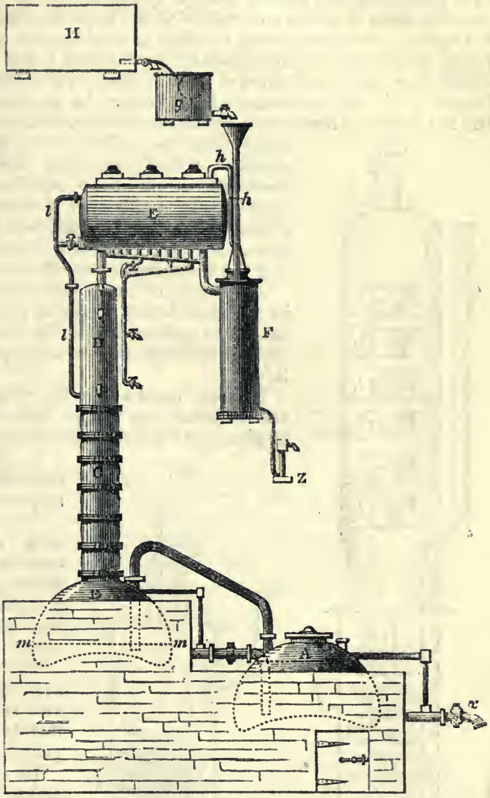
624



IMPROVED APPARATUS OF ÆNEAS COFFEY AND SONS, OF BROMLEY, NEAR BOW, FOR THE DISTILLATION OF SPIRIT.

analyser in at the bottom of the lower compartment of the rectifier. Here it ascends in a similar way, bubbling through the descending wash, until it arrives at F, above which it merely circulates round the earlier windings of the wash pipe, the low temperature of which condenses the spirit, which, collecting on the shelf at F, flows off by the tube into the finished spirit condenser.

625



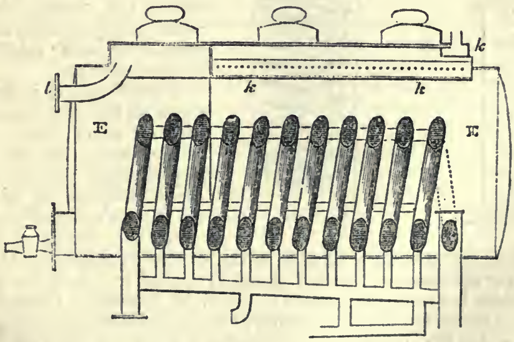
In order still further to economise heat, the water for supplying the boiler is made to pass through a long coil of pipe, immersed in boiling hot spent wash, by which means its temperature is raised before it enters the boiler. In fact, the saving of fuel by the employment of this still is so great, that only about three-fourths of the quantity is consumed that would be requisite for distilling any given quantity of alcohol in the ordinary still; and Dr. Muspratt estimates that in this way a saving will be effected throughout the kingdom of no less than 140,000 tons of coal per annum.

Very few persons have any idea of the enormous size of some of the distilleries. One of Mr. Coffey's stills at Inverkeithing works off 2,000 gallons of wash per hour, and one, more recently erected at Leith, upwards of 3,000 gallons.

Derosne's Still is very similar, in the principle of its action, to Coffey's, differing in fact only in the mechanical details by means of which the result is obtained.

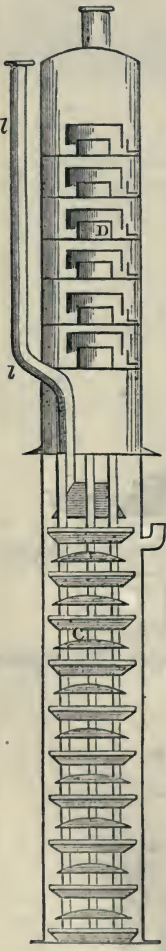
It consists of two stills, A and B, *fig.* 625. The mixture of steam and alcohol vapour from A passes into the liquid in B, which it raises to the boiling point. The vapours from B rise through the *distillatory* column C, and D (the *rectificatory* column); hence they traverse the coils of tubing in E (the *condenser* and *wine-heater*), and the alcohol

626



is finally condensed by traversing the worm in F (the *refrigerator*), whence it is delivered at Z. At the same time a steady current of the original alcoholic liquor is admitted from the reservoir H, into the exterior portion of the condenser F, by means of the tap, the flow from which is regulated by the ball-cock *g*. Whilst condensing the spirit in the worm the wash has its temperature raised, especially in the upper part, and thence it ascends by the tube *h* into the heater E, by the small orifices *k k*, *fig.* 626, where it is still further heated by the current of heated alcohol which has risen into the worm from the still, whilst at the same time assisting in the condensation of the spirit. After performing its office of condensation, and when nearly at the boiling point, the alcoholic liquor passes out by the tube *l*, and is conducted to the top of the distillatory column C. Here it trickles down over a series of lenticular discs of metal (shown in *fig.* 626), so contrived as to retard its progress into the still B, and yet permit the ascent of the steam. In this distillatory column (C, *fig.* 628) it meets the steam rising from the still B. The greater part of its alcohol is expelled, which, traversing the series of condensers before described, is ultimately liquefied and collected at Z; but, to complete the rectification, it descends into the still B, and, when above a certain level (*m m*), into A, which stills being heated by a furnace beneath, the final expulsion of alcohol is accomplished, and the spent liquor run off at *x*.

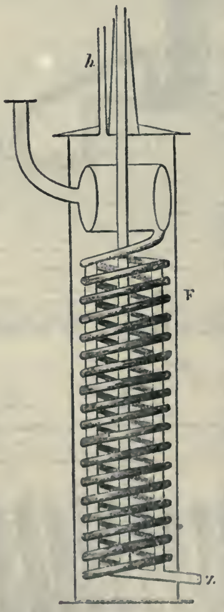
628



The details of the construction of the apparatus employed in the distillation of spirits have been here given, since this process is perhaps one of the most important of the kind; but various modifications are employed in the distillation of other liquids.

In some cases unusually effectual condensing arrangements are required, as in the manufacture of ether, chloroform, bisulphide of carbon, and bichloride of carbon.

627



In others higher temperatures are necessary, as in the distillation of sulphuric acid.

When the liquids to be distilled are acid, or otherwise corrosive, great care has to be taken especially that the worm or other condenser is of a material not acted upon by the acid. See ACETIC ACID, and SULPHURIC ACID.

The term 'distillation' is sometimes applied to cases of the volatilisation and subsequent condensation of the metals either in their preparation or purification.

In cases like mercury, potassium, and sodium, where they are condensed in the liquid state, or visibly pass through this state before volatilisation, this term is quite appropriate; but where the fusing and vaporising points nearly coincide, as in the case of arsenic, the term 'sublimation' would be more suitable.

Nevertheless, it is difficult to draw a precise line of demarcation between the two terms; for, in the cases of zinc, cadmium, &c., the metals being melted before volatilisation, and condensed likewise in the liquid state, the term is certainly correct.

For the details of construction of the distillatory apparatus we must refer to the articles on these several metals.

Distillatio per descensum is a term improperly applied to certain cases of distillation where the vapour is dense, and may be collected by descending through a tube which has an opening in the top of the distillatory vessels, and descends through the body of the vessel in which the operation of evaporation is going on, being collected below.

This is clearly merely due to the fact of the vapour being even at a high temperature more dense than atmospheric air, and might be performed with any body forming a dense vapour, such as mercury, iodine, zinc, &c.

It has, however, practically been confined to the English process of refining zinc. See ZINC.

The two most remarkable cases in which the process of destructive distillation is carried out on a manufacturing scale, are the dry distillation of wood, for the manufacture of wood charcoal, acetic acid, and pyroxilic spirit; and of coal, for the purpose of obtaining coal-gas, and coke. This process will be found fully described in the article on GAS, COAL.

Distillation of Essential Oils or Essences.—The separation of volatile flavouring oils from plants, &c., by distillation with water, will be fully treated under another head. See PERFUMERY; ESSENCES.

Fractional Distillation.—A process for the separation of volatile organic substances (such as oils) is very extensively employed in our naphtha works under this name.

If we have two volatile bodies together, but differing appreciably in their boiling points, we find, on submitting them to distillation in a retort, through the tubulature of which a thermometer is fixed, so that its bulb dips into the liquid, that the temperature remains constant (or nearly so) at the point at which the more volatile constituent of the mixture boils, and the distillate consists chiefly of this more volatile ingredient; and only after nearly the whole of it has passed over, the temperature rises to the point at which the less volatile body boils. Before this point has been reached, the receiver is changed, and the second distillate collected apart. By submitting the first product to repeated redistillation, as long as its boiling-point remains constant, the more volatile constituent of the mixture is ultimately obtained in a state of absolute purity. See NAPHTHA.

This method may in fact be adopted when the mixture contains several bodies; and by changing the receiver with each distinct rise of temperature, and repeating the process several times, a *fractional* separation of the constituents of the mixture may be effected.—H. M. W.

DISTILLATION, DESTRUCTIVE. Organic matters may be divided into two groups, founded on their capability of withstanding high temperatures without undergoing molecular changes. Bodies that distil unchanged form the one, and those which break up into new and simpler forms, the other. The manner in which heat acts upon organic substances differs not only with the nature of the matters operated upon, but also with the temperature employed. We shall study the subject under the following heads:—

1. *Apparatus for destructive distillation.*
2. *Destructive distillation of vegetable matters.*
3. *Destructive distillation of animal matters.*
4. *Destructive distillation of acids.*
5. *Destructive distillation of bases.*
6. *General remarks.*

1. *Apparatus for destructive distillation.*—Destructive distillation on a large scale is most conveniently performed in the cast-iron retorts used in gas-works. Where quantities of materials not exceeding fifteen or twenty pounds are to be operated on, for the purpose of research, a more handy apparatus can be made from one of the stout cast-iron pots sold at the iron wharves. They are semi-cylindrical, and have a broad flange round the edge. The cover should be made to fit in the manner of a saucepan-lid. The aperture by which the products of distillation are to be carried away should be of good size, and the exit pipe must not rise too high above the top of the pot before it turns down again. This is very essential in order to prevent the less volatile portion of the distillate from condensing and falling back. The exit tube should conduct the products to a receiver of considerable capacity, and of such a form as to enable the solid and fluid portions of the distillate to be easily got at for the purpose of examination. From the last vessel another tube should conduct the more volatile products to a good worm supplied with an ample stream of cold water. If it be intended to examine the gaseous substances yielded by the substances under examination, the exit pipe of the worm must be connected with another apparatus, the nature of which must depend on the class of bodies which are expected to come over. If the most volatile portions are expected to be basic, it will be proper to allow them to stream through one or more Woulfe's bottles half filled with dilute hydrochloric acid. Any very volatile hydrocarbons of the C^nH^n family which escape may be arrested by means of bromine water contained in another Woulfe's bottle. The pressure in the Woulfe's bottles must be prevented from becoming too great, or the leakage between the flange of the pot and its cover will be very considerable. The luting may consist of finely-sifted Stourbridge clay, worked up with a little horse-dung. A few heavy

weights should be placed on various parts of the lid of the pot, so as to keep it close, and render the leakage as little as possible. For the destructive distillation of small quantities of substances, I have been accustomed for a long time to employ a small still made from a glue pot, and having a copper head made to fit it. The luting for all temperatures not reaching above 700° may be a mixture of $\frac{3}{4}$ths linseed and $\frac{1}{4}$th almond meal, made into a mass of the consistency of putty. For the apparatus employed in the destructive distillation of wood, coal, bones, &c., on the large scale, the various articles in this work on the products obtained from those substances must be consulted.

2. *Destructive distillation of vegetable matters.*—The principal vegetable matters which are distilled on the large scale are wood and coal. We shall consider these separately.

Destructive distillation of wood.—The products obtained in the ordinary process of working are acetic acid, wood spirit or methylic alcohol, acetone, pyroxanthine, xylite, lignine, paraffine, creosote or phenic acid, oxyphenic acid, pittacal, several homologues of benzole, with ammonia, and methylamine. There are also several other bodies of which the true nature is imperfectly known. The greater part of the above substances are fully described in separate articles in this work. See ACETIC ACID; PARAFFINE, &c.

Peat appears to yield products almost identical with those from wood.

Destructive distillation of coal.—The number of substances yielded by the distillation of coal is astonishing. It is very remarkable that the fluid hydrocarbons produced at a low temperature are very different to those distilling when a more powerful heat is employed. The principal fluid hydrocarbons produced by the distillation and subsequent rectification of ordinary gas-tar are benzole and its homologues.—See HYDROCARBONS. But if the distillate is procured at as low a temperature as possible, or Boghead coal be employed, the naphtha is lighter, and the hydrocarbons which make its chief bulk belong to other series. See NAPHTHA.

3. *Destructive distillation of animal matters.*—Bones are the principal animal substances distilled on the large scale. The naphthas which come over are excessively fœtid, and are very troublesome to render clean enough for use. The products contained in bone-oil will be described in the article NAPHTHA. Horn and wool have been examined with reference to the basic products yielded on distilling them with potash. Horn under these circumstances yields ammonia and amylamine. Wool I find to afford ammonia, pyrrol, butylamine, and amylamine. My experiments on feathers, made some years ago, although not carried so far as those on wool, appear to indicate a very similar decomposition.

The products yielded by animal matters, when distilled *per se*, are very different to those obtained when a powerful alkali is added previous to the application of heat. If feathers or wool be distilled alone, a disgustingly-fœtid gas is evolved, containing a large quantity of sulphur. Part of the sulphur is in the state of sulphide of carbon. But if an alkali be added previous to the distillation, the sulphur is retained, and the odour evolved, although powerful, is by no means offensive. During the whole period of the distillation of ordinary organic matters containing nitrogen, pyrrol is given off, and may be recognised by the reaction afforded with a slip of deal wood dipped in hydrochloric acid. An interesting experiment, showing the formation of pyrrol from animal matters, may at any time be made with a lock of hair, or the feather of a quill. For this purpose the nitrogenous animal matter is to be placed at the bottom of a test tube, and a little filtering paper is to be placed half way up the tube, to prevent the water formed during the experiment from returning and fracturing the glass. The end of the tube is now to be cautiously heated with a spirit lamp, and, as soon as a dark yellowish smoke is copiously evolved, a slip of deal previously moistened with concentrated hydrochloric acid is to be exposed to the vapour. In a few seconds the wood will acquire a deep crimson colour. The fact of the presence of sulphur in wool, hair, or other albuminous compounds of that description, may be made very evident to an audience by the following experiment. Dissolve the animal matter in very concentrated solution of potash in a silver or platinum basin, with the aid of heat. Evaporate to dryness, and raise the heat at the end to fuse the potash and destroy most of the organic matters. When cold, dissolve in water, and filter into a flask half full of distilled water. To the clear liquid add a little of Dr. Playfair's nitroprusside of sodium; a magnificent purple tint will be immediately produced, indicative of the presence of sulphur. A very small quantity of hair or flannel will suffice to yield the reaction.

The above remarks on destructive distillation apply principally to highly complex bodies, the molecular constitution of which is either doubtful, as in the case of albuminous substances, or totally unknown, as with coals and shales. The destructive distillation of organic substances of comparatively simple constitution, such as acids and alkalis, sometimes yields products, the relation of which to the parent substance can be clearly made out. This holds more especially in the case of organic acids; the bases too often yield such complex results, that the decomposition cannot be expressed by an equation giving an account of all the products. We shall study a few cases separately.

4. *Destructive distillation of acids.*—The destructive distillation of acids takes place in a totally different manner, according as we have a base present, or the operation is carried on without any addition. Many if distilled *per se* undergo a very simple reaction, consisting in the elimination of carbonic acid, and the formation of a *pyroacid.* But if an excess of base be present, the decomposition often results in the formation of a ketone. We shall offer a few examples of these decompositions. Gallic acid, heated to about 419° Fahr., is decomposed into pyrogallic and carbonic acids, thus:

$$\underbrace{C^{14}H^6O^{10}}_{\text{Gallic acid.}} = \underbrace{C^{12}H^6O^6}_{\text{Pyrogallic acid.}} + 2CO^2$$

$$\mathbf{C^7H^6O^5 = C^6H^6O^3 + CO^2.}$$

There are cases in which the action of heat upon organic acids results in the formation of two substances, not produced simultaneously, but in two epochs or stages. In reactions like this, the first effect is the removal of two equivalents of carbonic acid, and by submitting the resulting acid to heat again, two more are separated. Under these circumstances, it is the second which is generally called the pyroacid. As an example, we will take meconic acid, which breaks up in the manner seen in the annexed equations:

$$\underbrace{C^{14}H^4O^{14}}_{\text{Meconic acid.}} = \underbrace{C^{12}H^4O^{10}}_{\text{Comenic acid.}} + 2CO^2 \qquad \underbrace{C^{12}H^4O^{10}}_{\text{Comenic acid.}} = \underbrace{C^{10}H^4O^6}_{\text{Pyromeconic acid.}} + 2CO^2$$

$$\mathbf{C^7H^4O^7 = C^6H^4O^5 + CO^2} \qquad \mathbf{C^6H^4O^5 = C^5H^4O^3 + CO^2.}$$

It will be seen that the hydrogen remains unaffected. Perhaps the name pyrocomenic acid would be preferable to pyromeconic acid, inasmuch as it is derived from comenic acid in the same manner as pyrogallic from gallic acid.

But pyroacids are not always derived from the parent acid by the mere elimination of carbonic acid; thus mucic acid, in passing into pyromucic acid, loses two equivalents of carbonic acid, and six equivalents of water, thus:

$$\underbrace{C^{12}H^{10}O^{16}}_{\text{Mucic acid.}} = \underbrace{C^{10}H^4O^6}_{\text{Pyromucic acid.}} + 2CO^2 + 6HO$$

$$\mathbf{C^6H^{10}O^8 = C^5H^4O^3 + CO^2 + 3H^2O.}$$

It does not invariably happen that the destructive distillation of acids *per se* results in the formation of a pyroacid; the disruption is sometimes more profound, the products being numerous and somewhat complex. Let us take, as an illustration, a case where all the results can be reduced to an equation. Oxalic acid, when heated in a retort without addition, yields water, oxide of carbon, carbonic and formic acids, in accordance with the annexed equation:

$$\underbrace{4(C^2O^3,HO)}_{\text{Oxalic acid.}} = 4\,CO^2 + 2\,CO^2 + 2\,HO + \underbrace{C^2HO^3,HO}_{\text{Formic acid.}}$$

$$\mathbf{2\,(C^2H^2O^4) = 2\,CO^2 + CO + H^2O + CH^2O^2.}$$

The admixture of sand, pulverised pumice-stone, or any other inert substance in a state of fine division, often remarkably assists in rendering the decomposition more easy and definite. Thus, if pure sand be mixed with oxalic acid, the quantity of formic acid is so increased, that the process is sometimes employed in the laboratory as a means of affording a pure and tolerably strong acid.

We have said that the destructive distillation of acids proceeds in a very different manner according as we operate upon the acid itself, or a salt of the acid. The distillation of the pure salt yields different products to those which are obtained when the salt or dry acid is mixed with a large excess of a dry base (such as quicklime), before the application of heat. If, in the former mode of proceeding, two atoms of the acid are decomposed, yielding a body containing for four volumes of vapour, the elements of two atoms of carbonic acid and two of water less than the parent acid, such body is called a ketone. Thus when two atoms of acetate of lime are distilled, the products are one atom of acetone and two of carbonic acid. Of course the carbonic acid combines with the lime, thus:

$$2(\underbrace{C^4H^3CaO^4}) = C^6H^6O^2 + 2(CaO,CO^2).$$

Acetate of lime. Acetone.

$$\mathbf{C^4H^6CaO^4 = C^3H^6O + CaCO^3}.$$

If, however, the salt is not of a very low atomic weight, and the quantities operated on are at all considerable, secondary products are formed, as in the dry distillation of butyrate of lime, when, if the substance is not in very small quantity, carbon is deposited, and a certain quantity of butyral, $C^8H^8O^2$ ($\mathbf{C^4H^8O}$) is formed, and probably other substances.

As an illustration of the decomposition undergone when acids are distilled with a great excess of dry base, we shall select that of benzoic acid, which under the circumstances alluded to yields benzole and carbonate of the base:

$$\underbrace{C^{14}H^6O^4} = C^{12}H^6 + 2(CO^2)$$

Benzoic acid. Benzole.

$$\mathbf{C^7H^6O^2 = C^6H^6 + CO^2}.$$

5. *Destructive distillation of bases.*—It has been found that the organic bases undergo a much simpler and more direct decomposition when subjected to destructive distillation in presence of alkalis than when they are exposed to heat without admixture. There are two bodies almost invariably found among the resulting products, namely, ammonia and pyrrol. In this respect, therefore, the organic alkalis behave like other nitrogenised animal and vegetable products. The decomposition is almost always rather complex, and it is very rare that the products are sufficiently definite to be arranged in the form of an equation. The most common substances found, are the alcohol bases, and these are almost invariably of low atomic weight. One great difficulty connected with researches on this subject, is owing to the fact of its being seldom that the products are in sufficient quantity to enable a thorough knowledge of the molecular constitution to be arrived at. Unfortunately this information is much wanted in consequence of the numerous cases of isomerism to be met with among the alcohol bases. Thus it is difficult, when working in very small quantities, to distinguish between bimethylamine and ethylamine, both of which have the formula C^4H^7N ($\mathbf{C^2H^7N}$). See FORMULÆ, CHEMICAL.

It is remarkable that there is a great similarity between the products of the destructive distillation of some of the most unlike nitrogenous substances. This is conspicuously seen in the case of bones, or rather the gelatinous tissues of bones, shale, and coal naphthas, and cinchonine. An inspection of the following table, compiled from a paper (by the writer of this article), 'On some of the Basic Constituents of Coal Naphtha,' will render this evident:—

Gelatinous Tissues.	Shale Naphtha.	Coal Naphtha.	Cinchonine.
Pyrrol.	Pyrrol.	Pyrrol.	Pyrrol.
Pyridine.	Pyridine.	Pyridine.	Pyridine.
Picoline.	Picoline.	Picoline.	Picoline.
Lutidine.	Lutidine.	Lutidine.	Lutidine.
Collidine.	Collidine.	Collidine.	Collidine.
. .	Parvoline.	. .	. .
. .	. .	Chinoline.	Chinoline.
. .	. .	Lepidine.	Lepidine.
. .	. .	Cryptidine.	. .
Aniline.	. .	Aniline.	. .

It is very possible that some of the above bases, having the same formulæ, but derived from different sources, will, in course of time, prove to be merely isomeric, and not absolutely identical. The author of this article has found that the chinoline of coal-tar is certainly not identical with that from cinchonine. The base from the latter source yields a magnificent and fast blue dye upon silk, when treated by a process which gives no reaction if the coal-base be substituted. It is unfortunate that the reaction is with the latter instead of the former, as it would have added one more to the list of gorgeous dyeing materials yielded by coal-tar.

6. *General Remarks.*—The tendency of numerous researches, made during the last few years, has been to show that there is no organic substance, capable of resisting high temperatures, which may not be found to exist among products of destructive distillation. By varying the nature of the substance to be distilled, and also the circumstances under which the operation is conducted, we can obtain an almost infinite variety of products. Acids, bases, and neutral substances, solid, liquid, and fluid hydrocarbons, organic positive, negative, and derived radicals, organo-metallic bodies

—all may be produced by the action of high temperatures on more or less complicated bodies. Much has already been done, but the facts at present accumulated relate merely to the superficial and more salient substances. On penetrating further below the surface far more valuable and interesting facts will came to light.—C.G.W.

DISTILLED WATER. Water converted into vapour by heat, and subsequently condensed. See WATER.

DITTANY. The root of the *Dictamnus Fraxinella*, a plant belonging to the Rue order, or *Rutaceæ*, formerly much used in medicine.

DISSOCIATION. The resolution of certain compounds at a high temperature into their constituents; the elements of which they are composed being capable of existing together under these conditions, without entering into combination. Thus, carbonic oxide is dissociated at a high temperature, oxygen being set free and combining with unaltered carbonic oxide to form carbonic acid gas, whilst free carbon is deposited. According to Mr. I. Lowthian Bell, this decomposition is of much importance in the reactions which accompany iron smelting in the blast-furnace. As dissociation is a purely physical phenomenon, hardly within the limits of this Dictionary, we may refer the reader to 'Leçons sur la Dissociation' (1864), by M. Henri Sainte-Claire Deville, who has made this subject peculiarly his own.

DIVI-DIVI, or *Libi-Davi*, is the pod of a leguminous shrub, the *Cæsalpinia coriaria*, which is indigenous to Jamaica, and some parts of South America. Mr. Rootsey obtained a mean produce of 6·625 grs. of leather from 60 grs. of divi-divi, while the same quantity of the best Aleppo galls yielded only a mean produce of 4·625. It appears, too, from Sir Humphry Davy's estimate, that 60 grs. of divi-divi contain 3·0475 grs. or 5·079 per cent. of tannin, and 60 grs. of galls, 2·12704 grs., or 3·450 per cent. Sixty grs. of oak bark yielded only 1·75 grain of leather; whence it follows that it contains but 0·805 of a grain of tannin to the drachm, or not more than 1·34166.

It has been tried as a dye instead of galls or sumach, but its use for this purpose is almost entirely abandoned. See LEATHER.

DIVING BELL. As it is frequently desirable to raise objects from the bottom of the sea or rivers, and to lay the foundation of piers and similar structures, some contrivance was desired to enable man to descend below the water, and to sustain himself while there. The first method adopted was the very simple one of letting down a heavily-weighted bell vertically into the water. As the bell descended, the air got overpressed, and the water rose in the bell, but never to the top, and within that space the man was sustained for some time. The air, however, was vitiated by the process of respiration, and the man had to be drawn up. It is curious to find that as early as 1693 a very complete system of diving without a bell was devised, as the following quotation will show:—

A. D. 1693. 'William and Mary, by the Grace, &c. &c. Whereas John Stapleton, gentleman, hath by his great study and expence invented a new and extraordinary engine of copper, iron or other mettal, with glasses for light joints, and so contrived as to permit a person enclosed to move and walk freely with under water, and yet so closely covered over with leather as sufficiently to defend him from all the jumpes of it. Also invented a way to force air into any depth of water, whereby the person in the aforesaid engine may be supplied with a continual current of fresh aire, which not only serve him for respiracon, *but may alsoe be useful for continuing a lamp burning, which he may carry about with him in his hand.* . . . Likewise a way to make the same again serviceable for respiracon, and by continually repeating the operacon, a man may remain a long time under water, in either of the said engines, without any other air than the sayd engines do contayne, whereby he shall be preserved from suffocation if any extraordinary accident should interrupt the current of fresh air afore menconed.'—*Letters Patent. Rolls Chapel. Edited by Bennet Woodcroft.*

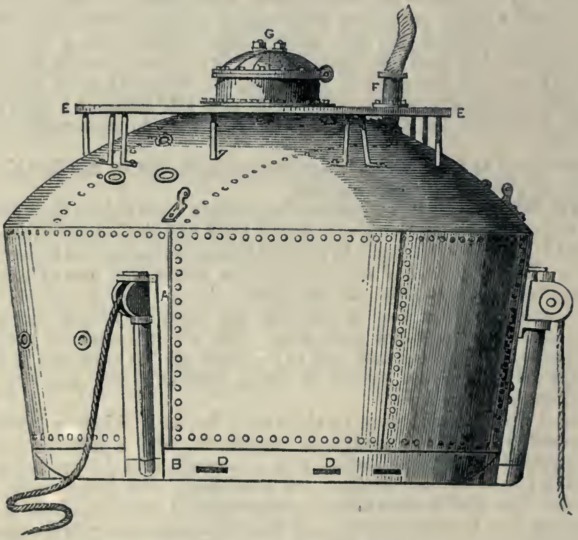
The defects were many in this apparatus, and Dr. Halley invented a bell the object of which was to remedy them.

Dr. Halley's bell was of wood coated with lead, and having strong glass windows above, to allow the passage of light to the diver. In order to supply air, a barrel was taken with an open hole in the bottom, and a weighted hose hanging by, and fitting into a hole at the top. From this barrel the air of the bell was supplied as frequently as it became vitiated, the barrels of air being sent down from above. Spalding improved upon Halley's bell, and again Friewald made some improvements on Spalding's, but in principle these bells were all alike. The modern bells are usually large and strong iron bells, with windows in the upper part. By means of an air-pump, placed on the surface, air is sent down to the divers in the bell, and the vitiated air is as regularly removed from the bell by other tubes through which it escapes. These diving bells are lowered by means of cranes, and are moved about in the water by those above, signals being given by the men below. The difficulty of moving this machine, renders it still inconvenient, and attempts were made to obviate this, by the construction of a diving bell upon principles entirely different. This new diving bell, to which the name of THE NAUTILUS was applied, proved useful in the construction of some parts of the Victoria Docks, and some works on the Seine. Although it is not now much used, a description of it is appended.

The nautilus machine is entirely independent of suspension; its movements are entirely dependent on the will of those within it, and without reference to those who may be stationed without; it possesses the power of lifting large weights *per se*, and at the same time is perfectly safe, by common care in its operations. This latter is the greatest desideratum of all. These advantages must strike all as combining those requisites of success which have been always wanting in the present known means for constructing works under water.

The form of the machine is not arbitrary, but depends entirely on the nature of the work to be performed, adapting itself to the various circumstances attending any given position. By reference to the annexed figures it will be perceived that when at rest, being entirely enclosed, its displacement of water being greater than its own weight, it must float to the surface (see *fig.* 629). Entering through a man-hole at the top (which is closed either from the inside or outside), you descend into the interior of the machine, portions of which are walled off on either side, forming chambers; these chambers are connected at or near the bottom of a pipe *a a* (*fig.* 630), which opens by a cock *b*, outwards to the external surrounding water. An opening in the bottom of the machine of variable dimensions is closed by a door or doors susceptible of being opened or closed at pleasure. The chambers W W, are likewise connected at top by a smaller pipe *c c*, which opens through the top of the machine, and to which opening is affixed a flexible pipe, with coils of wire spirally enclosed. Branches on this latter pipe T, allow also communication with the larger or working chamber.

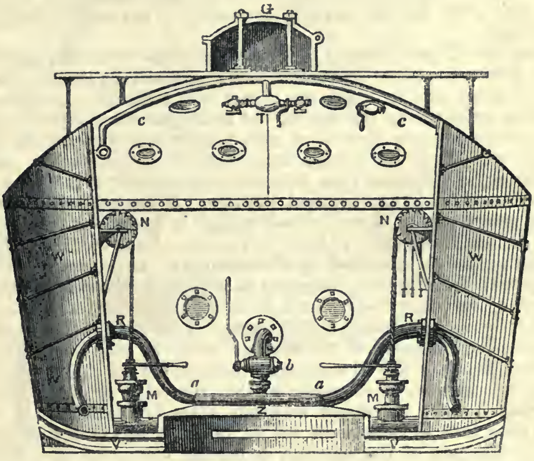
629



At the surface of the water placed on a float or vessel for the purpose, is a receiver of variable dimensions, to which is attached at one end a hollow drum or reel, to the barrel of which is affixed the other end of the flexible pipe *a*, leading to the top of the nautilus. At the other end of, and in connection with the receiver, is a powerful air-condensing pump. This combination represents the nautilus as adapted to engineering work.

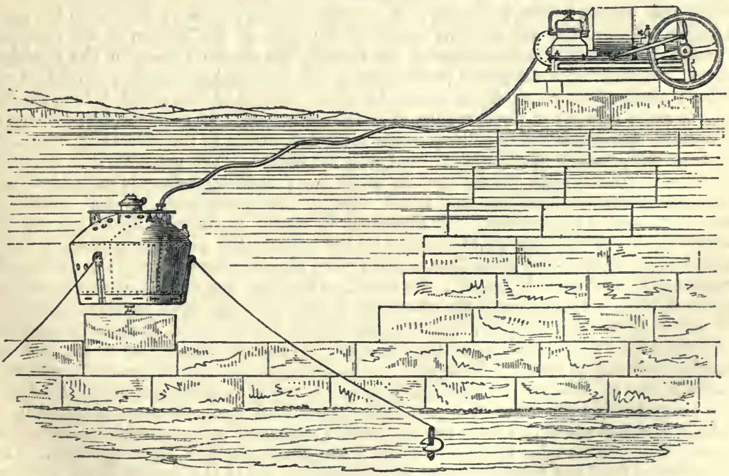
As to the *modus operandi*:—The operator with his assistants enters the machine through the top, which is then closed. To descend, the water-cock *b* is opened, and the external water flows into the chambers W W; at the same time a cock, on a pipe opening from the chambers outwards, is opened, in order that, the air escaping, an uninterrupted flow of water may take place into the chambers. The weight of water entering the chambers causes a destruction of the buoyancy of the machine, and the nautilus gradually sinks. As soon as it is fairly under water, in order that the descent may be quiet and without shock, the water-cock *b*, is closed. The receiver at the surface being previously charged by the air-pump to a density somewhat greater than that of the water at the depth proposed to attain, one of the branch-cocks on the pipe *c c*, connecting the chambers at top, is opened, and the air rushes into the working chamber, gradually condensing until a density equal to the density of the water without is attained; this is indicated by proper air and water gauges. These gauges marking equal points, showing the equilibrium of forces without and within, the cover to the bottom *z* is removed or raised, and communication is made with the under water surface, on which the nautilus is resting. In order to move about in localities where tides or currents do not affect operations, it is only necessary for the workman to step out of the bottom of the nautilus, and placing the hands against its sides, the operator may move it (by pushing) in any direction.

630



Where currents or tides, however, have sway, it becomes necessary to depend upon fixed points from which movements may be made in any direction. This is accomplished by placing, in the bottom of the nautilus, stuffing boxes of peculiar construction (M M, *fig.* 630), through which cables may pass over pulleys to the external sides,

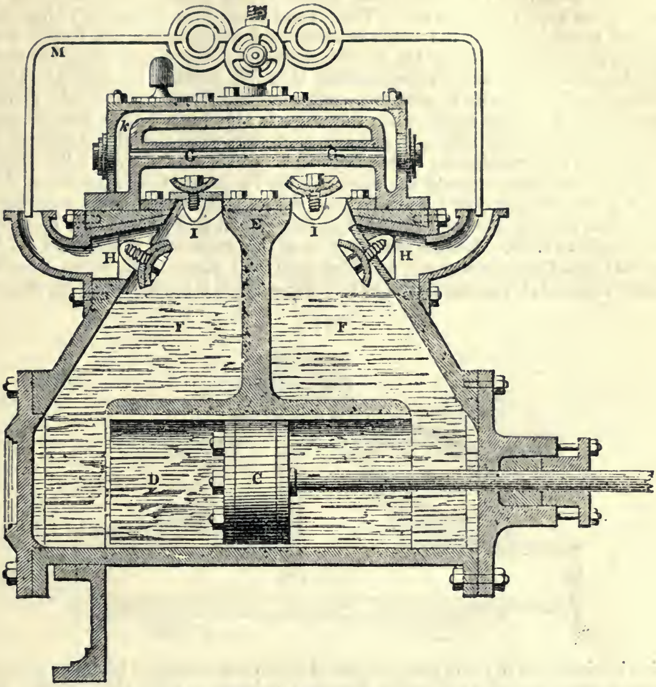
631



thence up through tubes (to prevent their being worn), to and over oscillating or swinging pulleys, placed in the plane of the centre of gravity of the nautilus, and thence to the points of affixment respectively (*fig.* 631). The object to be gained by having the swinging pulleys in the plane of the centre of gravity of the mass, is to hold the machine steady and to prevent oscillation. Within the machine, and directly over the above stuffing boxes, are windlasses for winding in the cables. By working these windlasses movement may be effected, and of course the number of these cables will depend on the variable character of the situation to be occupied. Having thus secured the means of descending, communicating with the bottom, and of movement, the next point is to ascend. Weight of water has caused a destruction of buoyancy at first, and consequent sinking; if then any portion of this water is removed, an upward effort will at once be exerted exactly proportionate to the weight of water thrown off. The air in the receiver at the surface being constantly maintained at a higher density than that of the water below, if we open the water cock on the top pipe, *c c*, throwing the condensed air from the receiver above directly on to the surface of the water in the chambers, movement and consequent expulsion of the water must take place, and an upward movement of the machine itself, which will rise to the surface.

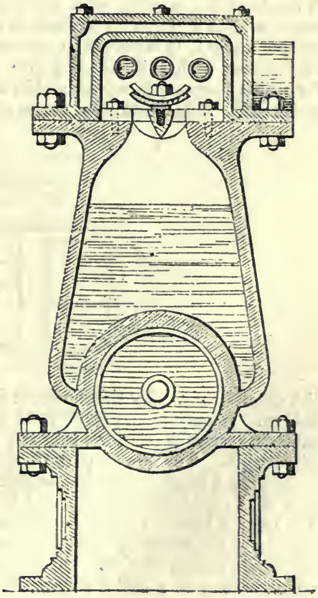
It is evident that if, previously to the expulsion of the water, the nautilus be affixed to any object below, the power exerted on that object will be exactly proportionate to the weight of water expelled, and the power will continue increasing until, there being no farther weight to be thrown off, the maximum effect is produced. To apply this power to lifting masses of stone or rock, proper arrangements are affixed to the centre of the opening in the bottom, by which connection can be made with the weight, admitting, at the same time, the swinging around of the object suspended, so that it may be placed in any required position. In the construction of permanent work, or the movement of objects whose weight is known, or can be estimated, a water, or, so called, lifting tube is placed on the side of the water chamber, which indicates the lifting power exercised by the nautilus at any moment. The advantage of this gauge will be recognised, inasmuch as without it the closest attention of the operator, working very cautiously, would be necessary to determine when the weight was overcome: by its aid, however, the operator boldly throws open all the valves necessary to develop the power of the nautilus, watching only the gauge. The water, having reached the proper level indicating the required lifting power, he knows the weight must be overcome, or so nearly so that the valve or cocks may be at once closed, in order that the movement may take place horizontally. A moment's reflection will show that, if there were not an index of this character, carelessness or inattention on the part of the operator, by leaving the cocks open too long, might develope a power greater than required, and the nautilus would start suddenly upward. The expansive power of air, acting upon the incompressible fluid, water, through the opening in the bottom, gives a momentum which, by successive developments of expansion in the working chamber, is constantly increasing in velocity, until, in any considerable depth of water, the result would be undoubtedly of a very serious character. Take, for exemplification, the nautilus in thirty-three feet of water, and bottom covers removed, and an equilibrium, at fifteen pounds to the inch, existing between the air and the water at the level of the bottom of the machine. Upward movement is communicated the instant the machine rises in the slightest degree, the existing equilibrium is destroyed, and the highly elastic qualities of air assume preponderance, exerting, from the rigid surface of the water below, an impulsive effort upward in the direction of least resistance. At each successive moment of upward movement the impelling power increases, owing to the increasing disparity between the pressure of air within struggling for escape. The machine, thus situated, becomes a marine rocket (in reality), in which the propelling power is exhausted only when the surface is reached, and a new equilibrium is obtained. It will readily be seen that, were this difficulty not overcome, it would be impossible to govern the nautilus; for, rising with great velocity to the surface, the machine is carried above its ordinary flotation, or water line, a little more air escaping owing to the diminished resistance as that level is passed; the recoil, or surging downwards, causes a condensation of the air remaining in the chamber; a portion of the space previously occupied by air is assumed by water; the buoyant power becomes less, the machine settles slightly more by condensation of the air, a larger space is occupied by water, and the nautilus redescends to the bottom with a constantly accelerating movement, seriously inconveniencing the operator by filling more or less with water, according to depth. For many months the difficulties just enumerated baffled all attempts at control. A weight attached could be lifted, but the instant it was entirely suspended,—before the valves could be closed,—upward movement was communicated beyond control. This difficulty so fatal has been overcome by an arrangement at the bottom of the nautilus, with channels which radiate from the opening in an inclined direction, debouching at the sides of the machine. The moment then that the air, by its expansion from diminished resistance, or by the introduction from above of a greater volume than can be sustained by the water below, reaches, in its downward passage, the level of these chambers, following the direction of least resistance, it passes through these channels and escapes into the surrounding water, without of course affecting the movement of the machine in the least.

632



The pump for supplying air to the diving bell or other suitable vessel is represented in *figs.* 632 and 633, and is constructed as follows:—D is a cylinder, opening at the upper part into a chamber or chambers F F, separated by a partition E. On the side of each of these chambers there is a valve H H, opening inwards, and at the upper part of the same are two valves I I, opening outwards into the valve chamber G. Outside the opening for each of the valves H, H, there is a cup, into which the end of the water supply pipe M passes; by this means a small stream of water is supplied to the cup, and is drawn from it into the chamber F to supply the waste in the operation of pumping. The valve chamber G is covered with a jacket *k*, having a space between it and the valve chamber that is filled with water from the water-pipe M, which affords a stream of cold water to carry off the heat from the condensed air which is forced into the chamber. The water thus supplied circulates through the tubes in the chamber and round them in the jacket, and thus cools the air in these tubes; it is then conveyed so as to be

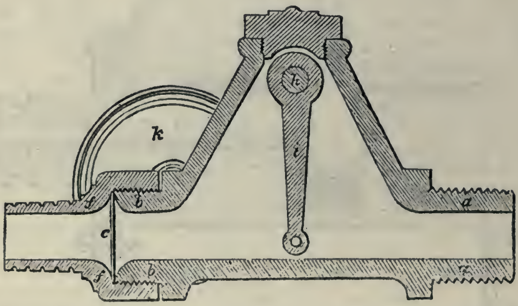
633



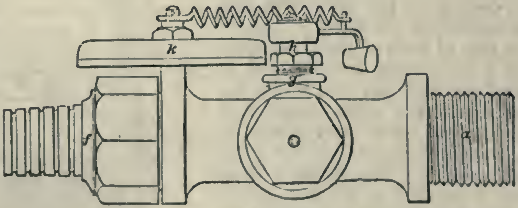
usefully employed in a steam-boiler, or is allowed to run off. The air and a small quantity of water is forced up from the cylinder D, by the stroke of the piston C, into the chamber F, which is thereby filled with water, and thus the air is expelled therefrom, a small quantity of the water passing with it and covering the valves, by which means they are kept tight and wet. The air and water thus discharged, after passing around the small tubes in the valve chamber and being cooled, are forced outward and conveyed to the condenser. On the return stroke of the piston, the other chamber F is filled, and air and water expelled from it in like manner through its valve into the valve chamber. There is always a sufficient quantity of water in the cylinder D and chamber F to fill the latter when the water is all expelled from the cylinder, by the piston C having been driven to one end of it, and when the piston returns to the opposite end of the cylinder the water flows in behind it, and draws in its equivalent in bulk of air and water through the valve H. On its return, this is forced out through the valve *k* into the chamber I, as mentioned above. The water being non-elastic, if the parts are kept cool enough to avoid raising steam, this process may be continued for any length of time. A transverse section of this apparatus is shown in *fig.* 633.

Figs. 634 and 635 represent the speaking tube and alarm bell above referred to. The construction of this mechanism is as follows:—There is a hollow casting, one portion of which is triangular in form, from one end of which a short tube *a* projects. This tube *a* has a screw cut on it, and a projecting flange at its junction with the triangle. This is screwed into the top of the diving vessel or armour from the inside, and projects through it to allow the coupling of a flexible or other hose to be attached to it. At the opposite angle, and in a line with *a*, there is a tubular projection *b*, provided with a screw to receive a cap *f*, to which is to be attached a piece of hose. Within the tube *f*, and at its junction with *b*, is placed a thin diaphragm of metal or other suitable material *c*, for which purpose, however, a thin silver plate that just fits the bore of the cap *f* is preferred. This diaphragm closes all communication between the diving vessel and the external air. By this means it is easy to converse through any required length of tubing. It may be desirable to fit a stop-cock into the tubular projection *b*, as a precautionary means of preventing the escape of air in the event of a rupture of the diaphragm. The upper part of the triangular enlargement of the speaking tube is tapped for a stuffing box at *g*, within which there is an axis *h*, which runs from side to side of the said enlargement, and through the stuffing box at one side. On this axis *h* is fixed a lever *i* within the said enlargement, which lever communicates with the surface of the water by means of a wire fixed at its reversed end, and running through the whole length of pipe. On the outer extremity of the axis *h* is affixed a hammer, which strikes on a bell *k* connected to the tube, as shown in the drawing. By this

634

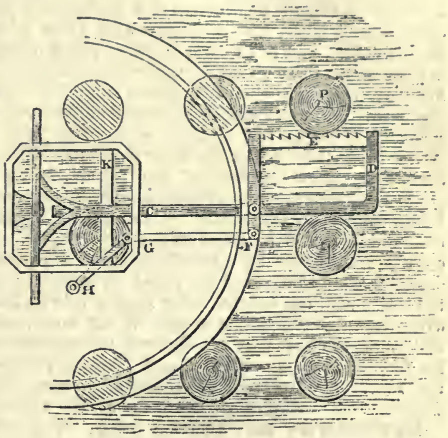


635



means the attention of the operator below may be drawn to the speaking tube when it is required to converse with him from the surface of the water, and the men whose duty it is to attend to the operator below can, by placing their ear at the end of the tube, hear the bell struck below as a signal for communication with them at the surface.

636

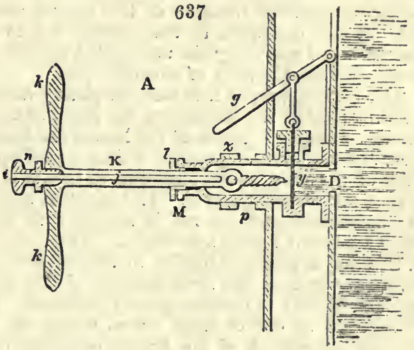


The only parts of the apparatus not yet described are the saw for cutting the tops of piles to an uniform level, the pump which enables the divers themselves to rise to the surface in the event of the flexible hose being detached or injured, and the contrivance for screwing an eye bolt into the side of the sunken vessels.

The arrangement of the saw-frame and connections are shown in *fig.* 636. Only as much of the bottom of the Nautilus is shown as will render the position of the saw understood. P is a pile which is required to be cut down to the same level as the others, E is the blade of the saw, D the framing by which it is stretched, C, D, the handle which rests on the cross bar K, to which is attached the upright part of the handle which is laid hold of by the workman inside when working the saw. H, G, F, a bent lever with two friction rollers at F, which guides the saw forwards while making the cut.

The pump for ascending in case of accident to the air hose is not shown in the drawing. It is a simple force pump placed in the working chamber, by which the ballast water in W W, *fig.* 630, can be pumped out so as to lighten the apparatus sufficiently to allow of its ascent.

637



The apparatus for fixing the eye bolts is shown in *fig.* 637. The operation of this apparatus is as follows:—It will be observed the chamber D opens outwards to the water, so that when the sliding partition or valve *y* is forced down by the lever *g*, the communication of the water with the chamber is cut off. The lid *z* being removed, a bolt *i* (or other operating tool or instrument) is placed within the chamber C; the rod K is forced through the stuffing box *l* until the recessed end of the rod contains the end of the bolt; the small rod *j* is then screwed through the stuffing box *n*, until the screw on the end of this rod has become affixed to the end of the bolt contained within the recess at *p*. The lid *z* of the chest is then fastened on, and the partition or valve *y* raised, the stuffing box M preventing the escape of air. Communication is thus opened between the chambers A and D, the latter being open outwards. The rod *i* is now pushed outwards by pressing on the handle *k* through the stuffing box *l*, until the vessel or object to be operated upon is reached, when the operation is performed as required. It will be observed that the stuffing box prevents the escape of air out of the bell or the admission of water into it, the stuffing box *n* having the same tendency. After the operation with the tool or instrument is complete, the rod *k* is disconnected by unscrewing the rod *j*, and is drawn into the chamber A by means of the handle *k*; the partition or valve *y* is again lowered, and the operations above described are repeated. It will hence be obvious that a number of eye bolts might in this manner be successfully inserted in the side of a sunken vessel from the diving bell, so that by hooking on the 'camels' the strain would be so distributed as to prevent injury by the process of lifting the said vessel.

DIVING DRESS, or **HELMET.** The diving helmet is, in principle, similar to the bell. In one case the head is enclosed in an air-tight metal covering, to which air is artificially supplied; in the other, the whole body is in a vessel fitted with pipes for the supply of fresh, and the removal of deteriorated, air.

The diving helmet is made of thin sheet-copper, which covers the head of the diver, large enough to admit of free motion, and pierced with three holes, which are covered with glass, and protected with brass wire. The diver wears a waterproof canvas jacket, and to this the helmet, which comes down over the breast and back, is fastened so tightly that no water can penetrate. Two weights, each about 40lbs., are suspended to a belt which passes round the diver, one in front, and the other at the back. This belt can be instantly unfastened in case of accident. Fresh air is supplied by means of a flexible waterproof pipe, which is attached to an air-pump in the barge from which the diver descends. This pipe passes under the diver's left arm, and enters the back of the helmet, being so contrived that the fresh air is made to impinge on the glasses, and thus prevents them in a great measure from being dimmed by the breath. From the back part of the helmet there is also led an eduction pipe, which carries off the breathed air. The attendants on the surface are communicated with by a signal line, which passes under the right arm. The diver descends from the side of the vessel by a rope or else by a wooden ladder, loaded at the lower end, the weight being kept at a little height above the ground. When the diver has descended, the weight is set down, and the rope slackened, so that the motion of the boat may not obstruct his movements. Heavy weights are attached to his feet to keep him steady; and he carries a line in his hand to guide him back to the rope. A waterproof dress entirely covers him, and thus he may remain under water five or six hours, perfectly dry all the while.

DIVINING; DIVINING ROD. The German miners who were brought over to this country at the instance of Queen Elizabeth, who was especially desirous of seeing the mineral treasures of this country developed, first introduced the divining rod. It has continued to the present day to be occasionally used in the mining districts—not merely by the uneducated miners, but by men of education and intelligence—for the discovery of mineral lodes.

The divining, or, as it is more frequently called in Cornwall, the 'dowsing' rod, is a forked twig of the blackthorn, the hazel, or the willow, of one year's growth. It is placed on the open palms of the hands, the fingers are closed upon each limb of the fork, and the point of junction is then turned up towards the operator, and then, by a twist of the arms, placed outwards, so that it is held with the muscles of the arm in a most constrained position. The operator, called 'a dowser,' walks over the ground to be examined, and the rod is supposed to turn downwards with irresistible force when a mineral lode is approached. There can be no question but the phenomenon in this case is precisely similar to that of table-turning. Fixedness of will operates involuntarily upon the rigid muscles of the arm, a movement is felt, and the slight impulse yielded to becomes greatly increased. Every fairly made experiment proves divining to be one of those errors which are born of ignorance, and perpetuated through the neglect of the proper education of the mind. Two or three well-established positions may serve to remove this superstition from those minds which can be brought to reflect on natural phenomena.

The divining rod is supposed to bend by virtue of some attractive power between the woody twig and the mineral lode.

1. Place the most approved divining rod over a mineral lode, so delicately poised that a breath will turn it. The metalliferous matter will exert no influence upon it.

2. Place the divining rod upon the open palms of the hands of the most approved 'dowser.' It will never move, however great may be the mass of metal.

Thus we have proofs that neither the metals, the twig, nor the man have any influence.

3. Close the hands tightly, keeping the arms still in an easy position. No change in the position of the rod will take place in passing over any number of mineral lodes.

4. Twist the arms in the way described, and then, and then only in the hands of a believer, will the rod bend; and it is a chance if it bends at the right time.

The divining rod is said to bend equally to water, hence it is used in some places to find that fluid; to blood, therefore it was used to track murderers; and to metals.

It is to be regretted that the human mind should cling, with so much obstinacy, to the errors of those days when everything was seen through the mists of superstition.

DOCIMACY. (*Docimasie*, Fr.) From the Greek Δοκιμάζω, I prove. See Assaying.

DOEGLING TRAIN OIL. The oil of the *Balæna rostrata*, or Bottle-nose whale,

DOG-TOOTH SPAR. Calcite, or carbonate of lime, crystallised in scalenohedra. Such crystals are common in the Mountain-limestone of Derbyshire.

DOG-WOOD. *Cornus sanguinea*, a small underwood known as the wild cornel, and as the common Dogwood. Little splinters of this wood are used by the watchmaker for cleaning out the pivot-holes of watches, and by the optician for cleaning deeply-seated small lenses. Its peculiarity is that it is remarkably free from silex. Toothpicks are also manufactured from dogwood.

DOG-WOOD BARK. The bark of the *Cornus florida*, a plant much used in the United States as a substitute for Peruvian bark in cases of fever.

DOLERITE. A variety of 'greenstone,' composed of augite and felspar. The difficulty of discriminating these minerals gives the name, from Δολερός, deceptive.

DOLLY; DOLLY-TUB. *A mining term* applied to a tub fitted with a perforated board, *the dolly*, to which a circular motion is given by a winch-handle, and thus imparts a similar motion to the ore. See Dressing of Ores.

DOLOMITE. (*Dolomie*, Fr.; *Dolomit* and *Bitterspath*, Ger.) A name applied to *Magnesian Limestone*, in honour of a distinguished French geologist and mineralogist of the last century, M. Deodatus Guy Silvanus Tancred de Gratet de Dolomieu. This mineral is essentially a double carbonate of lime and magnesia, containing, in the normal varieties: carbonate of lime, 54·35; carbonate of magnesia, 45·65; a percentage composition corresponding to the formula $CaO.CO^2 + MgO.CO^2$ (**$CaMg2CO^3$**). The relative proportion of the two carbonates is, however, subject to considerable variation, the species passing on the one hand into carbonate of lime, and on the other into carbonate of magnesia.

In its general characters, dolomite strongly resembles calcite or pure carbonate of lime, from which, however, it may be easily distinguished by its greater hardness and density, and by effervescing less briskly with acids. At the same time its crystalline forms are neither so varied nor so complex as those of calcite. It is notable that the crystals have a remarkable tendency to present curved faces, and from the nacreous lustre which they often possess, are commonly termed *pearl spar*. The presence of protoxide of iron replacing the isomorphous oxides, lime and magnesia, often causes the mineral to assume a brown colour after exposure to the atmosphere, whence such varieties are distinguished as *brown spar*. In this country, crystallised dolomite is common in the lead-mines of Derbyshire, Alston Moor, Leadhills, and the Isle of Man: the finest crystals, however, occur at Traversella, in Piedmont.

The massive and finely-granular forms of dolomite are very widely distributed, forming in certain districts rock-masses of considerable extent, and occasionally rising into mountains of characteristic boldness, well seen in the Dolomites of the Tyrol. In England, large deposits of magnesian limestone occur in the upper beds of the Permian system, or that group of rocks which immediately overlies the coal-measures, and of which the upper beds are commonly known as *Zechstein*, a name borrowed from their German equivalents. The principal deposits occur in the north-east of England, extending from the mouth of the Tyne in a south-westerly direction through Durham and Yorkshire, into the counties of Derby and Nottingham. In these beds the dolomite frequently assumes singular concretionary forms; whilst at Marsden, a few miles south of the Tyne, it presents a schistose structure, separating into thin layers of remarkable flexibility. A dolomitic limestone is also found in the so-called *Dolomitic Conglomerate* of Bristol, a rock which occurs locally at the base of the Trias, or New Red Sandstone, and contains fragments and pebbles of older rocks cemented together by a limestone more or less dolomitic. In addition to the recognised forms of dolomite, many limestone rocks, of various ages, are found, on chemical examination, to contain magnesia, and in some cases to pass into true dolomites. Dr. Sterry Hunt has shown, moreover, that the veins in certain marbles are dolomitic, whilst the base may be only an ordinary limestone; and also that the substance of some fossil shells is a dolomite, although the matrix is nothing more than limestone: this is notably the case with some of the fossils of the Trenton Limestone (Lower Silurian) of Ottawa, in Canada.

The origin of dolomite has long been a standing enigma to the geologist; but as the question is one of only theoretical interest, its discussion would be out of place in this article.

As building stones, the dolomites have been highly valued, those varieties being regarded as most durable which present a crystalline structure, and in which the carbonates of lime and magnesia exist in nearly atomic proportions. The quarries in the neighbourhood of Bolsover Moor, in Derbyshire, supplied the magnesian limestone employed in the construction of the new Houses of Parliament.

The dolomites of Durham are employed in the chemical works on the Tyne for the manufacture of sulphate of magnesia, or Epsom salts, although at present to a less extent than formerly.

Dolomite was employed first by the late Mr. Hugh Lee Pattison, for the manufacture of carbonate of magnesia, and it is still used for that purpose.

When dolomite is calcined, within certain limits of temperature, it is said to furnish an excellent hydraulic lime. M. H. Sainte-Claire Deville has called attention to the powerful hydraulic properties of caustic magnesia by its union with water to form a definite hydrate. It appears that if dolomite be calcined below a red heat, the carbonate of magnesia suffers decomposition, whilst the carbonate of lime remains almost intact; on slaking this calcined dolomite, the magnesia combines with water, and this hydrate cements the unaltered particles of carbonate of lime.—F.W.R.

DOMEYKITE. An arsenide of copper, occurring in Chili, in Bolivia, and at Lake Superior. Mr. D. Forbes found the domeykite of the Corocoro sandstone, in Bolivia, to contain copper 71·13; arsenic 28·41; silver 0·46. This has probably been formed *in situ* by the action of arsenical vapours on metallic copper disseminated through the sandstone. Faraday's *Condurrite* from Cornwall is closely allied to—if not identical with—domeykite.

DONARIUM. Bergmann supposed that he had detected, in a Norwegian mineral, a new metal, to which he gave the name of Donarium, from the Scandinavian god Donar. This metal is now proved to be identical with thorinum.

DONKEY ENGINE. A very small engine employed to pump water into boilers. If the use of the donkey engine were more usual than it is, we should hear less of steam-boiler explosions.

DONSHA. *Æschynomone Cannabina.* See Fibres.

DOOPARA RESIN. A resin obtained in considerable quantities in the East Indies from the *Vateria Indica*, which is used as a fragrant incense in the temples, makes an excellent varnish, and is sometimes called *East Indian Copal*, or *Gum Piney.*—*Simmonds.*

DORNOCK is a species of figured linen of stout fabric, which derives its name from a town in Scotland, where it was first manufactured for table-cloths. It is the most simple in pattern of all the varieties of the diaper or damask style, and therefore the goods are usually of coarse quality for common household wear. It receives the figure by reversing the flushing of the warp and woof at certain intervals, so as to form squares, or oblong rectangles upon the cloth. The most simple of these is a succession of alternate squares, forming an imitation of a checker board or mosaic work. The coarsest kinds are generally woven as tweels of three leaves, where every thread floats over two, and is intersected by the third in succession. Some of the finer are tweels of four or five leaves, but few of more; for the six and seven leaf tweels are seldom or never used, and the eight leaf twill is confined almost exclusively to damask.

DORSETSHIRE CLAY. Clay shipped from Poole in Dorsetshire. See Clay.

DOUK or **DOUKE.** Mr. Wallace, in his work on the mines of Alston Moor, expresses his belief that this term is derived from the Saxon *deagan*, to knead or mix with water. It is a soft substance, often found in veins, especially in crop veins, and where their walls or sides are formed of shale. It is evidently pounded or decomposed shale, though not unfrequently as compact as the rock from which it is derived, but differs from the latter in exhibiting no traces of bedding. Exposed to the atmosphere, it rapidly decomposes into a blue kind of clay.

DOWLAS. A coarse kind of linen.

DOWN. See Feathers.

DOWSING ROD. See Divining Rod.

DRAGON'S BLOOD (*Sang-dragon*, Fr.; *Drachenblut*, Ger.) is a resinous substance, which comes to us sometimes in small balls of the size of a pigeon's egg, sometimes in rods like the finger, and sometimes in irregular cakes. Its colour, in lump, is dark brown-red; in powder, bright red; friable; of a shining fracture; specific gravity 1·196. It contains a little benzoic acid, is insoluble in water, but dissolves readily in alcohol, ether, and oils. It is brought from the East Indies, Africa, and South America, as the produce of several trees, the *Dracæna draco*, the *Pterocarpus santolinus*, *Pterocarpus draco*, and the *Calamus rotang*.

Dragon's blood is used chiefly for tingeing spirit and turpentine varnishes, for preparing gold lacquer, for tooth tinctures and powders, for staining marble, &c. According to Herbenger, it consists of 9·07 parts of red resin called *Draconin*, 2 of fixed oil, 3 of benzoic acid, 1·6 of oxalate, and 3·7 of phosphate of lime. According to Johnstone, the resin of lump dragon's blood has the formula $C^{40}H^{21}O^{8}$ ($\mathbf{C^{20}H^{21}O^{4}}$), that of reed dragon's blood, $C^{40}H^{20}O^{9}$ ($\mathbf{C^{40}H^{40}O^{9}}$).

Pereira enumerates the following varieties of this substance found in commerce:—

1. *Dragon's blood in the reed; Dragon's blood in sticks* (*Sanguis Draconis in baculis*).

2. *Dragon's blood in oval masses; Dragon's blood in drops* (*Sanguis Draconis in lachrymis.*)

3. *Dragon's blood in powder.*
4. *Dragon's blood in the tear* (*Sanguis Draconis in granis*).
5. *Lump Dragon's blood* (*Sanguis Draconis in massis*).

Besides these, there are *Dragon's blood in cakes* and *False Dragon's blood in oval masses.*

DRAINING TILES. Burnt clay tiles, generally shaped in section like a horse-shoe, about one foot long, and two or three inches broad. These are much used in agricultural draining. See STONE-WARE.

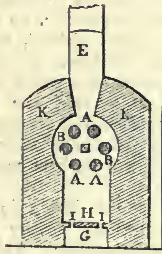
DRAWING CHALKS. Chalks or crayons are frequently nothing more than the natural production reduced to a convenient form: they are, however, sometimes prepared artificially; a few of these manufactures are named.

The Brothers Joel, in Paris, employ as crayon cement the following composition: 6 parts of shellac, 4 parts of spirit of wine, 2 parts of turpentine, 12 parts of a colouring powder, such as Prussian-blue, orpiment, white lead, vermilion, &c., and 12 parts of blue clay. The clay being elutriated, passed through a hair sieve, and dried, is to be well incorporated by trituration with the solution of the shellac in the spirit of wine, the turpentine, and the pigment; and the doughy mass is to be pressed into proper moulds, so as to acquire the desired shape. They are then dried by a stove heat.

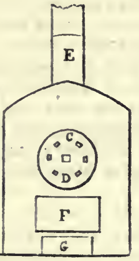
In order to make cylindrical crayons, a copper cylinder is employed, about 2 inches in diameter and 1½ inch long, open at one end, and closed at the other with a perforated plate, containing holes corresponding to the sizes of the crayons. The paste is introduced into the open end, and forced through the holes of the bottom by a piston moved by a strong press. The vermicular pieces that pass through are cut to the proper lengths, and dried. As the quality of the crayons depends entirely upon the fineness of the paste, mechanical means must be resorted to for effecting this object in the best manner. The following machine has been found to answer the purpose exceedingly well.

Fig. 638 is a vertical section through the centre of the crayon mill. *Fig.* 639 is a view of the mill from above. A, the mill tub, whose bottom B must be a hard flat plate of cast iron; the sides A being of wood or iron at pleasure. In the centre of the bottom there is a pivot C, screwed into a socket cast upon the bottom, and which may be strengthened by two cross bars D, made fast to the frame E. F, the millstone of cast iron, concave, whose diameter is considerably smaller than that of the vessel A; it is furnished within with a circular basin of wood G, which receives the materials to be ground, and directs them to the holes H, which allow them to pass down between the under part of the muller and the bottom of the tub, to undergo trituration.

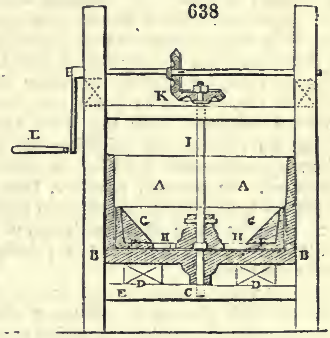
641



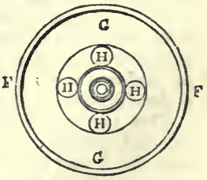
640



638



639



By the centrifugal motion, the paste is driven towards the sides of the vessel, rises over the sides of the muller, and comes again through the holes H, so as to be repeatedly subjected to the grinding operations. This millstone is mounted upon an upright shaft I, which receives a rotatory motion from the bevel-work K, driven by the winch L.

The furnace in which some kinds of crayons, and especially the factitious black-lead pencils, are baked, is represented in *fig.* 640, in a front elevation; and in *fig* 641, which is a vertical section through the middle of the chimney.

A A, six tubes of greater or less size, according as the substance of the crayons is a better or worse conductor of heat. These tubes, into which the crayons intended for baking are to be put, traverse horizontally the laboratory, B, of the furnace, and are supported by two plates C, pierced with six square holes for covering the axles of the tubes A. These two plates are hung upon a common axis D; one of them, with a ledge, shuts the cylindrical part of the furnace, as is shown in the figure. At the extremity of the bottom the axis D is supported by an iron fork fixed in the brick-work; at the front it crosses the plate C, and lets through an end about 4 inches square to receive a key, by means of which the axis D may be turned round at pleasure, and thereby the two plates C, and the six tubes A, are thus exposed in succession to the action of the fire in an equal manner upon each of their sides. At the two extremities of the furnaces are two chimneys E, for the purpose of diffusing the heat more equally over the body of the crayons. F, *fig.* 640, is the door of the fire-place, by which the fuel is introduced; G, *fig.* 641, the ash-pit; H, the fire-place; I, holes of the grate which separate the fire-place from the ash-pit; K, brick-work exterior to the furnace.

General Lomet proposes the following composition for red crayons. He takes the softest hematite, grinds it upon a porphyry slab, and then carefully elutriates it. He makes it into a plastic paste with gum arabic and a little white soap, which he forms by moulding, as above, through a syringe, and drying into crayons. The proportions of the ingredients require to be carefully studied.

Crayons or Chalks, *lithographic.* Various formulæ have been given for the formation of these crayons. One of these prescribes white wax, 4 parts; hard tallow-soap, and shellac, of each 2 parts; lamp-black, 1 part. Another is, dried tallow-soap and white wax, each 6 parts; lamp-black, 1 part. This mixture being fused with a gentle heat, is to be cast into moulds for forming crayons of a proper size. See Lithography.

DRESSING OF ORES. In metalliferous veins the deposits of ore are extremely irregular, and usually intermixed with gangue or vein-stone. In excavating the lode, it is usual for the miner to effect a partial separation of the valuable from the worthless portion; the former he temporarily stows away in some open place underground, whilst the latter is either employed to fill up useless excavations, or in due course sent to surface to be lodged on the waste heaps. From time to time the valuable part of the lode is drawn to the top of the shaft, and from thence conveyed to the dressing floors, where it has to be prepared for metallurgic treatment.

This process is known as Dressing, and in the majority of instances includes a series of operations. Hand labour, picking, washing, sizing, and reducing machinery, together with water-concentrating apparatus, comprise the usual resources of the dresser, but sometimes he may find it useful to have recourse to the furnace, since it may happen that, by slightly changing the chemical state of the substances that compose the ore, the earthy parts may become more easily separable, as also the other foreign matters. With this view, the ores of tin are often calcined, which, by separating the arsenic and oxidising the iron and copper, furnishes the means of obtaining, by subsequent washing, an oxide of tin much purer than could be otherwise procured. In general, however, these are rare cases; so that the washing almost always immediately succeeds the picking, crushing, or stamping processes.

Before entering upon the description of machinery employed in the concentration of ores, it is important to notice the principles upon which the various mechanical operations are based.

If bodies of various sizes, forms, and densities be allowed to fall into a liquid, in a state of rest, the amount of resistance which they experience will be very unequal, and consequently they will not arrive at the bottom at the same time. This necessarily produces a sort of classification of the fragments, which becomes apparent on examining the order in which they have been deposited.

If it be supposed that the substances have similar *forms* and dimensions, and *differ* from each other in *density* only, and it is known that the resistance which a body will experience in moving through a liquid medium depends solely on its form and extent of surfaces, and not on its specific gravity, it follows that all substances will lose under similar circumstances an equal amount of moving force.

This loss is proportionally greater on light bodies than in those having more considerable density. The former for this reason fall through the liquid which less rapidity than the denser fragments, and must therefore arrive later at the bottom, so that the deposit will be constituted of different strata, arranged in direct relation to their various densities, the heaviest being at the bottom, and the lightest at the top of the series.

Supposing, on the contrary, that all the bodies which fall through the water possess similar forms and equal specific gravities, and that they only differ from each other in point of volume, it is evident that the rapidity of motion will be in proportion to their *sizes,* and the larger fragments will be deposited at the bottom of the vessel.

As the bodies on starting are supposed to have the same forms and densities, it follows that the resistance they experience whilst descending through water will be in proportion to the surface exposed, and as the volumes of bodies vary according to the cubes of their corresponding dimensions, whilst the surfaces only vary in accordance with the squares of the same measurements, it will be seen that the force of movement animating them is *regulated by their cubes*, whilst their *resistance* is in proportion to their *squares*.

If, lastly, it be imagined that all the fragments have the same volume and density, but are of various forms, it follows that those possessing the largest amount of surface will arrive at the bottom last, and consequently the upper part of the deposit will consist of the thinnest pieces.

It is evidently then of the greatest importance that the grains of ore which are to be concentrated by washing should be as nearly as possible of the *same size*, or otherwise the smaller surface of one fragment, in proportion to its weight, will in a measure compensate for the greater density of another, and thus cause it to assume a position in the series to which by its constitution it is not entitled.

This difficulty is constantly found to occur in practice, and, in order as much as possible to obviate it, care is taken to separate by the use of sieves and trommels into distinct parcels, the fragments which have respectively nearly the same size. Although by this means the grains of ore may, to a certain extent, be classified according to their regular dimensions, it is impossible by any mechanical contrivance to regulate their forms, which must greatly depend on the natural cleavages of the substances operated on, and hence this circumstance must always in some degree affect the results obtained.

Each of the broken fragments of ore must necessarily belong to one of the three following classes:—the *first* class consists of those which are composed of the mineral sought without admixture of earthy matter; the *second* will comprehend the fragments which are made up of a mixture of mineral ore and earthy substances; whilst the *third* division may be wholly composed of earthy gangue without the presence of metallic ore. By a successful washing these three classes should be separated from each other.

The most difficult and expensive vein-stuff for the dressing floors is that in which the constituents have nearly an uniform aggregation, and where the specific gravities of the several substances approximate closely to each other. In such cases the ore is only separated from the waste after much care and labour, and often at the loss of a considerable portion of the ore itself. When, however, the ore is massive and distinct from the gangue, and the specific gravity of the latter much less than the former, then the operation of cleaning is usually very simple, effected cheaply, and with but little loss on the ore originally present.

Some of the more friable ores, when simply exposed to the influence of water, exhibit a large mechanical loss, so much so, that it is considered oftentimes more profitable to sell them without attempting their enrichment. Now it may be laid down as an axiom that water will always steal ore, and the longer it is exposed to its influence, and the more complicated the manipulation, the greater will be the loss incurred. In addition, the constitution of certain ores is so peculiar and delicate, that any attempt to concentrate them beyond a given standard, by varying the treatment, is seen to lead to an enormous loss, as will be apparent by inspecting the following memoranda of practical results:—

(A.)—The ore operated upon was sulphide of lead, associated with finely-disseminated iron pyrites, oxide of iron, quartz, and a small portion of clay slate. In each case the vein-stuff assayed 17 per cent. of metal.

	Quantity by weight		Quantity by weight[1]		
Assayed 17 per cent.	1	washed and concentrated to	·25	The loss on metal originally present in the ore by varying the mechanical treatment was .	61 per cent.

	·8	,, ,,	·69		16¾ ,,

---

[1] The quantity of ore by weight is, in the first instance, 1: this unit 1—which might have been a ton—was washed and dressed; then weighed, when it was found that 75 parts had disappeared as tailings. The dressed ore, 25 parts, was then assayed, when it appeared that the metallic loss was 61 per cent. In other words, say 1 ton afforded 17 units of metal, the dressed ore only contained $6\frac{6}{10}$ units. ($17 \times 61 = 10{\cdot}37$. Then 17 units $- 10{\cdot}37 = 6\frac{6}{10}$).

(B.)—Took two parcels of argentiferous lead ore, associated with carbonate of iron, a little quartz, and blende. Weight $34\frac{6}{20}$ tons, which assayed $42\frac{1}{2}$ per cent. for lead, and 29 ozs. of silver per ton of metal. Crushed and carefully elaborated the same through jigging and buddle apparatus, obtained $14\frac{13}{20}$ tons of ore, giving $54\frac{1}{2}$ per cent. for lead, and 22 ozs. of silver per ton of metal. The produce for lead was therefore raised 12 units at a loss of 49 per cent. of the initial quantity of metal and 95 ozs. of silver. The commercial loss attending this operation, after making the several charges and allowances incident to the metallurgic reduction, was 91*l.* 14*s.*, or equal to 2*l.* 14*s.* per ton on the original weight.

Numerous instances of heavy losses incurred in the concentrating processes could be adduced if space permitted. But it may be observed that excessive loss of ore will always occur from an excessive reduction of the stuff; that in the stamping or crushing of complex ores the softer ores will suffer a greater loss than the harder ore; that the proportion of loss in water dressing is generally in proportion to the fineness of the grains; that a maximum loss will occur when the stuff is so treated as to detach, instead of shattering the ore; and that the loss of silver associated with lead ore, frequently increases with every separate reduction and washing of the grains.

In order to determine the loss of metal which may arise in enriching ores, accurate assays and notations should be made of the quantity of vein-stuff lodged on the floors, which should be compared with the metallic contents rendered merchantable, and the differences estimated.

It is not possible to ascertain the value of an improvement which would secure an additional one per cent. from the quantity of orey stuff annually sent to surface from the several mines in the United Kingdom; but if it be reckoned only upon the sale value it would be scarcely less than 40,000*l.* per annum.

In determining the site for a dressing floor, and in making the mechanical arrangements, various points suggest themselves; since, if they are overlooked, much loss will ensue to the undertaking, or otherwise it is evident that they can only be corrected by involving the proprietary in an increased outlay as well as a greater current expenditure. The first consideration should be to secure an ample supply of water, with a good fall, and an extensive area of ground. With advantages of this nature the machinery will be worked cheaply, the stuff gravitate through the various processes without returning to create double carriage expenses, whilst the castaways may be sent to the waste heaps at a minimum cost. The second point to be settled, is the class of machinery to be employed. This must obviously be based upon the character which the ores may present. If massive, and associated with light waste, simple apparatus will suffice; but if the ore be sparsely diffused through heavy vein-stone, it is probable that the various apparatus will have to be constructed with great nicety, varied in their principles of action, and that much precaution will have to be observed in order to create as little slime as possible, as well as to secure the initial quantity of ore against undue loss. In the disposition of the machinery there is also considerable scope for practical intelligence: it is not enough to wash, crush, jig, and buddle the ores, mixing the resulting smalls incongruously together; but a judicious sorting should be commenced at the wash kilns, and upon this basis the various sizes kept distinct whilst passing through the washing floors. The dresser should also take care to keep the several ranges of mineral produces and degrees of fineness together.

With the view of assisting the judgment in deciding upon the machinery to be employed, the following Table of Specific Gravities is given:—

TABLE OF SPECIFIC GRAVITIES.

Metals.

	Specific gravity
Gold	19·25
Mercury	13·26
Lead	11·35
Silver	10·47
Copper	8·89
Iron	7·78
Tin	7·30
Zinc	7·00

Ores.

		Hard ness	Specific gravity
Lead:	Sulphide (galena)	2·5 to 2·75	7·5 to 7·6
	Sulphate	2·3 „ 2·7	6·25 „ 6·29
	Carbonate (white)	3·0 „ 3·5	6·46 „ 6·48

		Hardness	Specific Gravity
	Phosphate (green and brown)	3·5 „ 4·0	6·58 „ 7·04
	Chromate (bright red)	2·5 „ 3·0	6·0 „ 6·04
	Molybdate	2·7 „ 3·0	6·7 „ 6·8
Tin:	Oxide of tin	6·0 „ 7·0	6·5 „ 7·1
	Tin pyrites	3·0 „ 4·0	4·79 „ 5·1
Copper:	Sulphide	2·5 „ 3·0	5·5 „ 5·8
	Oxide	3·5 „ 4·0	5·9 „ 6·0
	Carbonate	3·5 „ 4·0	4·0 „ 4·1
	Pyrites	3·5 „ 4·0	4·15 „ 4·16
	Sulphate	2·2	2·21
	Silico-carbonate	2·0 „ 3·0	2·0 „ 2·2
Zinc:	Red oxide	4·0 „ 4·5	5·43 „ 5·52
	Sulphide	3·5 „ 4·0	4·02 „ 4·07
	Carbonate	5·0	4·33 „ 4·44
	Silicate		3·43
Antimony:	Sulphide	2·0	4·51 „ 4·62
	Jamesonite	2·0 „ 2·5	5·5 „ 5·8

Minerals associated with Ores.

	Hardness	Specific gravity
Wolfram	5·0 to 5·5	7·1 to 7·4
Iron pyrites (white)	6·0 „ 6·5	4·67 „ 4·84
Mundic	6·0 „ 6·5	4·83 „ 5·01
Sulphate of baryta	2·5 „ 3·5	4·3 „ 4·8
Carbonate of baryta	3·0 „ 3·75	4·29 „ 4·3
Carbonate of iron	3·0 „ 4·5	3·73 „ 3·82
Fluor-spar	4·0	3·0 „ 3·33
Quartz or silica	7·0	2·6 „ 2·7
Carbonate of lime	2·5 „ 3·5	2·5 „ 3·8

Ore-bearing Rocks.

	Specific gravity
Hornblende rock	2·8 to 3·2
Syenite	2·7 „ 3·0
Trap or basalt	2·8 „ 3·2
Grauwacke	2·5 „ 2·9
Porphyry, trachyte, and felspar	2·3 „ 2·7
Granite and gneiss	2·4 „ 2·7
Mica slate	2·6 „ 2·9
Clay slate	2·6
Limestone and dolomite	2·5 „ 2·9
Sandstone	2·4 „ 2·7

The following general deductions will also be found serviceable:—

First.—Absolute perfection in separation according to specific gravity cannot be arrived at, chiefly on account of the irregularity of form of the various grains to be operated upon.

Second.—The more finely divided the stuff to be treated, the greater is the amount of labour and care required, and the more imperfect will be the separation.

Third.—That reducing machine may be considered the most perfect which produces the least quantity of stuff finer than that which it is intended to produce.

Fourth.—It is necessary in determining the degree of fineness to which a mineral should be reduced, to consider the metallurgic value of the ore contained in it, and to set against this the value of the loss which will probably be incurred, together with the labour and expense attendant upon the manipulation.

Fifth.—The vein-stuff should be reduced to such a degree of fineness that the largest proportion of deads and clean ore should be obtained by the first operation, thus saving the labour and preventing the loss incident to a finer subdivision of the ore and more extended treatment.

Sixth.—That apparatus or plan of dressing may be considered the most efficient which, with stuff of a given size, allows at an equal cost of the most perfect separation, and of the proper separation of stuff of nearly equal specific gravity.

The average percentage to which the crop is to be brought, and the highest percentage to be allowed in the castaways being determined, it is evident that the more perfect the degree of separation the greater will be the amount of crop and castaways obtained at each operation, and the quantity of middles or stuff to be re-worked will be diminished.

Seventh.—We may further consider as a great improvement in dressing operations such apparatus or plan of working as will allow, without a disproportionate increase in the cost, of the equally perfect separation of fine and coarse stuff. This will be of especial benefit in the case of finely-disseminated ore, which is necessarily obliged to be reduced to a great degree of fineness.

Washing and Separating Ores.

The vein-stuff on arriving at the surface, is not only associated with a large amount of gangue, but is frequently much intermixed with clay, rock, and siliceous matter.

In order to get rid of the latter substances, it is usually washed and picked. The washing apparatus ought to be so contrived as to allow the cleansing to be effected both cheaply and expeditiously, and for this purpose a good volume and fall of water is always desirable. In accordance with the character of the ore the apparatus will have to be varied, but for lead, certain varieties of copper ore, as well as iron, or other abundant ores, the kiln is well adapted. In many mines rectangular grates are fitted to the bottom of the kilns, but a perforated plate would be found to furnish better results, since the former allows of the passage of flat irregular masses of stone, rendering the treatment in the jigging sieves less successful. The holes in the perforated plate should be conical, the largest diameter underneath, so that the stones may have unobstructed passage. In connection with the kiln-plate a sizing trommel should be used, and in order to economise both time and expenditure it would be judicious to introduce the vein-stuff and discharge the castaways by means of railways.

The picking of the stuff is a highly important operation. As a rule all picked ore should be selected, and the dradge deprived of the largest possible amount of waste before it is sent to the crusher. It is fallacious to suppose, because machinery will deal with large quantities expeditiously, that it is cheaper to subject the mass to its action; on the contrary, if correct calculations are made of the losses which will ensue on the initial quantity of ore before the residue is ready for the pile, the cost of the several intricate manipulations requisite to get rid of the castaways, the wear, tear, and maintenance of machinery, it will appear in the majority of cases that the most profitable method is to incur an extra first charge in order to reject the sterile portions by means of hand labour. The ragging hammer should therefore be brought into free requisition, and all worthless stones at once rejected; then in spalling such portions as have been ragged, an additional quantity of refuse should be excluded; whilst in the process of cobbing, either ragged or spalled work, the greatest care and attention should be given in order to bring the dradge to a maximum degree of richness.

Among the siftings and washings which ores are made to undergo, we would notice those practised on the Continent, *grilles anglaises,* and *step-washings* of Austria, *laveries à gradins.* These methods of freeing the ores from pulverulent matters, consist in placing them, at their out-put from the mine, upon gratings, and bringing over them a stream of water, which merely takes down through the bars the small fragments, but carries off the finer portions. The latter are received in cisterns, where they are allowed to rest long enough to settle to the bottom. The washing by steps is an extension of the preceding plan. To form an idea of this, let us imagine a series of grates placed successively at different levels, so that the water, arriving on the highest, where the ore for washing lies, carries off a portion of it, through this first grate upon a second closer in its bars, thence to a third, &c., and finally into labyrinths or cisterns of deposition.

The *grilles anglaises* are similar to the *sleeping tables* used at Idria. The system of these *gradins* is represented in *fig.* 642. Such system is resorted to for the purpose of sorting the small fragments of quicksilver ore intended for the stamping mill.

642

These fragments are but moderately rich in metal, and are picked up at random, of various sizes, from that of the fist to a grain of dust.

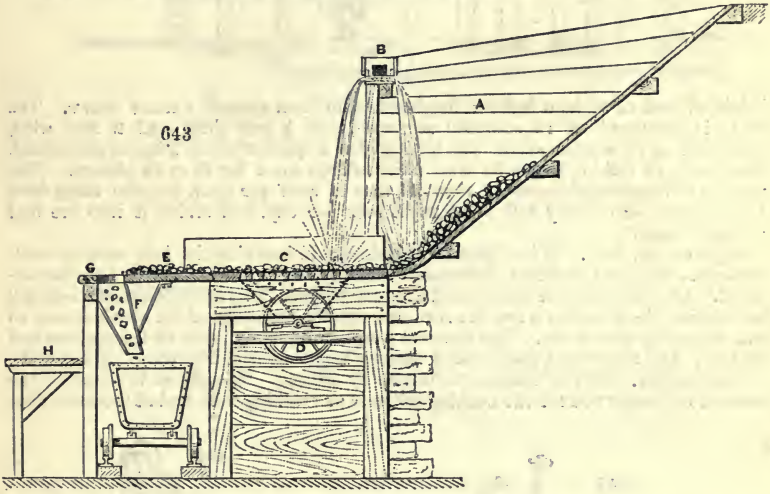
The ores are placed in the chest *a*, below the level of which 7 grates are distributed, so that the fragments which pass through the first, *b*, proceed by an inclined conduit on to the second grate *c*, and so in succession. (See the conduits *l*, *o*, *p*.) In front, and on a level with each of the grates *b*, *c*, *d*, &c., a child is stationed on one of the floors, fixed opposite to them.

A current of water which falls into the chest *a*, carries the fragments of ore upon the grates. The pieces which remain upon the two grates *b* and *c*, are thrown on the adjoining table *v*, where they undergo a sorting by hand; there the pieces are classified, 1, into gangue to be thrown away; 2, into ore for stamping mill; 3, into ore to be sent directly to the furnace. The pieces which remain on each of the succeeding grates, *d*, *e*, *f*, *g*, *h*, are deposited on those of the floors 3 to 7, in front of each. Before every one of these shelves a deposit-sieve is established (see *t*, *u*), and the workmen in charge of it stand in one of the corresponding boxes, marked 8 to 12. The sieve is represented only in front of the chest *h*, for the sake of clearness.

Each of the workmen placed in 8, 9, 10, 11, 12, operates on the heap before him; the upper layer of the deposit formed in his sieve is sent to the stamping-house, and the inferior layer directly to the furnace.

As to the grains which, after traversing the five grates, have arrived at the chest *x*, they are washed in the two chests *y*, which are analogous to the German chests. The upper layer of what is deposited in *y* is sent to the furnace; the rest is treated anew.

The kiln before adverted to is explained by *fig.* 643.

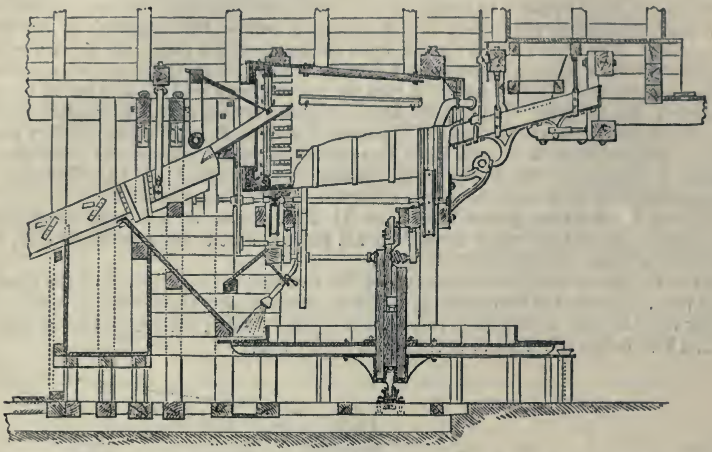


643

The vein-stuff is brought from the shaft by means of tram waggons, into the hopper A; water flows from the launder B, one portion distributing itself at the foot of the hopper, the other upon a cast-iron plate perforated with holes $1\frac{1}{4}$ inch diameter at top, $1\frac{1}{2}$ inch diameter at bottom, and 2 inches distant from centre to centre; the plate being 4 feet by 3 feet 6 inches. Between C and E, the washer stands. The fine stuff he rakes through the plate-holes, and that which is too coarse is drawn to E. Children standing on H, select the prill and dradge from the pile E, discharging such stones as are valueless through the shoot F, into the waggon beneath. The trommel D is constructed of perforated plates, having different degrees of fineness, in order to size the stuff which passes through into bins or compartments.

The washing arrangement shown in *fig.* 644 is in use at Przibram. The stuff is first introduced into a shoot, from whence it passes into a conical trommel, and is thence thrown upon a flat sieve, and divided into coarse and fine stuff, the former going to the rotative table, the latter to sizing sieves. The shoot at the entrance of the trommel is kept in movement by a cam shown underneath: the trommel rotates on carrier wheels, whilst circular motion is given to the picking table by means of a tangent wheel and screw. The inside of the trommel is fitted with ledges for lifting and dropping the stuff, water being continually introduced for washing and freeing it from slime and clay. A rose jet of water flows on the table for rendering the ore and waste more distinct to the eye. The small diameter of the trommel is 3 feet 9 inches; large diameter, 5 feet 4 inches; length of trommel, 9 feet. The diameter of the trommel carrier wheel is 2 feet 6 inches, outside diameter of picking table 14 feet, inside diameter 10 feet; height of back of table, 6 inches; height of table from ground, 2 feet 7 inches. The table is composed of 16 cast-iron segments, each ½ inch thick and 2 feet wide, supported on 16 wooden arms. The table makes a speed of about 2 inches per second. The length of picking line is 30 feet, which affords space for 15 or 16 pickers. This number of hands will dispose of about 15 tons of stuff per hour, the size being from 1 to 3 inches, or one boy will select say 4 tons per day, and divide it into ore and 'dradge' work.

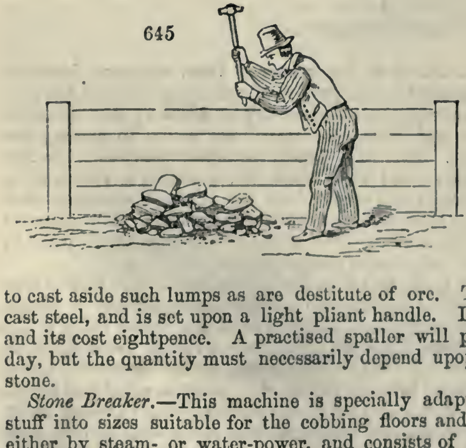
644



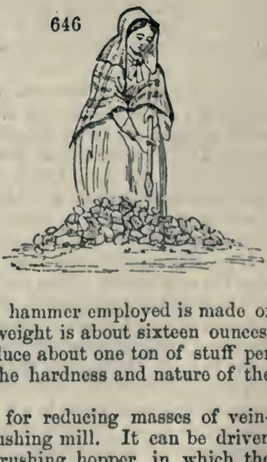
Ragging (*fig.* 645). It has been remarked that, in breaking the lode underground, numerous rocks are produced, throughout which valuable ore is more or less disseminated. After these stones are washed, they are ragged. This operation consists simply in reducing the stones to a smaller size, and rejecting as many of the sterile stones as can be readily picked out. The reserved heap is ultimately taken to the spallers and cobbers. The weight of a steel-headed ragging hammer varies from six to eight pounds.

Spalling (*fig.* 646), is usually performed by women. The object is to break the stones to a proper size for the bucking hammer or crushing mill, and at the same time to cast aside such lumps as are destitute of ore. The hammer employed is made of cast steel, and is set upon a light pliant handle. Its weight is about sixteen ounces, and its cost eightpence. A practised spaller will produce about one ton of stuff per day, but the quantity must necessarily depend upon the hardness and nature of the stone.

645



646

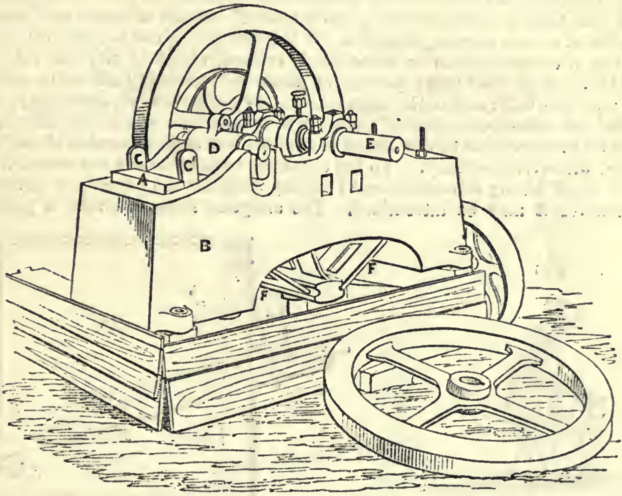


Stone Breaker.—This machine is specially adapted for reducing masses of veinstuff into sizes suitable for the cobbing floors and crushing mill. It can be driven either by steam- or water-power, and consists of a crushing hopper, in which the stone is broken between a pair of jaws, the one being fixed, the other actuated by knee-joint levers. The fixed jaw A, *fig.* 647, is a plate of cast iron, bedded in lead, and held in the frame B, by tapered cheek pieces C C′. The vibrating jaw plate D corresponds in this respect with the fellow plate A. The excentric shaft E gives motion to the toggles F F, which press forward the breaking jaw, D, about $\frac{3}{8}$ths of an inch. In the depression of the lever the jaw is drawn back by means of a strong India-rubber spring.

A stone dropped between the convergent jaws will be operated upon by a succession of bites, until it is crushed small enough to pass out at the bottom. The distance between the jaws at the bottom limits the size of the fragments. The frame of the machine is formed of one single casting, and although provided with bolt holes, yet is usually heavy enough to require nothing further than its own weight to retain it in working position, The apparatus should be fixed high enough either to allow a waggon to be placed under the jaws, or otherwise that the reduced stones may gravitate to the rollers of a crushing mill.

The width of the opening at the top of the jaws determines the size of the machines, and at the same time it represents the largest stone which can possibly be dealt with. The quantity of stone reducible in a given time must necessarily depend upon its degree of hardness, as well as upon its structure. In addition, the result is either lessened or increased, according to the minimum distance between the jaws, and the speed given to the excentric shaft.

647



The approximate duty rendered by stone-breakers of various size, at a speed of 200 revolutions per minute, is as follows:—

Length of jaw	Width between jaws at top	Power required	Produce per hour
inches	inches	horses	cubic yards
6	4	1½	1½
7½	4	1½	1¾
10	7	3	3
15	7	4	4½
20	9	5	6
18	12	8	8
24	12	10	10
24	15	15	13

At the Kirkless Hall Colliery, in Lancashire, it has been found that one ton of limestone falling through jaw pieces seven inches apart at the top is reduced into fragments which can be passed through a gauge one and three-quarters of an inch in diameter at a cost not exceeding threepence per ton, the coal for maintenance of engine being charged at three shillings and sixpence per ton. The various parts of the apparatus are of great strength, and the amount of wear and tear is comparatively small. In mines where it is requisite to reduce large quantities of vein-stuff, either for the cobbers, coarse sand jiggers, or crushing mill, this machine will prove an important and valuable auxiliary.

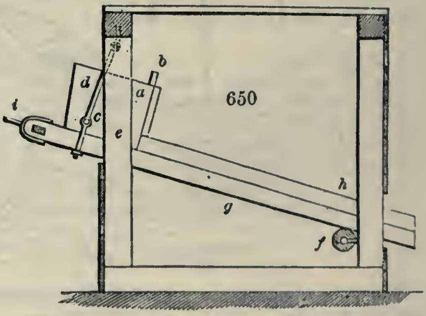
648

The jaw pieces of stone-breakers should be formed of double chilled iron: soft and badly-hardened iron is highly objectionable, since with the early inefficiency of the jaw pieces, together with cost and delay attending their replacement, the cost of reducing stone must be materially increased. A pair of hard jaws 12 inches by 9 inches will break from 2,000 to 3,000 tons of siliceous vein-stone. In large dressing establishments the stone-breaker is driven directly by a steam-engine. Small breakers, with jaws 7½ inches deep and 4 inches wide, are also frequently used for reducing orey vein-stone, derived from the 'coarse sand' jiggers.

Cobbing, fig. 648.—This work is generally performed by women, young girls, or boys. It consists of picking the best work from the dradge, and with a peculiarly shaped hammer, detaching from each piece the inferior portions, and thus forming either prill or best dradge ore. An expert cobber will manage to prepare about 10 cwts. of tolerably hard stuff per ten hours.

Sizing Apparatus.—In the various processes of dressing, no point is of greater importance than that of correctly sizing the vein-stuff, neither is there one demanding the exercise of a more correct judgment. If the particles of ore be reduced below their natural size a source of loss is immediately created, whilst if they are not brought within the limit of their size a portion of waste will probably adhere to each atom, forming a serious difference in the aggregate quantity of castaways, although such waste may afford but a low percentage of metal. The holes in the sieves or trommels should therefore be proportioned to the nature of the ore, but such apparatus should also be introduced wherever necessary. To the crushing mill, trommels are essential, whilst it will be found highly advantageous to employ them for the purpose of dividing the stuff whenever it may be intermixed. The simplest form of sizing is perhaps by the hand riddle, *fig*, 649, which is formed of a circular hoop of oak, ⅜ths of an inch thick and 6 inches deep. Its diameter ranges from 18 to 20 inches.

649



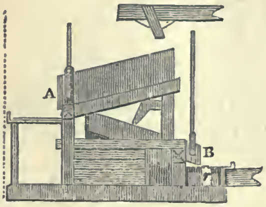
650

The bottom is made of a meshwork of copper or iron wire. The weight of an iron wire riddle is about seven pounds, and its cost 4*s.* 6*d.*

Fig. 650 represents a swing sieve employed in mines on the Continent. *a*, box into which the stuff to be sifted is introduced; *b*, regulating door; *c*, pendulating rod attaching the sieve frame to the frame *e*; *f*, friction roller carrying the sieve frame *g*. At *h* springs are fitted to each side of the frame, in order to give it a vibratory action; *i*, rod, giving motion to the apparatus, The width of the sieve frame is about one-third its length, but the sieve bottom only extends from the box, *a*, two-thirds of the length. The bottom of the sieve frame is subsequently contracted so as to form a shoot.

Fig. 651 is a swing sieve employed in the Hartz, for sifting the small fragments of the ores of argentiferous lead. Such an apparatus is usually set up on the outside of a stamps or washing mill. The two moveable chests or boxes A B, of the sieve, are connected together, at their lower ends, with an upright rod, which terminates at one of the arms of a small balance beam, mounted between the driving shaft of the stamps and the sieve, perpendicularly to the length of both. The opposite arm of this beam carries another upright rod, with cams,—placed so as to be pushed down by the driving shaft. During this movement the two lower ends A, B, are raised; and when the cam of the shaft quits the rod which it had depressed, the swing chests fall by their own weight. Thus they are made to vibrate alternately upon their axes. The small ore is put into the upper part of the chest A, over which a stream of water falls from an adjoining launder. The fragments which cannot pass through a cast-iron griddle in the bottom of the chest are sorted by hand upon a table in front of A, and are classed by the workman, either among the ores to be stamped, whether dry or wet, among the rubbish to be thrown away, or among the ores to be smelted by themselves. As to the small particles which fall through the griddle upon the chest B, supplied also with a stream of water, they descend successively upon two other brass wire sieves, and also through the iron wire *r*, in the bottom of B.

651



652

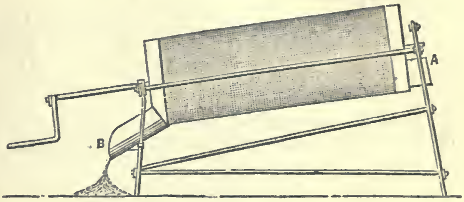


Fig. 652 shows the circular hand-riddle employed in the mines of Cornwall. Although this is in advance of hand riddling, yet it is by no means equal to the large sizing trommels employed in Germany.

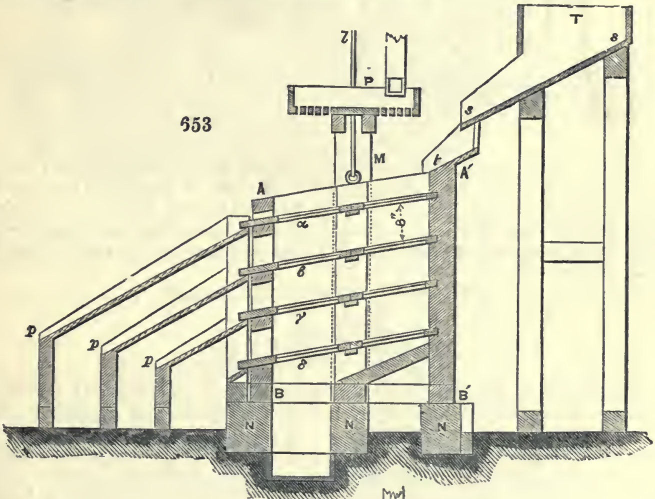
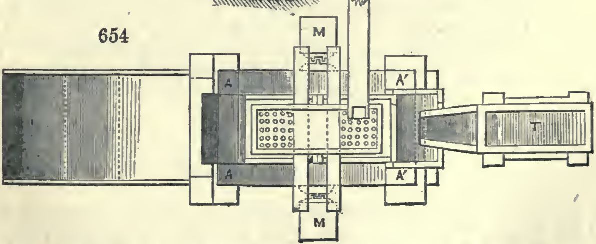
The ore is thrown in it at A, the coarser pieces passing longitudinally through the riddle into the shoot B. The riddle is turned by a hookhandle, as shown in the illustration; the meshes of the sieve vary from $\frac{3}{4}$ths of an inch to 1 inch square, according to the character and quality of the vein-stuff to be operated upon.

653



654

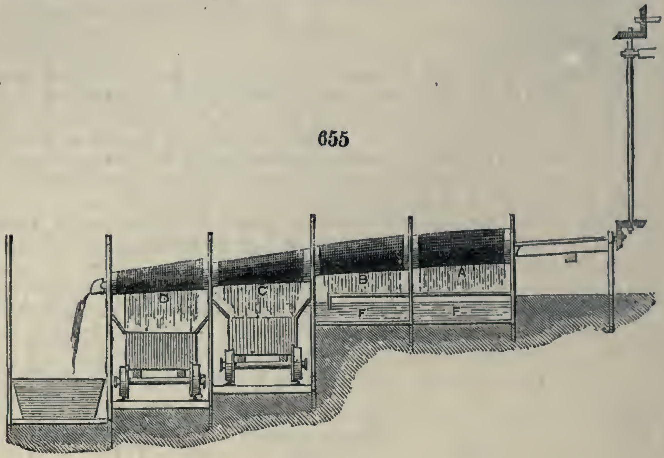


Figs. 653, 654 show an elevation and ground plan of a series of flat separating sieves. A A′, B B′ is a strong wooden frame. M M, guides for frame; N N N, basement upon which the sieve frame rests; P, cistern fitted with perforated plate through which clean water is distributed upon the sieves; T, hopper supplying the stuff to be sifted; *s s* bottom of ditto. The sieves are lifted by the rod *l* and make from 40 to 50 drops per minute. The sieves are set about 8 inches apart, and discharge the stuff upon the inclines *p p p*.

The holes in No. 1 sieve are ½ inch diameter.
" 2 $\frac{3}{8}$ "
" 3 $\frac{3}{16}$ "
" 4 $\frac{1}{12}$ "

Fig. 655 represents the trommel or sizing sieves formerly in operation at the Devon Great Consols. Although the yield of ore at these mines was extremely large, it may not be generally known that much of it was obtained from stuff yielding no more than from ¾ to 1½ per cent. of metal. The product of the lode on arriving at the surface was cobbed and divided into two classes, the first going to market without further elaboration, whilst the dradge or inferior portion was treated by various processes of washing. The whole was, however, crushed to such a degree of fineness as to pass through the following holes:—

655



Trommel A, holes $\frac{1}{20}$ inch diameter.
" B, " $\frac{1}{12}$ " "
" C, " $\frac{1}{10}$ " "
" D, " $\frac{1}{8}$ " "

The trommels were each 6 feet long, 24 inches diameter at the large end, and 18 inches diameter at the smaller, making 20 revolutions per minute, and altogether affording an area of 6,000 square inches.

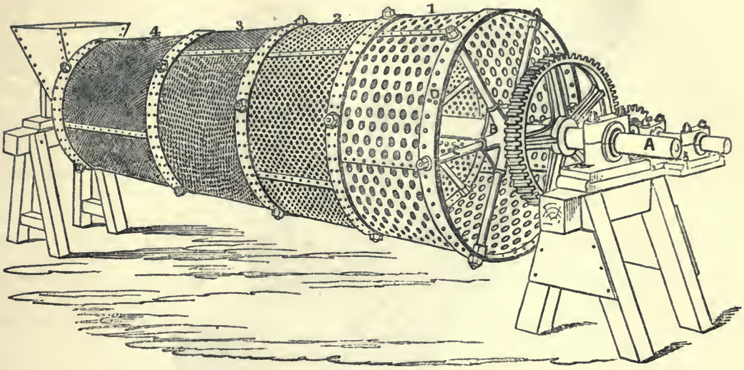
Continuous Trommels.—These are made of various diameters and lengths; the diameters of the perforated holes vary from two and a half inches to one-twentieth part of an inch. On a suitable wrought-iron shaft A, *fig.* 656, a cast-iron boss plate B, is fitted, the bosses receive six wrought-iron radial arms C, which pass through a thin but stiff wrought-iron ring D, governing the diameter of the trommel. The arms are fastened to the ring by means of outside and inside nuts, the perforated plates 1, 2, 3, and 4, are rivetted to the several rings, and in this way an excellent trommel is produced.

Conical Trommel.—The trommel *fig.* 657 may be used singly or in combination with others for sizing stuff coming from the wash grate clearing drum or crusher. The diameter as well as the length should be proportioned to the quantity of stuff to be treated within a given period.

The angle of the shell with the horizontal axis must also correspond to the diameter of the grains. The angle varies from three to five degrees, while the speed ranges from fifteen to twenty revolutions per minute.

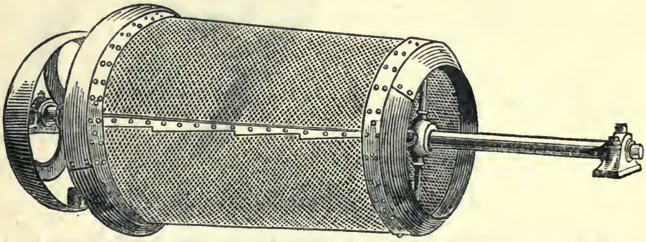
Double Conical Trommel, fig. 658.—For the purpose of obtaining three distinct sizes of stuff within the length almost of a single trommel and, without incurring much loss of fall, a double conical trommel is employed. Its use is, however, more for separating or dividing stuff for subsequent sizing, than for sizing directly to jiggers.

656

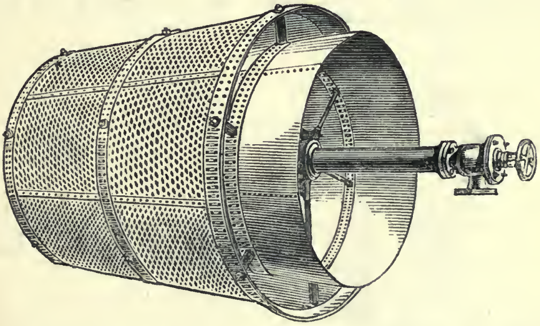


Cascade Trommels.—A system of six sizing trommels is shown in *Fig.* 659. Each trommel is 42 inches long, 21 inches diameter at the large end, and 18 inches diameter at the small end. At a speed of 20 revolutions per minute, the six trommels will dispose of from two to three tons per hour. The volume of water required per trommel to keep the holes clear is from two to three gallons per minute. The order of sizing is from great to small grains; that is, the first or uppermost trommel has the coarsest holes; each succeeding trommel having holes of lesser diameter. Through this arrangement the smallest holes and thinnest plates get only a minimum amount of wear. In order to convey the stuff from one trommel to another sheet-iron or wooden hoppers are employed.

657

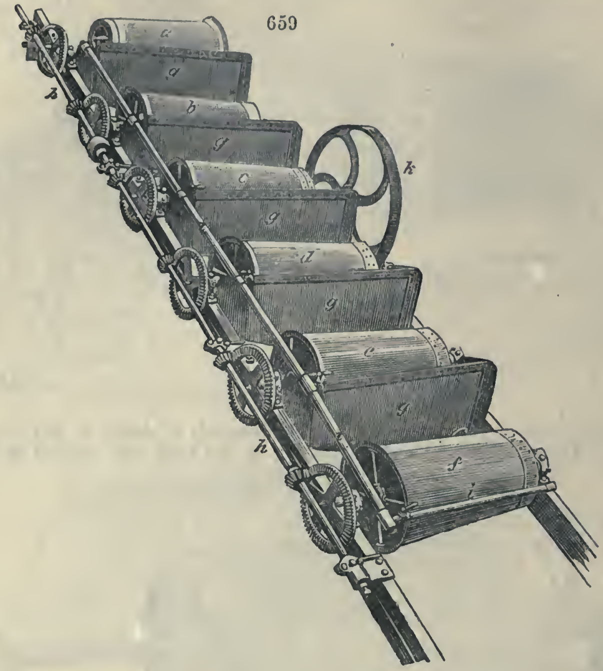


658



Each trommel is light, portable, and readily replaced. Instead of distributing the water by means of pipes, open launders are equally efficient. The trommels may be placed side by side, or run end-ways, and be driven by means of spur wheels or by a light chain crossed on the pulleys.

659

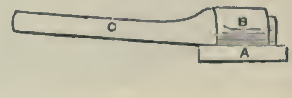


Grinding and Crushing Machinery.

In small mines, *Bucking*, *fig.* 660, is resorted to, instead of employing the crushing mill. This operation consists of pounding pieces of mixed ore on a slab of iron A, by means of a hammer or bucker B. The wall on which the plate A is placed, is about 3 feet high. The stuff to be pounded is placed behind the slab, and is drawn upon and swept off the plate by the left hand. In Cornwall it is customary to keep time with the blows and to stand to the bench · but in Derbyshire each operator works independently, and is usually seated.

660

661



The bucker, *fig.* 661, is formed of a wrought-iron steel-faced plate A, 3 inches square, with a socket B, for receiving a wooden handle C. Its cost is about 1*s.* 4*d.*

The reduction of vein-stone to a suitable size, so as to extract a maximum quantity of ore is a matter of considerable importance. The class of machinery to be employed must depend upon the normal constituents of the stone.

If the ore is of a massive character and of little value it may be selected from the waste at the stone-breaker; but if much intermixed with other minerals, it will be necessary to submit it to the crushing, stamping, or grinding mill. In the employment of either apparatus the object should be to secure free and unbroken grains of ore so as to readily collect them in the subsequent dressing processes.

The general application of reduction machinery may be briefly stated:—Stone-breakers, for tin, ironstone, copper, and lead ore dradge; size of stuff, from 1 to 9 inches. Crushing mills; for copper, and lead ore; in pieces, from 2 to 50 millimeters diameter. Stamps, for tin, lead, and copper ore, in grains, and pieces, from ½ to 75 millimeters. Grinding apparatus, for tin, silver, and auriferous ore, in grains, from ½ to 2 millimeters size.

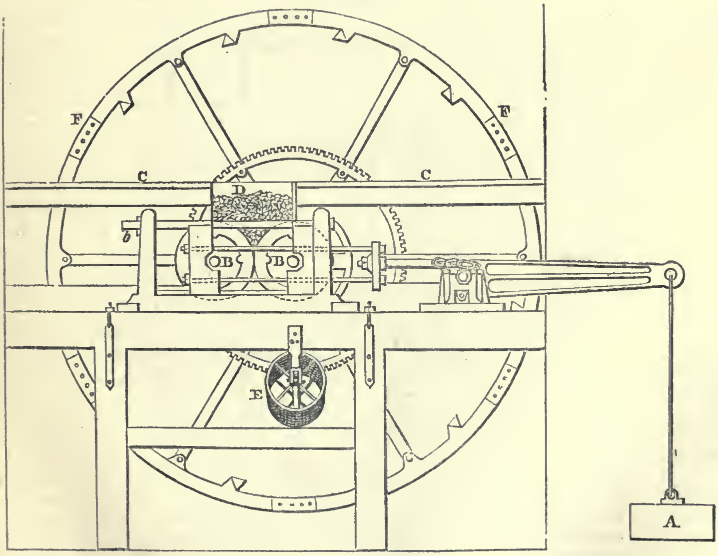
Crushing Mill. This machine was introduced by the late Mr. Taylor at Wheal Crowndale, near Tavistock, in the year 1804. In its simplest form it consists of two rollers mounted in a strong iron frame, and kept in contact by means of screws; motion is communicated to one of the rolls, either by a water-wheel or steam-engine, but the other is made to revolve by the friction generated between the moving roll and the stuff to be crushed. This mill is usually employed for reducing mineral substances which have already received some mechanical preparation, but machines have been contrived with a series of rolls, set below each other, into which the stuff is introduced as brought from the lode underground. In order to effect this operation, the upper rolls are fluted, and the lower ones have various speeds and diameters, but it may be remarked that although this arrangement has been somewhat extensively employed in the north of England, yet it has found few advocates either in Wales or Cornwall, or on the Continent.

The practice of keeping the rolls together by screws acting on the bearings is objectionable, since the entrance of a piece of steel, or other hard substance of greater width than the fixed opening between the rolls, immediately produces a stoppage and strains the apparatus, or otherwise causes serious breakages to some of the parts. In order to obviate these evils, the rolls are usually adjusted and kept in position by weighted levers pressing on their axis.

As the machines employed in Cornwall may be considered the most effective in operation, as well as complete in their construction, that type is selected for representation.

B B (*fig.* 662), are the crushing rollers fitted in a strong frame-work of cast iron, which is stayed by a wrought-iron bar *b*, and firmly bolted to longitudinal beams inserted in the walls of the crushing-house. The rollers revolve in bearings, which are so arranged as to slide in grooves, and therefore admit of the cylinders being brought

662



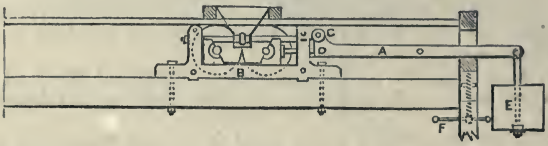
nearer to or separated farther from each other. To keep the rollers in contact and yet allow the action to take place, a weighted lever A is placed on each side, which by means of tension bars connected with one of the bearings, keep a constant pressure upon the rollers. The ore to be crushed is lodged upon a floor C, and introduced into a hopper D, from which it falls between the rolls; the requisite crushing pressure being attained by increasing or decreasing the weights applied to the end of the lever. The crushed ore passes from between the rollers B B into the higher extremity of an inclined cylinder E, made of coarse gauze, or perforated plate, which being set in motion by the same power as the rollers themselves, separates the pulverised material into two classes. That portion which passes through the sieve falls into a waggon placed on the floor of a house, whilst the other, which is too large to escape through the openings, is carried to the lower end of the cylinder from whence it passes into an inverted bucket-wheel F, by which it is again conveyed into the hopper to be re-crushed.

The modifications to the foregoing arrangement may be thus briefly noticed.

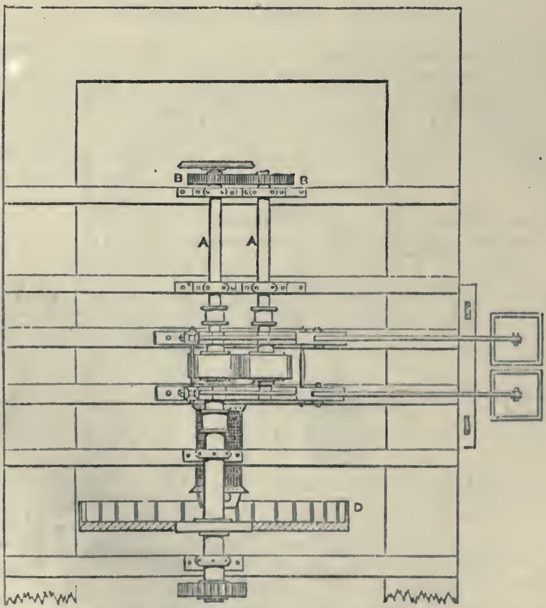
In some machines the feed-hopper is made of sufficient capacity to hold from 20 to 25 cwts. of stuff, which is introduced by means of a tram waggon, and renders hand feeding unnecessary. The shoot conveying the crushed ore to the rotating sieve, E, is sometimes divided at the bottom into two parts, one to deliver rough, and the other fine stuff, In connection with each division, is a cylindrical riddle revolving and separating the work according to the fineness or coarseness of the mesh employed.

A circular sieve divided midway into two parts, each of a different mesh, is in some instances advantageously substituted for two sets of seives; whilst, in other cases, circular sieves are omitted, the operation of sizing being performed by fixing perforated plates on the periphery of the inverted wheel.

663



664

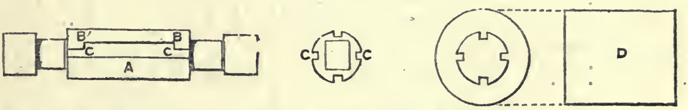


Instead of one roll being drawn towards the other, they are frequently kept in contact by direct pressure, which is effected as shown in *figs.* 663, 664.

A (*fig.* 663), lever hung to the cast-iron frame B at C, and pressing upon pin at D. When it is required to change the rollers, the pressure resulting from the lever A and weighted box E, is relieved by means of the screw tackle F.

The considerations which should be attended to in constructing a crushing mill, are, first, to make all the parts sufficiently strong to meet the varying resistances which continually occur in crushing. For this purpose, the framework to receive the rolls ought to be of good cast iron, the axles of the rollers of best wrought iron, and the cylinders of the hardest and most uniform metal. 2ndly. To design the machine, so that the matter to be crushed may be readily delivered into the hopper, sized by the circular sieves, for the dressing process; and such portions as are not properly crushed returned to the rollers without the intervention of manual labour. In order to effect this, the inverted, or raff wheel D, *fig.* 664, shown in section, ought to be made of sufficient diameter to allow the stuff, on being discharged, to descend by its own gravity, into the feed-hopper. 3rdly. To extend from the axis of the rollers, long tumbling shafts, A A, *fig.* 664, and fix on their ends the driving wheels B B, allowing a little play in the plummer blocks, so that any undue opening of the rolls may not vary the pitch line of the wheels B B, to such an extent as to endanger the safety of the teeth. 4thly. To construct the roll so that it may be readily changed, yet maintained on its axis without slipping when in motion. One of the most efficient plans for this purpose is shown in the following woodcut, in which A is the axis or arbor, and D the roll (*fig.* 665).

665



It will be seen that the cylinder roll is fitted with four internal projections; these are of the same length as the portion of the groove marked B B′, but no wider than the narrower part of the groove C C. When the cylinder is to be fixed on the axis, the studs are to be introduced into the recesses C, and the cylinder advanced into its working position, when it is turned until the studs fit into that portion of the recess between B B′, and which are then wedged to the roll by a close-fitting cutter.

5thly. The diameter of the rolls should be *decreased*, and the length *increased* in proportion to the fineness of the stuff to be crushed, since a fine material requires a longer line of contact, and not so large a grip as coarser substances.

In practice it has been found advantageous to make the roller placed on the driving shaft somewhat longer than that which is opposite, and to work the rolls by spur gearing rather than by friction, since the latter is proved to furnish less economical results than the former. It has also been found injudicious to harden the rolls by chilling; hence ordinary sand-cast rolls are most frequently employed.

The speed of the rolls varies from 45 to 60 feet per minute, but this necessarily differs with the character of the stuff to be crushed. Again, great variation is experienced in the quantities crushed within a given period, since a small amount of moisture in vein-stuff of a certain class, makes it cake, and will thus considerably reduce the produce of the mill. On the other hand, if the matter operated upon, be very dry, heavy, and brittle, as in the case of some varieties of lead ore, the produce may be much increased, since the mill can be driven at a great speed; a less bulk will have to pass for a given weight, and there will be a smaller quantity of material carried back by the raff wheel to be re-crushed.

Variable speeds have sometimes been tried in order to produce friction together with pressure at the line of contact, but it has been found that any departure from a uniform speed on the two surfaces absorbs a considerable additional amount of power, without materially augmenting the results.

The various dimensions and velocities of the rolls, crushing force and power employed, effective value of different mills, &c. now in use, may be gathered by referring to the Table at top of next page.

The *crushing machines* which are in general use at Alston Moor and the northern mines of this country, and where they have been employed for upwards of fifty years, differ in some respects from those described.

This machine is composed of one pair of fluted cylinders, *x x*, *fig.* 666, and of two pairs of smooth cylinders, z z, z′ z′, which serve altogether for crushing the ore. The two cylinders of each of the three pairs turn simultaneously in an inverse direction, by means of two toothed wheels upon the shaft of every cylinder, which work by pairs in one another. The motion is given by a single water wheel, of which the circle *a a a* represents the outer circumference. One of the fluted cylinders is

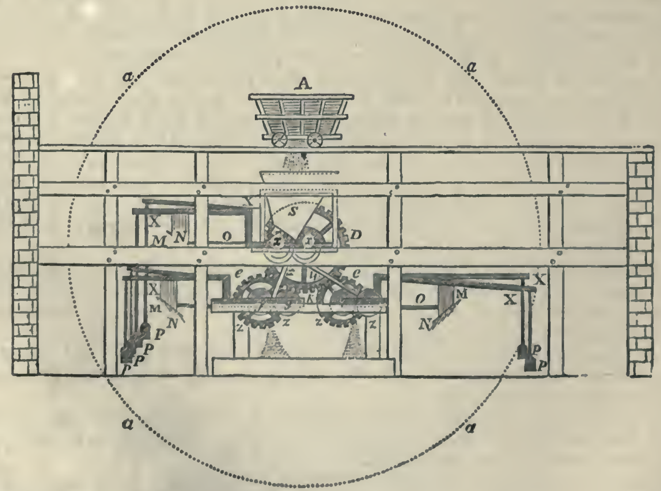
placed in the prolongation of the shaft of this wheel, which carries besides a cast-iron toothed wheel, geared with the toothed wheels *e e*, fixed upon the ends of two of the smooth cylinders. Above the fluted cylinders there is a hopper s, which discharges down between them, by means of a particular mechanism, the ore brought forward by the waggons A. These waggons advance upon a railway, stop above the hopper, and

666



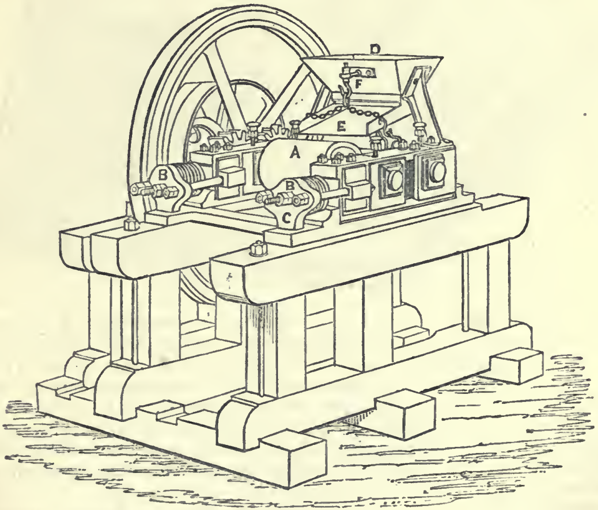
empty their contents into it through a trap-hole, which opens outwardly in the middle of their bottom. Below the hopper there is a small bucket called a shoe, into which the ore is shaken down, and which throws it without ceasing upon the cylinders, in consequence of the constant jolts given it by a crank-rod attached to it, and moved by the teeth of a wheel. The shoe is so regulated, that too much ore can never fall upon the cylinders and obstruct their movement. A small stream of water is likewise let into the shoe, which spreads over the cylinders, and prevents them from getting hot. The ore, after passing between the fluted rollers, falls upon the inclined planes N N, *fig.* 666, which turn it over to one or other of the pairs of smooth rolls.

These, the essential parts of this machine, are made of iron, and the smooth rolls are case-hardened, or *chilled*, by being cast in iron moulds. The gudgeons of both kinds move in brass bushes fixed upon iron supports *k*, made fast by bolts to the strong wood-work basis of the whole machine. Each of the horizontal bars has an oblong slot, at one of whose ends is solidly fixed one of the plummer-blocks or bearers of one of the cylinders *f*, and in the rest of the slot the plummer-block of the other cylinder *g* slides: a construction which permits the two cylinders to come into contact, or to recede to such a distance from each other as circumstances may require. The moveable cylinder is approximated to the fixed ones by means of the iron levers X X, which carry at their ends the weights P, and rest upon wedges M, which may be slidden upon the inclined plane N. These wedges then press the iron bar O, and make it approach the moveable cylinder by advancing the plummer-block which supports its axis. When matters are so arranged, should a very large or hard piece present itself to one of the pairs of cylinders, one of the rollers would move away, and let the piece pass without doing injury to the mechanism.

Besides the three pairs of cylinders which constitute essentially each crushing machine, there is sometimes a fourth, which serves to crush the ore when not in large fragments, for example, the *chats* and *cuttings* (the moderately rich and poorer pieces), produced by the first sifting with the brake sieve. The cylinders composing that accessory piece, which, on account of their ordinary use, are called *chats-rollers*, are smooth, and similar to the rollers Z Z and Z′ Z′. One of them is usually placed upon the prolongation of the shaft of the water-wheel, of the side opposite to the principal machine; and the other, which is placed alongside, receives its motion from the first, by means of spun wheel-work.

The general arrangement of a portable crushing mill may be gathered from *fig.* 667. The rollers A A are kept in close contact by means of the spring arrangement B B.

667



The spring itself is formed of discs of India-rubber alternating with discs of iron, both encircling an iron bar passing through and held firmly by the lug C. The stuff is thrown into the hopper D, and on motion being given to the rollers the inclined shoot E receives a percussive action by means of a horizontal lever or pallet attached to the shoot, and moved by one of the two cog wheels fixed on the ends of the rollers. The angle of the shoot is varied by lowering or raising the hook F.

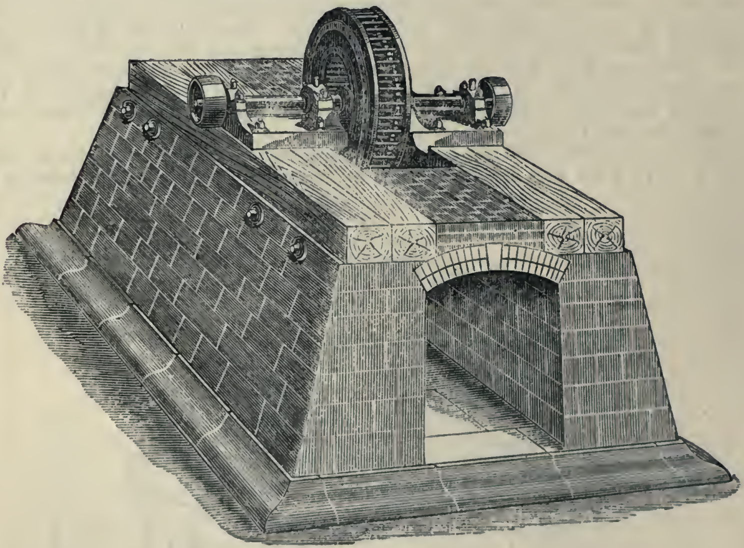
Carr's Disintegrator.—This machine, the invention of Mr. Thomas Carr, has proved to be well adapted for the reduction of semi-elastic vein-stone, ores, and material requiring to be shattered rather than crushed or ground. The illustration, *fig.* 668, shows an improved 6 feet 3 inches machine, with two solid shafts, blocks, and bedplate, the disintegrating wheels being without the necessary hood or cover. The inventor in his description states:—The machine consists of a series of four strong cylindrical iron cages, of various sizes, formed of bars with open spaces of from three to four inches between them, arranged concentrically one within another, around, and parallel with the shafts or axles and rotated therewith with extreme rapidity in contrary directions to one another by means of an open and a crossed strap, the first and third cages rotating to the right, and the second and fourth to the left, so that while there are only two motions in reality, yet from the way in which the cages intersect one another there are relatively four.

668



'The material is thrown in at the central orifice, either by shovels or elevators, and after the lumps, if very large, are broken by a stationary knife (fixed so that its blade may extend into the interior of the innermost cage, but never used with very hard materials), they are thrown out by centrifugal force from the first cage at a tangent to its circle, precisely as stones are hurled from a sling, and at a speed equivalent to that at which the beaters of the said cage are rotating (which is usually 50 feet per second) when meeting the beaters of the next cage, moving in an opposite direction, usually at 60 feet per second, a collision ensues similar to that which takes place between a cricket-ball and bat; the shock thus produced being compounded from the aggregate speed of the beaters, and the speed and weight of the material meeting them The projectile impetus of the flying material is thereby arrested, and a fresh impulse given it in an opposite direction, to meet the beaters of the third cage travelling the reverse way, and so on in like manner with the fourth one, when, if the material is of a friable and non-fibrous nature, it is shattered by these successive blows into a fine granular state, usually like that of gunpowder.

'The disintegrating wheels are made of various sizes, from 3 feet 6 inches to 6 feet 3 inches, the capacity of the latter being nearly double that of a 4 feet 6 inches machine. For pulverizing ores and vein-stones a 6 feet 3 inches size, made extra strong with steel bars, shafts, and stout wrought-iron disc plates, is recommended. At a silver-mine in Norway a 6 feet 3 inches machine is found to reduce from seven to eight tons of ore per hour, to a size varying from 0 to 4 millimeters, seventy to eighty per cent. of the quantity being suitable for jiggers, the remainder for slime tables. As a general result, the cost of reduction is reported to be one-half less than that incidental to pans and edge-runners.

In the following tabular statement will be found particulars of stuff reduced and horse-power required:—

Stuff	Size of machine	No. of Revs. per minute	Quantity per hour	Horse-power required
	ft. in.		tons	
Superphosphate guano, sulphate of ammonia, and bone-ash . . .	4 6		10 to 12	10 to 12
Rock asphalte	4 6	500 to 600	5	12
Fire-clay and shale	6 3		10 to 30	12 to 25
Moist clay	6 3	400	20	15
Blende	6 3	600	8 to 10	20
Calamine	6 3	120	15 to 20	20
Copper, silver, and other ores . .	6 3	500	7 to 8	20

Dingey's Pulveriser.—In this machine, *fig.* 669, Mr. Dingey has produced an apparatus for the reduction of hard vein-stone and ore to a fine state.

The machine is on what may be called the slab and muller principle. The operative parts consist of four plates revolving within a pan that rotates in the opposite direction. The pan is made of iron, 6 feet in diameter, with a vertical rim in which are twelve openings, each 15 inches in length by 5 inches in depth, fitted with fine perforated copper plates or wire gauze. The inner or grinding surface of the pan is lined with a set of plates or shoes, made of the best white iron, which can be detached and replaced readily when worn out. The pan revolves from right to left, or in a direction contrary to the apparent motion of the sun, borne on four friction rollers fixed on the four horizontal cross-arms of the foundation frame, and it derives its rotatory movement from the first-motion shaft by spur pinion and gearing on the exterior of the pan.

The horizontal shaft also drives a central pair of bevel wheels actuating a central spur-wheel taking into four pinions on the vertical shafts of the revolving plates, by which these plates are rotated with the sun, in a direction contrary to the pan. The plates are provided with white-iron shoes, each 30 inches in diameter, and are driven at a speed of 200 revolutions per minute. Thus it will be seen that by the combined motions the grinding surfaces are preserved in good order from wearing in grooves.

The material to be pulverised is fed into a hopper, and thence transferred by an Archimedean screw-motion to a circular launder, wherein it is subjected to the action of a stream of water, entering therewith in the centre of the pan, whence it is immediately carried under the revolving plates, ground and rapidly passed through the external gratings by the centrifugal force of the stream, and there received into a launder that conveys it direct to the buddles.

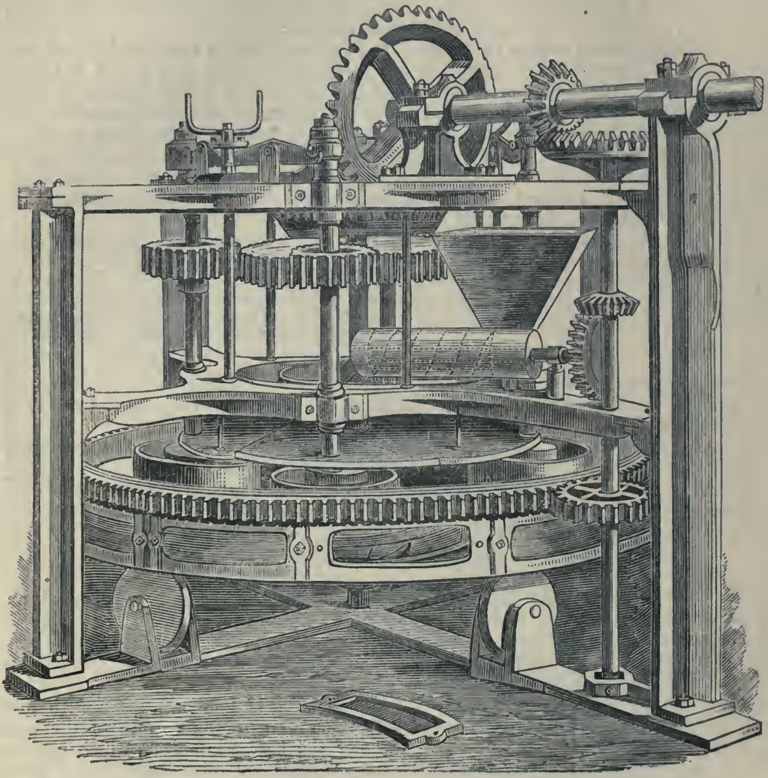
The whole machine is self-contained within four standards, with top, central, and bed plates and framing, so that it can be bolted down on a suitable foundation anywhere, for immediate work. It can be constructed in light parts, easily put together.

The motive power may be hydraulic or steam; a 10-inch single cylinder engine is sufficient for working it effectively.

This pulveriser is suited for the reduction of rough stamps'-work, and the grinding of gold and silver ores, tin roughs, skimpings, colours, clays, or earthy substances.

The work of one pulveriser is said to be equal to that of 24 Cornish heads of stamps, and the saving in working cost, in favour of the former, one-third less, the wear and tear in both cases being considered equal.

669

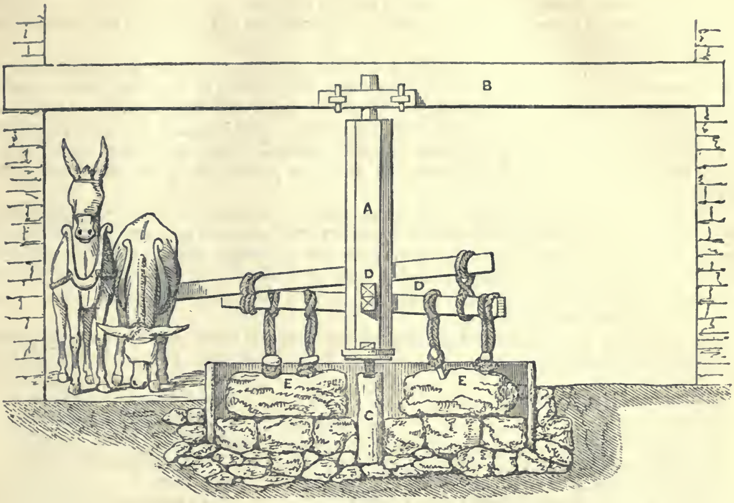


The first cost of 24 heads of stamps is about 200*l.*, of the pulveriser 150*l.* The grinding surfaces of the pulveriser lose 3 cwts. per month, whilst the stamps are said to lose 20 cwts. in the same time. At a comparative trial made at Wheal Jane, in Cornwall, on tin 'rows,' the cost of pulverising was 1*s.* 4½*d.* per ton; of stamping, 2*s.* 1¾*d.* per ton.

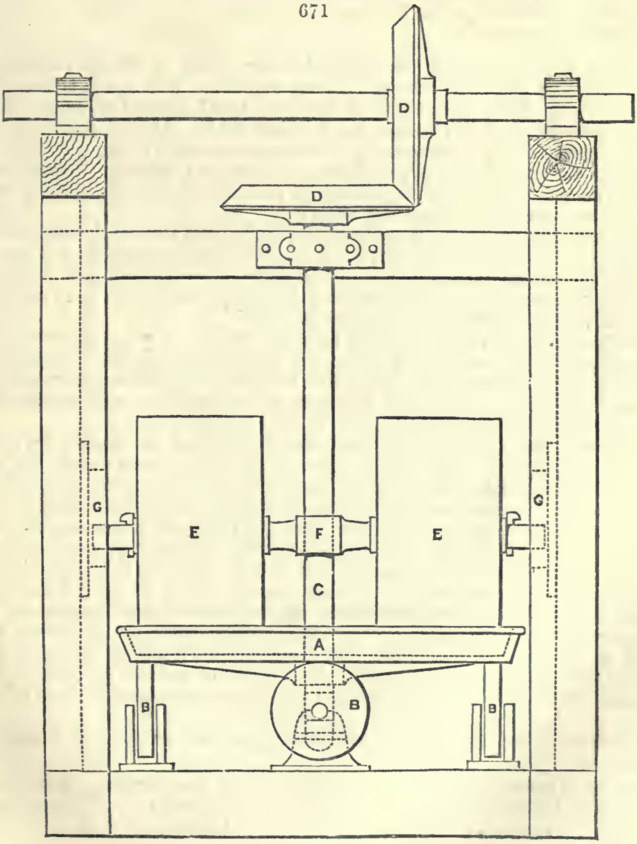
Arrastre or Tahona.—This machine is extensively employed in the mining districts of Mexico, for grinding silver ores previous to their amalgamation.

It consists of a strong wooden axle A (*fig.* 670), moving on a spindle in a beam B above it, and resting on an iron pivot beneath, turning in an iron bearing, which is inserted into a post of wood C, which rises about a foot above the ground in the centre of the arrastre. The shaft A is crossed at right angles by two stout spars D D, which form four arms, each about 5 feet long, one excepted, which is 9 feet long, to admit of two mules being attached to it; by this arm the machine is worked. The grinding is performed by four large porphyritic or basaltic stones, two of which are shown, E E. These are loosely attached by thongs of leather, or small sized rope, to the four arms, and are dragged over the ore, which is put in with water, until it is ground to a very fine slime or mud, called the *lama.* One of these machines, when in good working condition, will grind from 600 to 800 pounds weight of ore in twenty-four hours. In Guanaxuato, where the best and finest grinding is obtained in the arrastres, the lining or foundation and the grinding stones are, of coarse-grained porphyry, and form a rough surface. The cost of this apparatus in Mexico, including the paving of the bottom, and the four *metapiles* or stones, is on an average 7*l.* The original weight of a metapile is about 700 pounds, its dimensions are 2 feet 8 inches long, 18 inches broad, and 18 inches deep. Notwithstanding the hardness of the stones employed,

670



671



they are so worn as to become unserviceable in the course of ten or twelve weeks; the bottom, however, is only replaced once in twelve months.

This apparatus is well suited to patio amalgamation, but it affords bad results for the power expended.

Edge-mill.—This machine is employed for the purpose of reducing gold and silver ores to an impalpable powder. It is also used extensively in grinding flints, stones, slags, and a variety of other products. However much the details of this apparatus may vary, its principle is the same in all cases. Two vertical runners rotate on the outer circumference of a flat or slightly conical basin, and afford a frictional or grinding area *equal to the difference of distance performed by the inner and outer edges.*

The subjoined woodcut, *fig.* 671, represents a mill constructed at the Sandycroft Foundry, Flintshire. A, rotating pan, resting upon frictional wheels B; C, vertical shaft firmly keyed to pan A, to which motion is communicated by wheel gearing D. The runners E E revolve on arm F, and may be of cast iron or of stone bound with a ring of iron. These runners have no progressive motion, but have free play to rise or fall on the axis C, and in the stay slots G G.

The following dimensions and particulars are derived from one of the edge-mills recently working at the Fabrica La Constante, in the province of Guadalajara, Spain:

Diameter of edge-runner	6 feet.
Width of do. do.	centre 20 in. edge 16 in.
Weight of do. do.	3 tons 15 cwt.
Speed of runner	200 feet per minute.
Diameter of interior circle of runner	4 feet.
Gauge of stuff previous to its being ground	10 holes to the lineal inch.
Do. after it leaves the mill	60 " "
Quantity of stuff reduced per 10 hours	350 lbs.
Horse-power employed	7.

In some machines erected at the Real-del-Monte mines in Mexico the stones were 6 feet in diameter and 12 inches wide. They were fitted with a ring of wrought iron 3 inches thick. Each pair of runners revolved round a centre on its own axis, in a cast-iron basin of which the bottom was 7 inches thick. At first good results were obtained; each mill if kept constantly at work ground nearly 10 tons per week; but as their axles, and particularly the wrought-iron rings and cast-iron bottoms, began to wear hollow and to lose an even surface, the grinding rapidly diminished, and with one year's work they were completely worn out.

The chief advantage of this machine is its simplicity of construction and consequent small first cost; but all its parts require to be made of great strength, and therefore of proportionate weight: hence, in addition to the rapid wear to which it is liable, this apparatus becomes objectionable for countries where transit of heavy machinery is more than ordinarily difficult and expensive.

Horizontal mill.—For the purpose of reducing auriferous and argentiferous ores to an exceedingly fine powder, and where dry grinding is essential, no apparatus has been found more effectual than the horizontal mill. It affords the largest area of frictional surface for the least wear and tear, and accomplishes equal results at a cost not exceeding one-fourth of that incident to the edge-mill.

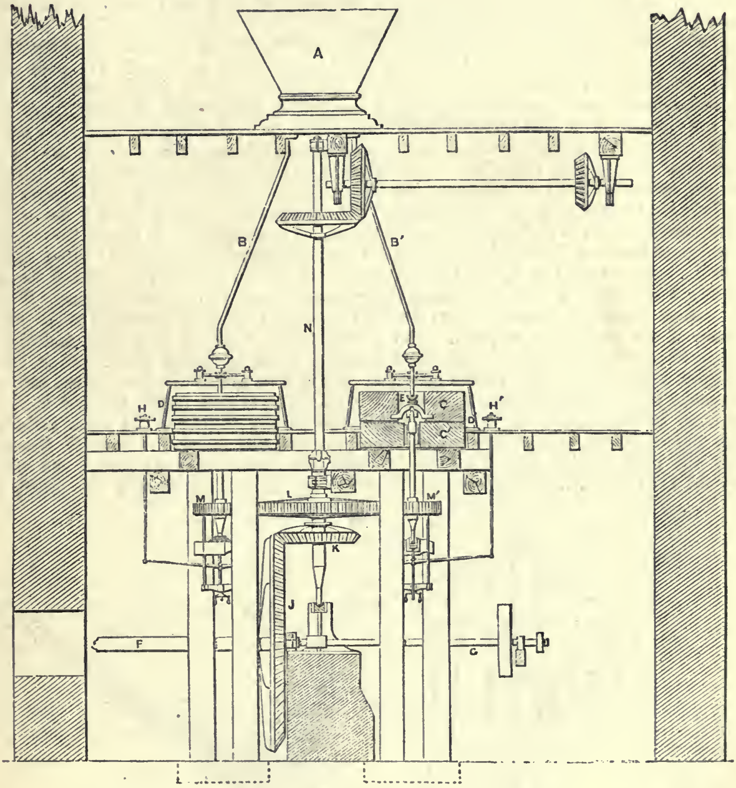
The construction of the horizontal mill will be rendered intelligible by the aid of the following illustration, *fig.* 672, in which one pair of stones is shown in section. A is a circular hopper, into which the stuff to be ground is introduced; B B, small pipes of sheet iron, for delivering the stuff between the surfaces of the runner C and bed-stone C′; D, casing enclosing the runner into which the ground material is delivered; E, hole in centre of runner; F, driving-shaft, with continuation shaft G, for giving motion to a Jacob's ladder if requisite; H H′, regulating screw for elevating runner C; J, driving-wheel; K, crown-wheel; L, wheel giving motion to pinions M M′; and N, vertical shaft, to drive any supplementary apparatus which may be required, such as sizing sieve, &c. Four pairs of stones are usually driven by the wheel L. The surface of the runner is in contact with the bed-stone, from the periphery to within one third of its diameter. The line of the runner then feathers upwards, in order to receive the stuff freely and to equalise the resistance throughout the area of the bed-stone.

The following particulars will convey much practical information relative to this machine:—

Diameter of stones	4 feet 2 inches.
Thickness of bed-stone	12 inches.
Ditto runner	14 inches.

No. of revolutions of stone per minute	108.
Gauge of stuff in hopper	100 holes to the square inch.
Ditto on delivery	3,600 ditto.
Quantity of stuff ground per 10 hours	1 ton per pair of stones.
Power employed in horses	About 5 per ditto.
Revolutions of sizing sieve	23 per minute.
Diameter of ditto	30 inches.
Length of ditto	108.
No. of holes per square inch in sizing sieve	3,600.
Character of runner	Coarse conglomerate.
Ditto bed-stone	Compact quartz, moderately hard.
Duration of runner	Average 18 weeks.
Ditto bed-stone	Ditto 22 ditto.
When dressed	Every third day.

672



From a series of practical experiments made on the same stuff by horizontal, crushing, and edge-mills, the following results have been obtained:—

	No. of Holes per sq. in. in Sizing Sieve	Quantity of Stuff ground in 10 Hours	Horse-power	Cost per Ton
		cwts.		s. d.
1. Horizontal mill	3600	20	5	2 3
2. Crushing mill	3600	13	5	1 7
3. Edge-mill	3600	13	7	6 10

Stamps.

Tin and some other of the more valuable ores are usually associated with and minutely disseminated in a hard crystalline gangue, requiring to be reduced to a fine powder before the valuable portions can be extracted.

Various contrivances have been employed for this purpose, but none of them seem to have entered into successful competition with the stamping mill. This apparatus essentially consists of a number of cast-iron pestles, each measuring about 20 inches high, and 6 by 10 inches in cross section. These are secured either to a wrought-iron or wooden lifter; a projecting arm is placed towards the top on each lifter, which may be slidden up and down so as to meet the wear of the pestle or any other irregularity. These lifters are retained in their vertical position by suitable metal or wooden supports. Motion is communicated by a revolving shaft in front, fitted with four or five projecting cams, each of which takes the arm, and lifting the pestle from 8 to 10 inches, lets it suddenly fall on the substances which may be underneath. The bottom on which the heads fall is formed by introducing hard stones or other suitable material, and pounding it until it becomes sufficiently solid. In most parts of the Continent of Europe, on the contrary, stamping mills are provided with solid cast-iron bottoms; these, however, require frequent renewal.

Around the pestles a wooden box or coffer is constructed, and covered in at the top; the back is partly open at the bottom in order to admit the vein-stuff. On each side one, and in front two openings are made, 7 or 8 inches square, which are fitted with wrought-iron frames, for the reception of perforated iron, copper, or brass plates, the bur of the punch or drill being towards the inside. As a precaution against the speedy destruction of the coffer from the constant scattering of fragments of stone, the inside is partially lined with sheet iron. The stuff to be stamped is supplied on an inclined plane, connected with a hopper at the back, in the front of which is a launder for affording a stream of water to the coffer. The stamped stuff passes through the grates into launders, and is thus directed to the floors. When water is the motive power, the number of heads is limited by the volume and fall of water available; three heads are the least number used, but a larger number is generally preferred. When steam-power is employed, a battery of heads sometimes includes 100 or more pestles. When in action these are elevated from 40 to 80 times per minute, according to the character of the stuff to be reduced. The pulverisation is said to be greatly facilitated by having four heads in the same chest or coffer, about 2½ inches apart. Each head is lifted separately, and the cams by which this is done are so disposed on the axle as to make the blows in regular succession. Great care is also taken whether it be in a large or small battery, to prevent any two pestles falling at the same instant; the object being to secure an equal load against the power. Practical dressers are not well decided as to the order in which the lifting of four heads in one coffer should take place, whether one of the inner pestles should precede the other, or whether a side pestle should be first lifted. A preference, however, seems to be given to the following method:—supposing a spectator to stand in front of a 4-head stamps, left side pestle first, right side second, right middle third, left middle last.

673

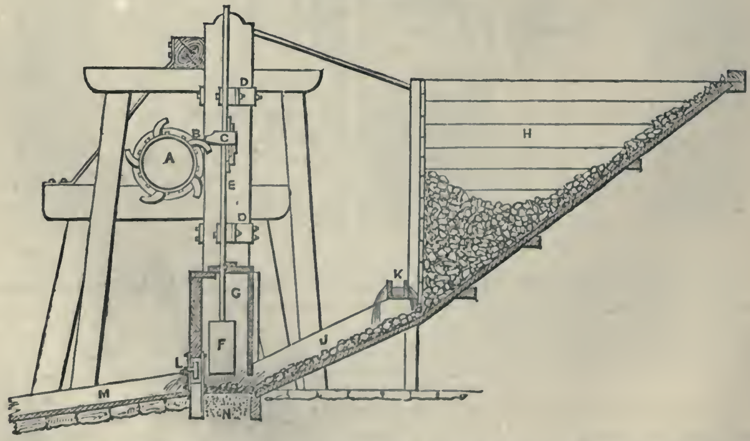


Fig. 673 represents the elevation of a steam stamps employed in Cornwall. A, axle; B, cams for lifting heads; C, tongue or projection on lifter; D D, guides for retaining lifter; E, the lifter; F, head of pestle; G, chest or coffer; H, hopper; J, pass connecting coffer and hopper; K, launder discharging water into the coffer; L, stamps grate; M, launder receiving the stuff which has been flushed through the grates; N, the bottom or bed of stamps.

The stamping process is not so simple as it may appear at first sight. Many of its particulars, such as the form of the coffer, mode of exit for the stuff, weight and rapidity of the pestles, and quantity of water employed, must be varied to suit the mode of dissemination and the structure and character of the ore, as well as of the matrix. Fineness of reduction is by no means always a desideratum, for if some kinds of stuff be reduced too low, much of the ore contained in it will be wasted, hence considerable judgment is necessary in selecting the grate best adapted to the stuff to be operated upon. Sometimes the grate is replaced by the 'flash,' which consists of a small hopper-shaped box, fitted to the front of the grate-hole. This box is provided with a shutter which is raised or lowered according as the ore is required in a fine or rough state. In dry stamping the fineness of the powder depends not on the grate, but on the weight of the pestles, the height of their fall, and the period of their action upon the substances beneath them. The following practical results are derived from the steam stamps at Polberro Tin Mines, Cornwall:—

Cylinder of engine, 36 inches diameter.
Diameter of the fly-wheels, 30 feet.
Weight of ditto, with cranks, shaft, and bolts, 42½ tons.
Power employed, 55 horses.
Reduced in 12 months, 30,201 tons of vein-stuff.
Average number of revolutions of stamp axles per minute, 8½.
Number of heads lifted per minute, 72, each 9 inches high.
Weight of each head, 600 lbs.
Average number of blows made per minute by each head, 45.
Weight of heads collectively, 19¼ tons.
Number of grates, 72.
Exposed area of front grates, 9 × 6 = 54 inches.
Ditto of end grates, 8 × 6 = 48 inches.
Number of holes to the square inch, 140.

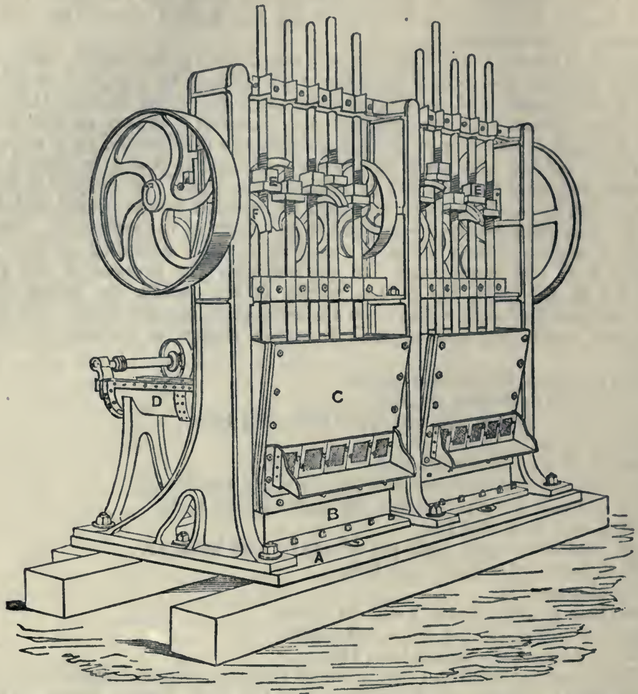
One of the most powerful and best arranged stamping engines in Cornwall, designed and constructed by Messrs. West and Sons, is at the West Phœnix Mines. Two vertical cylinders are employed, each 26 inches diameter, with 7-feet stroke. The weight of fly-wheel is 11 tons; speed of piston, 240 feet per minute. The length of stroke given by the cranks is 84 inches. The stamp axles, right and left of the engine, make 12 revolutions per minute, and drive at one and the same time 96 heads. The average weight of each stamp head is 600 lbs.; new, 800 lbs.; when worn out, 150 lbs.; dimensions of head, 20″ × 7″ × 11″, giving a sectional area of 77 inches. The number of drops per minute is 60; average drop, 10 inches. Number of heads in a battery, 4. Area of grate per battery box, 336 square inches, or 84 inches per head. Diameter of holes in grates, ½ millimeter. Weight of tin-stuff stamped per 24 hours, 18 cwts. per head. Average duration of head, 3 months. Weight of stuff stamped per head, 80 tons. Loss of iron per ton of stuff, from 9 to 10 lbs. Cost of stamp heads per cwt., 11*s.* Average weight of coal required to stamp 1 ton of stuff, 1 cwt.

The consumption of coal per 24 hours, is 4 tons, cost 7*l.* 4*s.* 0*d.* Engine driver's wages, 10*s.* Oil and grease, per month, 4*l.* The direct approximate cost of stamping, per ton of stuff, is therefore,

	s.	*d.*
Wear of stamp head	1	0
Coal	1	9½
Oil and grease		½
Total .	2	10

Fig. 674 represents a stamping mill arranged for the reduction of auriferous quartz, silver, and other valuable ores. The base consists of a cast-iron plate A, upon which is screwed a frame B, without end or side joints. A thick cast-iron bottom is dropped into this frame, upon which the stuff is pulverised. The coffer C, is made of cast-iron plates, bolted together at their edges. Each head is in connection with a grate or perforated plate. The feed is effected by means of an Archimedean screw, revolving in the trough D. The heads are solid cylinders of iron attached to wrought-iron lifters, and when in work are rotated by the action of the long cams F. The lift or rise of the head is varied by the blocks E E, which traverse a flat thread screw cut in the lifter. It will be seen that no stuff can be lost through the bottom of the coffer; whilst an economic advantage is secured by the use of a large area of perforated plate or grate. At a speed of 70 to 80 drops per minute one cwt. of stuff, is reduced to ½ millimeter size per hour, the quantity of water per head being about 4 gallons per minute.

674



German Stamping Mills.—To the German miners we are indebted for the general arrangement of the Stamping Mill. In a work, 'De Re Metallicâ,' by Agricola, edition 1621, many different mills are illustrated, showing clearly that all the essential features of the modern mill were then well known. In Rittinger's 'Lehrbuch der Aufbereitungskunde,' and other important works on Dressing, the subject of stamping mills is, generally, well and profoundly treated, and rendered clear by the aid of numerous illustrations. The following particulars of a practical character will, however, be interesting:—

Stamp Head.— Average weight, 300 lbs.
,, Minimum ,, 100 lbs.; maximum weight, 500 lbs.

Fall of Head.—Average 8 inches.
,, Maximum, 12 inches, for coarse stamping.
,, Minimum, 4 inches, for fine stamping.

Wear of Head.—Made of grey iron, after stamping 5 tons of stuff to a size of 1 millimeter.

,,	Hard tough stuff	11 to 13 lbs.
,,	Middling hard stuff	8 ,, 10 ,,
,,	Moderately ,, ...	5 ,, 7 ,,

Wear of Anvil or 'bottom' of cast iron 4 inches thick, per 5 tons of stamped stuff.

,,	Hard tough stuff	4 to 5 lbs.
,,	Middling ,, ...	3 ,, 4 ,,
,,	Moderately ,, ...	1 ,, 2 ,,

Order of fall.—Centre head first, then right and left.

Number of Heads in a Battery.—Three, at most five.

Stamping Results.—Weight of head, 250 lbs., fall 8 inches, making 60 drops per minute, will produce, in 24 hours,

,,	Stuff, 2 millimeters size	30 cubic feet
,,	,, 1 ,,	16 ,,
,,	,, ½ ,,	9 ,,

Cast-iron Bottoms—Will afford 3 per cent. higher result than can be obtained from a stone bottom.

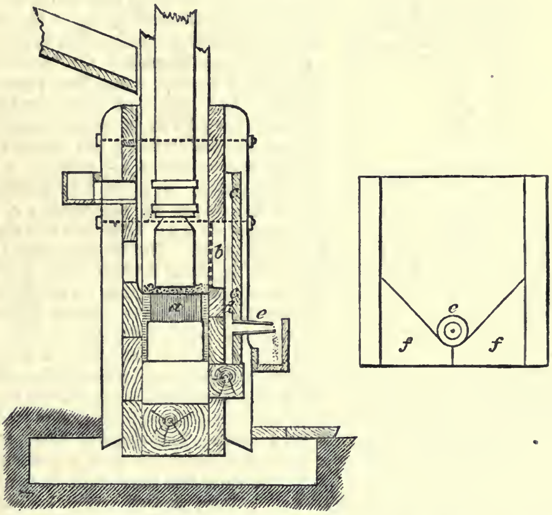
Water, per minute, per head:

	For direct discharge	3 to 5 gallons.
,,	Large stuff, 4 to 8 millimeters	12 gallons.
,,	Rough ,, 2 ,, 4 ,,	6 ,,
,,	Fine ,, 1 ,, 2 ,,	3 ,,

Space between head and inside of battery box 1 to 1½ inch, except at the side at which the stuff is introduced, where it is 2½ to 3 inches.

Some years ago the late P. Ritter von Rittinger contrived a battery box for stamping under water, *fig.* 675. *a*, cast-iron bottom wedged into the box; *b*, stamp screen set 1½ to 3 inches above the bottom; *c*, water-tight panel, made of strong boards fixed within a short distance from the front of battery box, the opening *d* extending several inches below the anvil of the battery; *e*, outlet-pipe, in the centre, and near to the lower edge of the panel. The bottom of the channel between the battery box and panel is inclined from both sides towards the outlet *e* by means of strips of timber inserted in the angles. The amount of discharge through the pipe *e* can be regulated, and the pipe is so fixed, that the water rises, and is kept at such a level above the stamp head, that the fall takes place entirely under water. At Schemnitz, the duty obtained by the use of this battery box is said to be nearly 50 per cent. greater than that obtained from the box previously in use.

675

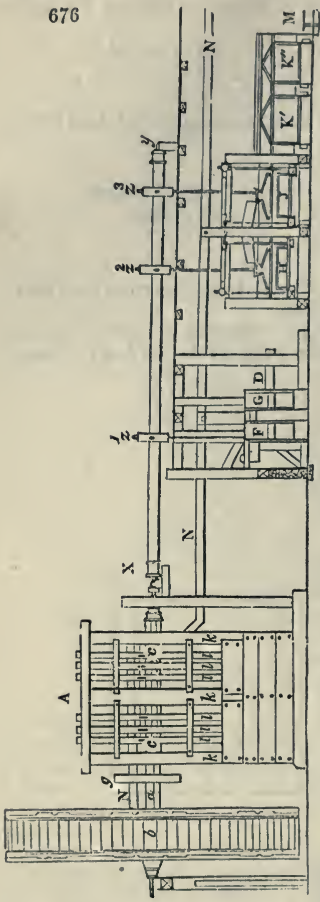


The feeding of the stamps is in some establishments effected by self-feeding hoppers, in others by manual labour; the batteries having, in the latter case, a small hopper attached, into which the stuff is thrown with shovels.

Fig. 676 is a set of stamping and washing works for the ores of argentiferous galena, as mounted at Bockwiese, in the district of Zellerfeld, in the Hartz.

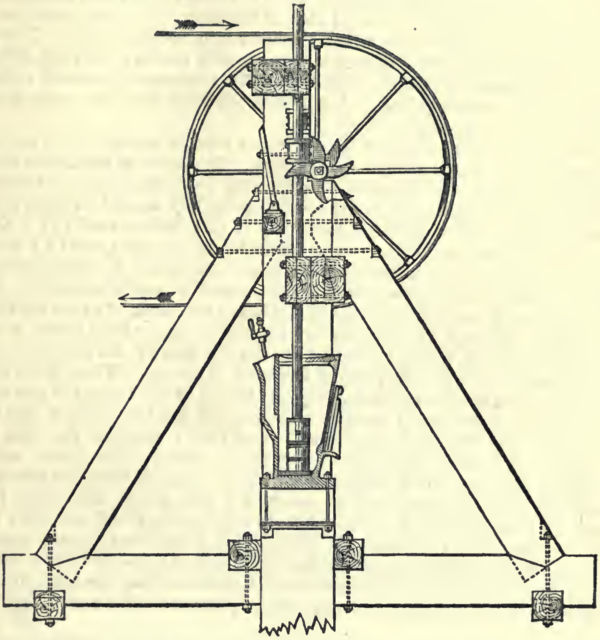
A is the stamp mill and its subsidiary parts: among which are *a*, the driving or main shaft; *b*, the overshot water-wheel; *c c*, six strong rings or hoops of cast iron for receiving each a cam or tappet; *g*, the brake of the machine; *k k k*, the three standards of the stamps; *l l*, &c., six pestles of pine wood, shod with lumps of cast iron. There are two chests, out of which the ore to be ground falls spontaneously into the two troughs of the stamps. Of late years, however, the ore is mostly supplied by hand; the watercourse terminates a short distance above the middle of the wheel *b*. There is a stream of water for the service of the stamps, and launders proceeding from it, to lead the water into the two stamp troughs; the launder of discharge is common to the two batteries or sets of stamps through which the water carries off the sand or stamped ore. There is a moveable table of separation, mounted with two sieves. The sands pass immediately into the launder placed upon a level with the floor, and separated into two compartments, the first of which empties its water into the second. There are two boards of separation, or tables, laid upon the ground, with a very slight slope of only 15 inches from their top to their bottom. Each of these boards is divided into four cases with edges; the whole being arranged so that it is possible, by means of a flood-gate or sluice, to cause the superfluous water of the case to pass into the following ones. Thus the work can go on without interruption, and alternately upon the two boards. There are winding canals in the labyrinth, N, N, N, in which are deposited the particles carried along by the water which has passed upon the boards. The depth of these canals gradually increases from 12 to 20 inches, to give a suitable descent for maintaining the water-flow. At D two percussion tables are placed. F, G, are two German chests. H, J, are two percussion tables, which are driven by the cams *z z*, fixed upon the main shaft X *y*. K′ K″ are two sloping sweep tables (*à balai*). The *German chests* are rectangular, being about 3 yards long, ½ a yard broad, with sides 18 inches high; and their inclination is such that the lower end is about 15 inches beneath the level of the upper. At their upper end, usually called the *bolster*, a kind of trough or box, without any edge at the side next the chest, is placed containing the ore to be washed. The water is allowed to fall upon the bolster in a thin sheet. The *sleeping tables* have upright edges; they are from 4 to 5 yards long, nearly 2 yards wide, and have fully a yard of inclination. The tables are sometimes covered with cloth, particularly in treating ores that contain gold, on a supposition that the woollen or linen fibres would better retain the metallic particles: but this method appears on trial to merit no confidence, for it produces a very impure *Schlich.*

676



Californian and Nevada Stamps.—The foundation is generally formed of vertical timbers, set close together, and firmly braced by means of cross timbers and bolts. Each piece of timber, 2 feet by 18 inches, is from 6 to 12 feet long, according to the nature of the ground, and height of the discharging grate. When the timbers are in position, the adjacent earth is firmly rammed together, and the foundation thoroughly consolidated. The sill, vertical, and diagonal timbers are strongly connected and laterally braced so as to render movement all but impossible. The stamps box is placed directly upon the vertical timber foundation, and is secured by bolts. The length of box shown in *fig.* 677, is 4 feet 6 inches, depth 4 feet, inside width 12 inches; and is so cast that bottom, sides, and ends, are in one piece. The feed opening is an aperture 4 inches wide and 3 feet 9 inches long. The discharge or grate opening is 45 inches long and 10 inches deep, the bottom edge being 4 inches above the top of the die. The grate is attached to a frame, secured by wedges in grooves cast in each end of the box, and by two lugs in front of the discharge opening. It is usually inclined at about 7½° with the view of facilitating the discharge of the stuff. For wet stamping, Russian sheet iron is employed, having holes varying from one half to one millimeter in diameter. The grate is attached to the frame by means of screws and to confine the 'flash' of the stuff, a piece of canvas hangs over the grate. The top of the cast-iron anvil, is of the same diameter as the shoe, and is from 4 to 6 inches high; the bottom is commonly square, large enough to extend from side to side of the battery box, the corners being removed, so that it may be withdrawn by the use of a pick point. The shoe is of the hardest white iron, 8 inches diameter and 6 inches high, with a shank tapering from 2 to 4½ inches. The shoe is attached to the head, by placing strips of pine wood, ¼ of an inch thick and ½ an inch wide around the shank. The strips of wood are tied by means of cord, and the head lifter gently driven home, the shoe striking a piece of timber until it is firmly fixed. When it is necessary to remove a shoe it is accomplished by driving a key into a key-way formed in the head for this purpose. The lifter is usually turned to a diameter of 3 inches, and is from 10 to 12 feet long; the head is of tough cast iron, 8 inches diameter and 15 inches high. At the top is a hole, slightly conical, about 7 inches deep, with a drift way for forcing the lifter from the head.

677



A stout wrought-iron hoop is put on hot at the top and bottom of each head so as to give it additional strength. To fix the lifter in the head a few blows of the hammer are first necessary, then a few beats in the ordinary way.

The gib tappet is 8 inches in diameter and 8 inches long, and made hollow so as to receive the lifter. The gib itself is two inches wide, nearly as long in the tappet, and with its inner face curved, to correspond to the circular hole, through which the lifter passes. The gib being fixed in place and the tappet put upon the lifter, is forced against the latter by means of two keys which are driven to such an extent as to maintain the tappet firmly in its position. This method is found to be in all respects satisfactory, and is superior to screw threads or key seatings. A partial revolution of the head is effected at each lift, and continues to some extent during the fall, causing, as it is alleged, a grinding as well as a stamping effect, and wearing the shoe more evenly than if no circular movement occurred. Guides of hard wood are preferred to iron. One set is placed below the tappet, about a foot above the battery box, a second set within 6 inches from the top. The width of guide is from 10 to 15 inches. Each cam piece has usually two arms, with faces 2 or 3 inches wide, the casting itself being of tough cast iron; the curve of the face is the involute of a circle the radius of which is equal to the distance between the centre of the cam axle and the centre of the lifter. The bottom of the cam is consequently perpendicular to the radius of the curve of the cam, and the stamp-head is uniformly lifted in a vertical line. In practice, the line of curvature necessary for the cam is obtained by taking—(1) a circular piece of board having a radius equal to the horizontal distance from the centre of the cam axle to the centre of the lifter; (2) a piece of thread with a pencil-point attached to the end; (3) measuring the desired lift of the head on the thread from such pencil-point, then attaching the end of the thread to the periphery of the circular piece of wood; (4) winding the thread on the periphery of the wood, laying the wood on a smooth board, unwinding the thread whilst being stretched to its utmost limit and at the same time tracing with the pencil-point the required curve. As it is desirable that the cam may be in contact with the tappet at the least practicable distance from the axle the curve is modified by giving to the cam a greater curvature near each of its ends. The cam point is also as near to the lifter as is practicable, without coming into actual contact. The axle is of round iron, from 4 to 6 inches diameter, turned, with two key-ways cut, for the purpose of securing the cams in their places. In some instances the shaft extends the entire length of the various batteries, but a separate light shaft for each battery of four or five stamps is preferred.

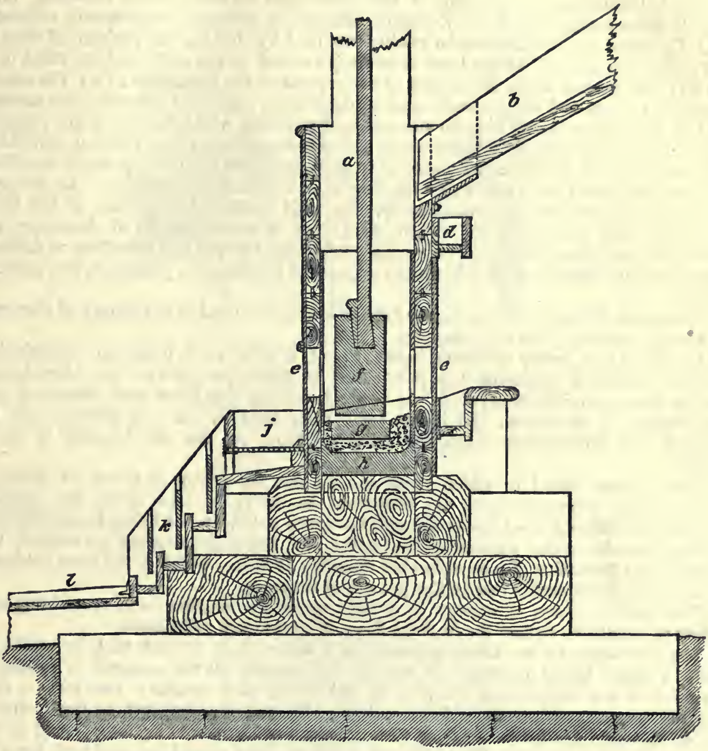
In such case each axle receives its motion from a counter shaft, the two shafts being connected together by means of belts and riggers. The order in which the heads fall varies in different mills, but the condition of having an uniform load on the engine at one and the same time, as well as a free and effective fall, should be observed. In a five-stamp battery the order of fall is commonly: (1.) Middle head; (2.) End right hand head; (3.) Second head on left; (4.) Second head on right; and (5.) End stamp head on left. The key-ways in the cams are cut so that when the latter are fixed, the heads are lifted in the order above stated. Occasionally quartz is crushed dry, but much more frequently water is admitted to the boxes by means of gas-pipes fitted with regulating cocks. When it is necessary to hang one or more of the heads a workman lays a smooth piece of board 1½ inch thick on the face of the cam as it is rising to the tappet, and holds the board whilst the head is lifting. When high enough a stud, articulated on a small shaft extending the length of the battery is put under the tappet, when the cam will freely revolve. To set the head in motion the board is again introduced and the stud withdrawn. The power required for each head of average weight, including friction, is about 1½ horse. The belts are manufactured out of a combination of canvas and India-rubber, and from the first motion to the intermediate shaft are sometimes as much as 2 feet wide. The belts from the second motion to the cam shaft are made of thinner material and are from 12 to 14 inches wide. The shafts are frequently provided with cast-iron driving riggers. In some cases, however, the riggers are constructed of either kiln-dried wood, with arms inserted in a cast-iron boss and then turned off in place, or they are built solid of well seasoned planks, on bored bosses and concentrically turned, after being keyed to the shaft.

In Colorado the stamp heads, are often, however, run more slowly, and have a greater fall than the heads employed in the Californian and Nevada mills. The average weight of head is from 500 to 600 lbs., minimum beats 15, maximum 40, average 30 per minute, with a fall of from 12 to 18 inches. The heads generally revolve and fall in an iron mortar, 4 or 5 feet long, 12 or 14 inches wide, the bottom being sometimes 9 or 10 inches thick. This casting is commonly laid on a block of timber, which rests on cross timbers. The mortar, is recessed for dies, having an octagonal base and a wearing cylindrical head of iron, commonly 8 inches in diameter. The battery box is entirely of wood and arranged so as to be readily removed. The 'grates' are of sheet iron, with very fine slot holes, about ⅛ of an inch long, and an equal distance apart.

The grate is usually from 9 to 10 inches wide, and the length of the box. It is fitted in a frame which is kept in position either by means of wedges or set screws. The lifter stem has usually a screw thread for adjusting the tappet, the latter being lightened by means of a key, driven in ways, cut in the tappet and stem. When the driving power is a steam-engine, power is frequently transmitted to a counter shaft by means of a belt and to the stamps axle by spur wheels. This axle, as in Cornwall, usually extends the length of the whole of the batteries. Water is introduced into each battery box, the quantity being sufficient to carry out the stuff as soon as it is reduced to the necessary degree of fineness. For the milling of gold ores, the ends of the battery box are lined with amalgamated copper plates, a third plate 10 or 12 inches wide, the length of the battery fixed in a frame, is secured in an inclined position behind the stamps, whilst a fourth but a narrower plate is placed on the front side of the box. The average weight of stuff stamped per day is believed to be less than a ton per head; the volume of water is, say 2,500 gallons per ton of rock. The tendency of improvements is in the direction of employing lighter heads, a lower fall, and an increased number of beats per minute.

Australian Stamps,—At the Port Phillip Company's Works, Clunes, Victoria, the battery box is set on a foundation of timber shown in *fig.* 678; the length of timbers in the under framing being 10 feet, depth 15 inches. On these transverse timbers are set running timbers 6 feet 6 inches wide, surmounted by logs having an aggregate width of 36 inches. On the latter rests the battery box. This is constructed partly of wood and partly of iron, with an internal iron casing. *a* lifter, *b* feeding shoot, *d* launder for supplying water, *e*, *e* back and front grate ways 9 inches wide, *f* stamp head, *g* cast-iron bed 3 inches thick and 10 inches wide, *j* perforated plate, *k* mercury boxes. The sectional width of head is 9 inches, depth 20 inches; width of internal casing 15 inches, width of battery box 18 inches, depth from feeding shoot to bottom of foot plate 4 feet 6 inches, depth from bottom edge of grate to surface of stamper plate 4½ inches. The weight of each head and lifter is 800 cwts.; number of blows, made per head per minute, 75; quartz reduced per head per 24 hours, and passed through screens having ten holes per lineal inch, 4 tons; quantity of water required per head per minute 8 gallons or 2880 per ton of quartz. The following statistical matter, compiled from R. Brough Smyth's most able and exhaustive work on the 'Gold-Fields and Mineral Districts of Victoria,' will indicate a variety of details connected with stamping machinery in that wealthy and thriving colony:—

678



Mineral District	Weight of Stamp head with shank and lifter	Fall of stamp head	No. of blows of stamp head per minute	Quartz crushed per head in 24 hours	No. of holes per square inch in grate	Horse-power per stamp head	Gallons of water per stamp head per hour	Loss of mercury per head per week
	Cwts. Cwts.	in.		Cwts. Cwts.				oz.
Ballarat . .	3¼ to 8	7 to 10	50 to 80	18 to 70	40 to 224	1 to 1½	220 to 600	nil to 8
Beechworth . .	4 „ 7¾	5 „ 16	45 „ 80	20 „ 80	65 „ 144	¾ „ 2	70 „ 480	nil „ 8
Sandhurst . .	5 „ 8	8½ „ 18	45 „ 72	15 „ 60	64 „ 130	¾ „ 1	211 „ 575	nil „ 4½
Maryborough .	4 „ 7½	8 „ 12	60 „ 80	30 „ 60	60 „ 140	¾ „ 1¾	200 „ 1116	½ „ 8

In addition, Mr. Smyth gives the following particulars of cost of crushing quartz and extracting the gold :—

	Ballarat	Clunes	Sandhurst	Maryborough	Castlemaine	Maldon
Average cost of raising and delivering one ton of quartz at the mill .	5/10½	12/10 to 27/1	8/10½	21/8	7/8½	27/4
Stamping quartz and extracting gold	2/10	7/5	2/9½	8/	3/9	14/4½

The following are among some of the advantages afforded by the stamping mill: (1.) It gives a direct dead blow, highly effective in reducing semi-elastic minerals; (2.) The force of the blow can be readily modified by shifting the position of the tappet; (3.) The free fall of the head is entirely exerted on the stuff, and its effect is in no way transferred to the framework or other parts of the apparatus; (4.) The repairs required are few and simple, such as an ordinary mine smith and carpenter can execute; (5.) A battery of heads may be stopped and repaired while the others are running; (6.) Single heads may be thrown out of use without affecting the working conditions of the mill; (7.) The mineral under treatment receives the least possible handling, and can be flumed at once either to dressing or amalgamating apparatus; (8.) Minerals can be readily reduced to a condition of fine sand, provided the faces of the heads are good; (9.) Speed, lift, the weight, size, form of head, position of discharge, and extent of grate way, admit of numerous variations to suit the condition of different minerals, and afford a wide field for the exercise of intelligence, judgment, and practical skill.

Pneumatic Stamps.—The ordinary form of stamps, as used in the county of Cornwall, is a simple and very old type machine.

It consists of heavy cast-iron heads, about 6 cwts. each, fixed on wrought-iron square shanks, a projecting tappet attached to the upper part of the lifter, against which the revolving cams come into contact, raising the lifter and liberating it at the height of 10 inches; the heavy head then falls by its own gravity, and impinges with considerable force the crushing blow on the ore beneath it in the coffer.

The greatest speed to which these stamps can be driven is about 60 blows per minute; and consequently in tin stamping, the heavy particles of tin ore, although reduced to sufficient size to pass through the grate holes, by not being kept sufficiently agitated, settle to the bottom of the coffer, and there get further pulverised, thus causing the formation of a considerable quantity of slime, which is far from desirable, and entails considerable loss in the process of dressing.

This ancient form of stamps is a rude primitive machine, and something more effective should be looked for in these days of mechanical refinement.

If a man were to set about pulverising a stone, it is evident that he would not take a large heavy hammer, of say 25 lbs. employ all his strength in raising the hammer a few inches, and allow it to fall of its own weight; but with a much lighter hammer, with quicker blows, and using his muscular strength on the downward blow, he would get far better duty with the same expenditure of power. And so with the *machine* for obtaining the same end, a lighter head should be used and force employed in the downward blow.

To meet these discrepancies, evident and important as they are, the pneumatic stamps has been devised.

As early as 1856 the idea was conceived of employing an air-sponge or cushion in the working of steam-hammers, by Mr. Carr, an Englishman; since then, many patents have been taken out for various plans of employing springs, and air-cushions for hammers.

The same principle applied for stamping purposes is employed in the pneumatic stamps patented by Mr. W. Husband of Hayle, Cornwall.

These stamps, generally two heads to the coffer, consist essentially of a cast-iron crank, to which is attached by means of a forked connecting-rod, a pneumatic cylinder; the stamps' lifter is a hollow turned wrought-iron shank, fixed to head, with a metallic piston attached; the piston works in the air cylinder, with the lifter projecting through either end, and the head operating in a closed cast-iron coffer.

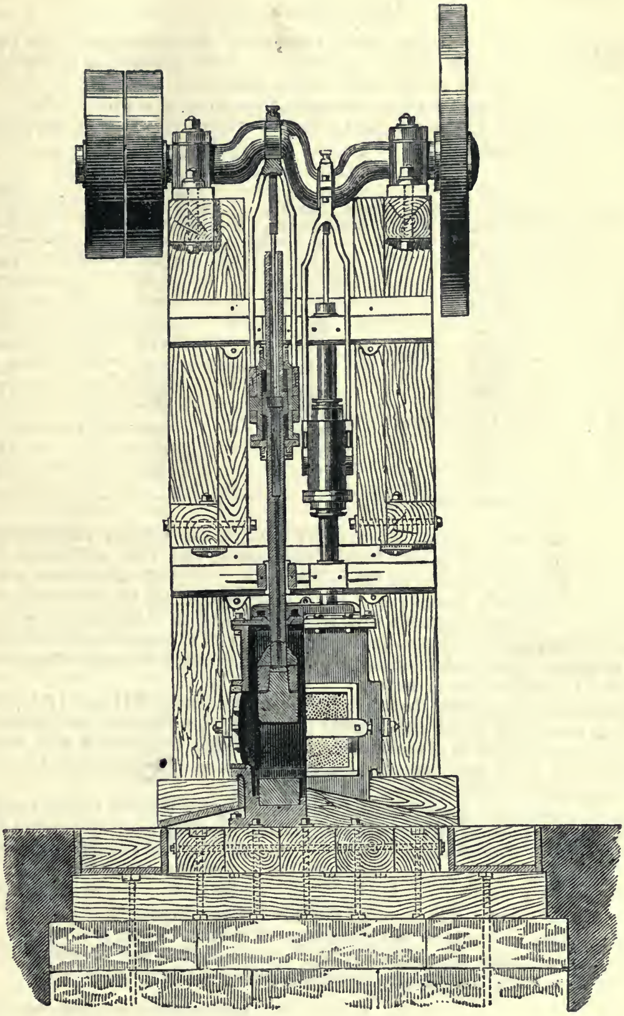
A rotatory motion being given to the crank, the cylinder is raised, the air it contains becomes compressed beneath the piston and the lifter with head attached, about 310 lbs. raised to the height of about 16 inches; as soon as the crank turns the centre, the compressed air yields back the force employed in its compression, and consequently a violent blow is given on the coffer.

A stream of water flows through the hollow lifter, discharging above the head into the coffer: this serves the double purpose of removing the heat generated through the compression of the air, and for providing the necessary water for stamping purposes.

Another object in making the lifter hollow, is to prevent crystallisation of the iron, from constant striking, and also to reduce its weight; the greater the weight of head, and the less in the lifter the better.

Arrangement is also made for giving the head a rotatory motion, so as to ensure an even wear on the face of the stamps' head.

679



These stamps are driven at about 150 blows per minute, and will reduce from *nine* to *eleven* tons of ore per head per day. At New Rosewarne Mine, Gwinear, 1¼ ton of stuff has been stamped with a consumption of 1 cwt. of coal, and from 6,000 to 7,000 tons of stuff with the loss of 5 tons of iron in the stamp heads. The stamps are exceedingly portable, which is a great advantage, and can be taken to pieces, carried to any part of the mine and erected with its portable engine in a few hours, requiring but little foundation.

A small battery may be used for prospecting purposes, and worked by horse or bullock power whenever it might be desirable to do so, the machine being made sufficiently portable for loading on a bullock dray.

In difficult or mountainous countries, where transport is expensive and dangerous, it is desirable that every part of a machine should be as light as possible, in order that it may be carried by mules or drawn by oxen; in the above machine this object is easily obtained, and several have been constructed for the gold-mines in Africa, Australia, and America, as well as for the mines of Cornwall and other parts of Europe.

Jigging Machinery.

In the jigging sieve only the initial velocity of the substances to be separated is obtained at each stroke. Were, however, the sieve plunged to a depth of, say 20 or 30 feet, the various grains would settle themselves according to their several velocities of fall, one over the other, assuming them to be of a uniform size.

The following Table shows the fall of various spheres of water in one second, the depth being in millimeters:—

Diameter Millimeters	Gold. Spec. Grav. 19·2 millimeters	Galena. Spec. Grav. 7·5 millimeters	Blende. Spec. Grav. 4 millimeters	Quartz. Spec. Grav. 2·6 millimeters
17·43	2614	1570	1066	780
11·32	2197	1320	898	653
8·71	1849	1110	750	550
6·16	1569	935	624	461
4·36	1307	785	514	385
3·08	1097	660	448	326
2·17	340	555	378	275
1·54	780	465	317	231
1·08	653	393	266	194
·77	548	327	210	163
·54	456	275	188	137

Let it be supposed that it is necessary to know the relative velocities of fall in water, of grains of gold, galena, blende and quartz, each 1·08 millimeter diameter. An inspection of the table shows the fall of gold to be 653 millimeters per second, galena 393, blende 266, quartz 194. Then, let it be assumed that the diameter of the grains vary; the foregoing table will show that gold of 6 millimeters would settle at bottom at the same instant as grains of galena 17·4 millimeters diameter, and that grains of galena 3 millimeters diameter would fall at about the same velocity as grains of quartz $11\frac{3}{10}$ millimeters diameter.

If, further, it be supposed that the grains varied between 8·71 and 17·4 millimeters diameters, some time would elapse after gold of 8·71 millimeters had settled before the galena would begin to deposit itself. With blende, however, of 8·71 millimeters, and quartz of 17·43 millimeters diameter, the grains of both would appear at the bottom almost at the same instant.

Two rules have been promulgated for determining the relative volumes of grains of different densities having the same velocity of fall in water, each rule giving a slightly different result. One in which the proportion between the maximum and minimum size of the grains is as the specific gravity of one to the other; the other in which the proportion is found by deducting 1, the equivalent of water, from the specific weight of the substance, and dividing the less into the greater.

Rule 1. Suppose a pile of stuff to consist of galena, blende, and quartz, and it is necessary to determine the maximum and minimum diameter of grains of each of these substances which shall have an equal velocity of fall in water. Then,

	Diameter of Grains having equal Velocity of Fall
Galena and Blende 4·0 : 7·5 :: 1 = 1·87 or	Galena 1 diam. Blende 1·87 diam.
Blende and Quartz 2·6 : 4·0 :: 1 = 1·53 „	Blende 1 „ Quartz 1·53 „
Galena and Quartz 2·6 : 7·5 :: 1 = 2·88 „	Galena 1 „ Quartz 2·88 „

Rule 2. If a pile of stuff consists of galena, blende, copper pyrites, and quartz, what will be the maximum and minimum diameter of the grain having an equal velocity of fall in water?

Diameter of Grains having equal Velocity of Fall

$$\left.\begin{array}{ll}\text{Galena} \;.\; & .\; 7{\cdot}5-1=6{\cdot}5 \\ \text{Blende} \;.\; & .\; 4{\cdot}0-1=3{\cdot}0\end{array}\right\} \text{ Then } \frac{6{\cdot}5}{3{\cdot}0}=2{\cdot}1 \text{ or } \quad \text{Galena 1 diam. Blende 2·1 diam.}$$

		Diameter of Grains having equal Velocity of Fall	
Copper Pyrites 4·1 − 1 = 3·1 Blende . . 4·0 − 1 = 3·0	Then $\frac{3{\cdot}1}{3{\cdot}0} = 1{\cdot}03$ „	Copper Pyrites 1 diam.	Blende 1·03 diam.
Copper Pyrites 4·1 − 1 = 3·1 Quartz . . 2·6 − 1 = 1·6	„ $\frac{3{\cdot}1}{1{\cdot}6} = 1{\cdot}9$ „	Copper Pyrites 1 „	Quartz 1·9 „
Galena . . 7·5 − 1 = 6·5 Quartz . . 2·6 − 1 = 1·6	„ $\frac{6{\cdot}5}{1{\cdot}6} = 2$ „	Galena 1 „	Quartz 4·0 „

As the latter rule will allow of a wider difference between the minimum and maximum diameter of the grains to be treated than the former, and is used by many practical engineers, it will, perhaps, be best to employ it, particularly in connection with ores and gangue, of a simple character; but apart from the rule itself, it will be desirable to bear in mind the following observations: (1) It will be impossible to separate by any hydraulic jigger a mixture composed of grains having an *equal* velocity of fall. (2) Separation of grains can only be effected by bringing the diameter of one set within such limits that the other will pass it within the descending range of the process. (3) If galena of 1 diameter and blende of 3 diameters are treated, the blende will be found at the bottom; galena of 1 diameter and blende of 2 diameters will be associated more or less together; whilst galena and blende of 1 diameter will fall with such a wide difference in their respective velocities as to leave each other at a very early period. The necessity of sizing stuff into equal volumes, so as to take advantage of the difference of fall due to their respective densities is therefore evident, as well as the fact that the nearer grains of stuff of equal volume approximate to each other in density, the greater length of fall will be requisite for their absolute solution.

Hand Sieve.—This apparatus, *fig.* 680, is formed of a circular hoop of oak, ⅜ths of an inch thick and 6 inches deep. Its diameter ranges from 18 to 20 inches. The bottom is made of copper or iron wire meshes, of various sizes. Sometimes perforated copper plate is employed, when the sieve is termed a copper bottom. The sieve is shaken with the two hands in a cistern or tub of water, an *ore vat* is, however, sometimes employed, and either fixed horizontally or in an inclined position. In using this sieve the workman (*fig.* 680) shakes it in the vat with much rapidity and a dexterous toss till he has separated the totally sterile portions from the mingled as well as from the pure ore. He then removes these several qualities with a sheet-iron scraper, called a *limp*, and finds beneath them a certain portion of enriched ore.

680

Deluing Sieve.—This sieve A, *fig.* 681, is either constructed with a hair or canvas bottom; the former is more expensive. but more durable. Its peculiar application is chiefly for the final treatment of ores previous to being put to pile, such ores having first passed through the finest jigging sieves, yet still maintaining a certain degree of coarseness and bearing a high specific gravity.

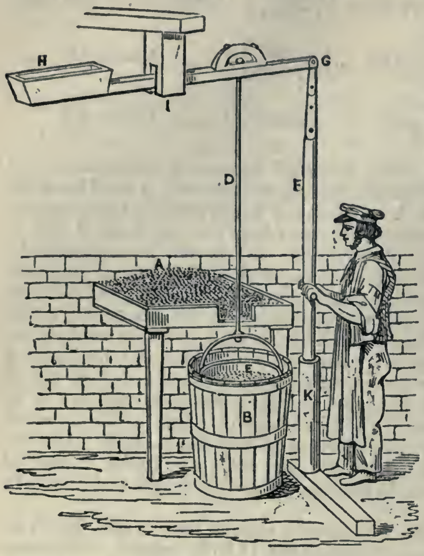
In the separation of ores from light waste, or such minerals as approach one another somewhat closely in their densities, this form of sieve is both good and effective, but to use it properly a considerable amount of dexterity and practice is requisite.

681

There are two principal methods of using it; by one a motion is given, whereby the waste is being constantly projected and carried over the rim into the kieve by a current of water forced through its bottom. This mode of treatment is adapted for poor ores. In the second case, when the ore is nearly pure, but still associated with a heavy gangue, a motion is given to the sieve whereby the water is forced through the ore, and made to traverse the surface of the mineral in concentric circles. This motion collects the waste into the middle of the clean result. By the first method about six tons per day may be passed through by each workman and enriched for the second operation. The weight of the sieve varies from four to five pounds, its diameter is twenty-six inches, depth four inches, and cost from 2*s.* 3*d.* to 2*s.* 6*d.*

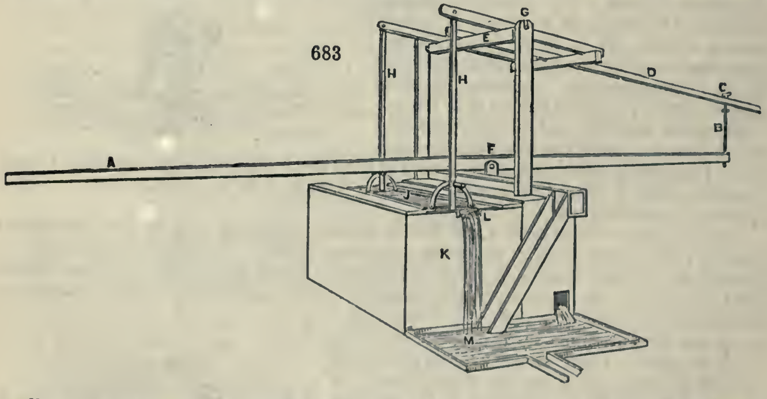
A jigging sieve, constructed as shown in *fig.* 682, is sometimes employed on the Continent. A represents the table on which the mineral is placed; B is a large kieve of water, in which the sieve is suspended by the iron rod D, set in motion by means of the arrangement F, G, H, suspended at I, and having at the extremity H a box for the reception of small stones, to be used for the purpose of counterpoising the weight of the sieve and several fittings. By moving the rod F, sliding in K, the workman gives the required motion to the sieve, and when its contents have been sufficiently washed, he removes them by the same means as when the hand sieve is employed.

682



Hand Jigging or Brake Sieve.—The brake sieve, *fig.* 683, is of rectangular shape as well as the cistern in which it is agitated. A, wooden lever, having its axis at F; B, piece of wrought-iron bolted to the end of lever A, whilst its upper end passes freely through a slot opening in lever D, and having two shoulder projections C; E, axis of lever D; G, bars connected with lever D, supported on axle E, and from which the iron rods H H depend; J, rectangular sieve; K, within the hutch; L, shoot for overflow of water; M, receptacle for retaining any fine ore which may escape with the water from L, as well as for receiving the hutchwork. A boy placed near the end of lever A, by the action of leaping, jerks it smartly up and down, so as to shake effectually the sieve J. Each jolt not only makes the fine part pass through the meshes, but changes the relative position of those which remain in the sieve, bringing the purer and heavier pieces eventually to the bottom. The mingled fragments of ore and stony substances lie above them, while the poor and light pieces are at the top: those are first scraped off by the *limp*, then the mixed portion, and lastly the ore, which is usually carried to the ore heap. The sieve frame may be made 2 × 4 feet inside, and 8 to 9 inches deep. The hutch should then be 5 feet long, 3½ feet wide and 4½ feet deep, constructed of good deal boards 2 inches thick. The quantity of stuff which a boy can jig in ten hours will depend upon several circumstances. With a sieve six holes to the square inch and a tolerably light waste, from five to six tons can be operated on.

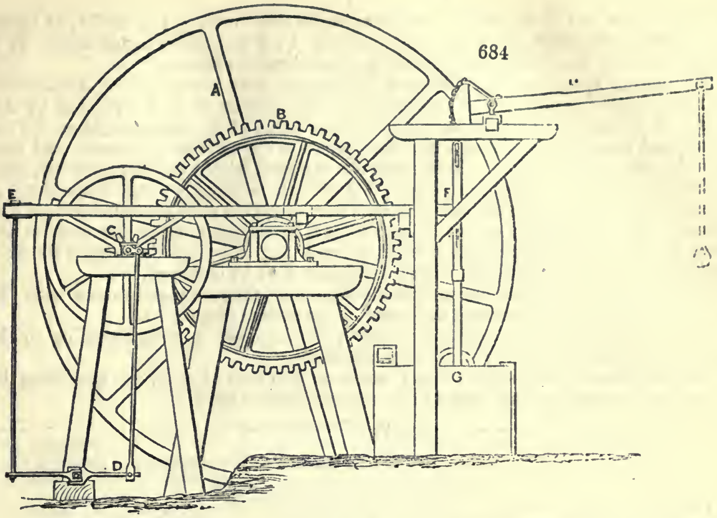
683



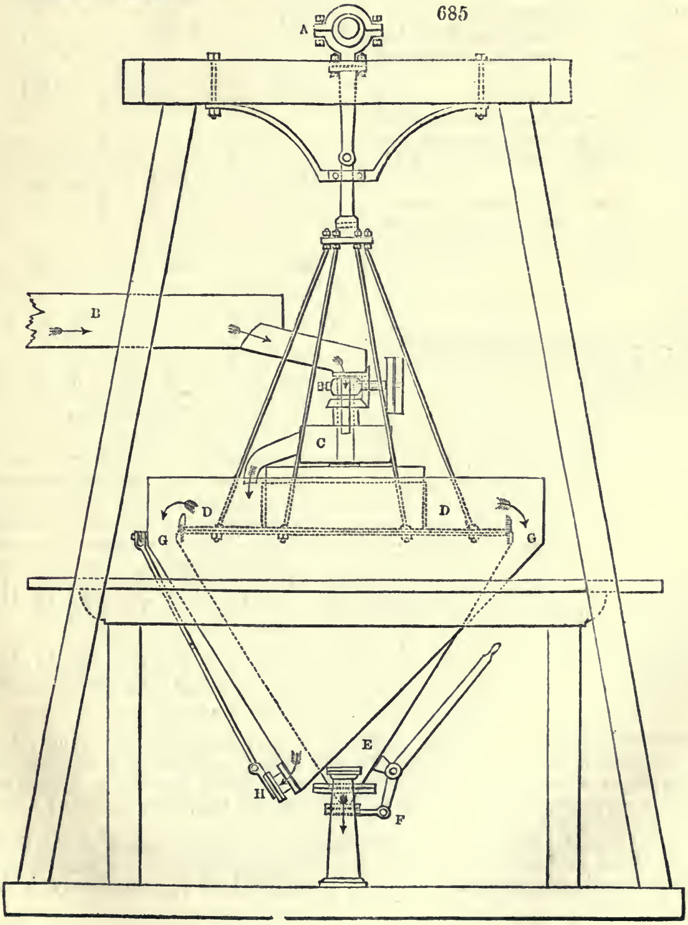
Machine Jigging.—The machine jigger. represented in *fig.* 684, is constructed on the same principle as the hand apparatus. The hutches are, however, somewhat larger, being 6 feet long, 4 feet wide, and 4 feet deep. A, fly-wheel; B, driving wheel; C, cog wheel receiving motion from B, and giving motion to a crank from which depends a rod attached to a lever D. The vertical rod E passes through a slot opening in the wooden lever F, and by these several combinations a vertical movement and jerk is given to the sieve contained in the cistern G.

When it is required to discharge the sieve, the lever H is depressed, and the pin

684



685



not seen in the end of the lever F, traverses in the slot shown in the bridle rod immediately below the bracket. The sieve measures 4 × 2 feet and 9 inches deep. It is strengthened by iron bands and numerous slips across the bottom.

The jigging apparatus, *fig.* 685, was introduced some years since at Allenheads, with satisfactory results. The larger and denser portion of stuff separated by this apparatus is conveyed by suitable launders to a series of sieves, arranged on the top of a conical reservoir, furnished with a feed pipe for the admission of water, and with an outlet pipe at the bottom. This reservoir is placed within another reservoir, also, in the form of an inverted cone, and provided with an outlet pipe at the lower part. A, excentric giving motion to the sieve; B, launder conveying stuff to such sieves; C, distributor, either stationary or revolving as may be required, delivering stuff to the sieves arranged on the top of the conical reservoir; F, valve for discharging the finer portion of the ore; G G, internal cistern furnished with an outlet valve H.

The sieves have a slight outward inclination, and the refuse substances with the waste water are carried over and deposited in the conical cistern G G.

The sieves should make from 150 to 200 pulsations per minute, according to the quantity and character of the stuff under treatment.

The following is the result of trials made on 160 tons of stuff, one half being delivered to this machine, the other to the common jigging hutch:—

	Machine	Hutchers	Difference in favour of Machine
Time:—	Hours	Hours	Hours

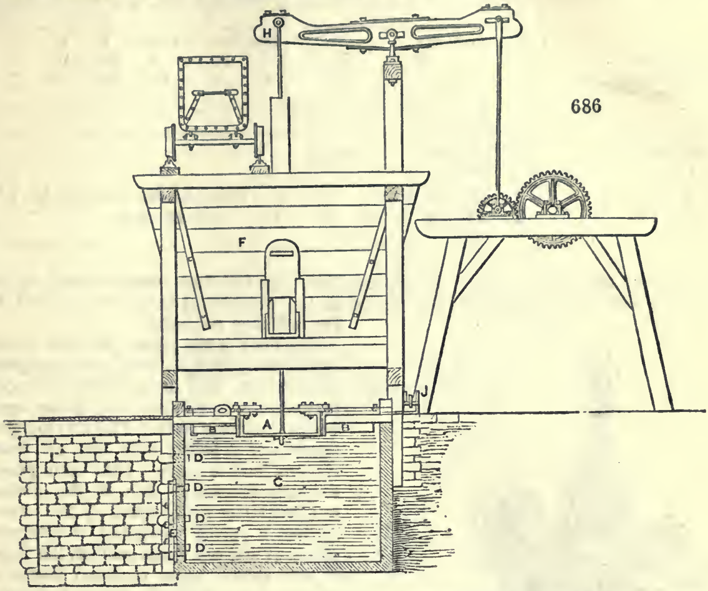
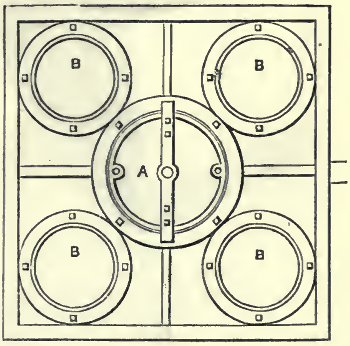
Petherick's Separator.—Figs. 686 and 687. A, the plunger or force-pump; B, receptacles fitted with sieves; C, hutch filled with water; D, discharge holes fitted with wooden plugs; E, moveable plate to admit of withdrawing the ore; F, hopper with shoots for supplying sieves; H, beam for giving motion to plunger piston A; J, launder for delivering water to hutch.

About the year 1831, Mr. Petherick introduced the above machine at the Fowey Consols Mines, in Cornwall. It was described in the 'Quarterly Mining Review,' January 1832: from which the following is extracted:—'This machinery is particularly intended to supersede the operation of *jigging* in separating ores from their refuse or waste. . . . In the separators, the sieves containing the ores to be cleaned are placed in suitable apertures in the fixed coffer of a vessel filled with water, connected with which is a plunger or piston working in a cylinder. The motion of the plunger causes the water to rise and fall alternately in the sieves, and effects the required separation in a more complete manner than can be performed by jigging. The variety in the extent and quickness of the motion required for the treatment of different descriptions of ores is easily produced by a simple arrangement of the machinery.



686

687



A principal advantage in this separator is derived from *the sieves being stationary* (in jigging, the sieve itself is moved) during the process; thereby avoiding the indiscriminate or premature passing of the contents through the meshes, which necessarily attends the operation of jigging, whether by the brake or hand sieve. Greater uniformity of motion in the action of the water, in producing the required separation, is also obtained; and superior facility afforded to the deposit in the water vessel (especially in dressing *crop* ores) of the finer and richer particles, which in jigging are principally carried off in the waste water.

The superiority of the patent separators over the ordinary means of cleaning ores will perhaps be best shown by reference to their actual performance. At the Fowey Consols and Lanescot Mines in Cornwall, where they were extensively used, seventeen distinct experiments were made on copper ores of various qualities from different parts of the mines, to ascertain the extent of the advantage of this mode of separation over the operation of jigging. Seventeen lots of ores, amounting together to about 300 tons, were accurately divided, one half was jigged, and the other half cleaned by the separator. A decided advantage was obtained by the latter in every experiment; the aggregate results being shown in Tables at top of next page.

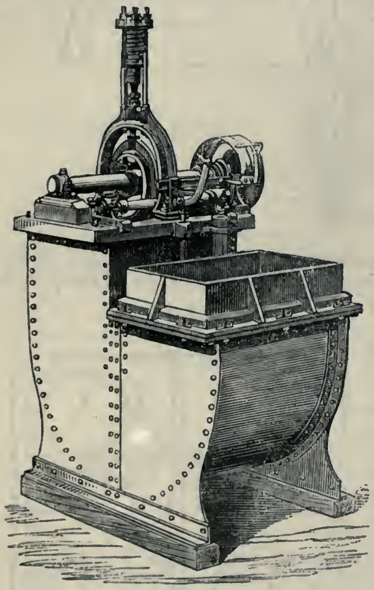
It must be obvious to those who are practically acquainted with the subject, that the poorer the stuff containing the ores, the greater must be the relative value of any improvement in the process of cleaning it. This was satisfactorily demonstrated by the trials made in the mines before mentioned, in dressing the *tailings*, which are

	Quantity of Marketable Ores returned			Percentage of Metal	Quantity of Metal				Value of Ores		
	Tons	cwts.	qrs.		Tons	cwts.	qrs.	lbs.	£	s.	d.
By jigging . .	76	19	0	$7\frac{3}{4}$	5	19	2	3	362	15	7
By the separators .	74	19	0	$8\frac{5}{8}$	6	9	0	18	396	6	7

Difference in the Value of Ores			In the Labour of Cleaning			Total			
£	s.	d.	£	s.	d.	£	s.	d.	
33	11	0	2	11	4	36	2	4	Being 9*s.* 8*d.* per ton, on 74 tons 19 cwts.

the refuse of the inferior ores. It appears that these tailings were dressed by the separators with more than triple the profit to the proprietors than that realised by the ordinary methods.

688



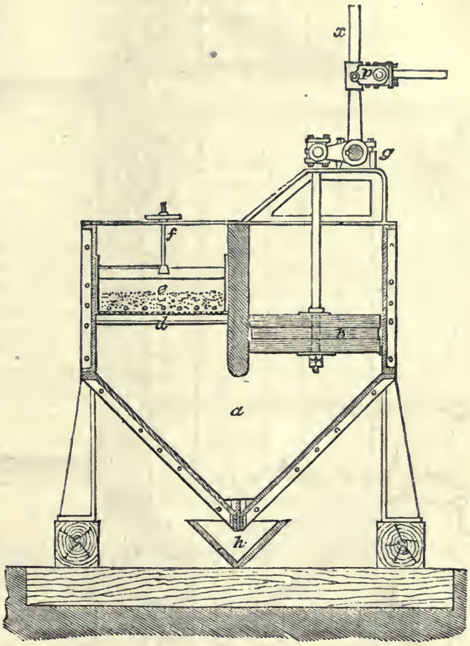
The body of the jigger, *fig.* 688, is constructed of wrought iron, the head-piece of cast iron. The sieve bottom is clipped between the head-piece and flange upon which the latter rests. The driving gear consists of a shaft, with fast and loose riggers, and a cam. This cam passes through the centre line of the piston-rod, the latter being lifted by the former against a spring composed of alternate plates of iron and India-rubber, the throw of the spring being rendered longer or shorter by means of screws and nuts. The valve for clearing the hutch is shown between the piston and sieve compartment. The sized sand when thrown upon the sieve is jigged; and on the completion of this operation, the skimming of the worthless portion is effected by hand.

Triple Sieve Jigger.—The three-sieve jigger is sometimes used for effecting a separation of lead and blende ore, associated with carbonate of iron, or heavy spar. The transverse section, *fig.* 689, shows hutch *a*, piston *b*, bridge *c*, regulating screw *f*, rocking shaft and gear *g*, and discharge launder *h*. The longitudinal section, *fig.* 690, exhibits three sieve plates *k*, three bridges *l*, each bridge enclosing an ore regulator, three discharge valves *m*, ore pipes *n*, furnished with stop valves *o*, ore trays *p*, fitted with perforated bottoms; and ore tray launders *r*. Sand suitably sized introduced at *s*, passes under the slide *t*, when it is progressed across the perforated plate to the first bridge; the ore flows into the receptacle *u*, while sand and ore, carried over the bridge, fall on the second sieve, and after treatment, pass to the third sieve. From the second sieve, mixed ore is obtained, from the third, a sand sparingly mixed with ore, and from the discharge shoot *r*, impoverished sand. The stuff lodged in the pipes *n*, is from time to time drawn into trays fitted with perforated bottoms, or otherwise, into boxes set in the ground. The ore regulators are formed so as to allow of the passage of large or fine grains, and of the enrichment of rich or poor stuff. Three or four of these jiggers may be combined together, so as to treat the sand as it comes from the trommels. Any necessary adjustment of stroke for jigging the stuff successfully is readily effected by shifting the cheek on the driving lever. Water may be supplied to the hutches, either by a wrought-iron pipe, furnished with a stop-cock, or by means of an ordinary launder.

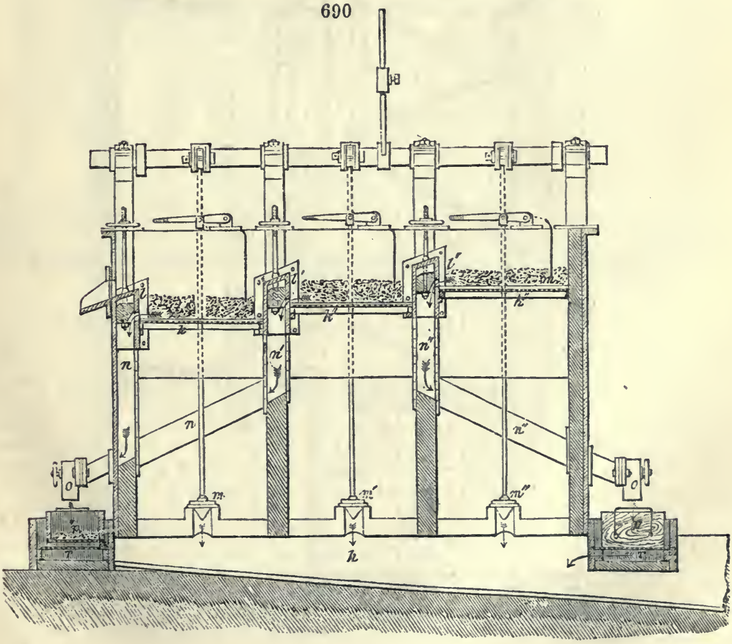
For jigging sand from two to ten millimeters in diameter, the pistons should make from seventy to eighty strokes per minute.

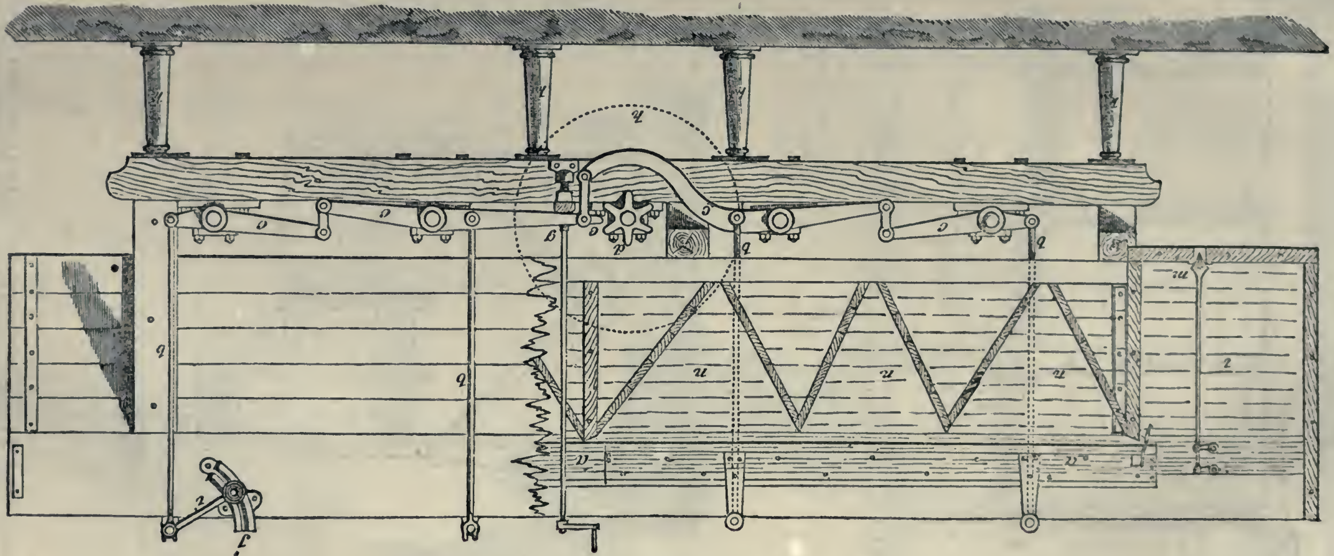
Hancock's Percussion Jigger.—This continuous jigger, *figs.* 691, 692, consists of a V-shaped hutch contained within a frame, a suspended sieve, foot gear, side rods, and cross-heads. *a*, sieve, the wooden frame strengthened by means of side and end plates of iron; *b*, side rods supporting cross-head; *c*, side levers, combined together by means of short links; *d*, cam wheel for lifting the levers and sieve; *e*, point of lever in contact

689



690



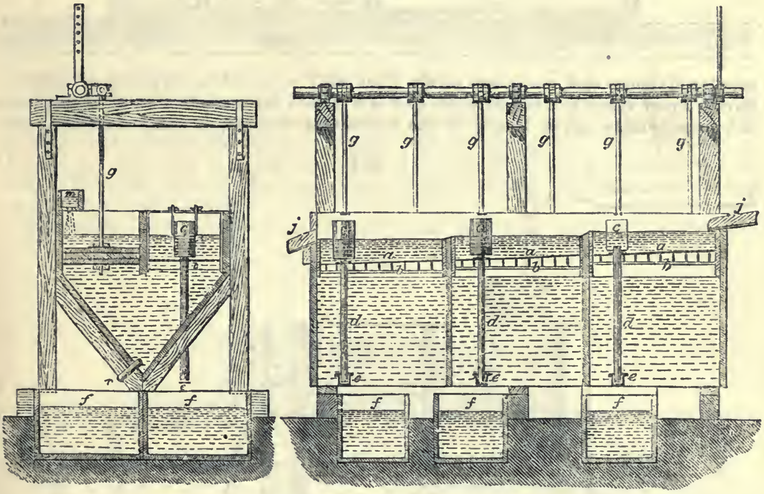


169

with the cam wheel; *g*, rod for regulating length of stroke and lifting side levers when necessary above the periphery of the cam wheel; *h*, driving rigger; *i*, radius bar for throwing the sieve horizontally; *j*, sliding block for lengthening or shortening the throw of the sieve; *k*, columns for carrying the hutch; *l*, waste compartment; *m*, valve for passage of water and castaways; *n*, ore compartments; *p*, pipe 2 inches diameter, one to each compartment for discharging the latter. The dimensions of the sieve are as follow: width 32 inches, depth 6 inches, length 20 feet. The sieve for dressing 1 to 3 millimeter stuff, has holes for the first 6 feet, 4 millimeters square; then, holes 3 millimeters square, until within 6 inches of the end, when it has holes 6 millimeters square. The wire bottom has a fall of ¾ of an inch in the total length. The ragging bars are 2½ inches deep, and are supported by a ¾ of an inch square bar of iron.

The stuff is introduced to the hutch by a 3-inch pipe, and is jigged from the head to the foot of the sieve, the ore falling between the ragging bars and thence into the V-shaped receptacles. The speed of sieve is 150 strokes per minute. The passage of water between the sieve frame and hutch is in a great measure prevented, as in Hugo Preuss's machine, by nailing on the bottom edge of the sieve frame a strip of leather about three inches deep. The total length of hutch is 22 feet. In Preuss's machine referred to and which was erected at Przibram in 1866, 3 sieves were employed, each slightly stepped one below the other; these were worked by means of shifting excentrics, and without any radius bars to effect a forward throw. At the Moonta Mines, South Australia, under the able direction of Mr. Hancock, the percussion jigger is found to despatch a large quantity of stuff in a given period. The ore consists of rich carbonates, sulphide of copper, and copper pyrites associated with a free light vein-stone.

692

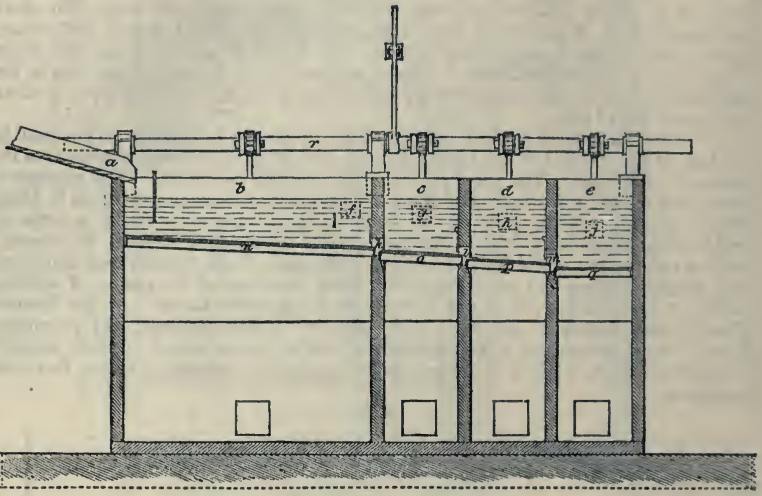


The jigger shown in *fig.* 693, is suitable for enriching coarse sand, that is, stuff composed of coarse grains from 2 to 7 millimeters diameter. In the longitudinal section, *a a a* the sieves are set so as to drop 1 inch in 36; *b*, grids supporting sieves; *c*, wrought-iron cylinders for regulating the outflow of ore and orey stuff; *d*, discharge pipes; *e*, regulators attached to pipes by means of set screws; *f*, ore boxes; *g*, piston-rods, two to each piston; *h*, driving lever; *j*, launder for admitting stuff to jigger; *k*, shoot for getting rid of castaways. In the transverse section *g* is the piston; *m*, launder for supplying water to piston boxes; *n*, draw-off plug; *y*, ore boxes.

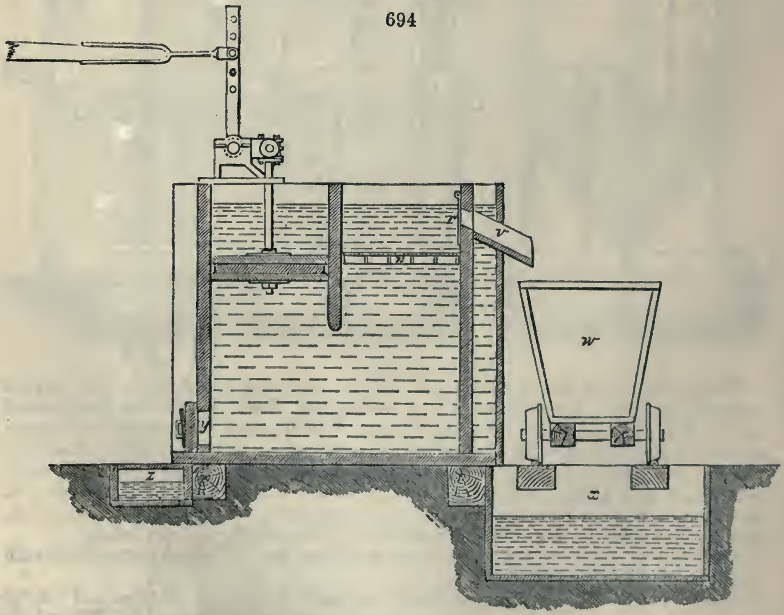
The width of sieve may vary from 20 to 30 inches, and the length increased to such extent as may be found desirable.

Utsch's Patent Jigger.—This machine, introduced by Messrs. Kember and Co. of London, is so constructed that the grains or particles of the material with which it is supplied are properly balanced, and subjected to an unvarying pressure, whilst a continuous self-acting delivery of the minerals is obtained. *Fig.* 694 is a longitudinal vertical section of the apparatus, and *fig.* 695 is a transverse section. *a*, supply launder; *b*, jigging compartment; *c*, *d*, and *e*, separating compartments; *f*, *g*, *h*, *j*, discharge holes, which may be fitted with regulators; *n*, *o*, *p*, inclined sieves; *q*, horizontal sieve; *r*, driving gear; *v*, discharge shoot from main sieve; *w*, waste waggon; *x*, drip receptacle; *y*, door through which stuff is withdrawn from hutch; *z*, launder for receiving contents of hutch. When using the jigger, the smaller divisions *c*, *d*, and *e*, are partly filled with equivalents, or grains of mineral having equal velocity of fall in water, and of a certain determinate size, observing that the proportionate size or density of the equivalents contained in every successive sieve must be increased. Further, as a preliminary to the effective separation of stuff, it is expedient that it should be sorted or classified according to the varying size of its constituents, or, if necessary reduced to a specified size. At the zinc-mines at Iserlohn, where the stuff consists of galena, blende, calamine, and carbonate of lime, a sieve 24

693



694



inches wide despatches 4 tons per hour, the grains varying in size from 2 to 4 millimeters. The size of stuff which can be treated per machine is 1 to 2, 2 to 4, 4 to 8, and 8 to 11 millimeters.

The fine sand jigger shown in *figs.* 695 and 696 is designed for the enrichment of sand from $\frac{1}{4}$ to 1 millimeter in diameter. The hutch is divided for 2 pistons, and a corresponding number of sieves. Compartments are formed underneath the sieves for receiving ore and orey stuff. The overhead gear consists of a shaft, driving wheels, and discs, the latter slotted for piston rod-pins. The pistons are hung so as to balance each other, and when 2 jiggers are employed the pistons of each are worked back to back. The discharged launders are not shown, but these deliver into a main launder set between the two hutches.

695

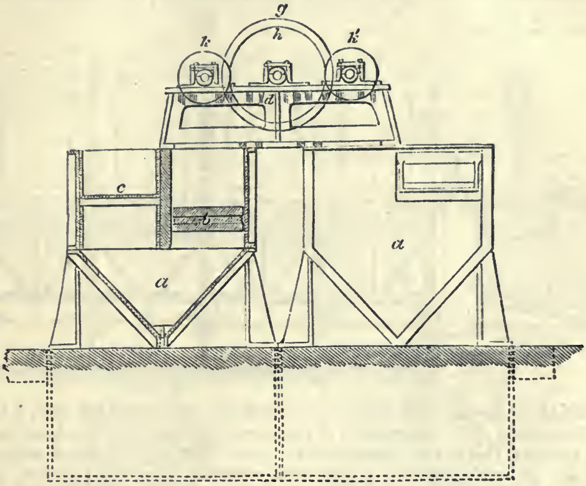


Fig. 696 is a section through the first piston and second sieve; *fig.* 695, a front elevation, cross section of hutch, and elevation of driving gear. *a*, hutch, 10 feet long, and $2\frac{3}{4}$ feet wide; *b*, piston, 5 feet long and 15 inches wide; *c*, sieve bottom of iron wire, supported on a wrought-iron grid, and held down by wrought-iron cross-bars; *d*, cast-iron head gear frame; *e*, jigger shaft; *p*, discs; *g*, driving rigger; *h*, driving wheel;

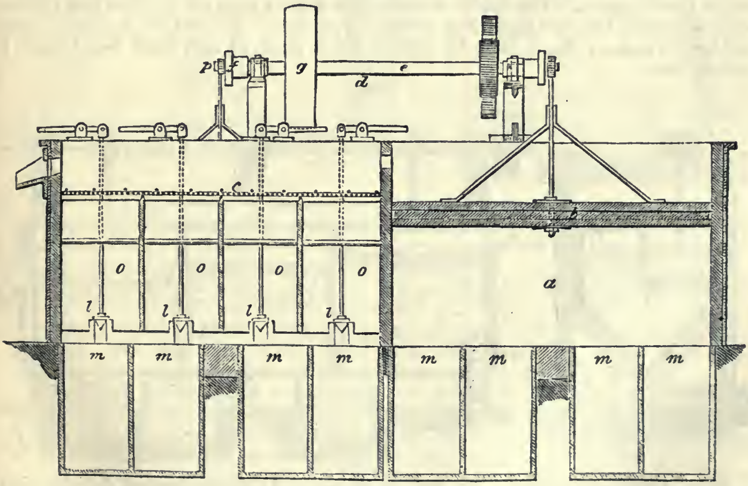
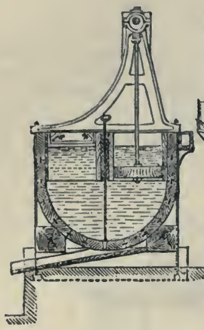
696



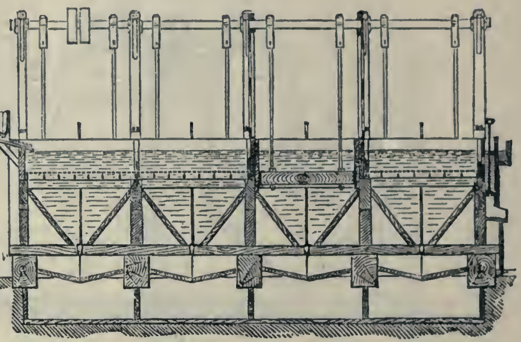
k k′, wheels on jigger shafts; *l*, discharge valves, 3 inches diameter; *m*, collecting boxes, 12 inches wide; *o*, receptacles, 15 inches wide. The piston-stroke is either lengthened or shortened by shifting and fixing the pins in the slotted discs; and, if necessary, slides are fitted to the discharge ways, for the purpose of modifying the thickness of the separating beds.

Fine Sand Jigger.—The Jigging Machine shown in *figs.* 697 and 698 is employed at a great number of silver, lead, and blende mines in Germany, and elsewhere, for the purpose of treating sand, classified or sized, into suitable sets of grains from ½ to 2 millimeters in diameter. The construction is rendered apparent from the longitudinal and transverse sections, the sieve bottoms are 34 inches long and 15 inches wide, depth of sieve from top of hutch 10½ inches, and from discharging slot 3½ inches, piston 30 inches long, 15 inches wide, and 4 inches thick. The box for discharging rough sand is 3 inches wide and 9 inches deep. The plug-valve for regulating outflow of stuff, 1 inch diameter; launder 3 inches wide, for taking off fine sand; plug valves 1½ inch diameter, for discharging stuff from sieve boxes. The outside dimensions of hutch are as follow:—length, 12 feet, 9 inches; width, 3 feet, 9 inches; height, 3 feet. For treating grains, say, ¾ millimeter in diameter, the piston should make about 200 strokes per minute, with a length of stroke of from ¼ to ⅜ths of an inch. For enriching and separating blende and lead ore the first two separating beds should be of lead ore grain from 3 to 4 millimeters diameter, and the other separating beds of coarse blende grains. The depth of beds must depend upon the richness and volume of stuff flowing into the apparatus within a given time. For the No. 1 sieve, it may be about 3 inches; No. 2 sieve, 2½ inches; No. 3 sieve, 1½ inch; and No. 4 sieve, 1 inch or less.

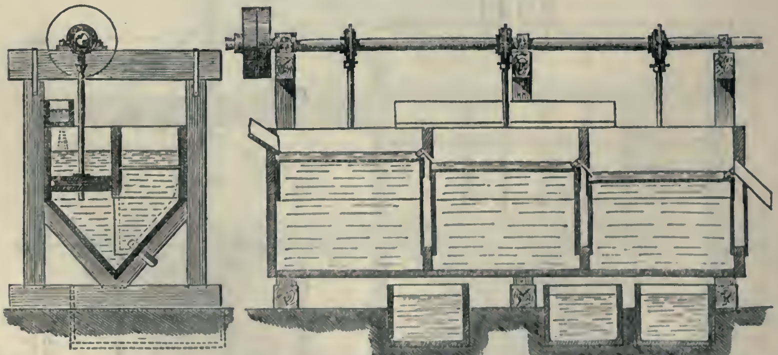
697



698



699



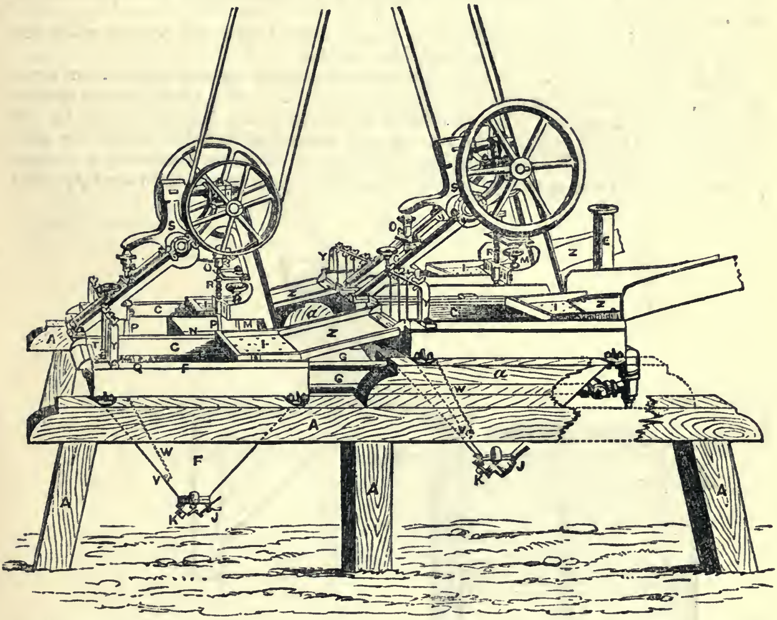
Slime Jigger.—This jigger, *fig.* 699, is in use at Iserlohn, Prussia, for enriching sand composed of clay, carbonate of lime, blende, and lead ore. The jigging is performed *on* the sieve; the ore and orey stuff being progressed into receptacles. In this respect it differs from those fine sand jiggers, where the orey products pass, through a coarse grain bed and sieve, into V-shaped boxes.

A *sheet of horse-hair* forming the sieve is placed between two sheets of wire or perforated places, having about eight holes to the lineal inch. The length of sieve is 30 inches; total length for 3 sieves, 7 feet, 6 inches; width of sieve, 12 inches. The depth from top of hutch to first sieve is 6½ inches; second sieve, 8½ inches; third sieve, 10½ inches; width of receiving chamber between the sieves, 2 inches. Each chamber is discharged at the side through a plug-hole into boxes set in the ground. The height of discharge openings into the several receptacles is about $\frac{3}{16}$ths of an inch, height of transverse plates above sieve bottom, ⅝″, ⅜″, and ¾ of an inch. The pistons make from 120 to 250 strokes per minute, according to the nature and fineness of the stuff treated. The quantity of water required per minute is from 1½ to 3 gallons per sieve.

Collom's Jigger.—The peculiar features of this jigger are its tappet piston gear, and the arrangement for discharging such grains of ragging as are too large to pass through the bed, and too heavy to flow from one sieve to another. The construction, as well as the mode of working the jigger, will be clearly understood from the following remarks:—

1. These machines should be firmly set upon a frame of square timber A (*fig.* 700).

700



2. The height of the vertical pipe E, supplying the clear water, through the regulating cocks to the hutches F, will be best determined by experience. Of the four regulating cocks, the sketch only shows one of the *lower* pair, viz, those through which the clear water passes before entering the pipes A, G.

3. The brass wire sieves H, on wood grids fastened with copper nails on the wood cross bars Q, should be set level *sideways*, about ¼ inch lower at the outlet than at the opposite end, and packed around the sides and ends with hemp or other suitable material. The side pieces C, and end pieces T, must be properly set in their places, and the whole secured by a wedge behind the outlet end of the side pieces.

4. The distributor I, and feed launders Z, should then be placed in position, and the regulating outlet arrangement J, applied. In this regulator there is a hole at both the front and the back. The holes that are found to be least convenient for discharging into the ore boxes should be fitted with wood-plugs K. To prevent an accumulation of stuff too light to pass through the 'bedding,' yet too heavy to be carried over the lips of the hutches, 'ragging-gear' is furnished. This consists of brass taper plugs, with wrought-iron stems, the stems being screwed and fitted with regulating thumb-screws, acting above and below the wrought-iron bridges Y. These plugs fit into bevelled brass seatings fixed in the sieving H. By regulating the height of these plugs, any undue accumulation of stuff is prevented.

The coarse raggings having passed through the seatings, falls into the portion of the hutch which is divided by thin wooden partitions W, and passes out through holes V.

5. Coarse ore should be placed upon the sieves, in grains twice the size of the sieve holes, and of the same ore, or mineral as that which is to be treated. The bed should be kept about $\frac{3}{4}$ inch thick; but in case of *rich* stuff, the thickness, should be less, varying to $\frac{1}{2}$ inch; and with *poor* stuff greater, extending to 1 inch, or even more if found necessary.

6. Clear water and a supply of stuff being furnished, and the machines started, the stop bolts, M, should be adjusted by turning them down until they are found to regulate the motion of the plunger N, so that each stroke shall be of *equal* length. *The speed should be about* 120 *strokes per minute.*

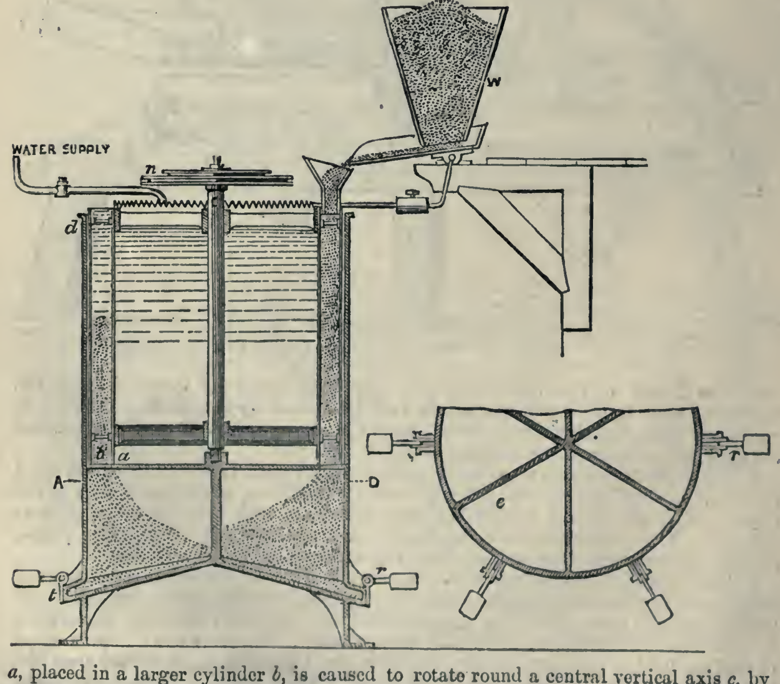
7. The degree of force operating upon the stuff may be increased by elevating nearer to the rocker S, the adjustible thimble O, on the top of the plunger, or stem P, or by increasing the supply of clear hutch water, or both. The stroke *should vary from* $\frac{1}{2}$ *inch to* 1 *inch.*

8. The spiral springs R should be just strong enough to strike the plunger against the stop bolts M, before the down stroke, but not stronger. Irregularity of stroke, viz., alternately long and short, may be remedied by attending to the adjustment in connection with the springs.

These jiggers have been introduced by Messrs. John Taylor and Sons, to whom the miner is indebted for the round and impeller buddles.

Hundt's Stream Separator.—This apparatus consists of an arrangement for separating, washing, or sorting ores and other substances according to the size or specific gravity of the particles. This is effected in a continuous manner by the agency of a body of water rotating in a horizontal direction, through which the substances are made to fall; and which are collected at distances increasing in inverse proportion to their size or specific gravity. For this purpose an annular vessel (*fig.* 701) *a*, placed in a larger cylinder *b*, is caused to rotate round a central vertical axis *c*, by means of a pulley or cone *n*. This annular vessel is open at top and bottom, and placed in the slightly larger and cylindrical vessel *d*, which is kept full of water during the action of the apparatus. The bottom of this vessel is divided into com-

701

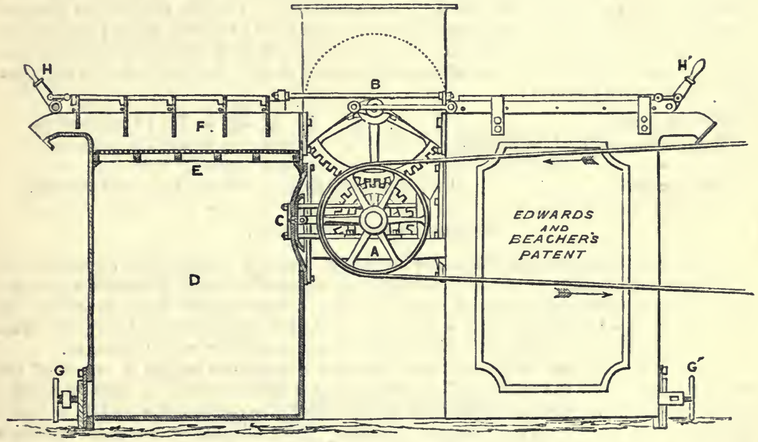


partments *e*, corresponding in number with the degrees of fineness into which it is desired to classify the ores. The vessel having been filled with water, the ore is caused to fall regularly through a spout into the body of water rotating with the vessel *a b*, round the axis *c*. In order to carry the water round with the vessel *a b*, a blade is fitted between the two cylinders *a* and *b*, which, if put in a suitable position does not interfere with the sorting.

The particles of ore having the greatest specific gravity will fall most rapidly through the water, and will consequently pass out at the bottom of the vessel *a b*, at a point nearest the stationary spout *t*, whilst the particles next in specific gravity will fall in the next compartment, and so on. The particles of ore to be classified according to their specific gravity must be as nearly as possible the same size, whilst any material in a granular state, and of the same specific gravity in all its particles, will be classed according to size. The action of the apparatus continues till the compartments *e* are full of ore. When full, the weighted levers *r*, are lifted up, and the ore allowed to escape with the water. In places where water is plentiful, the apparatus may be made to work continuously by giving to the opening *t*, such a size that no more water can escape with the ore than is continually supplied. The compartments *e*, may in this case be much smaller. Where water is scarce the quantity required may be reduced considerably by fixing a bottom to the inner cylinder *a*, and leaving this cylinder empty. The drum will thereby get a tendency to float, which may be overcome as far as necessary by putting ballast in it. By these means a quantity of water equal to the cubic contents of this cylinder will be saved; at the same time, by giving greater dimensions to the compartments *e*, the water will be made to do duty a longer time. The number of revolutions of the drum will be found in most cases to range between the limits of two to six per minute; the diameter of the drum from about four feet and upwards; the size of the ore grains, or particles, from one thirty-second to half an inch. The power required is extremely small, and one man can attend to a greater number of these machines.

Edwards and Beacher's Mineral and Coal Washing Machine, consists of two rectangular cisterns. Within a few inches of the top of these, perforated plates or screens, E *fig.* 702, are fixed, upon which the material to be washed is fed through a hopper, which also connects the two cisterns. On the inner sides of the cisterns are two apertures closed by flexible discs, or diaphragms of leather, C, which, when the machines are filled with water, cause it to rise and fall through a certain space, by means of a horizontal vibratory motion, which they receive from an excentric on a shaft, which is driven either by a steam-engine attached directly to it, or by a driving belt and pulley, A. See WASHING COAL.

702



The action of the flexible diaphragms is similar to that of cylinders and pistons, which are sometimes substituted for them. Above the driving shaft is a smaller one, B, which is driven at a slower rate by means of spur-wheels, and gives, by cranks or excentrics, a horizontal motion backwards and forwards to sets of scrapers F, above the cisterns. These are so arranged as to remove the upper stratum of the substance being acted upon, and discharge it into waggons or other convenient receptacles;

these upper strata are of course the lightest, the heavier part settling upon the perforated plates below.

When from the action of the machine a considerable quantity of material has accumulated upon these plates, the scrapers are thrown out of gear by means of apparatus attached, H H′, and the stuff raked off, the operation being then continued on fresh supplies. Doors, G G′, at the bottom of the machines, admit of any fine stuff which may pass through the perforated plates being removed from time to time as may be necessary.

These machines are in use for cleansing coal as well as other mineral substances.

In such cases the heavier stuff which remains upon the plates consists of shale and pyrites, very injurious substances in the manufacture of coke. One machine of two connected cisterns is capable of washing about thirty tons per diem of coal, but the quantity of mineral work will depend upon the amount of ore present in proportion to the waste. The size of the perforations in the screens is adapted to the quality of the material acted upon.

The introduction of water skimming jiggers into our British mines is probably due to Mr. John Hunt, late of Falmonth. This gentleman used an ore bed, two sieves divided by a low partition, two ore chambers, and a horizontal flow of water. Hunt's Specification, No. 707, is dated March 8, 1866.

In order to concentrate lead, zinc, copper, and other ores associated with vein-stone, coarse and fine sand jiggers should be employed, the former to receive the stuff from sizing trommels, the latter from trommels or classifiers. In the coarse sand jigger, stuff 10, 7½, 5, 3½ and 2 millimeters size is usually enriched *on* a plate, the holes in which are of *less* diameter than the grains, whilst in the fine sand jigger, sand 1¼, ¾ millimeter size is separated through the intervention of a bed of coarse grain ore, supported either on a perforated plate or wire work, the openings of which are *larger* than the grains to be collected.

For the purpose of effecting a good separation of ore from its gangue it is necessary to give great attention to the length of stroke, number per minute, and volume of flowing water. Every distinct class of vein-stuff will necessitate the observance of specific conditions, so that no absolute data can be offered; as, however, approximate figures may be useful, the following are given:—*Coarse sand jiggers*, speed from 60 to 75 strokes per minute; flowing or skimming water required, say ten to fifteen gallons each machine per minute. *Fine sand jiggers*, speed from 90 to 250 strokes per minute; piston and horizontal flow of water necessary, from fifteen to twenty gallons per minute.

The approximate length of stroke and piston speed for stuff ranging in size from one-third to ten millimeters, the area of the piston being that of the sieve, may be gathered from the following figures:—

Size of stuff	⅓,	½,	¾,	1¼,	2,	3¼,	5,	7½,	10	millimeters
Approximate length of stroke	¼,	⅜,	½,	1,	1¼,	1½,	2,	2¼,	2½	inches
Piston speed	150,	120,	110,	100,	60 to 75					per minute.

SEPARATORS OR CLASSIFIERS.

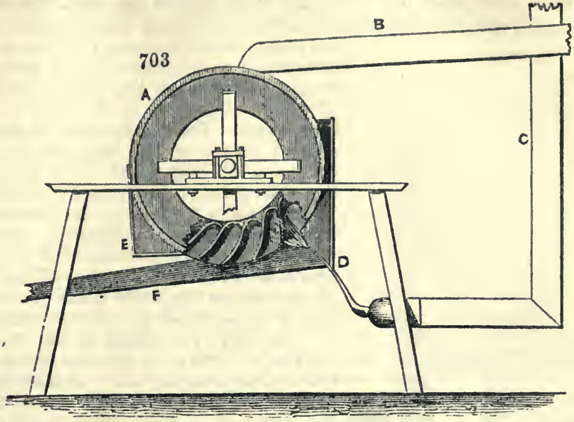
Of late years apparatus of this class have been steadily coming into operation, not only in lead and copper mines, but also in the dressing of tin ores. Unlike the trommel which groups together grains of equal volume irrespective of their densities, the classifier groups the grains into equivalents, that is to say, grains which differ from each other in their densities, but which have an equal velocity of fall in water.

To separate such grains in the after dressing process, advantage is taken of the resistance offered by the surface of a heavier over a lighter grain in passing upon a bed of ore as in the fine sand jigger, or in traversing the surface of a buddle or table. For the purpose of sizing stuff from x to grains of one millimeter diameter, trommels should be employed, but for dividing grains from 0 to 1 millimeter diameter, the cistern, cone, or expanding launder, will be found suitable.

Slime Separator.—This apparatus devised by Captain Isaac Richards, of Devon Great Consols, is employed for removing the slime from finely-divided ores which have passed through a series of sieves set in motion by the crusher. The finely-divided ores are for this purpose conveyed by means of a launder upon a small water-wheel, thereby imparting to it a slow rotatory motion. Whilst this is turning time is allowed for the particles to settle in accordance with their several densities; the result obtained, is, the heavier and coarser grains are found at the bottom of the buckets, whilst the lighter and finer matters held in suspension are poured out of the buckets and flow away through a launder provided for that purpose. The stuff remaining in the bottom of the buckets is washed out by means of jets of water obtained from a pressure-column 10 feet in height, and passes directly into the funnel, of a round buddle.

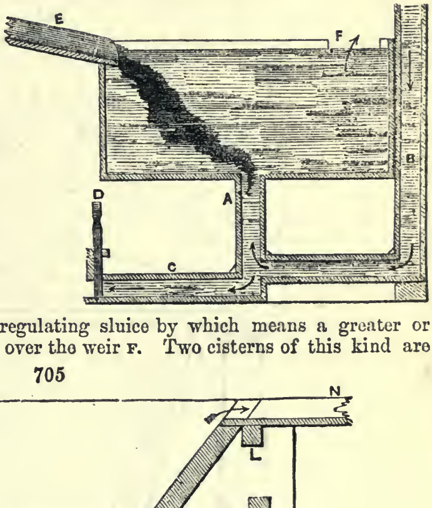
The wheel A, *fig.* 703, is 4 feet in diameter, 2 feet 6 inches in breadth; it has twenty-four buckets, and makes five revolutions per minute; B, launder for supplying the finely-pulverised ore; C, pressure-column; D, jet-piece; E, launder for conveying away the slime overflow of the wheel; F, launder for taking roughs to round buddle.

703

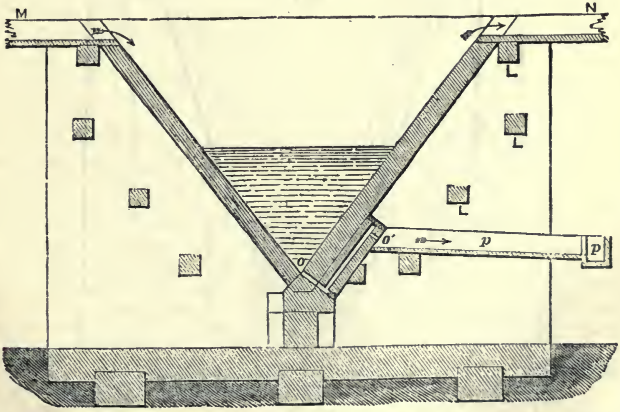


Sizing Cistern.—The tails from round buddles are sometimes passed through this apparatus. It consists, *fig.* 704, of a wooden box provided with an opening at the bottom, A, which is in communication with a pressure-pipe, B, an outlet, C, with a small regulating sluice, D. The stuff from the buddles enters at E, and the pressure in the column is so regulated as to allow the heavier particles of the stuff to descend, but at the same time to wash away at F the lighter matters that may be associated with the ore. This is done by having the outlet C of less area than the inlet, and fixing on the extremity D a convenient regulating sluice by which means a greater or less quantity of stuff may be passed over the weir F. Two cisterns of this kind are generally employed, the second being used to collect any rough particles that may have passed off from the first. The depth of a box may be 18 inches, its width 13 inches, and its length 3 feet 6 inches.

704

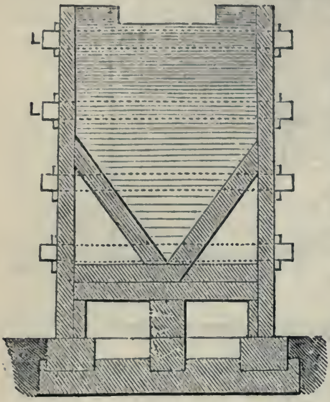


705

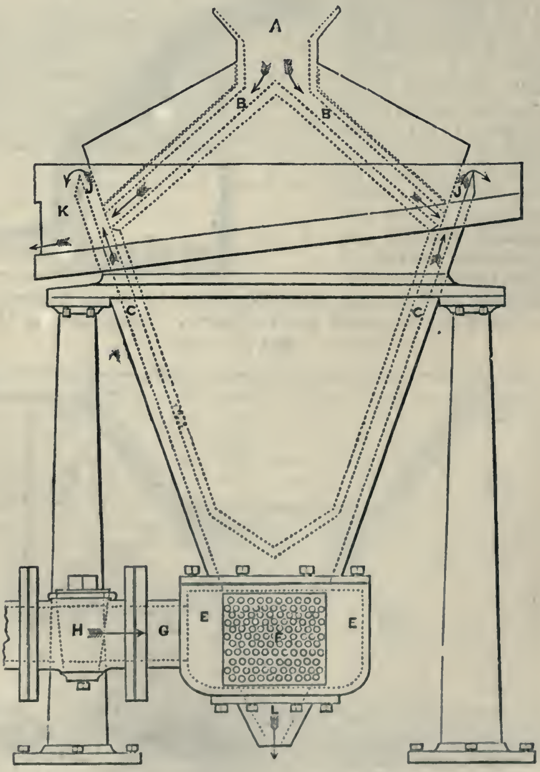


The arrangement of another separating box is shown in *figs.* 705 and 706. The slime water flows in at M; and water still holding a considerable portion of slime flows away from the opposite end. It is necessary that pieces of chip, small lumps, or other extraneous matter should be intercepted previous to entering this apparatus, also that the slime should be evenly sized by means of a trommel or sieve. The heaviest portion of the slime water in which the sand and ore are contained, is discharged at the hole *o*, about an inch square. The launders *p p*, are for the purpose of conveying the slime water either to buddles or shaking tables. The dimensions of the cistern No. 1 are: length, 6 feet; width, 1½ feet; depth 12 inches. But two other cisterns of similar form are attached. No. 1 cistern will work about 10 tons of stuff in 24 hours, and by widening the box from 18 to 27 inches it will get through 20 tons in 24 hours. Affixed to one side of the boxes are hammers so contrived as to give 30 blows per minute in the manner of a dolly tub. Care must be taken in the construction of these classifiers that the sides forming the pyramids be neither too steep nor too flat; if too flat, the sand is apt to settle until a quantity has accumulated, when it would suddenly sink and choke the discharge pipe *o′*; and if too steep the classifiers would become of inconveniently large dimensions. A gradient of 50° to the horizon is found to be the most suitable. The chief dimensions of two cisterns, viz. one working 10, and the other 20 tons, are given in the following Table:—

706



707



No. of Box	Ten tons			Twenty tons		
	Length of Box	Breadth of Box	Depth of Box	Length of Box	Breadth of Box	Depth of Box
	ft.	ft.	ft.	ft.	ft.	ft.
2	9	2	6	9	5	6
3	12	4	8	12	9	8
4	15	8	10	16	15	10

According to experiments made in the Stamping House of Schemnitz, where 12 tons are stamped in 24 hours, the 1st cistern separated from the slimes 40 per cent. of the ore; the 2nd cistern, 22 per cent.; the 3rd cistern, 20 per cent.; the 4th cistern, 12 per cent.; together, 94 per cent., leaving a loss of 6 per cent.

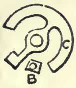
From No. 1 box every cubic foot of water flowing through gave 16 pounds of sandy matter. No. 2 afforded 13 pounds of finer stuff. No. 3, 16 pounds, and No. 4 yielded 12 pounds per cubic foot of water. It should be remarked that the outlet *o* is proportioned to the dimensions of the machine.

Cone Classifier, fig. 707. The ore and minerals, after passing through the crushing apparatus, are introduced at A, and flow through the spaces B B, passing into C C. At the bottom is a circular chamber E E, with a perforated cylindrical plate F. Water under pressure is supplied by the pipe G, and regulated by the cock H.

It will be seen that this apparatus consists of an external and internal cone with a space between them, and that a separation of the orey matter is effected by limiting the power of the water between the density of the stuff to be retained, and that which is to be discharged at J J into the shoot K.

At L the larger and denser portion of the mineral which has fallen through the ascending current of water, is conveyed either to a jigging machine or some other enriching apparatus.

709



708

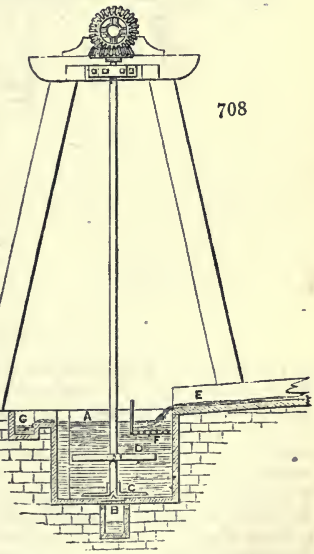


Fig. 708 represents a wooden cistern A, having an aperture B, at the bottom, about an inch diameter, which is alternately closed and opened by means of an iron plate C, fitted upon the vertical shaft, to which is also fixed an iron paddle D, which revolving horizontally keeps the ore and water in constant agitation. The tails from the various buddles, as well as the stuff from the coffers at the end of the strips, flow in at E, and pass through a perforated sizing plate F, into the cistern. The rougher and heavier portions escape through the hole B into a strip where it is continually stirred, in order that it may be evenly deposited, and at the same time freed from the lighter particles. The overflow containing fine ore passes in the launder G into catch pits, from which heads and middles are taken to be elaborated by means of buddles or other apparatus. When this separator is employed in tin dressing, it is usual to divide the stuff in the strip connected with the bottom of the box, into heads and tails. The first is taken direct to the stamps, and again pulverised with rough tin stuff; but before the tails can be so treated they are re-stripped in order to get rid of extraneous matter. A plan of the iron plate covering the discharge hole is shown on *fig.* 709. C, plate; B, discharge hole.

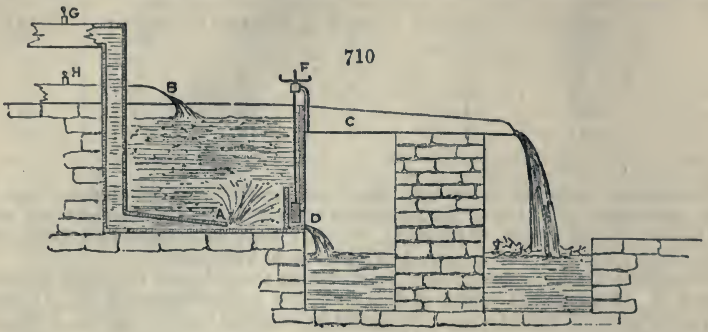
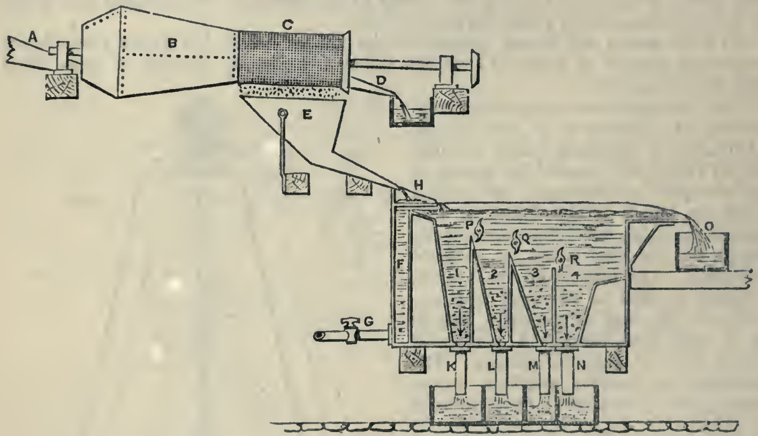
Wilkin's Separator.—This is a 'self-acting tossing machine, by which the rough particles are separated from the fine, and prepared for the inclined tables. The orey matter is carried into a small cistern by a stream of water which enters at the top and passes out at the opposite side, bearing the finer particles with it, whilst the rougher and heavier particles escape at the bottom through a rising jet of clean water, which prevents the fine and light particles from passing in the same direction.' A, *fig.* 710, inlet of clean water; B, launder delivering the orey matter; C outlet of fine and inferior stuff; D, discharge orifice for rough and heavy stuff. This operation must be regulated by a slide. A cistern, 10 feet square on the top and 18 inches deep, will pass through about 40 tons in 10 hours. When separating stamps work, a smaller cistern is employed, say about 14 inches square, 10 inches deep, this will despatch 6 tons in 10 hours.

710



A valuable form of classifier is shown in *fig.* 711, the peculiarity of which consists in the manner of introducing the water and slimes. Instead of the latter depending for separation upon the power of an ascending column of water, it here passes into a horizontal flow of greater or less volume and velocity, produced by altering the tap G. Compartments, viz. 1, 2, 3, and 4, are also fitted in the box, for the purpose of receiving mineral of different densities and size, which is discharged and washed in strips set underneath; A, inlet launder to trommel; C, trommel either of perforated plate, or wire gauze; D, shoot from trommel, serving to convey away the rougher portions. E, hopper for conveying stuff to shoot H, and from thence into the box; F, ascending column of water; G, tap for regulating the flow of water; K, L, M, N, outlet pipes for delivering the separated stuff to strips or buddles; O, launder for receiving overflow from cistern; P, Q, R, weirs regulating the length of the compartments, also for the purpose of effecting the disposition of the different minerals with which the ore may be associated.

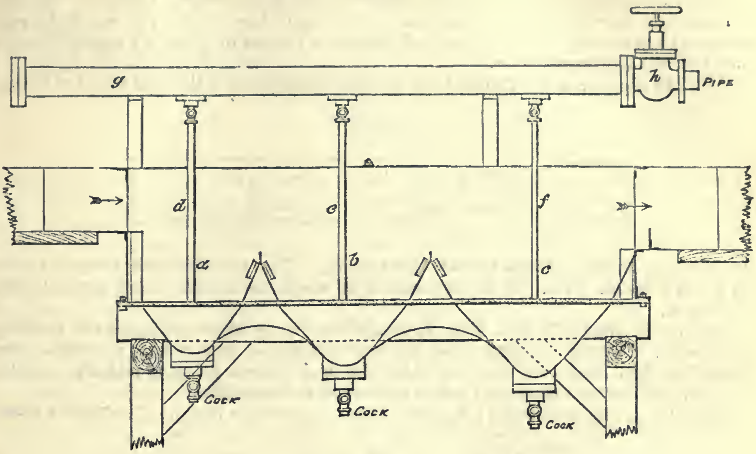
711



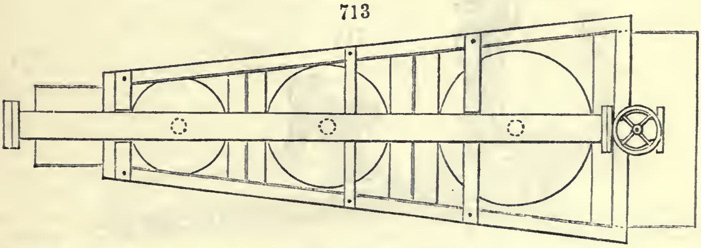
Horizontal Classifier.—This classifier, shown in longitudinal elevation *fig.* 712, plan *fig.* 713, and end elevation *fig.* 714, is frequently employed at lead and blende mines in Germany, and is known in some of the mines in this country. In many instances it is built of wrought and cast iron; but it may be equally well made in wood, and will cost much less. The slimey water is introduced at the narrow end; the heaviest equivalents fall into the first compartment, *a*; equivalents of the second degree into the second, *b*;

while the lightest collect into the third or largest one *c*; the result in each case being modified as may be desirable, by increasing or lessening the flow of water from the vertical pipes, *d*, *e*, *f*.

712



713

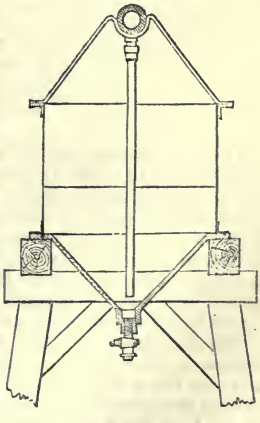


The length of the trough is six feet, greatest width 28½ inches, decreasing to 11½ inches, depth 18¾ inches, diameter of vertical pipes ¾ inch and of main pipe 3 inches; length of first receptacle 18 inches, second 24 inches, third 30 inches. The classified sand from first, second, and third compartments is in each case passed to suitably enriching machinery. The principle affecting the classification by the apparatus described is as follows:—

In a horizontal current of decreasing velocity, the larger equivalents introduced will be deposited first, decreasing in size in an equal ratio with the decreasing velocity, till with but a very slight flow even the finest slimes are deposited. A stream rising *vertically* with decreasing velocity, carries the smallest equivalents first away and only the larger ones remain, while in proportion to the decreasing velocity of the stream the fine and finest particles will eventually be deposited. In the construction of these classifiers, the following rules should be adhered to:—

The width of the first division should be $\frac{1}{10}$th of a foot for each cubic foot of slime water introduced per minute. The following divisions should increase in geometrical progression, thus, 1, 2, 4, &c. The length of the first division is usually taken at 6, the second, third, and fourth in arithmetical proportion, thus, 6, 9, 12, &c. The inclination of the sides of the box should be about 50°.

714



The Strake, Tye, and Strip.

These appliances may be considered modifications of each other. Instead of effecting a separation by relying upon subsidence according to the specific gravity of the substances, they are mechanically impelled against a volume of water so regulated as to carry off the lighter particles.

Fig. 715 represents the ground plan of a strake employed in the lead-mines of Wales.

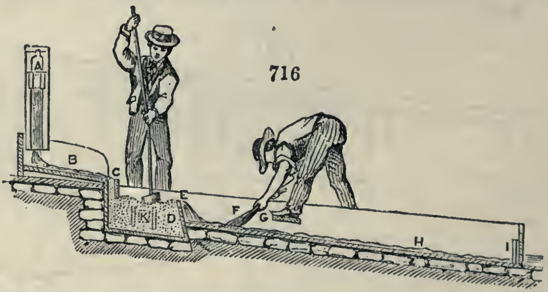
715

Its extreme length is about 18 feet, width 3 feet. The top increases from 18 inches to 2 feet 9 inches wide. It is constructed of wood, the bottom being covered with sheet-iron.

The tye is usually 20 feet long, 2½ feet wide, and is often employed for cleaning hutchwork. In some instances when the ore or dradge is very rich, it is crushed, and then tyed into heads, middles, and tails, the first portion going to pile, the middles re-tyed, and the tails treated as refuse or washed in the buddle.

Fig. 716, A, inflow of water; B, head of tye; C, partition board. The stuff is introduced into the cistern D, flows over the inclined front E, and is broomed at F. Between E and G are the heads, from G to H middles, H to I tails. At K is an outlet launder, regulated with a shute. An outline plan of the tye is shown, *fig.* 717.

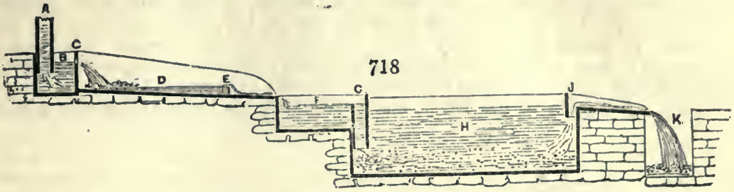
716



717

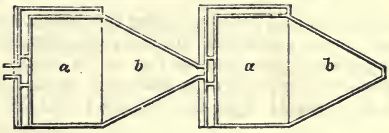
The strip also consists of a wooden box, with its bottom inclined at a greater or less angle, in order to suit the character of the stuff to be operated upon. The object of this apparatus is somewhat analogous to that of the separating box, viz. to deprive the ore of the fine particles with which it may be associated, and thereby to enrich it for subsequent treatment. A rather strong stream of water is employed, against which the mixed mineral is violently projected by means of a shovel. When ores are strong and clean in their grain, but little loss can occur from this process, provided proper care be exercised in conducting it; but if their structure be delicate, and the constituents intimately mixed, the wastage must necessarily by great.

The illustration, *fig.* 718, shows a strip, coffer, and settling cistern, with filtering apparatus contrived for lead ore. A, vertical launder 6 inches square, delivering water into the box B, 9 inches long by 26 inches wide at the point C; D, bottom of strip covered with sheet iron, 6 feet long and 16½ inches wide at E. At this point a ledge of wood is sometimes introduced for the purpose of modifying the velocity of the water and forming a kind of shallow reservoir, so as to allow the workman to stir the stuff. At the end of the strip a coffer, F, is fixed, 11 inches deep, 30 inches square; H, settling box, 6 feet long and 30 inches deep; K, outlet for waste water. At G is inserted a filtering launder, 13 inches deep, extending across the cistern. At J a similar launder is placed, about 9 inches deep. The water coming in at A, is lodged in cistern B, flows smoothly over the feather-edged board C, and falls into D; here the orey matter is exposed to its action, and a portion settles in F; the *florrin* and other light waste then descends through G, depositing itself in the box H; and to retain the valuable products as much as possible it is filtered at J, through a perforated plate covering the bottom of the launder. In stripping care must be taken to regulate the overflow of water at C; rough stuff must be subjected to a stronger current than finer matter, and the bottom of the strip should be constructed with a greater inclination. In some lead mines the buddles and hutchwork is stripped to be re-jigged, whilst the stuff resulting from the filtering box is hand-buddled until sufficiently enriched for the dolly. When ore is associated with a heavy matrix, and the grain breaks into a lesser size than the other particles, the stripping may be performed by inversion, that is to wash the orey product into the cover and filtering hutch, retaining the worthless portions at D.



718

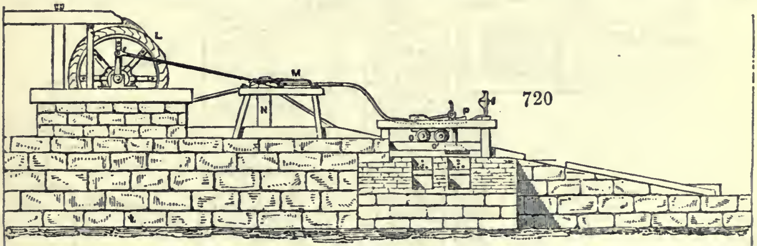
The flat buddle, *fig.* 719, is peculiar to the Welsh mines, and different from all others in its great proportional breadth as well as in its very trifling inclination.



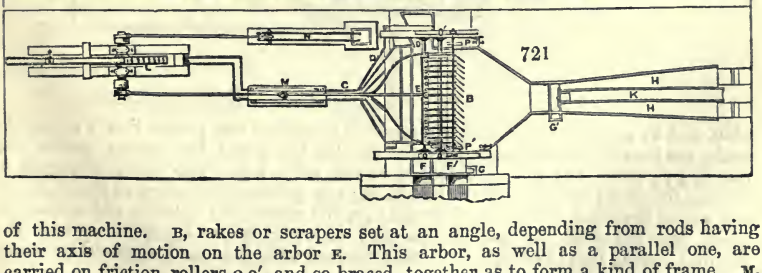
719

The stuff is placed in a small heap on one side of the supply of water, and drawn with a hoe partly against and partly across the stream to the other side of the buddle, losing in its passage all the lighter parts. A heap of ore treated in this manner may be deprived of a portion of blende and pyrites, minerals which from their high specific gravity may have resisted previous operations. *a*, platform of boards, inclined two and a half inches in seven feet. *b*, catch pit, two feet deep. The width of this buddle varies from ten to twelve feet.

Lisburne Buddle.—This apparatus has been successfully employed in separating blende from lead ores. *Fig.* 720 represents an elevation, and *fig.* 721 a ground plan of this machine.



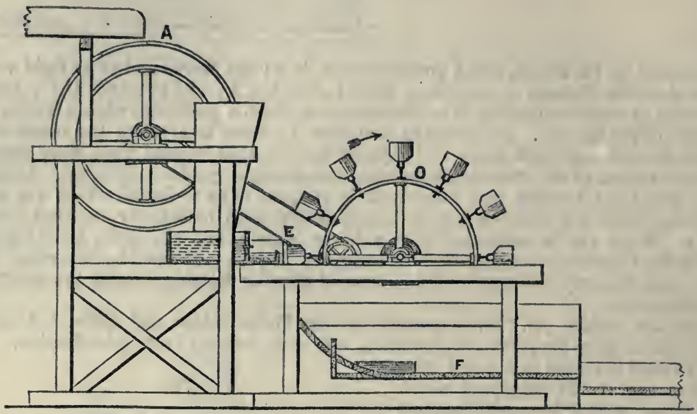
720



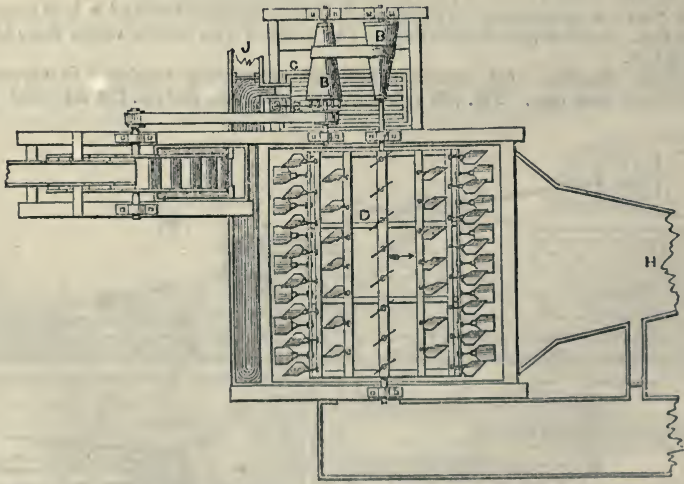
721

B, rakes or scrapers set at an angle, depending from rods having their axis of motion on the arbor E. This arbor, as well as a parallel one, are carried on friction rollers O O′, and so braced together as to form a kind of frame. M, rod attached to frame, and connected with water-wheel L. N, balance beam, counterpoising the frame, and rendered necessary in order to equalise the motion. P P′, balance catches, serving to support the third arbor when elevated. This arbor is also parallel to the other two, but has its position on the top of the guide frame shown in the elevation. It passes immediately under the angle of the L-shaped rods, and is mounted on friction wheels. Its action is as follows: When the scrapers have nearly completed their ascending stroke this arbor is elevated by means of the wedge-shaped projection on the top of the frame, and immediately the balance catch acts so as to retain it in this position during the descending stroke, at the termination of which the catch comes in contact with the projecting screw shown in the elevation, thereby dropping the scrapers upon the face of the buddle. Consequently, in the ascending stroke these scrapers plough the vein-stuff against the flow of the stream. The orey matter to be operated upon is introduced into the compartment shown on the top of the plan, and by means of the diagonal scrapers it is washed and passed slowly across the table, the heavier portion being delivered into the bin F, and the lighter matter into the box F′, whilst the tails are lodged in the strips H H. The water employed in driving the wheel is also used for the buddle; one portion of it serves to introduce the ore, whilst the other is regularly diffused over the surface of the table, and washes the waste from the stuff. In case the quantity of water is too large for settling the residues flowing into the strips H H, and connected with the bins F F′, discharge launders are provided at G,

722



723



The table of the buddle has an inclination towards the bins F F′, and catch pits H H. This machine makes about 12 strokes per minute, and may be furnished with any number of rakes. With 22 rakes, 40 tons of stuff may be concentrated in 10 hours, so as to afford ore for the deluing sieve, whilst the blende will be sufficiently cleaned for the market. The cost of this apparatus complete is about 30*l*.

Figs. 722 and 723 represent plan and side elevation of the knife or impellor buddle. The water-wheel A, is 6 feet diameter, and is constructed of wood, with sheet-iron buckets. The speed of the trommel is carefully adjusted to the character of the stuff intended to be treated. This is effected by shifting the band on the driving cones B B. Straw, heath, and other extraneous substances are prevented from entering the separating table by means of an iron grating C, fixed near the top of the hopper. The trommel, D, is formed of 3 iron hoops braced together by flat lateral bars, 6 feet in length. Into these bars are inserted the scrapers, which are set spirally in the form of a screw. The hoops may be from 2 to 4 feet diameter, ⅝ths inch thick, by 1¼ inch wide. The scrapers are made of light sheet iron, and are 9 inches wide by 4 inches deep, with shanks 3 inches long. Twelve rows of scrapers are mounted on the periphery of the trommel. The first, fifth, and ninth rows contain nine, and the remaining rows are fitted with eight scrapers. Each scraper is adjusted by slightly rotating the stem, and tightening the nuts over and under the trommel-ring.

The trommel is rotated against the flow of water. From the vertical axis of the trommel, the table F is more or less inclined, according to the density of the minerals to be separated. The enriched stuff is collected in the side-bin, 2½ feet in width by 8 feet in length. From this receptacle the sand may be transferred to jigging sieves, round buddles, or other suitable dressing apparatus. The stuff deposited in the strake H is either subjected to additional mechanical treatment, or, if sufficiently free from ore, taken to the refuse heap.

The 'work' to be enriched enters at C, on one side of the table, and is propelled against the flowing water by the action of the scrapers. The heavier portion is progressed across the table, and passed into an ore bin, through an opening 18 inches long and 3 inches deep. The lighter materials are drifted into the strake, and in this way a separation is effected. Great care must be taken to distribute the stream of water equally upon the surface of the table, and to proportion its volume so as to divide the inferior from the more valuable minerals. The water flowing from the wheel may serve not only to supply the table, but a part of it may also be diverted into the feed-hopper C, and any excess discharged by the launder J. The quantity of stuff which can be passed through this apparatus in a period of 10 hours will vary with the densities of the minerals to be separated. The impellor buddle has recently been improved by Mr. Henry E. Taylor of Aberystwyth, and applied to the washing of coal and ores. See Specification 889, A.D. 1874. At Restronquet Mine in Cornwall, the Messrs. Taylor and Sons employ this buddle successfuly in the treatment of tin ores.

At Wildberg in Germany, the floor of the buddle was divided by moveable ledges, and the stuff diverted to enriching tables.

Sand and Slime Dressing Machinery.

In most mines a large proportion of the ore is composed of dradge, and has to be brought to a fine state of subdivision either by the crushing mill or stamps. In this condition the ore is freed from sterile matter, and rendered fit for metallurgic treatment. A variety of machines have been invented and applied to this division of dressing, in which the leading principle is to produce a separation by subsidence, according to the density of the substances. In connection with this principle, the stuff is not permitted to have a vertical fall, but is traversed by a flow of water, on a table or bed set at such an angle to the horizontal plane as may be found expedient. With extremely fine stuff, apparatus including both of these features are sometimes subjected to a mechanical jar or vibration, so as to loosen and eject, as it were, the worthless matter with which it may be charged. In concentrating crushed or stamped ore, a certain quantity will often exist in a very minute state of division, unable to withstand the currents and volume of water necessary for the separation of the larger particles.

The amount and richness must necessarily depend upon the united produce and character of the ore, as well as the mode of treatment observed. A good dresser will form as little slime as possible, since when the ore is brought to this condition it is usually associated with a large mass of worthless matter; and not only so, but the expense of extracting it is materially increased. The loss under the most favourable manipulation is very large, whilst the machinery requisite is probably more complicated and expensive than any other section of the dressing plant. Although several machines are illustrated under this head, and many more might have been added, it does not follow that they may be advantageously employed for every variety of ore.

Thus an apparatus which would enrich slimes by one operation from 1½ to 5 per cent. might be both economical and desirable for treating copper ore, but would not be so important in the case of lead ore of the same tenure; for after deducting the loss of metal incident to the enrichment, charging the manipulative cost on the full quantity of stuff, and estimating the relative value of the two products, it might be found that one would scarcely leave a margin of gain, whilst the other would yield a satisfactory profit.

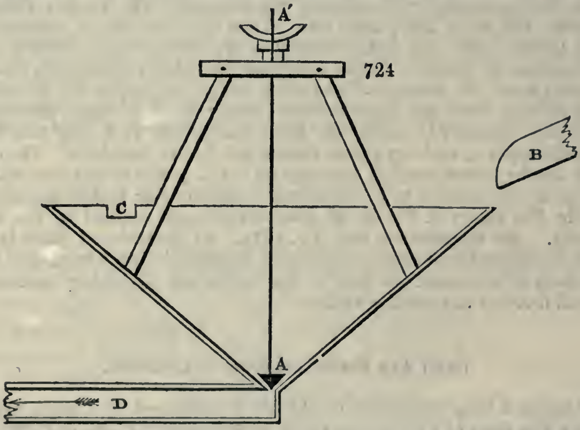
The proper sizing and subdivision of slime is as necessary as in the case of coarser work. In some of the German mines four or five distinct classes of slime are made, each class being treated on suitable enriching tables.

Richards' Slime Separator.—The water and stuff from the slime separated, is delivered through a launder into a pit, at the head of which is fixed a slightly inclined plank, divided into channels by slips of wood set in a radial direction from the aperture of the delivery launder. This pit has the form of an inverted cone, and since the water passes through it at a very slow rate, the more valuable and heavier matters will be deposited at the bottom. This apparatus thus becomes not only a slime pit, but also a slime separator.

The ordinary slime pit has usually vertical sides and a flat bottom; the slime and water enter it at one of its ends by a narrow channel, and leave from the other by the same means.

A strong central current is thus produced through the pit, which not only carries with it a portion of valuable slime, but also produces eddies and counter-currents towards the sides, which have the effect of retaining matters which from their small density should have been rejected.

The improved pit, *fig.* 724, receives its slimes from the launder B, and lets off a portion of them at C, whilst the richer and heavier matters, which fall to the bottom, escape through the launder D, regulated by means of the plug A, and screw A′.



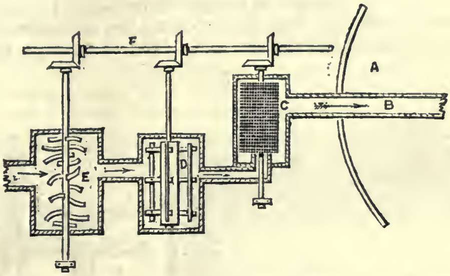
724

In many cases sand and slime stuff are much commingled with clay, and require to be broken and disintegrated before the ore can be extracted. A method for accomplishing this is shown in *fig.* 725. A is the circumferential line of a round buddle; B, launder, leading to such buddle; C, sifting trommel; D, rotating paddles; E, tormentor; F, driving shaft.

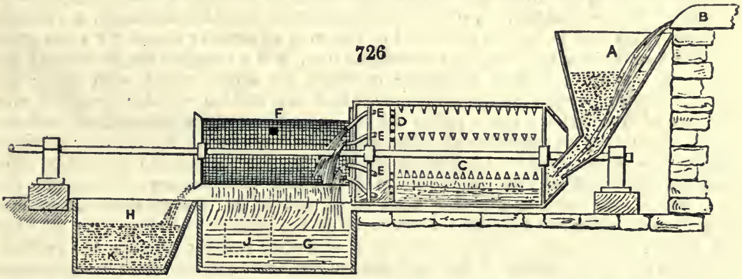
A modification of this method is found in the slime trommel, *fig.* 726. A, hopper, into which slimes are lodged; B, launder, delivering clean water into hopper A; C, trommel of sheet iron, fitted in the interior with spikes for the purpose of dividing the stuff; D, disc, perforated to prevent the passage of pieces of chips or bits of clay and stone; E, Archimedean pipes fitted into a disc of sheet iron, conveying water into gauze or perforated trommel F; G, slime cistern; H, cistern for receiving the rough stuff; J, slime outlet, communicating with round buddle, or other suitable apparatus; K, outlet for trommel raff, which may be delivered to a sizing cistern. The speed of the gauze trommel for fine slimes varies from 80 to 100 feet per minute.

Hand Buddle.—This apparatus (*fig.* 727), is somewhat extensively employed in lead-mines for the concentration of stuff which contains but a small proportion of ore, such as middles and tails resulting from the round buddle, or the tails from strips, &c. A rising column of water is shown at A. This flows into a trough B, and through peg-holes into C. Here the stuff to be treated is introduced, and continually agitated by the boy in attendance. The finer portion passes through the perforated plate at D, and is distributed by the fan-shaped incline E in an uniform sheet on the head of the buddles. A boy stands just below the line of the middles with a wooden rake; with this instrument he continually directs the descending current to the head of the buddle, and by this means succeeds in separating a larger proportion of the ore than would otherwise be done, Whether the rake or the broom be employed, it is found that some of the fine lead is *florrined* to the extreme tail of the buddle. In order to prevent this the frame G has been introduced. It is strained with canvas, and floats on the water. This canvas retains the fine lead, which is from time to time washed off in a cistern. The section to the first dotted line shows the heads of the buddle; from this to the second dotted line will be the middles, and from the second dotted line the tails commence. It must, however, be remarked that the exact line of heads, tails, and middles must depend upon their relative richness. The wooden rake is undoubtedly preferable to the broom, as will appear from the following experiment, everything being equal in both trials:—

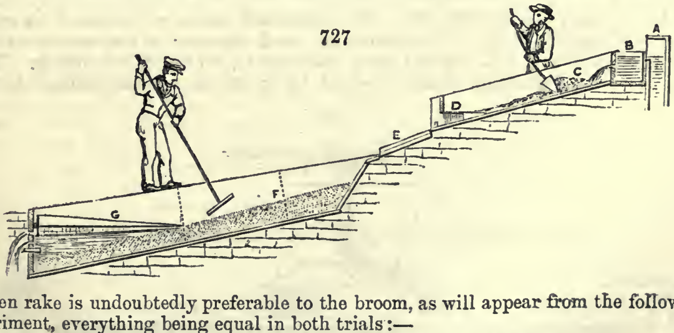
725



726



727



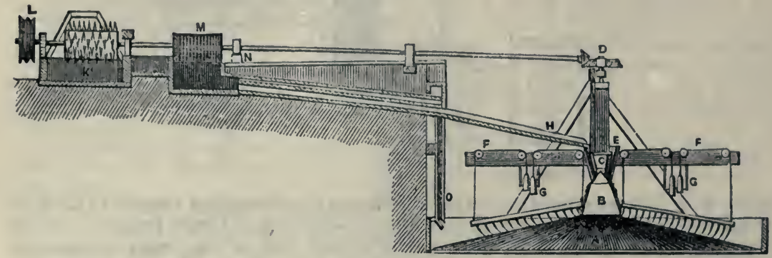
Stuff operated upon; tails from washing strips assayed 13 per cent.

	With broom	With rake
No. 1. Heads, assayed . .	16 per cent. . .	20 per cent.
„ 2. Middles, „ . .	$4\frac{3}{4}$ „ . .	$5\frac{3}{4}$ „
„ 3. Tails, „ . .	$4\frac{1}{4}$ „ . .	$1\frac{1}{2}$ „

It would be found a great improvement if these buddles were arranged so as to have their bottoms elevated when it might be necessary. As they are fitted at present the angle at the head is a constantly increasing one. The result is, the heads become poorer and the tails richer, as the operation proceeds, provided the fixed inclination of the buddle is correct at starting. In proportion to the poorness of the stuff the buddle should have its width increased, as well as be made shallower. If the stuff be also passed through a trommel before entering the buddle, the result will be found much improved.

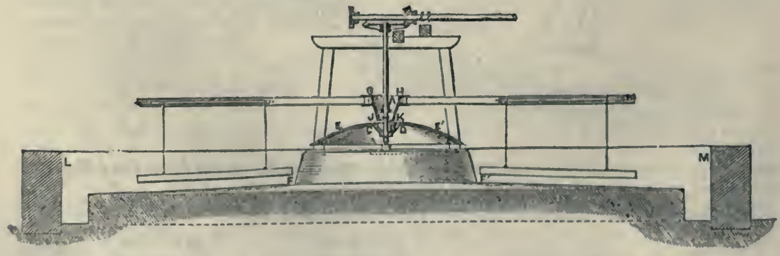
Round Buddle.—This machine serves to separate particles of unequal specific gravity in a circular space inclined from the centre towards the circumference. Its construction will be best understood by reference to *fig.* 728; in which A is the conical floor, formed of wood, and about 18 feet in diameter, on which the stuff is distributed; B is a cone, supporting the upper part of the apparatus, and serving to effect the equal distribution of the orey matter. D, wheel for giving motion to the arrangement; E, a funnel, perforated with four holes and furnished at top with an annular trough; F F are arms, carrying two brushes balanced by the weights G G; H is a launder, for conducting the stuff from the pit I; K is a receptacle in which the slimes mixed with water are worked up in suspension by the tormentor, which is a wooden cylinder provided with a number of iron spikes; L is a pulley taking its motion from a water-wheel, and M a circular sieve fixed on the arbor N. The stuff at K is gradually worked over a bridge forming one of the sides of a catch pit between the sieve M and the tormentor, from whence it passes off into the sieve by which the finer particles are strained into the pit I, whilst the coarser, together with chips and other like substances, are discharged on the inclined floor in connection with the launder O. From the pit I the stuff flows by the launder H into the funnel E, and after passing through the perforations flows over the surface of the fixed cone B, and from thence towards the circumference, leaving in its progress the heavier portions of its constituents, whilst the surface is constantly swept smooth by means of the revolving brushes. By this means the particles of different densities will be found arranged in consecutive circles. The arms usually make from two and a half to four revolutions per minute, and a machine having a bed 18 feet in diameter will work up from 15 to 20 tons of stuff per day of 10 hours.

728



In the ordinary round buddle the stuff is somewhat unevenly distributed, as well as imperfectly separated. This arises from the small diameter of the cone at its base, and the large volume of water and slime discharged upon its limited surface. These objections are to a certain extent removed by an improved round buddle, *fig.* 729.

729



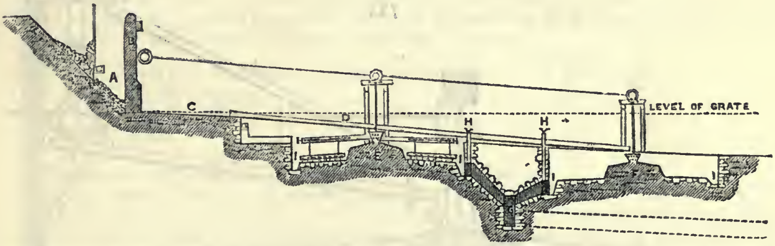
After the stuff has passed through a revolving trommel or grating connected with the apparatus, and to a certain extent sized, it is conveyed, by means of a launder, into a hopper A, and falls into the basin B. The slime from this basin flows freely over the convex plate E E′. It will appear that this arrangement secures an uniform distribution of the stuff, and at the same time the heavier portion is concentrated with greater rapidity than can be accomplished by means of the common rotating buddle.

The diameter of the hopper from G to H is 12 inches, from J to K 6 inches; the basin from C to D is 9 inches diameter, and the conical centre from F to F′ is 7 feet diameter. The buddle bottom is covered with plank in the usual way. Its diameter is 25 feet, with an annular ditch or gullet 12 inches wide. Into this gullet the sterile sand is scraped; and if the nature of the ground will admit, the bottom of the gullet may be sufficiently inclined to scour away the stuff, by the action of a stream of water. Captain Josiah Thomas states that the inclination of the buddle floor at Dolcoath varies from 1½ inch to ½ an inch in the foot; viz. for working 'roughs' 1½ inch, for slimes 1 inch, for treating stamps work, ½ an inch. The diameter of the wood centre F F′, also varies from 7 to 10 feet diameter. Mr. J. M. Pike, of Camborne, has furnished the following dimensions of a buddle erected at Tincroft:—

Floor of buddle, 20 feet diameter.
Inclination of floor of buddle, ¼ of an inch in a foot.
Wood cone, 9 feet diameter, depth 15 inches.
Number of arms in buddle, 6.
Height of arms from wood cone, 7 inches.
Speed of distributing plate, 2½ revolutions per minute.
Buddle, 21 feet diameter, filled in 24 hours to a depth of 13 inches. Contents 128 cubic feet, or 5⅓ cubic feet per hour, requiring 1,080 gallons of water, or 204 gallons per cubic foot of stuff treated.

The transverse section, *fig.* 730, shows the application of these buddles to the enrichment of tin ores. A, stamps pass; B, framework of stamps; C, stamps platform; D, launder for conveying stamp work to buddles E and F. Between the respective buddles runs a gullet, G, into which the waste flows, when the flushets, H H, are opened. The bed of each buddle is 20 feet in diameter, the annular spaces I I, one foot wide, making the distance from wall to wall 22 feet. It will be observed that the annular space is inclined towards the gullet, G. One buddle is sufficient to treat the stuff pulverised by a set of twelve or sixteen stamp-heads.

730

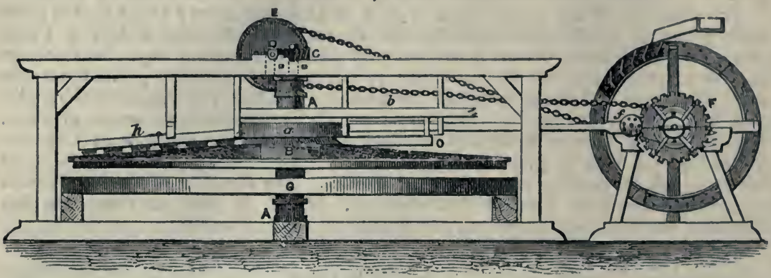


The inclination of the buddle bottom is ¼ of an inch per foot. Motion is given to the centre plate and arms by means of bevil gearing, moved by the stamping engine. The distributing plate of the buddle makes 2½ revolutions per minute. The stampwork, when passed through a perforated plate, having 36 holes to the lineal inch, can be concentrated at the rate of 5 cubic feet per hour.

Slime Buddle.—This machine, *fig.* 731, is said to effect the separation of the earthy matters from finely-divided ores more readily than the ordinary round buddle. For this purpose the pulverised ore is introduced near the centre of a large slightly conical rotating table, and flowing towards its periphery a portion of the upper part or head becomes at once freed from extraneous substances. Beyond this line of separation in the direction of the circumference, the stuff is subjected to the action of a series of brushes or rakes, and by means of a sheet of water flowing over the agitated slimes, clean ore is stated to be produced almost at a single operation.

The illustration, *fig.* 731, represents this machine at first erected at Clausthal, but it may be remarked that some of its mechanical details have been since judiciously modified by Mr. Zenner. A is an axis supporting and giving motion to the table B, 16 feet in diameter, and rising towards the centre 1 inch per foot; C, cast-iron wheel, 15 inches in diameter, operated on by the screw D. The tooth-wheel F drives the pinion *f*, the axis of which is provided with a crank giving motion to a rod fitted with brushes; G is an annular receiving box, 4½ inches wide and 6 inches deep; *a*, circular trough of sheet iron supported on the axis of the table an inch or two above its surface, and so divided that one quarter of it serves for the reception and equal distribution of the slime, whilst the other three quarters supply clear

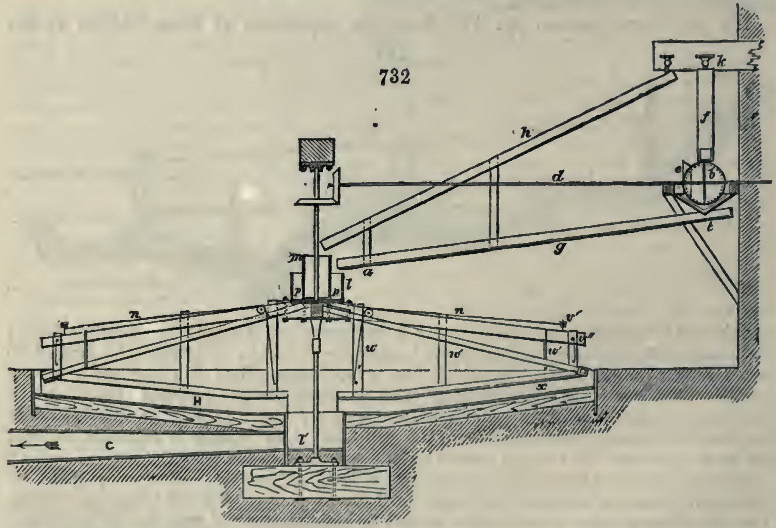
731



water; *b*, launder for supplying slime ore, behind which is another not shown, for bringing in clear water. o, trough supplying additional water to the stuff agitated by the brushes. One end of this water-trough is fixed about the middle of the table, whilst the other advances in a curved direction nearly to the circumference.

Concave Buddle.—The object of this apparatus, *fig.* 732, is to concentrate on the

732



periphery of the floor, instead of the centre. This arrangement gives an immense working area for the heads, and at the same time admits of the separation of a greater portion of the waste than can be effected by the ordinary round buddle. After the slimy water has been discharged on the edge, the area over which it has to be distributed is gradually contracting, thereby increasing the velocity of the flow, and enabling it to sweep off a proportionate quantity of the lighter matter associated with the ore. *a* represents the inflow slime launder; *b*, a separating trommel, through which the slimes pass previous to their entrance into the launder *a*. c, outlet launder, for taking off castaways; *d*, arbor giving motion to the buddle arms and diagonal distributing launders attached thereto, held by the braces *w w'*; *e*, bevel wheel on driving arbor; *f*, downwright launder, to which is affixed a regulating cock, *k*, for supplying slimes to trommel; *h*, launder for delivering clean water to circular box *m*, and which water passes through slot openings at *p p*, uniting with and thinning the slimy matter previous to its passing into the diagonal delivery launders; *l'*, circular pit for receiving tailings. Attached to the wooden bar *x* is a piece of canvas with corresponding pieces depending in a similar manner from each arm, and which serve to give an even surface to the stuff in their rotation. The slimes flow from four diagonal launders, each having its upper end in communication with the box *l*. The speed of the arms and diagonal launders must vary with the nature of the stuff to be operated upon; for rough sands eight revolutions per minute have been found sufficient, but for fine slimes from fourteen to sixteen revolutions in the same time are necessary. The inflow of slime and water should also be proportioned to the speed and density of the stuff to be treated. No precise instructions can be offered on this head, but an experienced dresser would easily determine the proportions after a few trials. The bed is 18 feet diameter, and has a declination of about 6 inches from the edge to the point where it unites with the horizontal portion of the floor.

Experiment on slime ore, very fine and much intermixed with carbonate of iron:—

	Per cent.
Produce before entering buddle . .	6
Heads of buddle averaging 3 inches deep and 22 inches wide	12½ and 30 oz. of silver per ton of lead.
Middles of buddle averaging 1¾ inch. deep and 18 inches wide . . .	6½ and 42 oz. ,, ,,
Tails of buddle averaging ¾ inch deep.	3 and 55⅔ oz. ,, ,,
Castaways	½

Time required to fill buddle, 3 hours; number of arms in buddle, 4; number of revolutions of arms per minute, 8.

Experiment on fine slimes, much associated with carbonate of iron:—

Produce before entering the buddle . . .	3 per cent.
Heads 3 inches deep, 16 inches wide . . .	7½ ,,
Middles 1½ do. 12 do. . . .	1 ,,
Tails	traces.

Number of revolutions of arms per minute 14; time required to fill buddle 5 hours.

In working this buddle one month upon the fine and rough slimes, indicated in the two foregoing experiments, the results obtained were:—

	Mean
Assay of stuff before entering the buddle . .	5·0 per cent.
Heads afforded	12·5 ,,
Middles	5·0 ,,
Tails	0·77 ,,

Experiment on slime ore containing 7½ per cent. of lead:

In 12 hours 4 tons were washed, and gave 14 cwts. of crop, 28 cwts. middles, 12 cwts. tails, and 26 cwts. of waste. The 14 cwts. of crop were washed in 3 hours, and afforded 3½ cwts. dressed slime ore, 5½ cwts. of middles, 4 cwts. of tails, and 1 cwt. of castaways. The middles resulting from both operations, viz. 33½ cwts. were washed in 8 hours, and gave crop 4 cwts., middles 12 cwts., tails 4 cwts. and waste 13½ cwts. The tails were now washed in 3 hours, and afforded 4 cwts. of middles and 12 cwts. of castaways. 16 cwts. of middles were also washed in 3 hours, and furnished 2 cwts. crop, 6 cwts. middles, and 8 cwts. of castaways. In addition, 10 cwts. of crop ore were washed during 3 hours, and gave 1$\frac{8}{10}$ cwt. of slime ore, crop 1 cwt., middles, 6 cwt., castaways 1 cwt.

The results, therefore, show that 4 tons of rough slimes were washed in 32 hours, and afforded 5½ cwts. slime ore at 43½ per cent., leaving 1 cwt. of crop at 31 per cent., and 12 cwts. of middles yielding 4¼ per cent. A comparison was also made with the shaking table; 5 tons of the same slimes were washed in 48 hours, and gave 7 cwts. of dressed ore, 1 cwt. of heads, and 8 cwts. of middles.

The Table at top of following page shows the results of an experiment made between the concave buddle and the ordinary round buddle; time occupied, 24 hours.

The tails lying upon the horizontal part of the concave buddle contained 27½ per cent. of zinc and 2½ per cent. of lead.

It will be perceived that the much larger crop from the concave buddle was more than twice as rich for lead, whilst it was only 2 per cent. richer for zinc.

Quartzose ore without blende was then tried, and a similar weight gave 1,570 lbs. of crop, affording 56½ per cent. or 888½ lbs. of lead, and 3,450 lbs. of middles of 14 per cent. produce, equal to 483 lbs. of lead, or together 5,020 lbs. of stuff containing 1,372 lbs. of lead. The round buddle, on the contrary, gave 455 lbs. of crop ore, of 63½ per cent., equal to 290 lbs. of lead, 2,900 pounds of middles, of 18½ per cent., representing 541 lbs. of lead, or a total of 3,365 lbs. of stuff, containing 831 lbs. of lead.

Fig. 733 represents a buddle arranged for the treatment of fine slimes. It is entirely constructed of metal, and every part is carefully fitted in order to secure an even and delicate action. The stuff is introduced into the hopper A, from whence it passes into

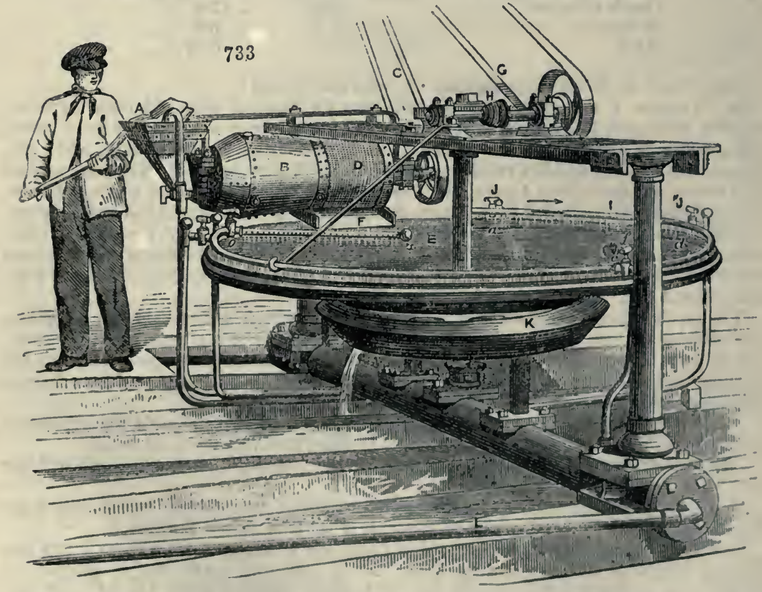
the trommel B, turned by the band C. The fine stuff passing through the perforated cylinder D, falls upon the shoot F, and flows upon the concave table E. This table revolves in the direction of the arrow and acquires its motion by means of the strap G driving the tangent wheel and screw shown at H. Concentric with the table a wrought-iron pipe I is fixed, which is pierced with numerous small holes. The quantity of water to this pipe is adjusted by the regulating cocks J J′ J″. Beneath the table is a circular receptacle or bottom K, having three compartments for receiving the washed stuff. From *a* to *d* the jets of water are comparatively light; from *d* to *c* the force of water is increased, and still further augmented in that portion of the circle extending from *c* to *o*, whilst from *o* to *x* it is sufficiently powerful to clean the buddle. In each of the sections a

733



portion of waste along with a little light ore is washed into the receptacles underneath, from whence it may flow into strips or buddles for further separation, or is otherwise manipulated upon a second buddle. The water is supplied to the machine under pressure by the pipe L. This apparatus will wash from 80 to 100 cubic feet of free slimes in 10 hours, or from 60 to 80 cubic feet of tough slimes in the same period. Lead stuff affording 4 per cent. with a light waste has been enriched to 40 per cent. in a second revolution, and in a third and fourth rotation 40 per cent. slime has been enriched so as to yield 60 per cent. of ore. The buddle table makes two revolutions per minute; its diameter varies from 8 to 10 feet, and the power required is about one-tenth of a horse-power. One boy can serve four buddles.

Rittinger's Rotating Buddle.—This apparatus is employed at Schemnitz, and is applicable to the treatment of fine slimes containing but a small proportion of metallic substances. The accompanying sketch (*fig.* 734) will serve to explain its construction and action. The machine may be said to consist of four principal parts:—

1st. The vertical axle *a*, which carries the buddle.

2nd. The surface of the buddle *b*.

3rd. The concentric launders *c c′*, for supplying the diluted slimes, as well as clean water to wash the mineral.

4th. The concentric launders *d d*, beneath the buddle for receiving the concentrated minerals and waste.

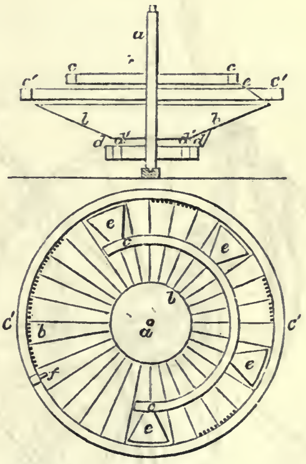
The vertical axle *a*, is fitted with a cast-iron centre-piece, which receives 16 wooden arms; these support the same number of segments, and form a circle 16 feet in diameter. Each segment is divided into two parts, by radial strips of wood, so that the whole surface of the buddle is divided into thirty-two parts, each being 5½ feet long, and having a fall of about 6 inches towards the centre.

Motion is given by a tangent wheel and screw geared at the upper end of the axle, one revolution in ten minutes being the required speed. Above the buddle are two concentric launders, the one *c′*, at the periphery, being for clean water, the other *c*, nearest the centre, for the contents of the sizing apparatus. The stuff is introduced by means of feeding boards on the outer circumference of the buddle.

Between each feeding board a fine sheet of water flows to the buddle from the launder *c*.

After the last feeding board, the launder forms a curve towards the centre of the buddle, and supplies along its length a thin fine stream of water, which washes the deposited stuff from top to bottom, carrying away all the lighter particles, and leaving only the heaviest minerals on the surface of the buddle. The buddle, after passing this point in the course of its rotation, comes under a strong jet of water flowing from a pipe *f*, supplied from a cistern about 12 feet above. This water flows with sufficient force to drive the concentrated mineral into the launders *d d*, which is divided into different compartments, for receiving the middles and waste from the buddle during its revolution. These are thrown away, unless it be found that the middles are worth repassing over the buddle. The finer the slimes, the more perfect is the result. The slimes from the sizing apparatus should be thin, from 2¼ to 4¼ lbs. of sand to a cubic foot of water being sufficient.

734



The water required for cleansing is from eight to nine-tenths of a cubic foot per minute.

The water for driving off the clean product is from one and a half to one and six-tenths of a cubic foot per minute.

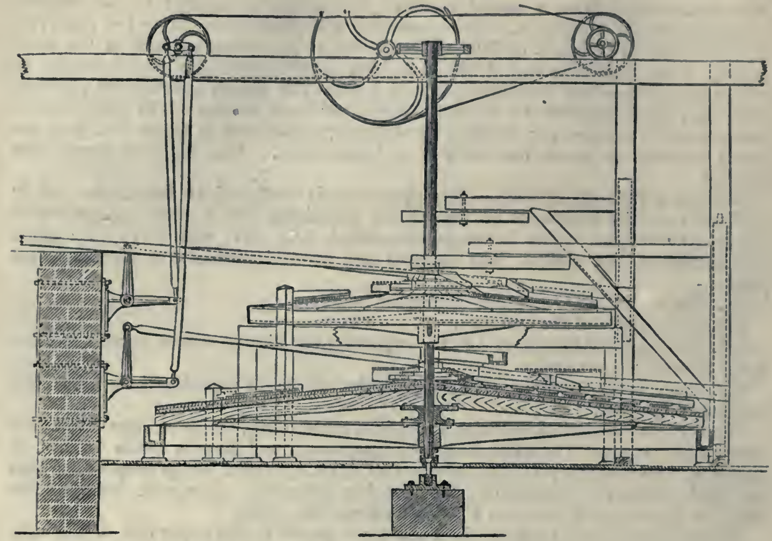
Altogether, the quantity of water required per minute is about 2¼ cubic feet.

The buddle, if properly constructed, extracts about 80 per cent. of the ore contained in the slimes, and will treat about 1 cwt. per hour. One-twentieth of a horse-power is sufficient for rotating the buddle.

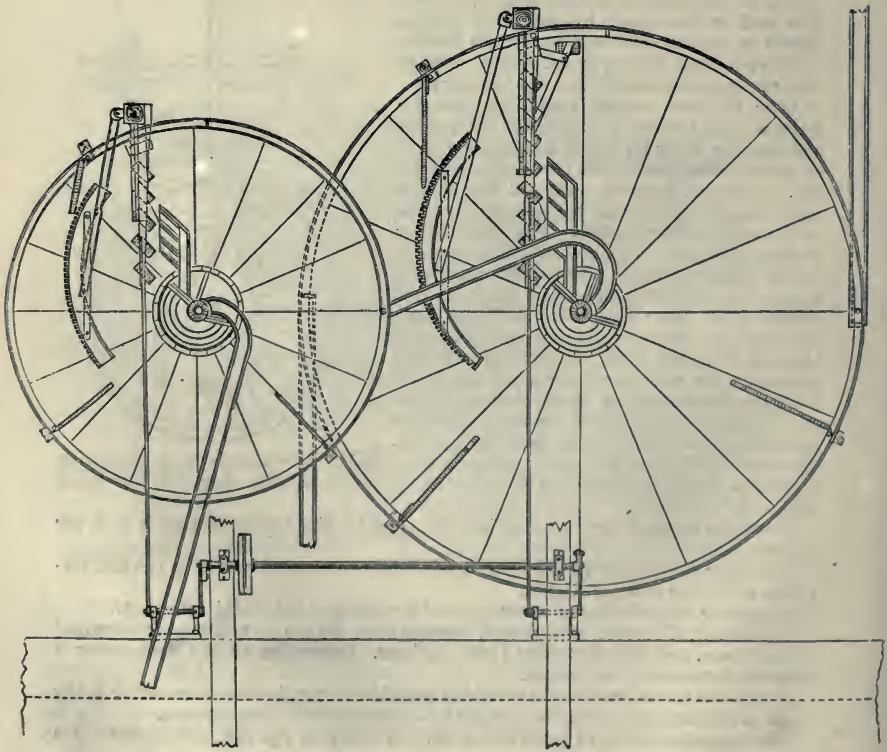
A valuable set of buddles for enriching palpable slimes, has been in use for many years at the lead and silver ore dressing establishment near Ems, Prussia.

The apparatus is shown in elevation *fig.* 735 and plan *fig.* 736, and consists of a

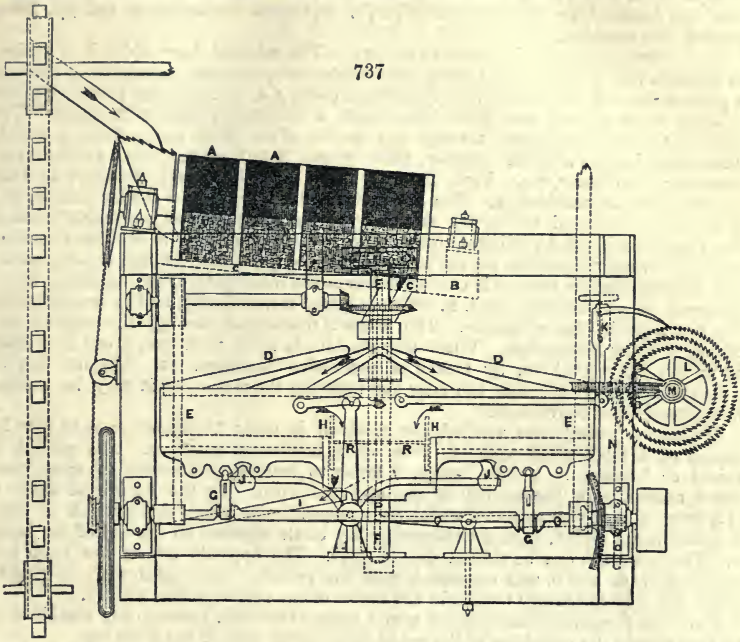
735



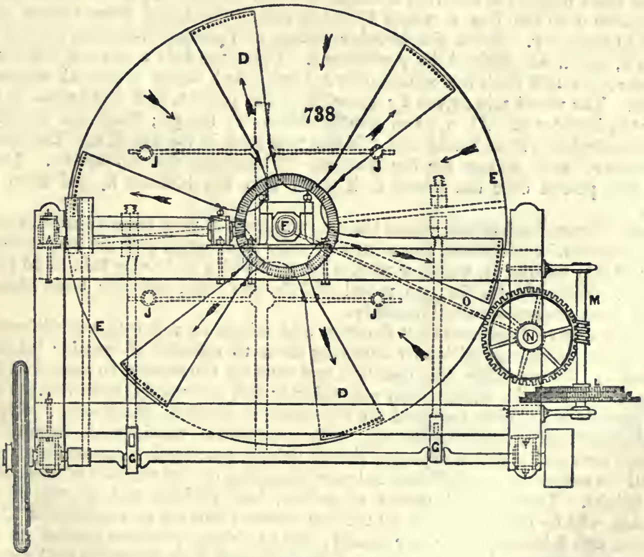
736



small and a large circular table, each rotated by means of a tangent wheel and screw. Slime of the fourth class, exceedingly fine, passes first to the small table 10 feet diameter, and after being deprived of the greater portion of its ore, flows to the larger table 18 feet diameter, where it is divided into a weakly-enriched product and waste. The fall of the table is 5°, and one revolution is performed in four minutes: the washing water is distributed by means of 3 short wrought-iron pipes, through a line of perforated holes, and a segmental launder; sufficient water being supplied to effect the desired separation, the brushes making 100 strokes per minute serving to clean the



737



738

table. A fixed launder or trough coincident with the periphery of the table is divided so as to receive the ore and orey stuff.

In addition to the machines already described, a slime or sludge dressing apparatus has been designed by Mr. Borlase. *Fig.* 737 represents an elevation, and *fig.* 738 a plan of this machine.

It is described by the inventor as follows:—The mineral from which it is desired to separate the metallic ore having been crushed or pulverised, is conducted through a pipe or channel into a revolving cylindrical sieve, A A. The larger parts pass into a shoot or launder B, and from thence into a self-acting jigging machine. The slime or fine portion passes through the meshes of the sieve into a shoot, C, and is discharged into an annular launder, from whence it falls either into a stationary or revolving distributor, D D. From thence it flows through suitable channels into the outer part of the machine, E. The apparatus is fixed on a perpendicular axis, F, and is kept in a continual oscillatory motion by means of cranks and connecting rods, G, the speed of the cranks being adjusted so as to keep the slime in continual motion, and at the same time cause the ore to descend and deposit itself at the bottom, whilst the waste or lighter portion is carried towards the inner part of the machine, where it passes over a moveable ring, H, which is raised mechanically, and in proportion as the ore rises in the apparatus. The waste is discharged through the outlet I, and conveyed away in launders. When the machine is filled with ore, it can be settled, as in the dolly machine, by means of percussive hammers, J J. The ore can be collected either by reversing the gear and lowering the ring H, or it may be washed into a receiver as convenient.

Motion is given to the vertical bar K, which is made to vibrate so as to turn by means of a ratchet the wheel L, fitted on a horizontal shaft, M. The ratchet is raised or lowered by a worm screw, in order to increase or decrease the speed rendered necessary by the quality of ore operated upon. On the horizontal shaft M is a worm pinion, that works a wheel on a perpendicular shaft, N, on which is fixed a second worm pinion, raising or lowering the tooth segment on the end of the beam O. This segment can be shifted out of gear. The opposite end of the beam O is attached to the rod P, and connected with the crossbar R, as also with the ring H, which has a reciprocatory motion in the centre of the perpendicular shaft F.

From the foregoing description it would appear that Mr. Borlase has combined in this apparatus the principles of the round buddle with that of the dolly tub.

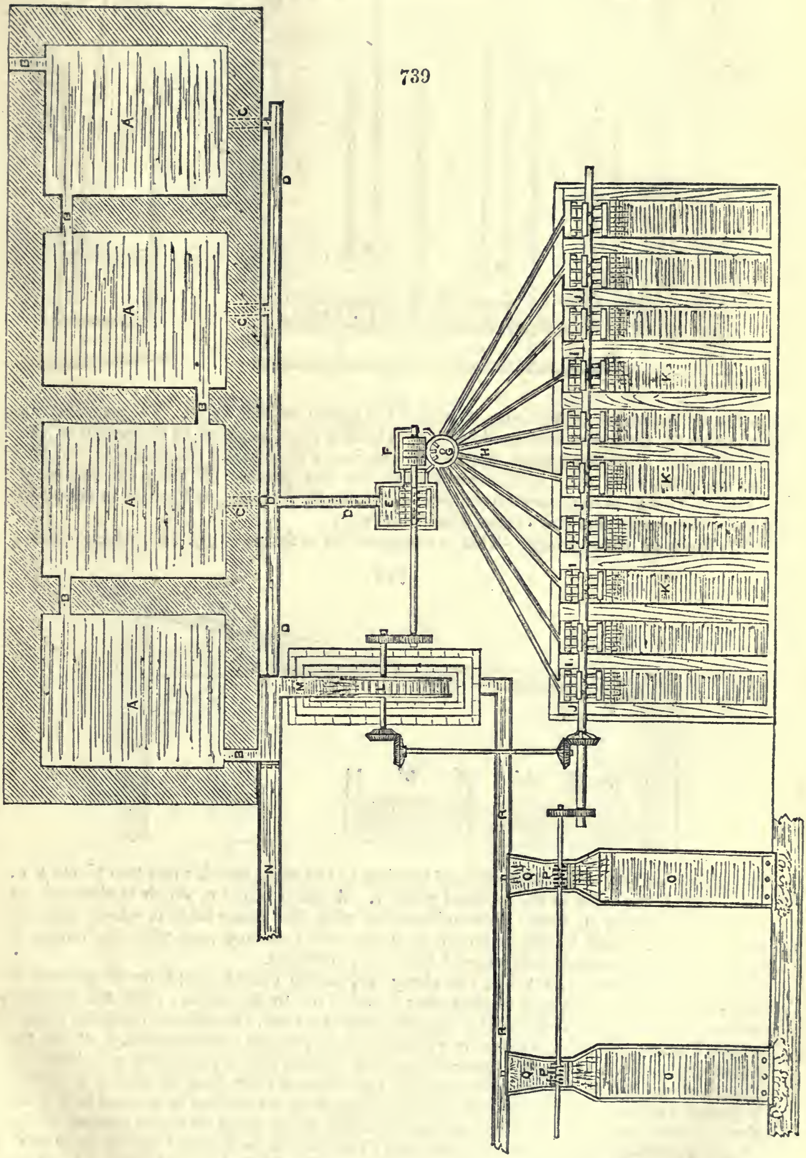
Slime Trunking Apparatus.—The illustration, *fig.* 739, shows the apparatus employed in some of the lead-mines of Cardiganshire. The slimes are lodged in the several settling pools marked A, and flow through the channels B. At C the slimes pass into the launder D to the box E, where they are comminuted, and from thence progress into the trommel F. From the circular cistern G, V-shaped launders diverge to the trunks K, which are divided by partitions I. Upon the axis J in each buddle head, paddles rotate, and flush the slimes over a head board, where a partial separation is effected. The wheel L is driven by water from the pools A, and any excess is carried off by the launder N. At O O two hand-buddles are shown; these are intended for the concentration of the heads and middles produced in the trunk K. The axis at P is furnished with spikes for the purpose of breaking up the slimes. After the water has passed over the wheel L, it flows into the launder R, and from thence into Q.

At the Minera lead-mines, where the ore produced is very massive and capable of a high degree of enrichment, the slimes average 9 per cent., and are concentrated by means of this apparatus, together with a round buddle and dolly tub, to 75 per cent. of metal. With six trunks, one round buddle, one man, and four boys, about nine tons of clean ore are obtained monthly.

Attempts have been made by Brunton and others to separate metalliferous ores of different specific gravities by allowing them to descend at regular intervals in still water. By reversing the operation and causing the current to ascend uniformly, the particles may be much more conveniently and accurately classified. This has been done in a machine designed by the late Mr. Herbert Mackworth. Suppose a funnel-shaped tube, larger at the top; with a current of considerable velocity flowing upwards through it, grains of equal size of galena, pyrites, and quartz, when thrown in, will be suspended at different heights depending on the velocity of the current at each height. Thus cubical grains of galena, iron pyrites, and quartz, of $\frac{1}{12}$ inch diameter, will be just suspended by vertical currents moving at velocities of 12 inches, 7 inches, and 5 inches linear per second; flat or oblong particles require rather less velocities to support them, inasmuch as they descend more slowly in still water than the cubical or spherical particles.

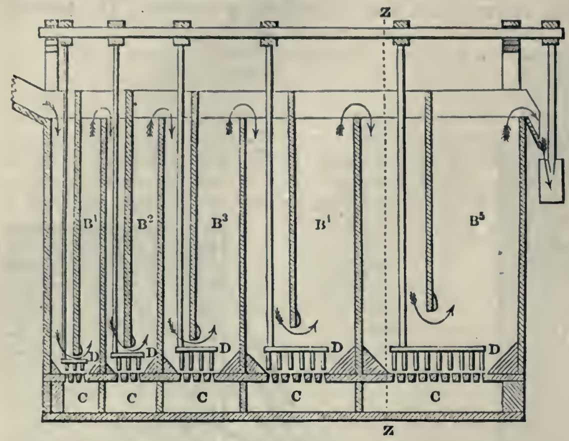
A simple form of applying this principle is presented by the vertical trunks shown in *figs.* 740 and 741. Metalliferous ore, after being classified by sifting, or tin ore as it comes from the stamps, may be allowed to flow mixed with water down the shoot A. The supply of water should be taken from a head so as to be perfectly uniform in quantity. The water mixed with the ore flows in the direction of the arrows down and then up the divisions B^1, B^2, B^3, B^4, B^5, each of which increasing in area, the velocity of the ascending current diminishes in the same proportion. The particles

739

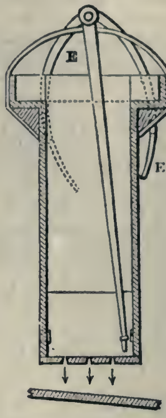


of greatest specific gravity will be deposited in the bottom of B^1. In the bottom of B^2 will be found small particles of great specific gravity and large particles of small specific gravity. The same relation will exist in B^3, B^4 and B^5, only the particles of each will be smaller in succession. The plugs in the holes C C C being opened as is found necessary, allow the accumulations in the bottom of each trunk to discharge themselves into separate troughs. The rocking frame and rakes D D constantly stir up the sediment so as to bring it under the action of the water. To produce the oscillation of the rakes, two spade-shaped plates E E are exposed to the action of the falling water discharged from the end of the box which rocks the frame to and fro. The ore in the first trunk is fit for smelting; the ore passing off from the bottom of the other trunks is in a very favourable condition for framing, or it may be sifted to remove the larger particles of less specific gravity.

740

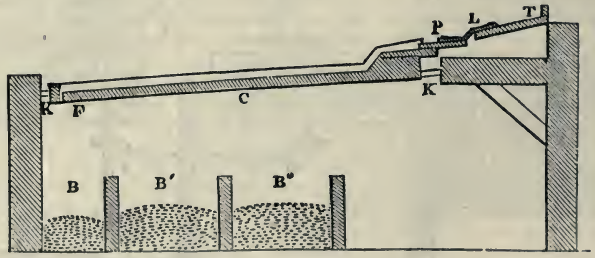


741



The Rack or Hand-frame.—This is composed of a frame C, *fig.* 742, which carries a sloping board or table susceptible of turning to the right or left upon two pivots K K. The head of the table is the inclined plane T. A small board P, which is attached by a strip of leather L, forms a communication with the lower table C, whose slope is generally 5 inches in its whole length of 9 feet, but this may vary with the nature of the ore, being somewhat less when it is finely pulverised.

742



In operating with the table, the slimy ore, to the extent of 15 or 20 pounds, is placed on the head T, and washed over L and P on to the table; then the operator with a toothless rake distributes it equally over the head, the richest particles remain on the highest part of the table by virtue of their greater specific gravity, whilst the muddy water falls through a cross slit at the bottom into a receptacle B. When the charge of ore has been thoroughly racked, the table is turned on its axes K K until it is brought into a vertical position, and the deposit on its surface is washed into boxes B′ B″. The box B′ will contain an impure slime, which must be again framed, whilst B″ will probably contain a slime sufficiently enriched to be finished by the dolly tub.

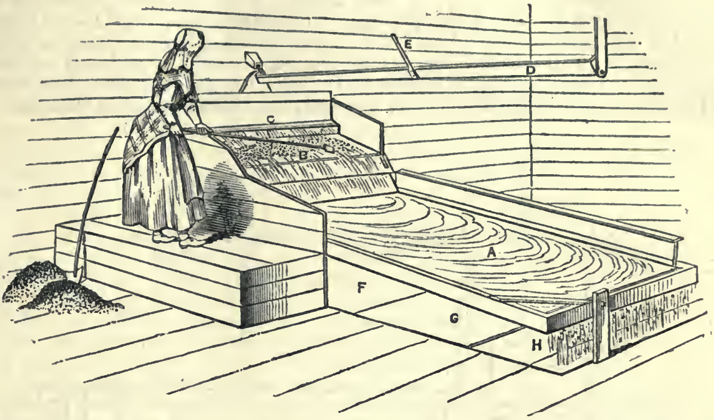
The slope of the rack table for washing tin stuff is 7¾ inches in 9 feet. The width is about 4 feet.

The average quantity of lead slime which can be washed per day of ten hours, is about 30 cwts., and the water necessary, say 600 gallons.

The general appearance of the rack is shown in the illustration, *fig.* 743. A, table;

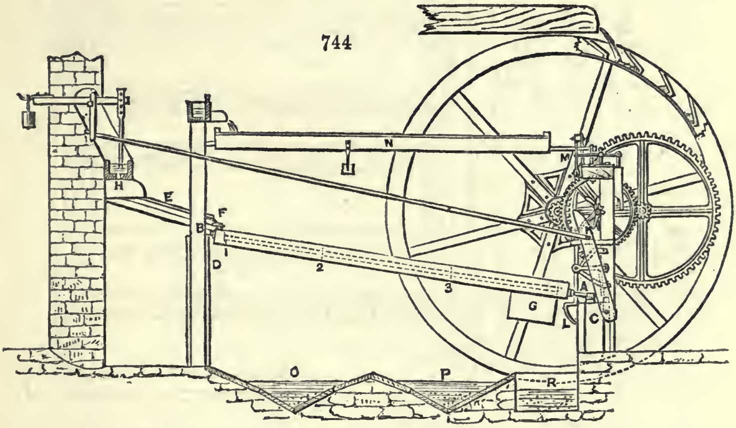
B, inclined plane upon which the stuff is lodged. Clean water flows over the ledge C. When the table A is turned in a vertical position, the racking girl washes it by depressing the lever E attached to the V-shaped launder D, thereby discharging the water which it may contain. The heads, middles, and tails are lodged in the compartments F, G, and H, respectively.

743



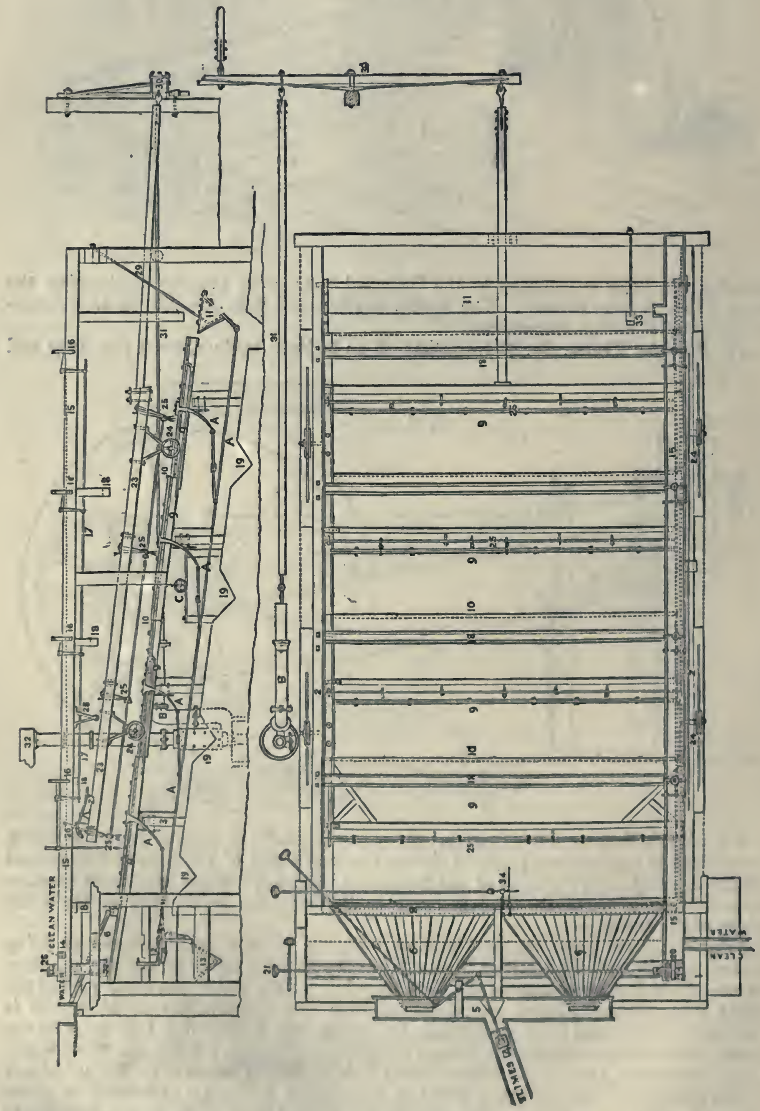
The Machine Frame, fig. 744, consists of an inclined table, about 8 feet long and 5 feet wide, with sides 5 inches high. At each end are fixed axles of iron, A B, which are centred in two vertical pieces of timber C D, and admit of the frame being turned perpendicularly. At the head of the frame is a ledge E, on which numerous lozenge-shaped pieces of wood are fixed in order to distribute the liquid stuff on the entire width of the frame.

744



From the frame head, the stuff falls on a sloping board F, which admits of being turned, as it is hung by leathern hinges, when the frame assumes an upright position. At one of the bottom corners of the frame is a box G, into which the chief part of the water from the table flows. In operating with this machine, the liquid matter is admitted to the frame head E, through the hole H, and flowing in a thin sheet on the table I, deposits the vein-stuff according to its varying specific gravity, the best quality being heads from 1 to 2, the middles from 2 to 3, whilst the tails are lodged at the end of the apparatus. To the water wheel is attached a horizontal axle fitted at given distances with cams, which disengage at the proper time parts of the machinery connected with the frame. The first cam acts on the rod K, and stops the flow of tin stuff; the second cam disengages a catch beneath the displacing box G, containing the frame water, and immediately the frame assumes a vertical position striking in its movement a catch at M, which upsets the V-shaped launder N, containing pure water, in such a way as to wash the ore on the table into two coffers O and P. The frame then returns to its horizontal position, and the orey matter is again admitted through H. One boy can manage twenty of these frames. When employed in cleaning tin stuff, the two coffers O and P are discharged into separate pits about 15 feet long, 6 feet wide, and 12 or 15 inches deep. The refuse from the end of the frames as well as the slimy water from the displacing box, is either thrown away or subjected to further treatment; the coffer O is usually taken to the hand frames, after which it is tossed and packed, whilst the stuff from coffer P is again submitted to machine framing.

745



Hancock's Slime Frame.—The ores and accompanying waste are brought into a state of suspension by water, and are then by adjustment made to pass over a slight fall, so as to produce the greatest regularity in its flow over tables fixed upon a given incline, each table having a sufficient drop from the table above. When the tables are sufficiently charged, clean water is introduced to pass over the table. The surfaces of the tables are subject to the action of brushes or brooms during a part or the whole time of both operations until the ore is sufficiently cleaned. In some cases the use of such brushes or brooms are dispensed with. The ore (on the tables) thus cleaned is washed off into cisterns by the action of water passing over the surfaces of the tables after they are raised to nearly perpendicular positions.

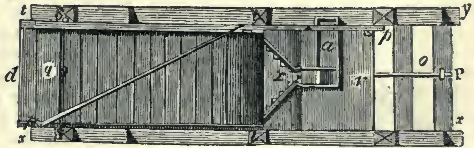
Fig. 745 represents, 1, framework to carry the gear on each side of the machine; 2, the stretcher or pivot piece on which all the tables are resting; 3, centre bearings of the tables, to which is attached an adjusting screw for raising or lowering them; 4, a slide valve, which admits or shuts off, as required, the ores, which are previously brought into a thin consistency with water; 5, launder through which the ores, pass to the heads, which are divided into sections and numbered; 6, the ores, &c., dropping from the heads into a launder, 7, the working edge of which is made level by an adjusting screw at each end for the ores to pass over; 8 is a stretcher, passing over the heads in both ends, bolted to 1, from which 6 and 7 are supported by three adjusting screws; 9 are four tables over which the ores have to pass, first receiving the deposit of the cleanest or best ores, and the rest in gradation; 10, the drop or fall from one table to another; 11, the balance cistern, into which the refuse from the tables passes, and when full, by lifting the catch 12 it forms a balance for turning up the tables to be washed down, each table being connected with rods and lever A; this done, such catch is lifted up, and 13 forms a returning balance for the tables; at 14 a stream of water is introduced, passing into 15 as a receiver; on the turning up of the tables, valves 16 are lifted by lever and rod 17, and admit the water into perforated launders 18 to wash off the ores into receivers 19, through which it passes out into deposit hutches. The slide valve 4 having admitted a sufficient quantity of ore, which has been deposited on the tables, is now closed, and the valve 20 is opened by the dresser at rod handle 21, through which a supply of water passes into launder 22, and flows over the tables for the purpose of cleaning the ores. The framework for the brushes 23 is carred on four wheels 24, each table being supplied with a brush 25, which brushes its respective table upwards, and on arriving at the heads of the tables, the brushes being all connected, are lifted by lever and 26 slips into the catch 27, and the brushes pass back over the tables without touching until the lever of the catch is struck out by 28, and the brushes drop again on the tables. Each brush is adjusted by screws and carried on arbors running across the frame. This frame with its appendages is propelled by a rod 29, attached to a beam 30, that can be worked by any sufficient power that may be applied.

The ores passing from the third and fourth tables through the two lower receivers 19 into a cistern, are lifted by a plunger B, attached to beam 30, by a rod 31, and passes back by launder 32 to be readmitted into slide valve 4, and repass the tables. In 11 balance cistern is a valve 33, which on the dropping of the table lets out the contents. 34 is a catch for holding the frame and brushes during the time of turning down and washing the tables. The machine is to be worked with or without brushes, as the character of the ores may require. It may be extended or diminished to any number of tables, and their size may vary as may be found necessary on the same principle. C is a wheel acting as a parallel motion for the plunger pole and running on a bar of iron.

This machine was in constant use at the Great Polgooth Mine for some time, and it is said effected a saving of 30 per cent. in the dressing of slime ore. It is not so well adapted for rough as for the treatment of fine slimes.

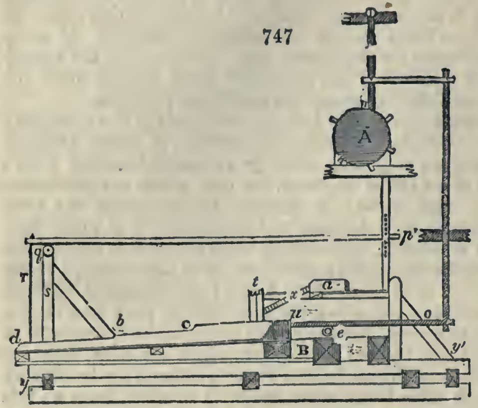
Percussion Table.— The diagrams, *figs.* 746, 747, 748, exhibit a plan, vertical section, and elevation of one of these tables. The *arbor* or shaft, is shown in section perpendicularly to its axis, at A. The *cams* are shown round its circumference, one of them having just acted on *n*.

746

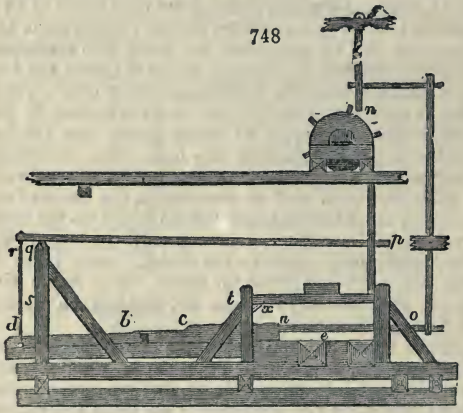


These cams, by the revolution of the arbor, cause the alternating movements of a horizontal bar of wood, *o*, *u*, which strikes at the point *u* against a table *d*, *b*, *c*, *u*. This table is suspended by two chains *t*, at its superior end, and by two rods at its lower end. After having been pushed by the piece, *o*, *u*, it rebounds to strike against a block or bracket B. A lever *p*, *q*, serves to adjust the inclination of the moveable table, the pivots *q* being points of suspension.

747



748



The stuff to be washed is placed in the chest *a*, into which a current of water runs. The ore, floated onwards by the water, is carried through a sieve on a small sloping table *x*, under which is concealed the higher end of the moveable table *d b c u*; and it thence falls on this table, diffusing itself uniformly over its surface. The particles deposited on this table form an oblong slope upon it; the successive percussions that it receives determine the weightier matters, and consequently those richest in metal, to accumulate towards its upper end at *u*. Now the workman by means of the lever *p*, raises the lower end *d* a little in order to preserve the same degree of inclination to the surface on which the deposit is strewed. According as the substances are swept along by the water, he is careful to remove them from the middle of the table towards the top, by means of a wooden rake. With this intent, he walks on the table *d b c u*, where the sandy sediment has sufficient consistence to bear him. When the table is abundantly charged with the washed ore, the deposit is divided into three bands or segments *d b*, *b c*, *c u*. Each of these bands is removed separately and thrown into the particular heap assigned to it. Every one of the heaps thus formed becomes afterwards the object of a separate manipulation on a percussion table, but always according to the same procedure. It is sufficient in general to pass twice over this table the matters contained in the heap, proceeding from the superior band *c u*, in order to obtain a pure slime; but the heap proceeding from the intermediate belt *b c*, requires always a greater number of manipulations, and the lower band *d b* still more. These successive manipulations are so associated that eventually each heap furnishes pure slime, which is obtained from the superior band *c u*. As to the lightest particles which the water sweeps away beyond the lower end of the percussion table, they fall into launders, whence they are removed to undergo a new manipulation.

749

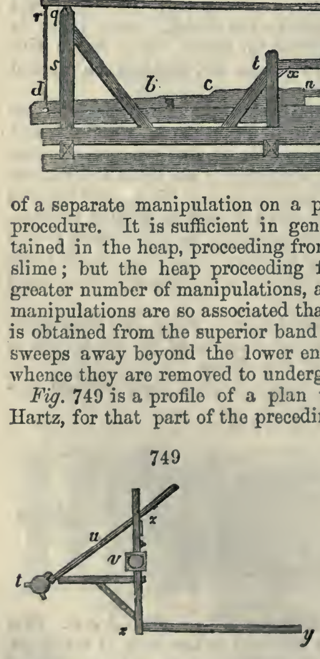


Fig. 749 is a profile of a plan which has been advantageously substituted, in the Hartz, for that part of the preceding apparatus which causes the jolt of the piece *o u* against the table *d b c u*. By means of this plan, it is easy to vary, according to the circumstances of a manipulation always delicate, the force of percussion which a bar *x y*, ought to communicate by its extremity *y*. With this view a slender piece of wood *u* is made to slide in an upright piece, *v x*, adjusted upon an axis at *v*. To the piece *u* a rod of iron is connected, by means of a hinge *z*; this rod is capable of entering more or less into a case or sheath in the middle of the piece *v x*, and of being stopped at the proper point, by a setscrew which presses against this piece. If it be wished to increase the force of percussion, we must lower the point *z*; if to diminish it, we must raise it. In the first case, the extremity of the piece *u*, advances so much further under the cam of the driving shaft t; in the second, it goes so much less forwards; thus the adjustment is produced.

The water for washing the ores is sometimes spread in slender streamlets, sometimes in a full body, so as to let two cubic feet escape per minute. The number of shocks communicated per minute, varies from 15 to 36; and the table may be pushed out of its settled position at one time three quarters of an inch, at another nearly 8 inches. The coarse ore sand requires in general more water, and greater slope of table, than the fine and pasty sand.

The following remarks on the Freiberg *Shaking Table*, are by Mr. Upfield Green, formerly of the Wildberg Mines, Prussia. The bed of the table is about fourteen feet long, by six feet wide, and is formed of double one-inch boards, fastened to a stout frame. The table is hung by four chains, the two hindermost are generally two feet long with an inclination of 2 to 4 inches. The two front ones, which are attached to a roller for the purpose of altering the inclination of the table, are five feet six inches long, and hang perpendicularly when the table is at rest.

The tables receives its action from cams inserted in the axle of a water wheel, acting on the knee of a bent lever. The slimes after being thoroughly stirred up by a tormentor, are conveyed by a launder in a box, where they are still further diluted with clean water, and passing through a sieve with apertures corresponding to the size of the grain to be dressed, flow upon an inclined plane furnished with diffusing buttons, and from thence drip on to the shaking table.

In treating rough slimes the two hindermost chains are set at an inclination of 5 to 6 inches, and the table with an inclination of 4 to 6 inches on its length, makes 36 to 39 pulsations of 5 to 6 inches in length per minute. About 2½ cubic feet of diluted slimes, twelve of clean to one of slime-water, enter the table per minute.

Before commencing the percussive action, the table is covered with a thin layer of rough slimes, and during the first few minutes only clean water is admitted. In consequence of the quantity of water and violent motion employed, the smaller and lighter particles of ore are likely to drift down the table, and a rake is therefore employed at intervals to reconvey such particles towards the head of the table. Care must, however, be taken not to allow the water to wear furrows in the deposit. From two to three hours are usually required for the roughest sand-slimes to deposit four to five inches on the head of the table. The crops are twice more passed over the shaking table, and afterwards dollyed. The rapidity of movement and quantity of clean water increase with each operation. The tails of the first operation, which are considerably poorer than the original stuff, may be either thrown away, or once more passed over the table, when the crop will be fit for treatment along with a fresh quantity of original slime. The treatment of fine slimes is similar to that of the rough, with the exception that the inclination of the table, quantity of slime-water, proportion of clean water, and length of stroke, constantly decrease with the degree of fineness of the slime; and the number of strokes increase in proportion. In fact, for the finest slimes, the table has no greater inclination than one inch on its whole length, while the stroke, of which 35 to 45 per minute are made, is no longer than ¼ to ½ an inch. The time required for dressing varies with the nature of the slime operated on, five tons of rough slimes occupies sixty-eight hours, whilst the same quantity of very fine slimes requires no less than four times that period.

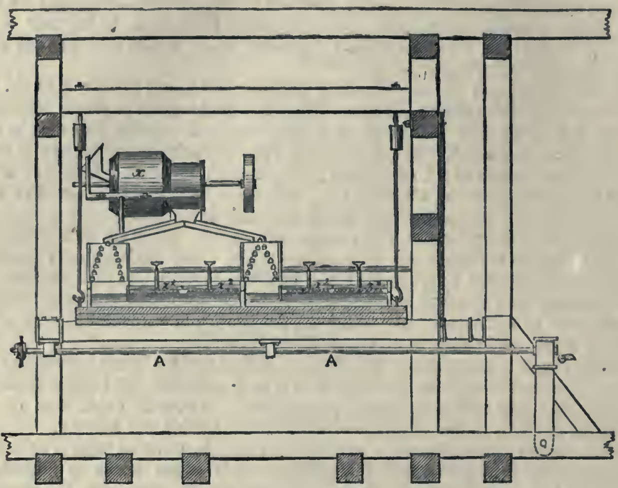
Rittenger's Percussion Tables.—The primary object intended to be accomplished by these tables, is the extraction of gold, silver, and other valuable ores from the veinstuff with which they may be associated.

Figs. 750, 751, represent front elevation and plan of two tables in one frame, divided by the strip S; these tables are suspended by rods from the points O, in such manner that they represent an inclined plane, the upper or higher end being at M N.

The sand and water, after passing through the sizing trommel x, is supplied to the tables at l l, the other places z^1 and z^2 being for the admission of water only. As the tables are suspended from four points, they are free to oscillate in one direction, that is, at right angles to the direction of their inclination. The oscillation is produced by a cam wheel acting upon the end of the beam A, upon which the table is mounted, the cam pushing it in one direction, and a spring bringing it back with a sharp blow, when the cam catches it, and a quick succession of blows is the result. It will thus be seen that the stuff under treatment is subjected to two forces, the one being the stream of water tending to wash the particles to the bottom of the table, the other being the blow, to bring the ores over to the ridges s s'. The effect of these combined forces is to induce the heavier or metallic particles to describe in their descent curvilinear lines, the light materials suspended in the water reaching the bottom of the table much quicker, and being less acted upon by the side blows, describe the shorter line r r', and leave the table almost in a straight line from the feeding plane l and l.

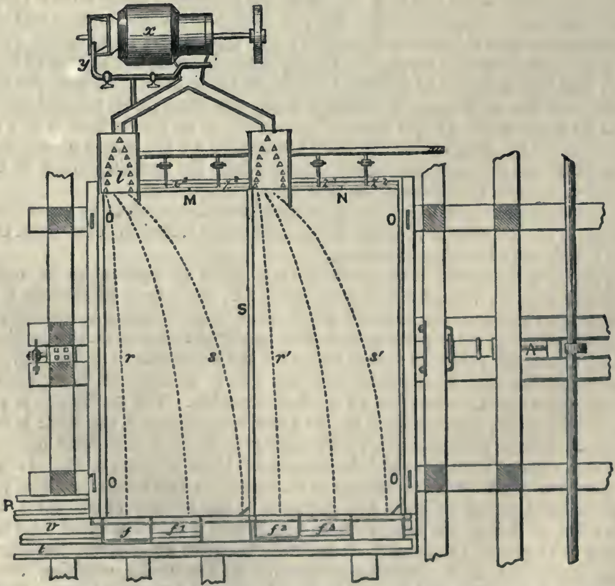
The tables are mounted on a rectangular frame, to which also is fixed the transverse beam which receives the blow. The surfaces of the table are planed as smooth as possible, and are framed in and divided by the strips s. Each table is about 8 feet long by 4 feet wide.

750



At the lower end of the tables are openings, f, f^1, f^2, f^3, under which are three parallel launders, which receive the stuff from the respective divisions of the table, the launder t receiving the clean mineral, the launder v a mixture of ore and waste, and the launder R the waste. To obtain successful results from these tables, care must be taken that the surfaces are perfectly smooth, and that in the direction of the blows they are set so as to be quite horizontal.

751

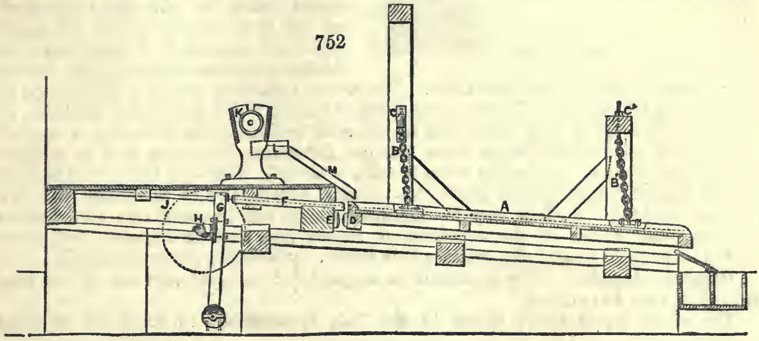


The stamp work must not flow on a feeding board above a foot in width.

The length of stroke and number of blows vary according to the stuff to be treated; the coarser the material, the longer, stronger, and fewer blows are necessary. The quantity of water containing mineral in suspension, to be fed on a single table, is of coarse stuff 1·2 gallon, containing 4 pounds of sand and of slimes, three-quarters of a gallon of water, containing about 13 ounces of sand in suspension. The action of these tables is precisely that of the vanning shovel; and any ore which can be cleaned upon the shovel can be dressed in a superior manner upon the table.

Two tables, making 120 blows per minute, require to be driven by a 15-feet water-wheel, and 50 gallons of water per minute. Each additional table will take 30 gallons of water per minute to drive it.

752

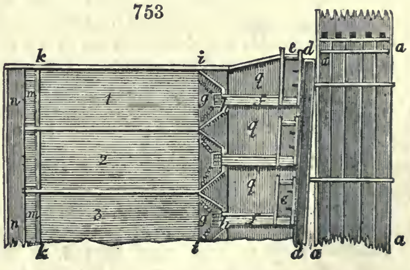


The shaking table shown in *fig.* 752 has the merit of being extremely light, requiring little power, and of performing its work in a highly satisfactory manner. A, table swung by chains, B B', its width being 3 feet and length 12 feet. A greater or less inclination is given to the table by raising or lowering the screws C C'. At the upper end of the table is a buffer, D, which acts against a counter-buffer, E. A sliding bar, F, is also fitted between the table and percussion lever G. This lever is struck by cams fitted on the axis H, driven by the runner J. The slimes to be treated flow into the cistern K, 30 inches long, 13 inches wide, and 18 inches deep. Into this box a tormentor is introduced for the purpose of breaking up the slimes. The bottom is fitted with a launder L, 7 inches long and 5 inches wide. From this launder proceeds a head-board M, expanded to the width of the table, and fitted with buttons, for the purpose of dispersing the slimes equally on the head of the table.

About five tons of rough slime are enriched per day on four tables, whilst from nine to ten tons of enriched slime are despatched in a similar period.

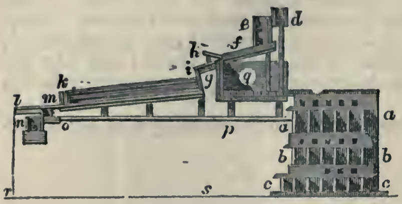
Sleeping Tables.—Figs. 753, 754 represent a set of *sleeping tables. Fig.* 753 is the plan, and *fig.* 754 a vertical section. The ores, reduced to a sand by stamps, pass into a series of launders, *a a*, *b b*, *c c*, which form three successive runs below the level of the floor of the works. The sand taken out of these launders is thrown into the cells *q*; whence they are transferred into the trough *e*, and water is run upon them by turning two stop-cocks for each trough. The sand thus diffused upon each table, runs off with the water by a groove *f*, comes upon a sieve *h*, and spreads itself upon the board *q*, and thence falls upon the sleeping table *i k*. The under surface *k* of this chest, is pierced with holes, which may be stopped at pleasure with wooden plugs. There is a launder *m*, at the lower end of each table to catch the light particles carried off by the water out of the chest *i k*, through the holes properly opened, while the denser parts are deposited upon the bottom of the chest. A general launder *n*, passes across at the foot of the tables *i k*, and receives the refuse of the washing operations.

753



In certain mines of the Hartz, *sweeping tables* are employed. The whole of the process consists in letting flow, over the sloping table, in successive currents, water charged with the ore, which is deposited at a less or greater distance, as also pure water for the purpose of washing the deposited ore, afterwards carried off by means of this operation.

754

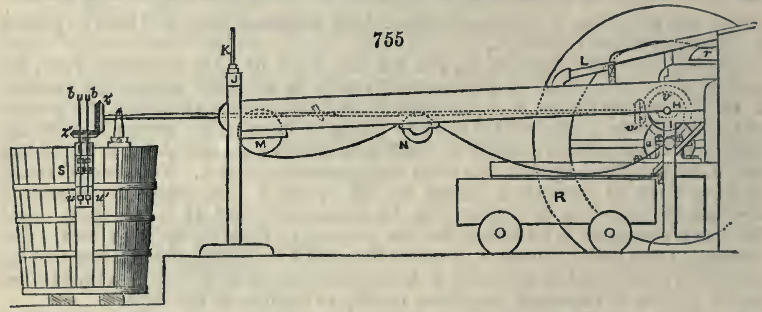


At the upper end of these *sweeping tables*, the matters for washing are agitated in a chest, by a small wheel with vanes, or flap-boards. The launder of the muddy waters opens above a little table or shelf; the launder of pure water, which adjoins the preceding, opens below it. At the lower part of each of these tables, there is a transverse slit, covered by a small flap with hinges, opening outwardly; by falling back towards the foot of the table. The water spreading over the table, may at pleasure be let into this slit, by raising a bit of leather which is nailed to the table, so as to cover the small flap when it is in the shut position; but when this is opened, the piece of leather then hangs down into it. Otherwise the water may be allowed to pass freely above the leather when the flap is closed. The same thing may be done with a similar opening placed above the launder. By means of these two slits, two distinct qualities of slime may be obtained, which are deposited into two distinct canals. The refuse of the operation is turned into another launder, and afterwards into ulterior reservoirs, whence it is lifted out to undergo a new washing.

Brunton's Machine.—This apparatus is adapted for the concentration of ore contained in very fine slimes.

The small water-wheel, shown in *fig.* 755, is sufficient to drive six of these machines, viz. three on each side. Before the stuff is permitted to enter upon the rotating cloth, it is disintegrated, and passed through a sizing trommel; it then flows over the head or dispersing board L, on to the cloth. This cloth rotates towards the stream on two axles, H and M, and is supported by a third roller N. It is also stiffened in its width by numerous laths of wood. Clean water is introduced behind the entrance of the slime, in order to give it the proper consistency. Different degrees of inclination are given to the cloth by raising or lowering the roller M, by means of the screw K. The heavier particles lodged on the cloth are caught in the waggon R, whilst the light matter is floated over the roller M.

755



One revolution of the cloth is made in 4½ minutes; its length is about 29½ feet, so that the speed is 6½ feet per minute. The width of the cloth is 4 feet 2 inches.

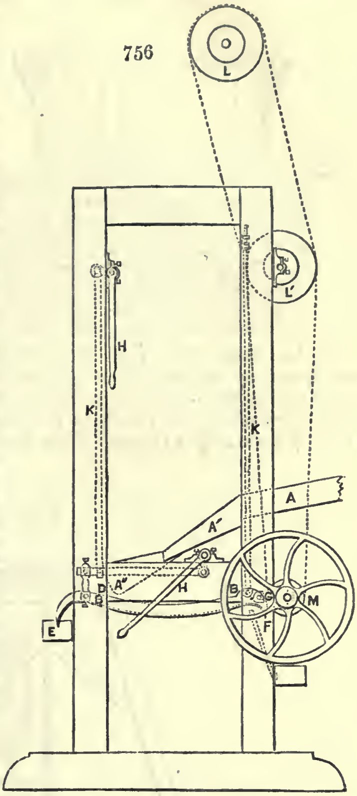
Before the slime comes upon the cloth, it is reduced to a size of $\frac{1}{60}$th of an inch, and yields an average of 1½ per cent. of copper; but by means of this machine the stuff is concentrated so as to afford 5 per cent. In ten hours it will clean 1½ ton. The speed of the cloth must, however, be varied with the condition of the stuff; if it be very poor, the cloth must travel very much slower, since the enrichment requires a longer period of time.

At the end of the machine, and worked by the same water-wheel, is a dolly tub: but the dimensions and mode of working this apparatus are fully stated at page 154.

Bradford's Slime Apparatus, fig. 756, is intended to imitate that of the vanning shovel. The slime enters by the launder A, about 5 inches wide, and descends on the inclined head A′, which expands from the width of the launder to within a few inches of the width of the table frame B. The slime box A″ is perforated at D with numerous holes, each of which is fitted with small regulating pins.

The table B B is 2 feet 2 inches wide, and 2 feet 10 inches long, with bottom formed of sheet copper. It is suspended by the vertical rods K, K, and varying degrees of inclination are given to the table by altering the levers H H. For he purpose of quickening or decreasing the action of the table two cones are employed L L′, upon which the driving band is shifted as may be necessary. A band from a runner, fitted on the axis of the cone L, communicates motion to a pulley wheel M, upon the shaft of which are cranks attached to connecting rods G, giving motion to the table.

756



When the machine is in operation, the ore flows over at F, into the launder baneath it, whilst the waste is carried over the opposite end into the trough E.

Professor B. Silliman and Mr. J. D. Whitney give the following particulars of results results realised by this machine :—

The total weight of ore stuff dressed during 122 days was 11,948,900 lbs. of rock stamped and crushed, or 5,080 tons miners' weight.

The total ore sold from this quantity of stuff was 128 gross tons (2,352 lbs.), or $2\frac{51}{100}$ per cent. of the stuff worked over. By the Captain's vans the average richness of the stamp work (forming much the larger part of what goes to the separators) for 22 weeks was 2·32 per cent. The humid assay of the average work from the stamps for five weeks in July and August gave for the richness of the stuff dressed on the separators 3·28 per cent. of ore, or 0·984 per cent. of metallic copper. There is, therefore, an apparent loss in the tailings of $\frac{77}{100}$ per cent. of 30 per cent. ore, or $\frac{23}{100}$ of copper. The amount of ore, however, lost in the tailings does not exceed $\frac{5}{10}$ to $\frac{6}{10}$ per cent., or about $\frac{15}{100}$ per cent. of copper. The actual products of working, therefore, as may be seen, exceed for the machines the average richness of the Captain's vans.

Of the total ore produced in this time, 181,126 lbs. came from the separators, and 160,858 lbs. from the jiggers. The whole amount of stuff, therefore, required to produced this amount of ore, estimated from the above ratio (1·15 : 1) is 768,680 lbs. This may be taken approximately as the actual quantity which passed over the separators, and if calculated on the Captain's vans, it should have produced 177,961 lbs. of ore, while in fact it did produce 181,126 lbs., or a variation in excess for the machines of only 3,210 lbs. Each of the separators, therefore, dresses about $1\frac{1}{2}$ ton of rock daily, of stuff yielding an average of 2·5 per cent. of 30 per cent. ore.

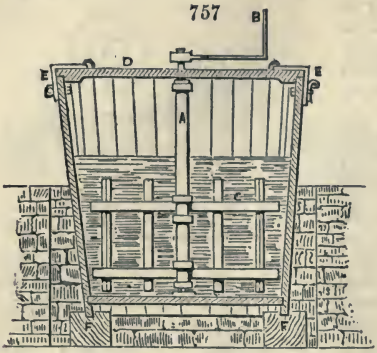
Dolly Tub or Packing Kieve.—This apparatus is employed for the purpose of excluding fine refuse from slime ore, which has been rendered nearly pure by previous mechanical treatment. In using it the workmen proceed thus :—

The kieve *fig.* 757, is filled to a certain height with water, and the dolly A introduced. A couple of men then take hold of the handle B, and turning it rapidly, cause the water to assume a circular motion. The tossing is then commenced by shovelling in the slime until the water is rendered somewhat thick. After continuing the stirring for a short period, the hasps E E are loosed, and the bar D with the dolly are suddenly withdrawn. The tub is then packed by striking its outside with heavy wooden mallets. When this operation is terminated, the water is drawn off through plug-holes in the side of the tub.

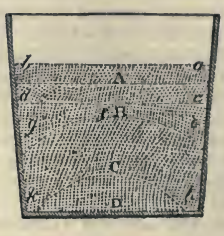
The object of the rotatory motion created by the dolly is to scour off clayey or other matter adhering to the ore, whilst the packing hastens the subsidence of the denser portions. In one portion of this kind four distinct strata may be procured, as indicated by the lines *a b*, *c d*, *e f g*, *h* c *k*, in *fig.* 758.

The upper portion, viz., from A to B, will probably have to be set aside for further washing, whilst the slime C should be fit for market. The conical nucleus in the centre of the tub generally consists of coarse sand, and is usually further enriched on a copper bottom sieve, or else submitted to the action of a tye, or other suitable apparatus.

757

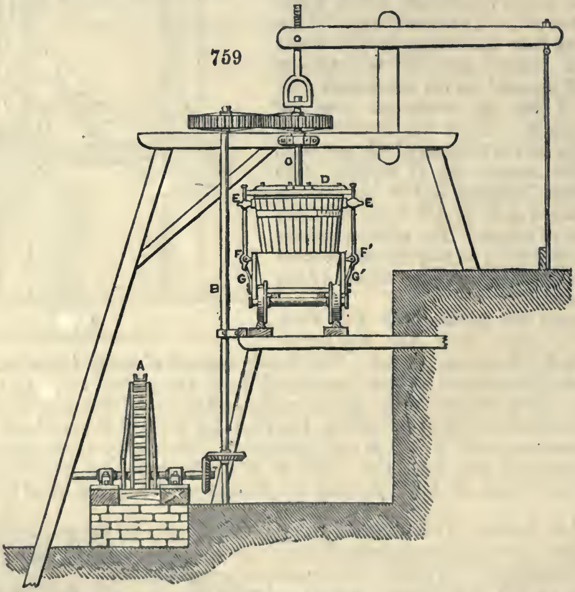


758



Machine Dolly Tub.—This tub, *fig.* 759, is packed by machinery represented in the accompanying woodcut, in which A is a small water-wheel, working a vertical shaft B, and driving another shaft O. At the bottom of this is fixed a notched wheel D, which presses outwardly the hammers E E; these are mounted upon iron bars F F′, and violently driven upon the side of the kieve by means of springs G G′.

759



The degree to which ore can be concentrated by dollying must evidently depend upon several conditions:—1st. The initial percentage of the ore. 2nd. The condition to which it is reduced. 3rd. The matrix with which it is associated. 4th. The proportion of water employed. And lastly, if the rotation and packing have been judiciously performed. An experiment upon some sand slime lead ore, much intermixed with fine carbonate of iron, gave the following results:—

Introduced into dolly tub, 17 cwts., assayed, 48 per cent.

Time required to introduce stuff	6	minutes.
Dolly rotated	5	,,
Dolly withdrawn—		
Tub packed	5	,,
Running off water	6	,,
Skimming and cleaning out tub	20	,,
Total	42	,,

Top skimmings	4 cwts., assayed	20 per cent.
Second	1¼ „	45 „
Clean ore, middles	5½ „	65 „
„ bottom	4½ „	67½ „
	15¼	
Fine Slime	1¾	
Total	17	

It may be remarked, that none of the various processes of dressing is more satisfactory than that of dollying, since, if carefully conducted, little or no loss of the total quantity of ore can occur.

Vanning is a method commonly practised by the tin-dressers of Cornwall and Devonshire, by which they ascertain approximately the richness and properties of the ore to be treated. If the object be to determine the value of a pile of stuff, it is carefully divided, then sampled, and a portion, say a couple of ounces, given to the vanner. If the stuff thus given should be rough, it is reduced to the tenure of fine sand, and in this state put upon the vanning shovel. The operator now resorts to a cistern or stream of water, and by frequently dipping the shovel into it, and imparting to the shovel when withdrawn a kind of irregular circular motion, he succeeds in getting rid of a greater or less portion of the waste: that which remains on the shovel is then considered equal to dressed work and assayed. So accurately is this operation performed by many of the tinners, that parcels containing only fifteen pounds of tin ore per ton of stuff, are sold by it to the mutual satisfaction of both buyer and seller.

The vanning process is also well adapted for determining the properties of an ore. If, by this method, vein-stuff should withstand concentration, no machinery is likely to dress it. If also the loss of ore is found great, then the apparatus to be employed for effecting the enrichment will have to be carefully considered and constructed.

760

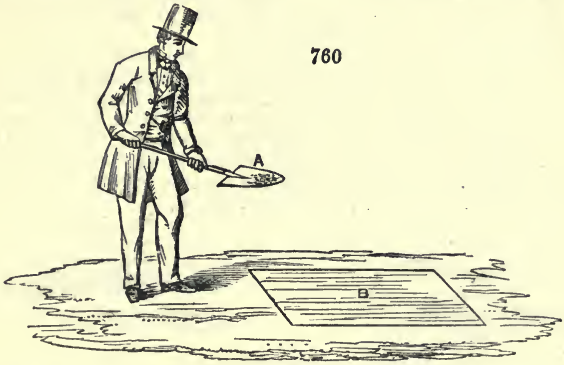


Fig. 760. The vanning shovel A, is 14 inches long, and 13 inches wide at the top, the edge of which is slightly turned up. The shovel is also formed with a hollow or depression. The handle is about 4 feet long. The vanning cistern is shown at B.

Hushing.—It often occurs, that the water employed on the dressing floors makes its escape below the refuse or waste heaps. This may be used for the purpose of hushing, which operation is performed in the following manner. The husher diverts the escape water into a rivulet and introduces a given quantity of waste. He then builds a dam or reservoir, with a door or trap valve at the high end, in order to collect the necessary water for hushing, and puts aside all the large stones lying in the middle of the hush gutter in order to form them into a wall. After this, he starts his hush by lifting the door of the dam, which slides in a wooden frame adapted for that purpose.

This allows the water to rush out, and displaces the waste to a certain depth, at the same time driving it forward.

If the hush has bared or uncovered a further quantity of large stones in the middle of the gutter, they are again removed to one side, since they would retard the force and action of the water. When these impediments are removed, the water is repeatedly discharged from the reservoir until the waste is hushed off the ore, which is found lying in holes, and around earth and fast stones, in the bed of the rivulet. A clay bottom is found to be most favourable for hushing, and the velocity and power of the stream should be proportioned to the size and density of the waste to be treated.

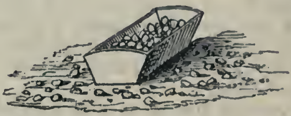
FORWARDING AND LIFTING APPARATUS.

Besides the machinery required for the enrichment of ores, it is a matter of great importance to introduce such auxiliary arrangements as shall not only facilitate actual dressing, but also be in themselves somewhat inexpensive. In this division, as in every other, the means should be strictly adapted to the end, and ought not to bear a cost disproportionate either to the circumstances or prospective advantages of an undertaking.

The shovel, *fig.* 761, usually employed in British mines is of triangular shape, and made of good hammered iron pointed with steel. The dimensions vary, but one of an average size is about 11 inches wide at the top, and 13 inches from the point to the shank, weight 4 pounds, and costs one shilling; to which must be added, five pence for the hilt, or handle. The hilt should be of ash, free from knots and slightly curved.

761

762

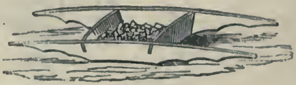


Picking Boxes, fig. 762, are employed for the purpose of collecting the prill and dradge ore from the stuff with which it may be mechanically intermixed. These boxes or trays are handled by children. They are made of deal, 1 inch thick, of the following dimensions: Length, 16 inches; depth, 7 inches; width at bottom, 7 inches; width at top, 10 inches; and cost about 1*s.* 3*d.* each. A ledge of wood to serve as a handle is sometimes nailed to the ends of the box.

Wheel-barrow.—The sides, ends, and bottom, are composed of deal 1¼ inch thick. The ends are mortised to the sides, whilst the bottom is generally fastened by means of nails, and bound with slips of hoop iron at the angles. Hoop iron is also employed to protect the upper edges of the barrow. The wheel is often made of wrought iron, (⅝ round) and 14 inches diameter. Its axes rotate in wrought-iron ears. The extreme length of the sides of a well-proportioned barrow is 60 inches, depth at centre 9 inches; the ends are inclined as shown in the *fig.* 763. The cost of a barrow with wrought-iron wheel complete, will vary from 6*s.* 6*d.* to 7*s.*

763

764



Hand Barrow.—When large quantities of stuff have to be removed from place to place on the surface, and where it would be inconvenient to use the wheel-barrow, a barrow having handles at both ends is employed (*fig.* 764). It is made of deal plank 1¼ inch thick; the length of the sides is 5 feet 6 inches; depth in centre, 9 inches; width, 18 inches at top and 10 inches at bottom; length, 24 inches at top and 18 inches at bottom; cost complete about 4*s.* 6*d.*

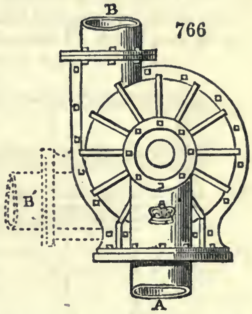
765

Railroads.—The gauge of surface roads varies from 15 inches to 2 feet 6 inches within the rails. Instead of manufactured rails, common flat wrought iron, 2½ inches wide and ½ inch thick, is oftentimes employed. An extremely serviceable rail is formed of a strip of timber 2 inches square, upon which is laid wrought-iron, 1¼ inch wide and ¼ inch thick, fastened by means of nails or screws.

Tram Waggon and Turn-table.—A tram waggon and turn-table is shown *fig.* 765. The waggon built of wrought iron, with cast-iron wheels. The latter are usually 12 inches diameter, with flanges 1 inch deep and tires from 2 to 3 inches wide. The turn table is of cast iron. It does not rotate, but the waggon is easily directed to either line of rail by means of the circular ring: the elliptical loops in advance serving to guide and place the wheels on the rails.

Lifting Apparatus.—It sometimes happens that the surface is nearly level, and affords very little natural fall. In such case the enrichment of ores becomes more expensive from the necessity of shifting some of the various products by manual labour, and of introducing lifting appliances in order to procure the requisite elevations for carrying out the various elaborative processes. It is, moreover, scarcely practicable from the conformation of the ground to form useful reservoirs of water within a reasonable distance; neither does it commonly occur in such cases that a free supply can be obtained for washing.

The pumping engine is therefore required to furnish the requisite quantity of water. This is generally conveyed over the floors by wood launders, often interfering with each other and obstructing the direct circulation of carts, railways, &c. Now if a stand-pipe or pressure column were erected at the engine, and a main judiciously laid throughout the floors, it is obvious that it would not only remedy this evil, but also afford water for the several washing purposes, as well as motive power for common, dash, or other wheels, together with turbines, flap jacks, &c.



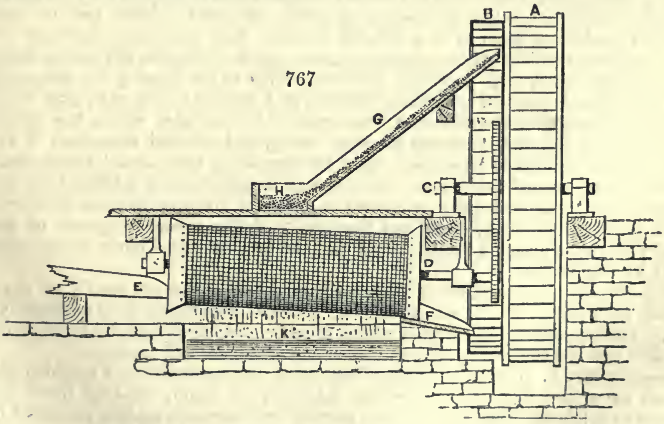
766

When an inconsiderable proportion of water has only to be raised to a higher level the common shoe or chain-pump will be found to render effective service; but when a larger stream is requisite it would be better to employ the rotatory pump. This pump, *fig.* 766, has been brought to great perfection by Messrs. Gwynne. A is the suction-pipe, and B the discharge, the dotted lines showing the discharge B, horizontal when required.

Pumps of the following dimensions are stated to raise and discharge per minute for medium lifts, say from 10 to 30 feet high:—

Diameter of discharge-pipe.	Diameter of suction-pipe.	Gallons of water per minute.
1½ inch.	2 inches.	25
3 inches.	4 "	70
4 "	5 "	150
5 "	6 "	300
6 "	7 "	500
7 "	8 "	1400

Stuff consisting of slimes and sand may be readily elevated by means of a Jacob's ladder or the Archimedean screw. For short elevations, combined water and raff wheels may be advantageously employed.



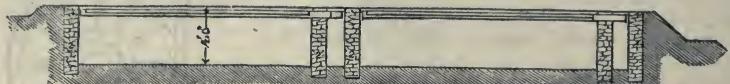
767

Fig. 767, A, water-wheel; B, raff or inverted wheel; C, axis of both raff and water wheels, carrying a tooth driving wheel; D, sizing trommel; E, launder for inlet of stuff; F, discharge launder; G, shoot delivering water and raff to launder H; K, cistern receiving slime from trommel.

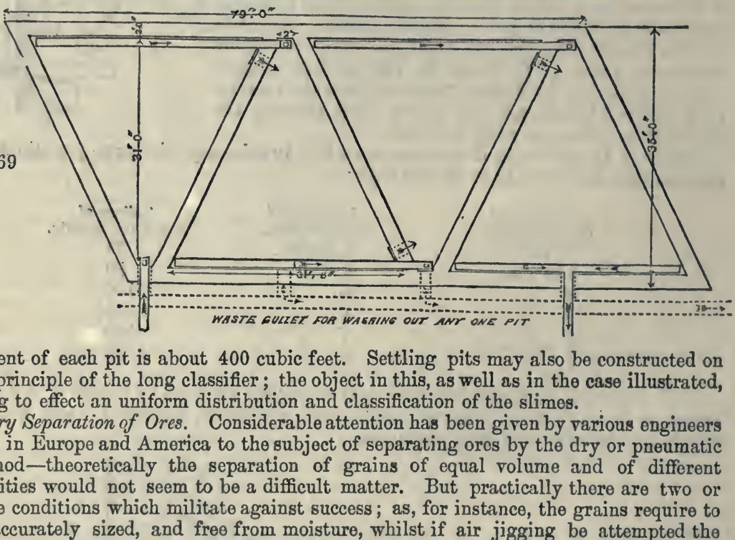
Slime Pits.—In the several operations of cleansing ores from mud, in grinding, and washing, where a stream of water is used it is impossible to prevent some of the finely divided portions floating in the water from being carried off with it. *Slime pits* or *labyrinths*, called *buddle holes* in Derbyshire, are employed to collect fine sand and slime at a little distance from the place of agitation.

Settling Pits.—The slime pits shown in section *fig.* 768 and plan *fig.* 769 are constructed on the principle of the Classifier. The viscid water from the jiggers and buddles, takes the direction of the arrows. The stuff deposited in such a system of pits, will gradually vary from a maximum degree of coarseness at the head of the first pit, to the least degree of fineness at the end of the fourth pit. Should the water flowing into the pits be moderately charged with ore, the latter will be found mostly at the narrow ends, and may therefore be readily collected for mechanical enrichment. For the purpose of running off the pits, a side gullet is constructed which is in communication by means of iron slides, one to each pit. The aggregate length of the pits is 40 feet, width 31 feet, width of dividing walls 2 feet, depth of pit 4 feet. The content of each pit is about 400 cubic feet. Settling pits may also be constructed on the principle of the long classifier; the object in this, as well as in the case illustrated, being to effect an uniform distribution and classification of the slimes.

768



769



Dry Separation of Ores. Considerable attention has been given by various engineers both in Europe and America to the subject of separating ores by the dry or pneumatic method—theoretically the separation of grains of equal volume and of different densities would not seem to be a difficult matter. But practically there are two or three conditions which militate against success; as, for instance, the grains require to be accurately sized, and free from moisture, whilst if air jigging be attempted the feed to the sieve must be altogether uniform, and the bed such as to offer an equal resistance throughout the whole of its surface. In countries where the climate is both dry and hot, water scarce, carriage heavy, and mineral abundant, it is just probable that pneumatic separation might be resorted to with partial satisfaction. If the ores were crushed and sized, then exposed to the effects of a current of air, the lighter grains would naturally be ejected to a greater distance than the heavier ones; but it may be assumed beforehand that most of the grains composed of gangue and ore would be grouped together, and that the loss on such a mode of concentration would be very heavy.

Magnetic Separation of Ores. When ores and vein-stones are nearly of the same density, their separation by water dressing is almost impracticable or necessarily very slow. Further, the value of such ores is greatly diminished both by the cost of enrichment and the comparatively low percentage of the dressed product.

Recently Mr. F. J. King of London has found that carbonate and sulphide of iron, as well as copper pyrites are rendered magnetic by simply heating these ores in a retort or calciner. Carbonate of iron, parting with carbonic acid, is converted into a magnetic oxide of iron, whilst iron and copper pyrites, each yielding up one atom of sulphur becomes magnetic pyrites. In order to apply this important fact to the treatment of ores, Mr. King has designed a suitable retort and magnetic machine, and separates blende from carbonate of iron, copper pyrites from blende, and any mixture of ores in which one portion can be rendered magnetic, first getting rid of the lighter gangues by water dressing.

Calcining Ores. In Taylor's 'Records of Mining' published in 1829, a description and drawing of Brunton's continuous calciner is given. This apparatus has long been used at various mines in Cornwall for getting rid of arsenic, sulphur and other impurities with which tin-stuff is sometimes associated. The table is about 12 feet diameter, and makes from six to eight revolutions per hour, the stuff being introduced at the centre, and discharged at a point on the periphery of the table. Oxland and Hocking's calciner is now adopted at several mines, and consists of a trommel mounted on carrier wheels, about three feet inside diameter and 32 feet long, with a fall of 1 in 16 or 1 in 24, according to the size and nature of the stuff to be treated. The inside of this trommel is lined with fire-brick, the fire-place being at one end, and a feed-screw at the other. The calcination is performed by the heat generated in the fire-place passing through the cylinder. The cylinder makes from six to eight revolutions per hour. Inside of the cylinder, for about two-thirds of its length from the fire-place, are four longitudinal ledges, as in a mortar mill, for the purpose of turning over the stuff.

The time necessary for passing a charge from the entrance to the exit point in the trommel varies from three to six hours.

From the calciners the stuff is taken to various dressing machines, and sufficiently concentrated for the smelting furnace.

Other continuous calciners are in use, some for the purpose of producing sulphurous vapours to form sulphuric acid, such as Gerstenhöfer and Hasenclever, and which doubtless admit of ready application to the treatment of tin ores.

The machinery requisite for the enrichment of distinct classes of ore cannot well be grouped within the limits of a specification. The quantity of stuff to be disposed of within a given period, the value of the ore, the character of the vein-stone, the difference of density between one substance and another, the price of labour, together with any other direct or collateral feature, must carefully be considered. But in most cases, the machines enumerated in the following list may be successfully applied for the purposes stated:—

Reducing Machinery.

1. Stone-breakers	For reducing to fragments all hard and *non-elastic* stuff, for the cobbing process, crusher, stamps, and disintegrator.
2. Crushing mill	For reducing to grains stuff for the hand-pickers, jiggers, and buddles.
3. Disintegrators	For producing sand for jiggers or buddles.
4. Edge runners, horizontal mills, and pulverizers	For reducing dradge grains for treatment on buddles and tables.
5. Stamps	For reducing stuff for treatment in fine sand jiggers, buddles, or tables.

Washing Apparatus.

1. Kilns	For disintegrating and freeing vein-stone, in order to render it suitable for hand picking, cobbing, stone-breaker and crusher, also partly for the sizing trommels and jiggers.
2. Wash Trommels	Ditto.

Sizing and Classifying Apparatus.

1. Trommels	For sizing stuff, sometimes for hand picking, but chiefly for coarse and fine sand jiggers.
2. Single and divisional classifiers, ascending columns, dividing cones, and pyramidal boxes	For classifying stuff for fine sand jiggers, buddles and tables.

Concentrators.

1. Rotatory separator	For freeing sand from slime, and partly classifying the sand for jiggers or buddles.

2. Jiggers . . .	For getting rid of worthless vein-stuff and increasing the metallic percentage of the resulting product for subsequent treatment.

SEPARATING AND ENRICHING MACHINERY.

1. Rough jiggers . .	For dividing stuff into (1) castaways, (2) orey stuff, (3) ore, the stuff ranging in size from 10 mm. to x.
2. Coarse sand jiggers .	For separating grains from 2 mm. to 10 mm. into (1) waste, (2) orey stuff, (3) ore.
3. Fine sand jiggers .	For separating sand from ¾ mm. to 2 mm. into (1) waste, (2) orey stuff, (3) ore.
4. Slime sand jiggers .	For separating sand from 0 mm. to ¾ mm. into (1) waste, (2) orey stuff, (3) ore.
5. Convex and concave buddles . . .	For separating sand from ¾ mm. to 2 mm. into (1) waste, (2) orey stuff, (3) ore.
6. Side and end blow tables . . .	For separating sand from 0 mm. to ¾ mm. into (1) waste, (2) orey stuff, (3) ore.
7. Brunton and slime tables . . .	For separating sand from 0 mm. to ½ mm. into (1) waste, (2) orey stuff, (3) ore.

General Table relating to Ore Dressing Machines.

	Approximate quantity worked per 10 hours	Approximate horse-power required	Gallons of water required per minute
	cwts.		
Rotating picking table . . .	200	$\frac{1}{20}$	
,, ,, band . . .	150	$\frac{1}{20}$	
Common skimming jigger, coarse stuff	2½ per sectional inch	$\frac{1}{10}$	1½

End ,, ,, ...	100	$\frac{1}{4}$	7
Dead frames			

In the year 1857, Herr Von Sparre, of Eisleben, Prussia, patented four machines for separating substances of different specific gravities, in all of which water is employed, either as a medium through which the said substances fall under the action of gravity, or as an agent for facilitating the motion of portions of the said substances along inclined surfaces. The particulars, together with illustrations, will be found in Patent No. 1405 for the year 1857.

The mechanical preparation of tin and copper ores has from time to time been noticed by several writers. In 1758 Borlase described the method employed in the west of Cornwall. Twenty years later, Price, in his *Mineralogia*, added to Borlase's description, and illustrated some of the apparatus then in use. Afterwards Dr. Boase published, in the second volume of the *Transactions of the Geological Society of Cornwall*, an article upon the dressing of tin in St. Just. In volume four, Mr. W. Jory Henwood inserted a paper on dressing; and some general remarks will be found on the subject in De la Beche's *Report on the Geology of Cornwall*. The enrichment of lead ores has been noticed by Forster, in his *Section of Mineral Strata*; also by Warington W. Smyth, in his memoir *On the Mines of Cardiganshire*, in the second volume of the *Memoirs of the Geological Survey of Great Britain*. In 1858, Mr. James Henderson presented a paper to the Institution of Civil Engineers 'on the Methods generally adopted in Cornwall in Dressing Tin and Copper Ores,' to which we are indebted for some of our illustrations. In the 'Proceedings of Mechanical Engineers, 1873,' will be found valuable papers on the 'Mechanical Appliances for Dressing Tin and Copper Ore,' by Mr. Henry T. Ferguson, and on the 'Tin Stream Works in Restronquet Creek,' by Mr. Charles D. Taylor.

In France, Dufrenoy, Elie de Beaumont, Coste, Perdonnet, Huet and Geyler, and Moissenet have treated on the mechanical enrichment of copper, tin, and lead ores. The latter gentleman has frequently visited this country, and given the results of his observations in a highly interesting memoir, entitled *Préparation du Minéral d'Etain dans le Cornwall*, and also in the *Annales des Mines*, tome ix. 1866. But it is to Germany we must look for an exhaustive literature on the Dressing of Ores, and machinery employed therein. In 1867, 1870, and 1873, Von Rittinger's *Lehrbuch der Aufbereitungskunde* appeared, with an atlas, containing forty-nine plates. In 1872 *Die Aufbereitung*, by M. F. Gaetzschmann, with an atlas of sixty-six plates, was published. In addition Hundt of Siegen, Neuerberg of Kalk, Cologne, Utsch of Iserlohn, Hoffmann of Lohmansfeld, Max Braun of Altenberg, and many others have promoted the science and art of Dressing. In England there are hopeful signs that the subject will be deemed worthy the attention of Mine Engineers. Continuous machinery is in operation at several mines, and its use somewhat extending. In South Australia Hancock has successfully applied himself to the subject of continuous Dressing; while in America the mechanical enrichment of minerals will necessarily command much consideration. Too much attention cannot be given to this section of mining economics; for with the increasing production of ores, especially of ores of low produce, and the ill-adapted machinery oftentimes employed, the loss in concentrating them is an item of most serious moment.

In this paper we have included those machines which have been long employed in our metalliferous mines,—many of them having been proved by experience to be most economical,—together with such of the modern introductions as appear to promise the most advantage, and some suggestions which cannot but be valuable, since the principles involved are founded upon the universal laws of gravitation, as applied to solids and fluids in motion.

It is not essential to describe the dressing routine observable in a particular mine, since it is scarcely possible to observe the same system in any two distinct concerns. In the various modes of treatment, however, it may be remarked that the two leading features will always be *reduction* to a proper size and *separation* of the ore from the refuse. Until the vein-stuff arrives at the crusher or stamps, the labour is chiefly one of picking and selecting; but from these machines usually commence a long series of divisions, subdivisions, selections, and rejections. To follow these out in their various ramifications would not only exceed the limits of this paper, but would perhaps be misunderstood by those not intimately acquainted with the subject.—J. D.

DRUGGET is a coarse, but rather slight, woollen fabric, used for covering carpets, and as an article of clothing by females of the poorer classes.

The manufacture of druggets of various kinds has been of late years considerably improved; and carpets, many of them handsomely figured, are now found in common use.

DRUID-STONES. Masses of quartzose rock scattered as loose blocks over the Chalk downs in the south of England, and known variously as Druid-stones, Sarsen-stones, and Greyweathers.

DRUSE. *A mineralogical term*, signifying a hollow space in veins of ore or in rocks, which is lined with crystals. A *drusy* cavity is one covered with crystals.

DRY BONE. A term sometimes applied by American miners to calamine or carbonate of zinc.

DRY GRINDING. The practice of employing dry stones has been long adopted for the purpose of quickening the processes of sharpening and polishing steel goods. The dry dust from the sand-stone, mixed with the fine particles of steel, being inhaled by the workmen, produces diseases of the pulmonary organs to such an extent, that needle and fork grinders are reported rarely to live beyond the ages of twenty-five or thirty.

Mr. Abraham, of Sheffield, first invented magnetic guards, which, being placed close to the grindstone, attracted the particles of steel, and thus protected the men from their influences. Still they suffered from the effects of the fine sand-dust, and the grinders heedlessly abandoned the use of them altogether.

Mr. Abraham devised another plan, which is employed, although only partially, in the Sheffield works. The grindstone is enclosed in a wooden case, which only exposes a portion of the edge of the stone; a horizontal tube proceeds at a tangent from the upper surface of the circle to the external atmosphere. The current of air generated by the stone in rapid revolution, escaping through the tube, carries off with it nearly all the dust arising from the process. It is curious to find so simple a contrivance frequently rejected by the workmen, notwithstanding that sad experience teaches them, that they are thereby exposing themselves to the influences of an atmosphere which produces slowly but surely their dissolution.

DRYING OILS. When oils, especially linseed and nut oils, are boiled with litharge or oxide of lead, they acquire the property of solidifying or *drying* quickly on exposure to the atmosphere. These are very useful to the painter, as without them the pigments with which they are mixed would remain soft. The oxide of lead appears to establish a state of more easy oxidation in the oils, so that they assume readily the conditions of a resin.

DRY ROT. This kind of decay in wood is ascribed to the attacks of fungi, especially to *Polyporus hybridus* and *Thelephora puteana.* There is no doubt that, by the formation of fungus, rot or decay may be commenced, and continued to a certain extent; but there are numerous cases where rot is due to an entirely different cause—a spontaneous decomposition.

Dry rot differs but little in the causes producing it, or in the result, from WET ROT. They are both alike the effect of the conversion of the carbon of wood into carbonic acid, and its hydrogen into water. The process is again the same as that by which wood is converted into humus, and into brown-coal. Mayer gives the analysis of oak wood, and of humus produced from it, as follows:—

	Oak wood.	Humus.
Carbon	52·53	48·32
Hydrogen	5·27	4·57
Oxygen	42·20	36·58

In this change, 7·73 per cent. of carbonic acid and 2·8 per cent. of carburetted hydrogen are disengaged.

The examination of the decay of wood, and its conversion into the brown powder (humus) which marks rottenness, shows that the change is almost entirely dependent on the absorption of oxygen. The decrease in the volume of wood during its decay is difficult to account for, unless we suppose, which is probable, that as much escapes in the form of carburetted hydrogen as there does of carbonic acid and water.

Hollow trees are sometimes met with, whose wood is entirely decayed away, nothing being left but the bark, and a quantity of pulverulent wood, which is altogether disproportionate to the hollow space. In most cases, likewise, the cavity extends so far below the lateral opening in the trunk that we cannot suppose the decayed wood to have been washed away by rain, at least, not during the last stages of the change. It is, therefore, very desirable that continued careful observations should be made with regard to this point. On the other hand, the slight loss of substance by the wood during the first stages of its decomposition, explains why the alteration of wooden piles under water appears to have taken place without any diminution of volume. If, indeed, besides this, inorganic substances—for instance, silica—should be introduced into the place of the organic constituents separated, it would not be difficult to account for the increased firmness and density presented by wood which has remained for some time under water. It has been seen that the conversion of ligneous fibre into a pulverulent substance, and into humus, admits of adequate explanation by means of the three cases mentioned above, and, what is especially important, that it may be supposed to take place independently of external oxygen. The formation of carbonic acid is, then, during the first stages of the decomposition, either extremely small or altogether wanting. The change commences with the separation of oxygen and hydrogen in the form of water, and the separation of oxygen and carbon, as carbonic acid, does not commence until a later period. It is, likewise, probable, that at a still later period carbon and hydrogen are separated in the form of carburetted hydrogen.

The remedy for dry rot is the use of such substances as will, when penetrating the wood, combine with its albuminous matter, and solidify it. Hence corrosive sublimate, sulphate of copper, and arsenic acid have been found to be excellent preservatives. Where they can be applied, nitric acid and sulphuric acid are very advantageous, especially where the growth of fungi is the cause of rot, or when vegetation has followed the decomposition, as it not unfrequently does. See WOOD PRESERVING.

DUALINE. A sawdust gunpowder impregnated with nitroglycerine. It resembles dynamite in most respects, but is not equal to it. See DYNAMITE; EXPLOSIVE COMPOUNDS.

DUCK. (*Duk*, a cloth, Swedish; *Tuch*, Ger.) A coarse cloth, a light sort of canvas. It is used for common articles of apparel, for small sails, and the like.

DUCTILITY (*Streckbarkeit*, Ger.) is the property of being drawn out in length without breaking, possessed in a pre-eminent degree by gold and silver, as also by many other metals, by glass in the liquid state, and by many semifluid, resinous, and gummy substances. The spider and the silkworm exhibit the finest natural exercise of ductility upon the peculiar viscid secretions from which they spin their threads. When a body can be readily extended in all directions under the hammer, it is said to be malleable, and when into fillets under the rolling press, it is said to be laminable.

There appears to be therefore a real difference between ductility and malleability; for the metals which draw into the finest wire are not those which afford the thinnest leaves under the hammer or in the rolling press. Of this fact iron affords a good illustration. Among the metals permanent in the air, 17 are ductile and 16 are brittle. But the most ductile cannot be wire-drawn or laminated to any considerable extent without being annealed from time to time during the progress of the extension, or rather the sliding of the particles alongside of each other, so as to loosen their lateral cohesion. See MALLEABILITY.

Table of the Ductility and Malleability of Metals.

Ductile and malleable metals in alphabetical order	Brittle metals in alphabetical order	Metals in the order of their wire-drawing ductility	Metals in the order of their laminable ductility
Cadmium	Antimony	Gold	Gold
Copper	Arsenic	Silver	Silver
Gold	Bismuth	Platinum	Copper
Iron	Cerium	Iron	Tin
Iridium	Chromium	Copper	Platinum
Lead	Cobalt	Zinc	Lead
Magnesium	Columbium	Tin	Zinc
Mercury	Iridium	Lead	Iron
Nickel	Manganese	Nickel	Nickel
Osmium	Molybdenum	Palladium	Palladium
Palladium	Osmium	Cadmium	Cadmium
Platinum	Rhodium		
Potassium	Tellurium		
Silver	Titanium		
Sodium	Tungsten		
Tin	Uranium		
Zinc			

DULSE. The *Rhodymenia palmata.* See ALGÆ.

DUNES. Low hills of blown sand, which are seen on the coasts of Cheshire and Cornwall, in this country, and also in many places skirting the shores of Holland and Spain.

DUNGING, in calico-printing, is the application of a bath of cow-dung, diffused through hot water, to cotton goods in a particular stage of the manufacture. Dunging and scouring are commonly alternated, and are two of the most important steps in the process. See CALICO-PRINTING.

DUNSTONE. Magnesian limestones of a dun colour, occurring near Matlock in Derbyshire.

DUTCH FOIL, LEAF, or **METAL.** A composition of copper and zinc, or of beaten bronze or of copper leaf. See ALLOYS; BRASS; and BRONZE POWDERS.

DUTCH LIQUID. A name given to an oily substance produced by the action of chlorine on olefiant gas. It was discovered at the close of the last century by an association of Dutch chemists.

DUTCH RUSH. *Equisetum hyemale.* This rush is known also as the *Large branchless Horse-tail.* The dried stems are much employed for polishing wood and metal. For this purpose they are generally imported from Holland.

DYEING (*Teinture,* Fr.; *Färberei,* Ger.) is the art of imparting to and fixing upon wool, silk, cotton, linen, hair, and skins any colour, with sufficient tenacity not to be removed by water or the ordinary usage to which these fibrous bodies are exposed when worked up into articles of raiment or furniture. We shall here consider the general principles of the art, referring, for the particular dyes and the manner of treating the stuffs to be dyed, to the different tinctorial substances in their alphabetical order.

Dyeing, although altogether a chemical process, and requiring for its correct explanation an acquaintance with the properties of the elementary bodies, and the laws which regulate their combination, has been practised from the most ancient times, long before any just views were entertained of the nature of the changes that took place; and it is still practised by many who know very little of chemical science: indeed, like many of the other chemical arts, its practice is often in advance of the science by which its principles are explainable. The art no doubt originated in that love of distinction inherent in the human mind, inducing man, for its gratification, to stain his dress or his skin with the gaudy colours of the vegetable kingdom. The earliest historical record speaks of coloured garments being worn as marks of distinction for offices both political and religious, and also as marks of favour. Jacob gave his favourite son Joseph a coat of many colours, and Moses speaks of a raiment dyed blue, and purple, and scarlet, and of sheepskins dyed red, circumstances which indicate no small degree of tinctorial skill. He enjoins purple stuff for the works of the Tabernacle and the vestments of the high priests.

In the article Calico-Printing it has been shown, from Pliny, that the ancient Egyptians cultivated the art of dyeing with some degree of scientific precision, since they knew the use of mordants, or those substances which, though they impart no colour themselves, yet enable white robes (*candida vela*) to absorb colouring drugs (*colorem sorbentibus medicamentis*).

Tyre, however, was the nation of antiquity which made dyeing one of its chief occupations and a staple of its commerce, and it is asserted by all writers upon the subject, that the invention of the celebrated purple dye, known as the Tyrian purple was made in that city, and the king of Phœnicia, being so captivated with the colour, it is stated that he made it one of his principal ornaments, and it became afterwards, and continued to be for many centuries, a badge of royalty.

The discovery of the purple dye is said to have been made 1,500 years before the Christian era. It must have met with a very early and general appreciation, and rapid commercial progress, as we find that, nine years after the above date, the Children of Israel, an enslaved people, on their leaving Egypt, had in their possession large quantities of this dye; it was extensively used by them, a short time after, for the furniture of the tabernacle and the vestments of the priests; and in after years this dye was always named amongst the valuable spoils of war. That it was the dress of royalty at a very early period, is indicated by the mention, amongst the spoils of the Midians collected by the Israelites, of the purple garments worn by their kings.

The juice employed for communicating this dye was obtained from two different kinds of shell-fish, described by Pliny under the names of *Purpura* and *Buccinum*; being extracted from a small vessel, or sac, in their throats, to the amount of only one drop from each animal. A darker and inferior colour was also procured by crushing the whole substance of the buccinum. A certain quantity of the juice collected from a vast number of shells being treated with sea-salt, was allowed to ripen for three days; after which it was diluted with five times its bulk of water, kept at a moderate heat for six days more, occasionally skimmed to separate the animal membranes, and when thus clarified was applied directly as a dye to white wool, previously prepared for this purpose by the action of lime-water, or of a species of lichen called *Fucus*. Two operations were requisite to communicate the finest Tyrian purple: the first consisted in plunging the wool into the juice of the purpura; the second, into that of the buccinum. Fifty drachms of wool required one hundred of the former liquor, and two hundred of the latter. Sometimes a preliminary tint was given with coccus, the 'kermes' of the present day, and the cloth received merely a finish from the precious animal juice. The colours, through probably not nearly so brilliant as those producible by our cochineal, seem to have been very durable, for Plutarch says, in his 'Life of Alexander' (chap. 36), that the Greeks found in the treasury of the king of Persia a large quantity of purple cloth, which was as beautiful as at first, though it was 190 years old.

The quantity of purple, said to be found by Alexander in the treasury of the king of Persia, is differently stated:—1st, as *amounting* to 5,000 talents; 2nd, as being of the *value* of 5,000 talents; 3rd, as weighing 5,000 quintals. Besides these discrepant statements, it is not clear whether these values or weights refer to cloth dyed or to the dye-drug, although it would be an important fact to know that the dye could be thus preserved for a length of time. Horace celebrates the Laconian dye in the following lines:—

> Nec Laconicas mihi
> Trahunt honestæ purpuras clientæ;

which have been translated as—

> 'No honourable lady dependents
> Spin Laconian purple for my use.'

Notwithstanding its almost universal use in more ancient times, it gradually declined, so that, either from the difficulty of collecting the dye, or the tedious complication of the dyeing process, so expensive was it that, about the commencement of the Christian era, one pound of the purple wool of Tyre cost, in Rome, about thirty pounds of our money.

Notwithstanding this enormous price, such was the wealth accumulated in that capital, that many of its leading citizens decorated themselves in purple attire, till the emperors arrogated to themselves the privilege of wearing purple, and prohibited its use to every other person. This prohibition operated so much to discourage this curious art as eventually to occasion its extinction, first in the Western and then in the

Eastern empire, where, however, it existed in certain imperial manufactories till the eleventh century.

Gage, Cole, Plumier, Réaumur, and Duhamel have severally made researches concerning the colouring juices of shell-fish caught on various shores of the ocean, and have succeeded in forming a purple dye, but they found it much inferior to that furnished by other means. The juice of the buccinum is at first white; it becomes by exposure to air of a yellowish green bordering on blue; it afterwards reddens, and finally changes to a deep purple of considerable vivacity. These circumstances coincide with the minute description of the manner of catching the purple-dye shell-fish which we possess in the work of an eye-witness, Eudocia Macrembolitissa, daughter of the Emperor Constantine VIII., who lived in the eleventh century.

The beautiful purple dye, which is now extracted from guano, is probably closely allied, both in property and appearance, to the Tyrian purple.

Dyeing seems to have been little cultivated in ancient Greece. The people of Athens generally wore woollen dresses of the natural colour: a circumstance forming a peculiarity in that nation, composed of a people who were such lovers of art.

The Romans appear to have bestowed some care upon the art of dyeing. In the games of the circus parties were distinguished by colours. Four of these are described by Pliny: the green, the orange, the grey, and the white. The following ingredients were used by their dyers:—A crude native alum mixed with copperas, copperas itself, blue vitriol, alkanet, lichen rocellus or archil, broom, madder, woad, nut-galls, the seeds of pomegranate and of an Egyptian acacia.

In Europe the progress of dyeing, as of all other arts, was completely stopped for a considerable time by war and invasion, and did not revive till about the beginning of the thirteenth century, and then so rapidly did its progress extend in some localities, that, towards the beginning of the fourteenth century, there were no less than two hundred dyeing establishments in Florence. At the same time the Italians and Venetians also prosecuted the art of dyeing to a large extent.

The art of printing proved for dyeing, as well as for other arts, its great pioneer and propagator. In the middle of the sixteenth century, Plictho's 'Art of Dyeing' was printed, which gave general instructions for dyeing all kinds of fabrics, and laid the foundation for that improvement of this art, which soon after followed throughout Germany, France, and England.

In the East, the art of dyeing did not experience that decline which passed over all the arts of Europe; hence the beautiful dyes of India maintained their high character: and, to this day these dyes are produced by processes differing little from those practised in the days of Pliny.[1]

The discovery and opening of America to commercial enterprise formed an era in the history of the art of dyeing, as from that country were introduced a variety of new dye-drugs, such as logwood, brazilwood, quercitron, cochineal, annotta, &c., which, with the discovery of the use of tin as a mordant about the same time, gave the dyer a facility and power of producing such a variety of tints, and of such a depth, durability, and lustre, that it is now difficult to conceive possible to have been produced in former times.

About the same time was discovered the art of using indigo as a dye, which it is believed the ancients only knew as a pigment. The introduction of this dye-drug into this country met with strong opposition; concerning which a writer in the 'Penny Cyclopædia' says:—

'Indigo, the innoxious and beautiful product of an interesting tribe of tropical plants, which is adapted to form the most useful and substantial of all dyes, was actually denounced as a dangerous drug, and forbidden to be used, by our Parliament in the reign of Queen Elizabeth. An act was passed authorising searchers to burn both it and logwood in every dye-house where they could be found. This act remained in full force till the time of Charles II., that is, for a great part of a century. A foreigner might have supposed that the legislators of England entertained such an affection for their native woad, with which their naked sires used to dye their skins in the old times, that they would allow no outlandish drug to come in competition with it. A most instructive book might be written illustrative of the evils inflicted upon arts, manufactures, and commerce, in consequence of the ignorance of the legislature.'

More recently another class of dye-drugs have been introduced, and have superseded some of those of the former century; these are bichromate of potash, red and yellow prussiate of potash, manganese, catechu, arsenic, &c.

---

[1] In India was discovered the mode of dyeing Turkey red, which is the most durable dye known, as well as the richest tint that can be produced on cotton. It was introduced into France and England about the middle of last century, and is still carried on and practised with much perfection.

Colours are not, properly speaking, material; they are impressions which we receive from the rays of light reflected, in a decomposed state, by the surfaces of bodies. It is well known that a white sunbeam consists of an indeterminate number of differently-coloured rays, which, being separated by the refractive force of a glass prism, form the solar spectrum, an image divided by Newton into seven sorts of rays: the red, orange, yellow, green, blue, indigo, and violet. Hence, when an opaque body appears coloured, for example, red, we say that it reflects the red rays only, or in greatest abundance, mixed with more or less of the white beam, which has escaped decomposition. According to this manner of viewing the colouring principle, the art of dyeing consists in fixing upon stuffs, by means of corpuscular attraction, substances which act upon light in a different manner from the surfaces of the stuffs themselves. The dyer ought, therefore, to be familiar with two principles of optics; the first relatively to the mixture of colours, and the second to their simultaneous contrast.

Whenever the different coloured rays, which have been separated by the prism, are totally reunited, they reproduce white light. It is evident, that in this composition of light, if some rays were left out, or if the coloured rays be not in a certain proportion, we should not have white light, but light of a certain colour. For example: If we separate the red rays from the light decomposed by a prism, the remaining coloured rays will form by their combination a peculiar bluish green. If we separate in like manner the orange rays, the remaining coloured rays will form by their combination a blue colour. If we separate from the decomposed prismatic light the rays of greenish yellow, the remaining coloured rays will form a violet. And if we separate the rays of yellow bordering on orange, the remaining coloured rays will form by their union an indigo colour.

Thus we see that every coloured light has such a relation with another coloured light that, by uniting the first with the second, we reproduce white light; a relation which we express by saying that the one is the complement of the other. In this sense, red is the complementary colour of bluish green; orange, of blue; greenish yellow, of violet; and orange yellow, of indigo. If we mix the yellow ray with the red, we produce orange; the blue ray with the yellow, we produce a neutral tint; and the blue with the red, we produce violet or indigo, according as there is more or less red relatively to the blue. But these tints are distinguishable from the orange, green, indigo, and violet of the solar spectrum, because when viewed through the prism they are reduced to their elementary component colours.

If the dyer tries to realise the preceding results by the mixture of dyes, he will succeed only with a certain number of them. Thus, with red and yellow he can make orange; with blue and yellow, green; with blue and red, indigo or violet. These facts, the results of practice, have led him to the conclusion that there are only three primitive colours: the red, yellow, and blue. If he attempts to make a white, by applying red, yellow, and blue dyes in certain quantities to a white stuff, in imitation of the philosopher's experiment on the synthesis of the sunbeam, far from succeeding, he will deviate still further from his purpose, and the stuff will by these dyes become coloured of a depth varying according to the quality of the stuff used; until a full black is produced. Nevertheless, the principle is applicable, and in many cases adopted in practice by blending the yellow, red, and blue rays in order to produce or improve an otherwise imperfect white. When a little ultramarine, cobalt blue, prussian blue, or indigo is applied to bleached goods with the view of giving them the best possible white, if only a certain proportion be used, the goods will appear whiter after this addition than before it. In this case the violet blue forms with the brown yellow of the goods a mixture tending to white, or less coloured than the yellow of the goods and the blue separately were. For the same reason a mixture of prussian blue and cochineal pink, or archil and cudbear, is used for whitening of silks in preference to a pure blue, for on examining closely the colour of the silk to be neutralised, it was found by the relations of the complementary colours, that the violet was more suitable than the pure blue alone. The dyer should know, that when he applies several different colouring matters to stuff, as yellow and blue separately, they will appear green, not because the colouring matters have combined, but because the eye cannot distinguish the points which reflect the yellow from those which reflect the blue, and it is this want of distinction that produces the combined colour. With such a dye the colour will appear of different tints, the blue or yellow prevailing according to the position in which it is placed to the eye, whether seen by reflected or transmitted light, but when the dye applied to the stuff is in chemical union, producing a green, such as arsenite of copper, the yellow and blue rays cannot be thus distinguished. Other instances of mixed colours will be seen by examining certain grey substances, such as hairs, feathers, &c. with the microscope, by which it is seen grey colour results from black points disseminated over a colourless or slightly-coloured surface. The microscope may be thus usefully applied by the dyer to distinguish whether a colour be the result of a mixed or a combined dye.

The dyer should also be acquainted with the law of the simultaneous contrast of colours. When the eye views two colours close alongside of each other, it sees them differing most, in the height of their tone, when the two are not equally pale or full-bodied. They appear most different, when the complementary of the one of them is added to the colour of the other. Thus, put a green alongside of an orange, the red colour complementary of green being added to the orange, will make it appear redder. And in like manner, the blue complementary of orange being added to the green, will make it appear more intensely blue.

It is not sufficient to place complementary colours side by side to produce harmony of colour, the respective intensities having a most decided influence; thus, pink and light green agree, red and dark green also; but light green and dark red, pink and dark green do not; therefore, to obtain the maximum of effect and perfect harmony, the following colours must be placed side by side, taking into account their exact intensity and tint:—

Primitive Colours	Secondary Colours	
Red . . .	. Green	. Light blue; Yellow; Red
Blue . . .	. Orange	. Red; Yellow; Blue
Yellow orange .	. Indigo	. Blue; Red; Yellow
Greenish yellow	. Violet	. Red; Blue; Yellow
Black . . .	. White	. Yellow; Blue; Red

The mixed contrast gives the reason why a brilliant colour should never be looked at for any length of time, if its true tint or brilliancy is to be appreciated; for if a person looks, for example, at a piece of red cloth for a few minutes, green, its complementary colour is generated in the eye, and adding itself to a portion of the red, produces black, which tarnishes the beauty of the red. This contrast explains why the shade of a colour, may be modified, either favourably or otherwise, according to the colour which the eye has previously looked at. An example of the first instance is noticed, when the eye first looks to a yellow substance, and then to a purple one; and as exemplifying the second case looking at a blue and then at a purple.

The relations of dyeing with the principles of chemistry constitute the theory of the art, properly speaking; this theory has for its basis the knowledge—

1st. Of the nature and properties of the bodies which dyeing processes bring into contact.

2nd. Of the circumstances in which these bodies are brought together, facilitating or retarding their action.

3rd. The phenomena which appear during their action; and,

4th. Properties of the coloured combinations which are produced.

The first of these generalities embraces a knowledge of the preparations which stuff necessarily undergoes previous to dyeing, and also the preparations of the dye-drug before bringing it into contact with the stuff.

The operations to which stuffs are subjected before dyeing, are intended to separate from them any foreign matters which may have become attached, or are naturally inherent in the stuff. The former are such as have been added in the spinning, weaving, or other manipulations of the manufacture, and are all removed by steeping in an alkaline lye and washing. The second are the natural yellow colouring substances which coat some of the various fibres, both vegetable and animal; and the chlorophylle, or leaf-green of vegetables. The removal of these is generally effected by boiling in soap and alkaline lyes. A weak bath of soda, in which the stuff is allowed to steep for some time, and then washed in water, is generally the only preparation required for wool, in order that it may take on a uniform dye.

To remove the gummy or resinous matter from silk, it requires boiling in soap-lye; however, its removal is not essential to the stuff combining with the dye, as silk is often dyed while the gum remains in it, in which case it is only rinsed in soap-lye at a very moderate heat, to remove any foreign matters imbibed in the process of manufacture.

Vegetable fibre, as cotton, has such natural resinous matters that retard the reception of the dye removed by boiling, either with or without alkaline lyes; but the natural dun colour of the fibre is not removed, which from the laws of light and colour already referred to, would interfere with the production of bright light tints; under these circumstances, the natural colour of the fibre has to be previously removed by bleaching: for which see the article, Bleaching.

The necessary preparation of the dye-drugs within the province of the dyer, is to obtain the colour in a state of solution, so as to allow the fibre to absorb it, and to produce chemical combination, or to get the dye or colour in such a minute state of division as it will penetrate or enter into the fibre of the stuff. These preparations embrace the formation of decoctions, extracts, and solutions, and also in some cases of precipitation, previous to immersing the stuff into the bath. Stuffs, chemically considered, have but a feeble attraction for other matters, so as to combine with them chemically; still that they do possess certain attractions is evident from various phenomena observed in the dyeing processes, and that this attraction is possessed with different degrees of intensity by the different fibres, is also evident from the ease and permanence that woollen stuff will take up and retain dyes compared with cotton; and also, that certain dyes are retained and fixed within or upon one kind of fibre and not at all in another. This may be determined by plunging the dry stuff into solutions of the salts, and determining the density of the solution before the immersion and after withdrawing the stuff. Wool abstracts alum from its solution, but it gives it all out again to boiling water. The sulphates of iron, copper, and zinc resemble alum in this respect. Silk steeped for some time in a solution of protosulphate of iron, abstracts the oxide, and gets thereby dyed, and leaves the solution acidulous. Cotton in nitrate of iron produces the same effect. Wool put in contact with cream of tartar, decomposes a portion of it; it absorbs the acid within its pores, and leaves a neutral salt in solution in the liquor. Cotton produces no such effect with tartar, showing by these different effects that there are certain attractions between the stuff and dyes. This attraction, however, may be more what is termed a catalytic influence, the fibres of the stuff producing a chemical action with the salt or dye, with which it is in contact. This attraction or affinity of the fibre for the dye-drug, does not produce a very extensive effect in the processes of dyeing. More probably the power of imbibing and retaining colours possessed by the fibre is more dependent upon a mechanical than a chemical influence.

All dye-drugs must in the first instance be brought into a state of solution, in order that the dye may be imbibed by the fibre; but if the fibre exerts no attraction for the colour so as to retain it, it is evident that so long as it remains capable of dissolving in water, the stuffs being brought into contact with water, will soon lose their colour. A colour thus formed does not constitute a dye, however strongly stained the stuffs may appear to be, in or out of the dyeing solution; in order to form a dye, the colour must be fixed upon or within the stuff, in a condition insoluble in water. Hence the mere immersion of the stuff into a solution of a colour will not constitute a dye, except where the stuff really has an attraction for the colour and retains it, or causes a decomposition by which an insoluble compound is fixed upon it, such as is referred to by putting stuffs into solutions of iron. The abstraction of the colour from a solution by the immersion of the stuff, is often the result of a mechanical attraction possessed by porous substances, enabling them to absorb or imbibe certain colouring matters from solutions that are held by a weak attraction by their solvents. On this principle, a decoction of cochineal, logwood, brazil-wood, or a solution of sulphate of indigo, by digestion with powdered bone-black, lose their colour, in consequence of the colouring particles combining by a kind of capillary attraction with the porous carbon, without undergoing any change. The same thing happens when well-scoured wool is steeped in such coloured liquids; and the colour which the wool assumes by its attraction for the dye, is, with regard to most of the above coloured solutions, but feeble and fugitive, since the dye may be again abstracted by copious washing with simple water, whose attractive force therefore overcomes that of the wool. The aid of a high temperature, indeed, is requisite for the abstraction of the colour from the wool and the bone-black, probably by enlarging the size of the pores, and increasing the solvent power of the water.

Those dyes, whose colouring matter is of the nature of extractive, form a faster combination with stuffs. Thus the yellow, fawn, and brown dyes, which contain tannin and extractive, become oxygenated by contact of air, and insoluble in water; by which means they can impart a durable dye. When wool is impregnated with decoctions of that kind, its pores get charged by capillarity, and when the liquid becomes oxygenated, they remain filled with a colour now become insoluble in water. The fixation of iron oxide and several other bases also depends on the same change within the pores or fibre; hence all salts that have a tendency to pass readily into the basic state are peculiarly adapted to act as a medium for fixing dyes; however, this property is not essential.

In order to impart to the stuffs the power of fixing the colour in an insoluble form upon it, recourse is had to other substances, which will combine with the soluble and form with it an insoluble colour; and it is not necessary that this new substance should have an attraction for the stuff, or be capable of passing into a basic form, any more than the original colour, but it is necessary that it be rendered insoluble while in contact with the stuff.

Such substances, used to unite the colour with the stuff, have been termed *mordants*; it appeared that they had a mutual attraction for the stuff and colour, and combining with the stuff first, they afterwards took up the colour; but this is only so in some instances. A few examples will illustrate the action of these mordants. If a piece of cotton stuff is put into a decoction of logwood, it will get stained of a depth according to the colour of the solution, but this stain or colour may be washed from the cotton by putting it into pure water, the colour being soluble. If another piece of cotton stuff be put into a solution of protosulphate of iron, and then washed from this, a portion of the iron will have undergone oxidation, and left the acid, and become fixed upon the fibre and insoluble in water. Whether this oxidation is the result of an influence of the stuff, or the effect of the oxygen of the air and water in which the goods are exposed, it does not now matter; this fixed oxide, however, constitutes an example of a mordant, by its combining with the stuff. If this stuff is now put into a decoction of logwood, the colouring matter of the logwood will combine with the oxide of iron fixed upon the fibre, and form an insoluble colour, which after washing will not remove from the stuff. If, instead of washing the stuff from the sulphate-of-iron solution in water, it be passed through an alkaline lye of soda or potash, the acid holding the iron in solution is taken hold of by the alkali, and removed. The oxide of iron is thus left upon the stuff in a much larger quantity than in the former case, and as firmly fixed, although not by any attraction between it and the fibre, but simply by being left within it. And this stuff being now put into the logwood liquor, will form a dye of a depth according to the quantity of iron thus fixed upon the stuff, and equally permanent with that which had been fixed on the stuff by the oxidation in working.

Such then are the methods of fixing within the stuff insoluble colours from soluble compounds, and from these remarks the necessity of having the dye in solution will also be evident.

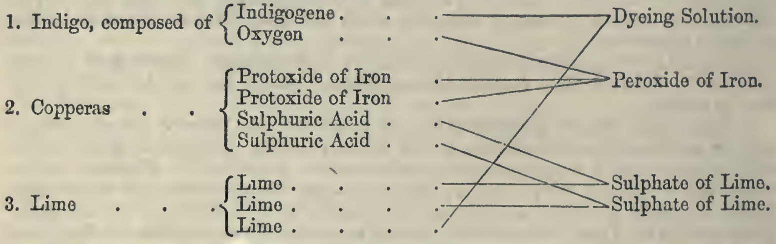
Suppose again that the sulphate of iron be mixed with the logwood decoction, there will be produced the same colour or dye as an insoluble precipitate: if the cotton stuff is put into this, no colour worthy of the name of a dye will be obtained, as the cotton will not imbibe within its fibre this precipitate. Place woollen stuff in the same liquid, and there is formed a very good dye, the woollen fibre having imbibed a great portion of the solid precipitate, probably owing to woollen fibres being much larger than those of cotton. Thus, with cotton and other stuff that will not imbibe freely solid precipitates, the mordant must be fixed within the fibre previously to applying the colouring substances, such as the vegetable decoctions. It will also be seen that the dye which is the product of combination between the mordant and colour is not that of the natural colour of the drug, but the colour of the compound. Hence the great variety of tints capable of being produced from one dye-drug, by varying either the kind or intensity of the mordant. So that in the above instances, it is not the colour of the hematoxylin fixed on the stuff, but its compound with iron, or tin, or alumina, as the case may be, all of which give different tints.

It is this principle of rendering bases insoluble while within the fibre, by chemical means, that has brought to the use of the dyer a great number of mineral dyes which in themselves, whether separate or combined, have no attraction whatever for the fibre; such as solutions of sulphate of copper, and yellow prussiate of potash, nitrate of lead, and bichromate of potash, &c. Suppose the stuff to be dyed a yellow by the two last-named salts were first put into the solution of lead and then washed previously to being put into the bichromate solution; the greater portion of the lead would be dissolved from the stuff, and a very weak colour would be obtained. If the stuff from the lead solution was put directly into the bichromate solution, a very good dye would be the result; but the portion of the solution remaining upon the surface of the stuff will combine with the chrome and form a precipitate which the fibre cannot imbibe, but it will form an external crust or pigment upon the surface, which blocks up the pores, and exhausts to no purpose the dye, causing great waste: hence the stuff from the solution of lead is put into water containing a little soda or lime, and the lead is thus reduced to an insoluble oxide within the fibre. The goods may now be washed from any loose oxide adhering, and then passed through the bichromate solution, when the chromic acid combines with the oxide of lead, forming a permanent yellow dye. Thus it will be seen that whether the combination of the colour with the stuff be chemical or mechanical, the production of the dye which is fixed upon the fibre is certainly a chemical question, and the dyer should be familiar with the nature and principles of these reactions.

There are a few instances where the dye produced does not come within the sphere of these principles, there being no mordants required, nor any combination of the colour formed within the stuff, but the dye-drug in its natural hue is fixed within the fibre. Such colours have been termed *substantive*, to distinguish them from those produced by means of mordants which are termed *adjective.* Amongst this class of dyes and dye-drugs stands pre-eminent indigo-blue. Indigo in its natural state is entirely insoluble in water, and is of a deep blue colour. The composition of this blue indigo is represented as—$C^{16}H^5NO^2$ ($\mathbf{C^8H^5NO}$). But it is found capable of parting with a portion of the oxygen, and by so doing, losing entirely its blue colour; and in this deoxidised condition it is soluble in alkaline lyes and lime-water; this colourless compound is termed *indigogene.* The opinión of Liebig upon the constitution of this substance was, that indigo contained a salt radical, which he termed *Anyle*, composed of $C^{16}H^5N$ ($\mathbf{C^8H^5N}$). He considered that indigogene or white indigo is the *hydrated* protoxide of this radical, and that blue indigo is the peroxide, represented thus—

Salt radical, anyle, $C^{16}H^5N$. Indigogene, $C^{16}H^5NO. HO$. Blue indigo, $C^{16}H^5NO^2$.

Advantage is taken of this property of indigo, of parting with its oxygen and becoming soluble, to apply it to dyeing, and it is effected by the following means, when for the purpose of dyeing vegetable stuff, as cotton; from the circumstance of these operations being done cold, the method is termed the cold vat, which is made up as follows:—The indigo is reduced to an impalpable pulp, by being ground in water to the consistence of thick cream. This is put into a suitable vessel filled with water, along with a quantity of copperas, and newly-slaked lime, and the whole well mixed by stirring. After a short time the indigo is deoxidised and rendered soluble by a portion of the lime which is added in excess, the reaction being represented thus:—



The peroxide of iron and sulphate of lime are precipitated to the bottom, and the indigogene and lime form a solution of a straw colour, with dark veins through it.

The operation of dyeing by this solution is simply immersion, technically, *dipping.* The stuff by immersion imbibes the solution, and when taken out and exposed to the air, the indigogene upon and within the fibre rapidly takes oxygen from the atmosphere, and becomes indigo-blue, thus forming a permanent dye, without any necessary attraction between the indigo and the stuff.

The indigo vat for wool and silk is made up with indigo pulp, potash, madder, and bran. In this vat the extracts of madder and bran perform the deoxidising functions of the copperas in the cold vat, by undergoing a species of fermentation.

Pastel and woad, either alone or with the addition of a little indigo, are also used for the dyeing of wool and silk stuff, the deoxidation being effected by the addition of bran, madder and weld. In dyeing with these vats, the liquor is made warm, and they require much skill and experience to manage, in consequence of their complexity, being always liable to go out of condition, as the dyeing goes on, by the extraction of the indigogene and the modification of the fermentable matter employed to deoxidise the indigo to supply that loss. The alkaline solvent also undergoes change, so there must be successive additions of indigo and alkali; the principal attention of the dyer is the maintaining the proper relation of these matters, as too much or too little of either is injurious.

Sulphate of indigo forms an intense blue solution, unaffected also by mordants. Vegetable stuffs dipped in this retain no dye, for the washing-off the acid in order to preserve the fibre removes the colour; but animal fibre, such as woollen and silk, becomes dyed; a portion of the blue remains upon the stuff after washing-off the acid, being retained by capillary attraction. This dye is termed *Saxon blue*, but it has very little of the permanence of indigo or *vat blue*, although it is also a substantive colour.

Another truly substantive colour is that dyed by *carthamus* or safflower, but the fixation of this dye upon the stuff differs from any of those referred to. Like indigo, it has no affinity for any base or substance capable of forming a mordant; its solvent is an alkali, but in this dissolved state it does not form a dye. The mode of proceeding in dyeing with carthamus is, first, to extract the dye from the vegetable in which it is found, by soda or potash, which is afterwards neutralised by an acid previous to dyeing, which renders the colour insoluble, but in so fine a state of division that no precipitation can be seen for some time and the stuff immersed in this imbibes the colour within its fibre, its lightness assisting this action, as the precipitate will remain suspended in water for days before it will subside. Vegetable fibre takes up this dye as easily as animal, but whether by an attraction for the stuff, or by a mechanical capillary attraction of the fibre is not so easily determined. A piece of stuff suspended in a vessel filled with water, having in it some insoluble carthamine, all the colouring particles will flow to and combine with the fibre from a considerable distance, giving a proof of the existence of some force drawing them together.

Such then are the various conditions and principles involved in the processes of fixing the dye within or upon the stuff.

During the operations of dyeing there are certain circumstances which have to be attended to, in order to facilitate and affect certain hues or tints of colour. Thus, with many of the colouring substances, heat not only favours but is necessary for the solution of the dye, and also its combination with the stuff or mordant. Decoctions of woods are always made by hot water, and the dyeing processes with decoctions are in hot liquor. When the colouring matter of quercitron bark is extracted by boiling water, the colour produced upon the stuff will be a rich amber yellow, but if the extract be made by water at 180° Fahr., a beautiful lemon yellow will be the dye produced by it, using the same mordant in each case. Colours dyed by madder and barwood must be done at a boiling heat during the whole process, or no dye is effected. Sumach, another astringent substance, is most advantageously applied at a boiling heat; and in order to have a large body of this dye fixed upon the stuff, it should be immersed in the liquor while hot and allowed to cool together, during which the tannin of the dye undergoes some remarkable change in contact with the stuff. Safflower dyes are kept cold, so are tin bases, Prussian blues, and chrome yellows: by applying heat to the last a similar result is effected to that with bark; instead of a lemon yellow, an amber yellow will be obtained. Almost all colours are affected less or more by the temperature at which they are produced. Some mordants are fixed upon the stuff by heat, such as acetate of alumina; the stuff being dried from a solution of this salt at a high temperature loses part of the acid by being volatilised, and there remains upon the fibre an insoluble suboxide, which fixes the dye. These remarks respecting the methods apply more particularly to vegetable stuffs, as cotton, and in many cases also to silk, but wool is always dyed at a high heat. Although wool seems to have a much greater absorbing power than cotton, the latter will absorb and become strongly dyed in a cold dye-bath, in which wool would not be affected; but apply heat and the wool will be deeply dyed, and the dye much more permanent than the cotton.

The permanence of colours is another property to be carefully studied by the practical dyer, as the colour must not be brought under circumstances that will destroy its permanency during any of the operations of the dye-house. The word 'permanent,' however, does not mean *fast*, which is a technical term applied to a colour that will resist all ordinary operations of destruction. For instance, a Prussian blue is a permanent colour, but not a fast colour, as any alkaline matter will destroy it; or a common black is permanent, although any acid matters will destroy it; while Turkey red is a fast colour and not affected by either acid or alkaline matters. A few of the circumstances affecting colours in the processes they are subjected to may be referred to in this place. If, for instance, the air in drying the dyed stuff in a hot chamber be moist, there is a great tendency to the colour being impaired in these circumstances. For example, a red colour dyed with safflower will pass into brown, a Prussian blue will pass into a grey lavender, whilst chrome yellows take an amber tint. Almost all colours are more or less affected by being subjected to strong heat and moisture; even some of those colours termed fast are affected under such circumstances. A dry heat has little or no effect upon any colour, and a few colours are made brighter in their tint by such a heat, as chrome orange, indigo-blue, on cotton, &c.

Some of these effects of heat and moisture differ with different stuffs; thus indigo-blue upon cotton is not so much affected as indigo-blue upon silk, while safflower-red upon cotton will be completely destroyed before the same colour upon silk will be perceptibly affected. The same colouring matter fixed by different mordants upon the same stuff is also differently affected under these conditions.

Light is another agent effecting a great influence upon the permanence of colours, which should be also considered by the dyer. Reds dyed by a Brazil wood and a tin mordant, exposed to the light, become brown; Prussian blue takes a purple tint; yellow becomes brownish; safflower-red yellowish, and these changes are facilitated by the presence of moisture; such as exposing them to strong light while drying from the dye-bath, either out or within doors. The direct rays of the sun destroy all dyed colours; even Turkey red yields before that agency.

Boiling was formerly prescribed in France as a test of fast dyes. It consisted in putting a sample of the dyed goods in boiling water, holding in solution a determinate quantity of alum, tartar, soap, and vinegar, &c. Dufay improved that barbarous test. He considered that fast-dyed cloth could be recognised by resisting an exposure of twelve hours to the sunshine of summer, and to the midnight dews, or of sixteen days in winter.

In trying the stability of dyes, we may offer the following rules:—

That every stuff should be exposed to the light and air; if it be intended to be worn abroad, it should be exposed also to the wind and rain; that carpets, moreover, should be subject to friction and pulling, to prove their tenacity; and that cloths to be washed should be exposed to the action of hot water and soap. However, such tests are not at all applicable to most of the colours dyed upon cotton stuff. Not many of them can stand the action of hot water and soap, or even such acids as the juice of fruits. Indigo-blue, one of the most permanent dyes on cotton, yields its intensity to every operation of washing, even in pure water.

Delaval's observations on the nature of dyes may be thus summed up. In transparent coloured substances, the colouring substance does not reflect any light; and when, by intercepting the light which was transmitted, it is hindered from passing through substances, they do not vary from their former colour to any other colour, but become entirely black; and he instances a considerable number of coloured liquors, none of them endued with reflective powers, which, when seen by transmitted light, appeared severally in their true colours; but all of them, when seen by incident light, appeared black; which is also the case with black cherries, black currants, black berries, &c., the juices of which appeared red when spread on a white ground, or otherwise viewed by transmitted instead of incident light; and he concludes, that bleached linen, &c. 'when dyed with vegetable colours, do not differ in their manner of acting on the rays of light, from natural vegetable bodies; both yielding their colours by transmitting, through the transparent coloured matter, the light which is reflected from the white ground:' it being apparent, from different experiments, 'that no reflecting power resides in any of their components, except in their white matter only,' and that 'transparent coloured substances, placed in situations by which transmission of light through them is intercepted, exhibit no colour, but become entirely black.'

The art of dyeing, therefore (according to Mr. Delaval), 'consists principally in covering white substances, from which light is strongly reflected, with transparent coloured media, which, according to their several colours, transmit more or less copiously the rays reflected from the white,' since 'the transparent media themselves reflect no light; and it is evident that if they yielded their colours by reflecting instead of transmitting the rays, the whiteness or colour of the ground on which they are applied would not in anywise alter or affect the colours which they exhibit.'

But when any opaque basis is interposed, the reflection is doubtless made by it rather than by the substance of the dyed wool, silk, &c., and more especially when such basis consists of the white earth of alum, or the white oxide of tin; which, by their strong reflective powers, greatly augment the lustre of colours. There are, moreover, some opaque colouring matters, particularly the acetous, and other solutions of iron, used to stain linen, cotton, &c., which must necessarily themselves reflect instead of transmit the light by which their colours are made perceptible.

The compound or mixed colours are such as result from the combination of two differently-coloured dye-stuffs, or from dyeing stuffs with one colour, and then with another. The simple colours of the dyer are red, yellow, blue, and black, with which, when skilfully blended, he can produce every variety of tint. Perhaps the dun or fawn colour might be added to the above, as it is directly obtained from a great many vegetable substances.

1. Red with yellow, produces orange; a colour, which upon wool is given usually with the spent scarlet bath. To this shade may be referred flame colour, pomegranate, capuchin, prawn, jonquil, *cassis*, chamois, *café au lait*, aurora, marigold, orange-peel, *mordorés*, cinnamon, gold, &c. Snuff, chestnut, musk, and other shades are produced by substituting walnut peels or sumach for bright yellow. If a little blue be added to orange, an olive is obtained. The only direct orange dyes are annotto, and subchromate of lead.

The latter is never used for dyeing orange upon silk and wool, while the former is now never used for cotton. An orange with annotto is very fugitive, even upon the animal fibre; but much more so upon cotton. Subchromate of lead is produced upon cotton by dyeing it first a deep chrome yellow by acetate of lead and bichromate of potash, as already noticed, and then passing the stuff so dyed through a hot solution of an alkali or lime, which changes the dye from the yellow chromate to the state of subchromate, which is deep orange. See SILK and WOOL DYEING.

2. Red with blue produces purple, violet, lilac, pigeon's neck, mallow, peach-blossom, *bleu de roi*, lint-blossom, amaranth, &c.

Thus a Prussian blue dyed over a safflower red, or *vice versâ*, will produce any of these tints by varying the depth of the red and blue according to the shade required; but the same shades can be produced direct by logwood and an aluminous or tin mordant; the stuff being steeped in sumach liquor previously to applying the tin mordant produces the reddish or purple tint when such is required.

3. Red with black; brown, chocolate, maroon, &c. These tints are produced by various processes. To dye a deep orange by annotto liquor, and then form over it a black by sumach and sulphate of iron, gives a brown; or dye the stuff first a rich yellow by quercitron and a tin mordant, and then over the yellow produce a purple by passing it through logwood; chocolates are thus produced. A little brazil-wood with the logwood gives more of the red element. When maroon is required, the red is made to prevail, and so by a judicious mixture, these various tints are produced. Brown, especially upon cotton fibre, is more often produced direct by means of catechu. Steep the stuff in a hot solution of catechu, in which the gummy principle has been destroyed by the addition of a salt of copper; then pass through a solution of bichromate of potash at boiling heat, when a rich brown is obtained.

4. Yellow with blue; green of a great variety of shades; such as nascent green, gay green, grass green, spring green, laurel green, sea green, celadon green, parrot green, cabbage green, apple green, duck green, &c.

Green is essentially a mixed dye, and produced by dyeing a blue over a yellow or a yellow over a blue. In almost all cases the blue is dyed first, and then the yellow, and according to the depth of each or any of these are the various tints of green produced. With silk and wool, one kind of green dye may be produced simultaneously by putting sulphate of indigo into the yellow dye-bath, and then working the previously-prepared or mordanted stuff in this. With cotton, an arsenite of copper (Scheele's green) may be produced by working the stuff in a solution of arsenite of potash or soda, and then in sulphate of copper, which produces a peculiar tint of green.

5. Mixtures of colours, three and three, and four and four, produce an indefinite diversity of tints: thus, red, yellow, and blue form brown olives and greenish greys; in which the blue dye ought always to be first given, lest the indigo vat should be soiled by other colours, or the other colours spoiled by the alkaline action on the vat. Red, yellow, and grey (which is a gradation of black) give the dead-leaf tint, as well as dark orange, snuff colour, &c. Red, blue and grey give a vast variety of shades; as lead-grey, slate-grey, wood-pigeon grey, and other colours too numerous to specify.

Care must be taken, however, in mixing these colours, to study the depth of the tint required; as, for instance, were we wishing to dye a slate-grey, and to proceed first by dyeing a blue, then a red, with a little of the grey, we should produce, instead of a slate grey, a purple or peach. The arrangement referred to, applies only to the elements of the colours that enter into the composition of the various tints, so that a slate-grey is a blue with a small portion of red, and a still smaller portion of the black element, that produces the grey tint. Thus, dye the stuff first a deep sky-blue by the vat, then by passing through a solution of sumach, with a small quantity of logwood, brazilwood, copperas, and alum, grey will be produced. The brazilwood gives the red tint, sumach and copperas the black tint, the logwood assisting in this, and with the aid of the alum throwing in the puce or dove-neck hue; and thus by the variation of these hues by such arrangements, any of the grey tints can be produced. See CALICO-PRINTING.

ANILINE DYES. Dyeing and printing have undergone a considerable change through the introduction of these dyes. The colours produced are more brilliant than formerly, and, since the use of mordants has been almost dispensed with, the processes are very much shorter. The styles and patterns have undergone a marked change.

These dyes, however, have not yet supplanted the use of dyewoods and the other colouring matters formerly in use. They are not so permanent, and at the same time they are much more expensive. But continued improvements in the modes of producing and applying these dyes will no doubt greatly advance and develope their commercial importance.

Reference to the article ANILINE, and also to CALICO-PRINTING, will show the simplicity of the applications of these tinctorial substances, and the great variety of decided colours and varying tints which are produced.

We have not only the true aniline colours available for the use of the dyer and calico-printer, but we have the Murexide Dyes, and others of an analogous description—especially such as belong to the Picric Acid series—which, by intercombination, produce an almost infinite variety.

In dyeing silk and wool with aniline colours no mordant is required. Solution in a suitable solvent (acetic acid or alcohol) is all that is necessary. In the case of the rosaniline salts, however, a neutral solution and a temperature not exceeding 180° F. are requisite.

In dyeing vegetable fibres, albumen, glutin, gelatine, casein, tannin or tannic acid, &c. are used as mordants.

In printing with these colours the process is the same as in the case of steam colours. Either the mordant is first printed on the fabric, which is then steamed and dyed, or the colouring matter is thickened with the mordant (albumen, &c.), the fabric dyed with this, and then steamed so as to fix it.

Aniline Black has been quite recently produced by the direct oxidation of aniline on cotton fibre. A mixture consisting of an aniline salt, perchloride of copper, and chlorate of potash, is printed on the cotton, which is then exposed to an atmosphere of steam. After some time a black is developed.

The following figures show the rapidity with which aniline and its derivatives have fallen in price during the last few years, and thus give an idea of their rapid industrial development:—

Aniline and Colours. Average Prices.

Colour	1860			1866			1872		
	£	s.	d.	£	s.	d.	£	s.	d.

DYER'S ALKANET, *Anchusa tinctoria.* See ALKANET.

DYER'S MADDER, *Rubia tinctorum.* See MADDER.

DYER'S OAK, *Quercus infectoria.* See GALLS and OAK.

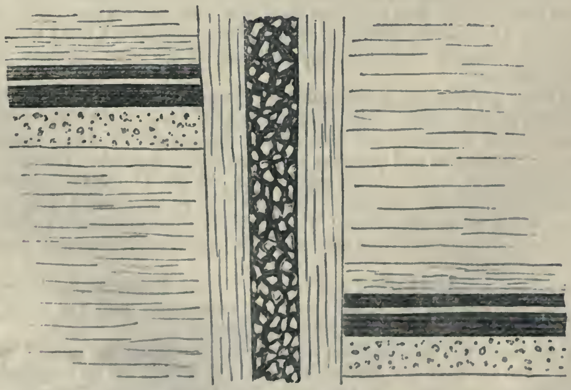
DYER'S ORCHELLA WEED, *Roccella tinctoria.* See ARCHIL; ORCHELLA.

DYER'S SAFFLOWER, or Bastard Saffron. The *Carthamus tinctorius.* The flowers are of a deep orange colour, but they are used for dyeing various shades of red. The flowers of the carthamus are employed in Spain for colouring dishes and confectionary. See CARTHAMUS.

DYER'S WOODROOF. *Asperula tinctoria.* The roots of this plant are used in some parts of Europe, particularly Dalmatia, instead of madder for dyeing wool and cloth of a reddish colour; but in bulk the crop obtained is inferior to that of the madder.—*Lawson.*

DYKE. (Scot. a *wall* or *fence.*) Applied to those wall-like intrusions of igneous rock which fill up rents and fissures in the stratified rocks. They may sometimes fill up pre-existing rents and fissures, but they usually burst through and displace the rocks through which they are forced. Dykes are generally understood to be connected with the volcanic rocks below, from which they have been forced, in a molten state,

770



through the superincumbent rocks—often overflowing the newer strata; filling fissures which may have been pre-existent, or may have been formed by the mechanical force of the fluid mass in its upward movement. The substances of which dykes are composed is basalt, in one or the other of its varieties—or trap in some of its many forms. Dyke-matter is of different degrees of fineness, some of it being coarse and granular, and some of it of a fine texture, like the cinder of iron furnaces. The Giant's Causeway is a good example of the lithological character of the rocks forming dykes, or they are like the 'whin-sill' of South Staffordshire or the greenstone rocks of Rowley and other places.

In the North of England the dykes have been very carefully examined. From the 'Practical Treatise on Mine Engineering,' by G. C. Greenwell, we extract the following notices of some of the principal dykes observed in the Newcastle coal-field:—

Name	Magnetic bearing	Width	Dislocation
		feet	fathoms
1. Hitchcroft dyke, near Alnwick .	N. 72° W.	69	
2. Acklington dyke	N. 80° W.		
3. Blyth dyke	N. 60° W.		
4. Mausoleum dyke, Hartley . .	N. 61° W.	9	8½
5. Swallow dyke, ,, . .	N. 65° W.	12	12
6. Coaley Hill dyke . . .	N. 45° W.	11	
7. Walbottle Hill dyke . .	N. 45° W.		
8. Tynemouth dyke	N. 63° W.	12	
9. Willington or Tudhoe dyke . .	N. 82° W.	8	
10. Cockfield dyke . . .	N. 45° W.	66	6

Many of these dykes passing through the coal, by dissipating the volatile bitumen, bring it into an anthracitic state, and in some instances the coal is actually coked by the heat of the intrusive mass.

The main dyke running from near Cullecoates, in a south-westerly direction to Hedley, is usually called the 90-fathom dyke, because it has a downthrow to the north from 90 to 180 fathoms.

The Mausoleum dyke (*fig.* 770) was discovered and passed through in the workings of the low main seam at the depth of 53 fathoms in the Old Hartley Colliery, its position being nearly underneath the mausoleum in the Seaton Delaval grounds; hence its name. It is frequently called the 'Hartley Whin Dyke.' By it the strata are thrown down to the north-east to the extent of 8½ fathoms. This dyke consists of two walls of basalt of the thickness respectively, of 9 feet and 4 feet 4 inches, separated from each other by a mass of the *débris* of other strata of the thickness of 8 feet 10 inches.

771

In the neighbourhood of Dudley, in South Staffordshire, these overflows of trap, upon the beds of coal, and in many cases through them, are strikingly exhibited. *Fig.* 771 shows the passage of a dyke through the coal, the portions of the coal near the trap being changed by its heat, or 'blacked,' as it is locally called, the coal losing all its brilliancy. The late Mr. Jukes thus describes these intrusive dykes in the coal of South Staffordshire:—

'All parts of these galleries, indeed, were riddled, as it were, with these trap veins running here and there in the coal, and also in the sandstone, altering the coal to a greater or less extent, according to the bulk of the trap, but producing very little apparent alteration in the sandstone.

'From the fine tortuous and branching veins which the rock forms, it seems hardly possible to suppose that at the time of its injection it was not in a fluid state and almost perfectly liquid. The distances to which these narrow veins run seem also to make it necessary to suppose that, at the time of injection, it had a temperature not merely just sufficient to melt it, but a much higher one; sufficiently high to allow of the loss of a considerable quantity of heat, and yet for the matter to remain still molten in its passage to very considerable distances from the volcanic focus.'

DYNAMITE. In 1867 Mr. Nobel, in his endeavours to lessen the dangers attending the use of nitroglycerine, made the important observation that the readiness or certainty with which it is exploded through the agency of a detonation is not reduced, but, on the contrary, somewhat favored by mixing the liquid with solid substances in themselves thoroughly inert. This discovery led at once to the production by Nobel of solid, or more or less pasty, preparations of nitroglycerine, which under the name of dynamite were first brought before the public in 1867. The form in which dynamite was first presented to the public was that of a soft, readily-moulded powder of a pink or buff colour, which consisted of about 75 parts of nitroglycerine held absorbed by 25 parts of a porous, infusorial, silicious earth known in Germany as 'Kieselguhr'. The moist appearance of this powder favored the opinion that the nitroglycerine would be liable to exude from it; and it undoubtedly was open to this objection. Dynamite has, however, been supplied for some time past in the form of small cylindrical cartridges consisting of the material in a compact condition, enclosed in a single wrapping of parchment-paper. These cartridges are consolidated by pressure whereby any excess of nitroglycerine which the porous earth will not hold absorbed, is expelled, and thus the separation of the nitroglycerine in dressing, handling, transport, or exposure to elevated temperatures appears effectually guarded against. The consistence of the dynamite charges is like that of dry putty. The Kieselguhr selected as the medium for the application of nitroglycerine appears the material best calculated to hold absorbed a large proportion of the liquid, and to retain it even when the mixture is submitted to considerable pressure. Mr. Abel, in his paper 'On Explosive Compounds,' published in the 'Proceedings of the Institution of Civil Engineers,' states that when dynamite factories were established in the outskirts of Paris during the siege, and this particular silicious earth could not be procured, a series of experiments was instituted for the purpose of discovering a good substitute. The most efficient absorbents next to this material were found to be precipitated silica, kaolin, tripoli, precipitated alumina and sugar, but none of these appeared thoroughly equal to Kieselguhr in their power of retaining a very large proportion of the oil. Eventually the ashes of Boghead coal were used for the production of dynamite during the siege of Paris. Mr. Nobel's No. 2 dynamite, which is sold as a cheaper blasting agent than the so-called No. 1, contains a much smaller proportion of nitroglycerine mixed with finely-powdered saltpetre, and resin or coal, but this cartridge can only be used when the violent crushing and rending action of the stronger dynamite is not required.

The danger, real or supposed, attending the use of dynamite has led to many restrictions, not only on its manufacture, but on its transmission: the following particulars contributed to one of our scientific periodicals in 1873 will be read with some surprise a few years hence:—

'Not very long ago a coasting screw steamer embarked a cargo of 42 tons of dynamite at the Dynamite Company's works, on the Aryshire coast, to be distributed along the west coast of England and Wales—at Whitehaven for the Cleator and Furness hæmatite ironstone districts; at Aberystwyth for Mid-Wales, at Cardiff for South Wales, at Sydney for the mining districts of the Forest of Dean, Gloucestershire, and the South Midland Counties; and at Hayle, in Cornwall, for the county, and the adjoining county of Devon. Soon afterwards another cargo of 25 or 30 tons was shipped and despatched to the north-east coast of England *viâ* the Forth of Clyde Canal, to be delivered in varying quantities at Newcastle; at Redcar, for the districts of Cleveland and North Yorkshire; and at Goole, for East and West Yorkshire. Since these arrangements have been put in train for establishing agencies in, and sending large quantities of dynamite into, the North of Scotland—Aberdeenshire, Caithness, &c., and various parts of Ireland. More recently additional large consignments have been forwarded to the principal agents in England, and at present arrangements are in progress for sending a very large cargo down along the west coast. The greatest proportion of the material yet despatched from the dynamite works seems to have been greedily absorbed into use in the districts that are reached with more or less ease from Whitehaven, and thither a number of consignments have found their way, both by railway and steamer.

'Great anxiety is being manifested to get large supplies of dynamite sent out to the Australian colonies, and it is not unlikely that a ship-load will accordingly soon be sent to the other side of the world. Shipowners, equally with railway companies, still 'boggle' at, and express great fear of, dynamite, otherwise considerable quantities of it might already have found their way to the antipodes.

'Besides being used in pit-sinking and coal-getting, in slate-quarrying and limestone-quarrying, in the ironstone mines and the metalliferous mines generally, in railway cutting, tunnelling, &c., dynamite is proving itself to be eminently serviceable in breaking up and removing the immense masses of mixed iron and slag which form the bottoms, or 'salamanders,' of blown-out blast furnaces. It is also about to be used extensively in subaqueous blasting on the Clyde for the removal of a large quantity of a whinstone dyke that occupies the bed of the river near Erskine Ferry; and we have recently learned that half a ton of it is to be employed in connection with the torpedo experiments that the naval authorities have at present in progress.'

The following particulars respecting the storing of dynamite cannot but prove interesting to those who are using this useful explosive agent:—

'The district store magazines are constructed in accordance with plans approved of by the Inspector of Gunpowder Factories and Magazines. At first they were intended to contain a maximum quantity of five tons, but there is some expectation that the license may be extended to twice that amount. The internal dimensions of these magazines are 12 feet 6 inches square, by 8 feet high from floor to top of side walls. In structure they are so simple that they may easily be erected by the ordinary tradesmen found in the mining districts. The walls may be of 9-inch brick and mortar work; but where stone walls, of hammer-dressed rubble set in mortar, can be more conveniently or economically used, it is recommended that they should be 15 inches thick.

They are arranged on what is technically known as the 'shelf system,' the internal fittings consisting simply of joists or battens set on edge, resting on the floor, and let half-way into the end walls for further security. Upon these as bearers, cross-spars, 3-inch by 1-inch, cut out of flooring boards, or similar materials, and kept an inch or so apart, are pegged down on the joist with wood tree-nails, and the vertical, 3-inch by-½ inch, wood strips are fastened on the walls in a similar manner; the latter being put four inches apart, so as to prevent the packing-boxes chafing on the rough walls. On the shelves thus described the boxes of dynamite are placed in rows, and the floor space within the doorway may be of earth, clay, or sand, and should be raised six or eight inches above the level of the ground outside. By this simple arrangement the use of special magazine shoes or slippers is dispensed with. The door in each case consists of red pine frame, 1½ inch thick, covered back and front with ⅞-inch flooring boards, grooved and feathered; the outside boards being put on vertically, the inside boards horizontally, and the spaces between being packed with dry sawdust or sifted engine ashes. It is fitted with strong double-tail hinges, and provided with a good, safe, and strong lock and key, all of brass by preference. It is insisted that the doors always open outwards, and that when closed they shall shut against a hardwood kerbstep. The roof, main, or corner principals are formed of sound red pine battens, 9-inch by 3-inch, having spars 6-inch by 2½-inch, spaced two-feet centres, and well secured to the principals and wall-plates in the usual manner; the spars being covered on the lower side with ⅝-inch close-jointed lining-boards, and the spaces between the spars being packed similarly to the doors, and then sacked over and slated. A square box ventilator, with cowl, is placed in the apex of the roof, and the whole is finished off with lead or zinc ridge-plates on skews and lead or zinc cover on the top of the ventilator, the air spaces for ventilation on the lower side of the cowl being covered with perforated zinc. A district store magazine of a different design, but of the same size, has been approved of by Major Majendie. It consists entirely of wood, the framework having a covering of 3-inch planking, which is carefully coated with tar outside and inside, to preserve the timber, and then felted over externally to render it watertight. Suitable provision is made for the ventilation, and then the magazine is covered over with sand or earth, to the depth of 1½ yard on the top, by 2½ to 3 yards at the sides, finished with turf sods, and provided with requisite drainage, &c.

'All exposed ironwork in the interior of these magazines is distinctly prohibited by Her Majesty's Inspector of Gunpowder Factories and Magazines, so that wood-pegs or tree-nails or zinc nails are preferred for all fastenings. If iron nails are anywhere used they must be punched in and puttied over. Where it is practicable, Major Majendie urges the desirability of a high fence being placed round the magazine with a locked door; such a fence as may be made with old railway sleepers has been strongly recommended.

'Consumers' store-magazines are arranged for, which are capable of containing one ton of dynamite. They are also arranged on the 'shelf system,' and are 6 feet 6 inches square internally, and 6 feet 6 inches from the floor line to the top of the side walls.

'Special licenses for storing dynamite in magazines of approved construction are granted by the Home Secretary: the quantity stored in any one magazine being never more than five tons, unless with the authorisation of the officer of state. Important conditions are laid down as regards the distance of the site of the proposed magazine from buildings of various kinds. For instance, a magazine licensed for five tons of dynamite may not be nearer to a royal palace, or the metropolis, as defined in the Local Management Act of 1855, than three miles. It may not be nearer than two miles to any magazine belonging to the Crown, and containing gunpowder or any other explosive. Then lesser distances, varying down to 200 yards, are stipulated for in the case of any borough or market town, church, hospital, other magazine or store for explosives, dwelling-house and factory, or workhouse (except with the consent in writing of the occupier), school or charitable institution, highway, river or sea-wall, canal or railway. But the limits as to distances may be lessened, however, in special cases, if, in the opinion of the Government Inspector, the natural features of the site selected admit of so doing without endangering the public safety. The authorities desire it to be distinctly and clearly understood that, where an applicant to have a magazine licensed is unable to comply with the conditions of the general license as to distances, construction, &c., it is open to apply for a special license, which is in all cases granted where the proposition appears to be one which can be safely acceded to. For example, a person desirous of using dynamite finds that he is unable to erect the necessary magazine at the required distance of 200 yards from a dwelling-house, factory, &c. In this case it would be for him to consider whether he should reduce the quantity, or whether he should so construct or protect his magazine as to render the full distances assigned in the general license unnecessary. It might happen that a quantity of, say, a quarter of a ton, would answer all his purposes, and, in this case, reduced distances would clearly be admissible. Again the full distances of the general license are not insisted upon when such protection is obtainable as is afforded by burrowing into the earth, or into the face of a colliery or mine waste heap, and protecting by mounds, or traverses, &c.'

See Explosive Compounds; Gun-Cotton; Nitroglycerine.

DYSODILE. A combustible mineral found in secondary limestone, at Melili, near Syracuse, in Sicily. It is laminated and fragile, and has an argillaceous odour when breathed on. It burns with a crackling noise, and considerable flame, with much smoke, giving out a fœtid smell, whence it has acquired the name of *Stercus Diaboli* or *Merda del Diavolo* in Sicily. It is also found in some parts of France—(Bristow, 'Glossary of Mineralogy.') A kind of dysodile has been brought from the Mersey river in Tasmania, and has been described by Prof. Church under the name of *Tasmanite.*

Tasmanite is a material of organic origin, found in Tasmania, described sometimes as resinferous or combustible shale; it is distinctly laminated, the organic matter, which occurs in scales, being disposed in planes parallel to the lamination, and probably causing it. These scales are of a reddish-brown colour, and form from 30 to 40 per cent. of the rock. The average diameter of the discs is about ·03 of an inch, while their thickness at the centre is sometimes as much as ·007. As none of the ordinary solvents of resinoids seemed capable of dissolving out the carbonaceous constituent of the mineral, the following plan of effecting the separation was adopted:—A large quantity of the mineral was crushed to a coarse powder, placed in a Phillip's precipitating glass, and strong hydrochloric acid poured upon it. A trace of carbonic anhydride was thus set free from the small quantity of carbonate of calcium present, while the alumina and ferric oxide of the mineral were partly dissolved. These actions break up the mineral, and the 'scales' mostly became disengaged and floating, owing to the high gravity of the hydrochloric solution, which had been further increased by the addition of chloride of calcium. The scales were collected by a strainer, and repeatedly washed by decantation, the inorganic matter being reduced to a minimum. The substance thus prepared presents such remarkable distinct chemical and physical characters as to lead to its receiving a distinct name. When tasmanite is heated in the air it burns readily, with a very smoky flame and offensive odour. Submitted to destructive distillation, it fuses partially, and yields oily and solid products of a disagreeable smell, resembling the odour of Canadian petroleum. Qualitative analysis of tasmanite showed it to contain a large quantity of carbon and hydrogen, and a considerable portion of sulphur. It was found impossible to free the specimens completely from mineral impurities, even with the most careful mechanical treatment. The sulphur detected was an integral part of the carbonaceous matter itself, and not owing to the presence of an inorganic sulphide or sulphate; this was proved in several ways, and was further confirmed by the observation that the more completely the mineral matter had been removed, the more sulphur was found in the specimen of tasmanite operated upon.

E

EAGLE-STONE. A name applied to nodular concretions of iron-stone, which present a concentric structure, and are often hollow, containing loose materials, which rattle when the stone is shaken.

EAGLE-WOOD. (*Bois d'Aigle*, Fr.) The wood of the *Aquilaria Malaccensis* or *A. ovata.* This is the 'aloes-wood' of commerce; an exceedingly aromatic wood, much used in Hindostan and in all Mohammedan and Catholic countries for fumigation and incense. The trees, belonging to the *Aquilariaceæ*, are natives of tropical Asia. Eagle-wood, or aloes-wood, is also yielded by the *Aloexylon Agallochum.*

EARTH. Common *alluvial* deposit, or *agricultural soil.* Weight of a cubic foot varies from 95 to 125 pounds. Specific gravity from 1·5 to 2·0.

EARTH-COAL, or Earthy Brown Coal. A name sometimes given to Lignite or Brown Coal. See Brown Coal, Lignite.

EARTHENWARE. See Pottery.

EARTH-FLAX. Asbestos is sometimes so called. See Asbestos.

EARTH-NUT. The fruit of the *Arachis hypogæa*, a leguminous creeping plant, native of India, South Africa, and South America. It is cultivated in North America and Southern Europe. The legumes are ripened under ground, whence the name, and the seeds are edible.

EARTH-NUT OIL. (*Huile d'Arachide; Huile de pistache de terre*, Fr.; *Erdnussöl*, Ger.) The oil expressed from the earth-nut by cold pressure. It is nearly colourless, and has an agreeable odour. It is used for culinary purposes instead of olive oil, but it is liable to become rancid much sooner. The hot-pressed earth-oil is coloured, and has a disagreeable taste and smell. A soap made from the oil of earth-nuts is manufactured in France, and to some extent in Germany. Earth-nut oil is much used by watchmakers.

EARTHS. (*Terres*, Fr.; *Erden*, Ger.) It has been demonstrated that the substances called Earths, and which, prior to the electro-chemical discoveries of Davy, were deemed to be elementary bodies, are all compounds of certain metallic bases and oxygen. Five of the earths, when pure, possess decided alkaline properties, being more or less soluble in water, having (at least three of them) an acrid alkaline taste, changing the purple infusion of red cabbage to green, most readily saturating the acids, and affording thereby neutral salts; these are *baryta*, *strontia*, *lime*, (*calcia*), *magnesia*, and *lithia.* The earths proper are *alumina*, *glucina*, *yttria*, *zirconia*, and *thorina*; these do not change the colour of infusion of cabbage or tincture of litmus, do not readily neutralise acids, and are quite insoluble in water.

EARTHY BITUMEN. A bituminous schist found at Hurlet near Glasgow, and in the Binney quarries near Edinburgh. See Bitumen.

EARTHY COBALT. A manganese ore, containing oxide of cobalt sometimes to the amount of 33 per cent. See Wad.

EARTHY MANGANESE. See Wad and Manganese.

EAST-INDIA BLACK WOOD. The Sit Sâl of the natives of India; the *Dalbergia latifolia.* It is a wood of a greenish black colour, with light coloured veins. It takes a fine polish, and is very heavy. This wood is sometimes called East India Ebony.

EAU DE COLOGNE. See Perfumery.

EAU DE JAVELLE. A solution of 'chloride of potash,' occasionally used as a bleaching agent. See Chloride of Potash.

EAU DE LUCE. See Perfumery.

EBONITE. A name given to vulcanised India-rubber, or Vulcanite. The process of manufacture has been fully described under Caoutchouc. Ebonite has been applied almost to every kind of small ornamental manufacture. A large trade is done in imitations of jet ornaments made of it. It is also used for electrical machines and apparatus. In Poggendorf's 'Annalen,' 1873, F. Kohlrausch has a paper on the expansibility of ebonite by heat. He observed that ebonite lids stuck fast in glass vessels and even cracked them. Some experiments were therefore made, and ebonite was found to be three times as expansible as zinc.

The coefficient for 1° was found to be

0·0000770 measured between 16°·7 and 25°·3
0·0000842 „ „ 25°·3 and 35°·4

thus the increase with the temperature is very considerable. The linear coefficient of expansion for the temperature t can be put

$$0{\cdot}000061 + 0{\cdot}0000076\,t,$$

Two strips of ebonite and sheet zinc, when rivetted together, curve very materially with even a moderate heating. A thin strip of ivory, 20 centimes in length, cemented by means of isinglass to a similar one of ebonite, forms a delicate thermometer, seeing that its free end moves through several millimeters for one degree. The curvature in consequence of unequal expansion may be most simply demonstrated by the aid of a mere plate of ebonite, for, owing to its bad conductivity, it curves considerably when heated on one side. See CAOUTCHOUC.

EBONY. Of this black wood three kinds are imported:—

The *Mauritius Ebony*, which is the blackest and finest grained.

The *East-Indian Ebony*, which is not of so good a colour.

The *African Ebony*, which is porous and bad in point of colour.

The ebony of the Mauritius is yielded by the *Diospyros Ebenus.* Colonel Lloyd says, that this ebony when first cut is beautifully sound, but it splits, like all other woods, from neglectful exposure to the sun. The workmen who use it immerse it in water, as soon as it is felled, for from six to eighteen months; it is then taken out, and the two ends are secured from splitting by iron rings and wedges. Colonel Lloyd considers that next to the Mauritius, the ebony of Madagascar is the best, and next that of Ceylon.

The Mauritius ebony is imported in round sticks like scaffold poles, about fourteen inches in diameter. The East-Indian variety comes to us in logs as large as twenty-eight inches diameter, and also in planks. The Cape-of-Good-Hope ebony arrives in England in billets, and is called billet wood, from about three to six feet long and two to four inches thick.

The uses of ebony are well known.

White Ebony comes from the Isle of France, and is much like box wood. See GREEN EBONY.

EBULLIOSCOPE. See EBULLITION ALCOHOLOMETER.

EBULLITION. (Eng. and Fr.; *Kochen*, Ger.) *Boiling.* When the bottom of an open vessel containing water is exposed to heat, the lowest stratum of fluid immediately expands, becomes therefore specifically lighter, and rises through the colder and heavier particles. The heat is in this way diffused through the whole liquid mass, not by simple communication of that power from particle to particle as in solids—called the *conduction* of heat—but by a translation of the several particles from the bottom to the top, and the top to the bottom, in regular succession. This is denominated the *carrying* power of fluids, being common to both liquid and gaseous bodies. These internal movements may be rendered very conspicuous and instructive, by mingling a little powdered amber with water, contained in a tall glass cylinder, standing upon a sand-bath. That this molecular translation or locomotion is almost the sole mode in which fluids get heated, may be demonstrated by placing the middle of a pretty long glass tube, nearly filled with water, obliquely over an argand flame. The upper half of the liquid will soon boil, but the portion under the middle will continue cool, so that a lump of ice may remain for a considerable time at the bottom. When the heat is rapidly applied, the liquid is thrown into agitation, in consequence of elastic vapour being suddenly generated at the bottom of the vessel, and being as suddenly condensed at a little distance above it by the surrounding cold column. These alternate expansions and contractions of volume become more manifest as the liquid becomes hotter, and constitute the *simmering*, vibratory sound which is the prelude of ebullition. The whole mass being now heated to a pitch compatible with its permanent elasticity, becomes turbulent and explosive under the continued influence of fire, and emitting more or less copious volumes of vapour, is said to boil. The further elevation of temperature, by the influence of heat, becomes impossible in these circumstances with almost all liquids, because the vapour carries off from them as much heat in a latent state as they are capable of receiving from the fire.

The temperature at which liquids boil in the open air varies with the degree of atmospheric pressure, being higher as that is increased, and lower as it is diminished. Hence boiling-water is colder by some degrees in an elevated situation, with a depressed barometer, than at the bottom of a coal-pit in fine weather, or, when the barometer is elevated. A high column of liquid also, by resisting the discharge of the steam, raises the boiling point. As we ascend from the sea-level, the boiling point becomes lower; the table at the head of page 181 illustrates this.

In *vacuo* all liquids boil at a temperature about 124° F. lower than under the average atmospheric pressure. For a table of elasticities, see VAPOUR. Gay-Lussac has shown that liquids are converted into vapours more readily, or with less turbulence, when they are in contact with angular or irregular, than with smooth surfaces; that they therefore boil at a heat 2° F. lower in metallic than in glass vessels, probably owing to the greater polish of the latter. For example, if into water about to boil in a glass matrass, iron filings, ground glass, or any other insoluble powder, be

Places	Yards high	Inches of pressure	Boiling point

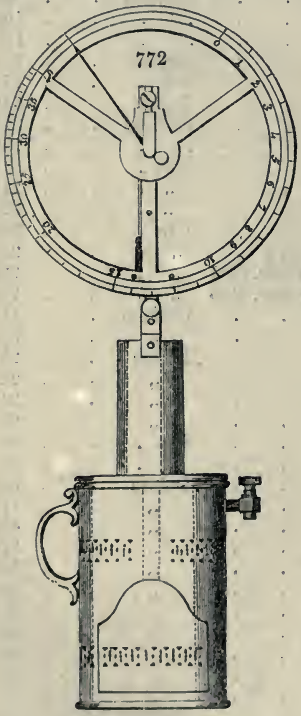
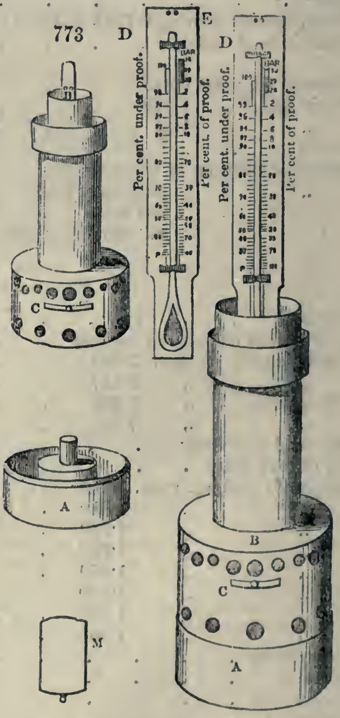
EBULLITION ALCOHOLOMETER. That the boiling temperature of water is increased by holding neutro-saline and saccharine substances in solution has been long known, and has been the subject of many experiments, made partly with the view of ascertaining from that temperature the proportion of the salt or sugar, and partly with the view of obtaining a practical liquid bath. But it seems to have been reserved for the Abbé Brossard-Vidal of Toulon to have discovered that the boiling temperature of alcoholic liquors is, in most cases, proportional to the quantity of alcohol, irrespectively of the quantity of neutro-saline or saccharine matter dissolved in them. When, however, such a quantity of dry carbonate of potash, or sugar, is added to a spirituous liquor as to abstract or fix in the solid state a portion of the water present, then the boiling temperature of that mixture will be lowered in proportion to the concentration of the alcohol, instead of being raised, as would be the case with water so mixed. But, generally speaking, it may be assumed as a fact, that the boiling point of an alcoholic liquor is not altered by a moderate addition of saline, saccharine, or extractive matter. On this principle, M. Brossard-Vidal constructed the instrument represented in *fig.* 772, for determining by that temperature the proportion of alcohol present. His chief object was to furnish the revenue boards of France with a means of estimating directly the proportion of alcohol in wines, so as to detect the too common practice of introducing brandy into their cities and towns under the mask of wine, and thereby committing a fraud upon the *octroi*; as the duty on spirits is much higher than on wines.



772



773

The above instrument consists of a spirit-lamp, surmounted by a small boiler, into which a large cylindric glass bulb is plunged, having an upright stem of such calibre that the quicksilver contained may, by its expansion and ascent when heated, raise before it a little glass float in the stem, which is connected by a thread with a similar glass bead, that hangs in the air. The thread passes round a pulley, which turning with the motion of the beads causes the index to move along the graduated circular scale. The numbers on this scale represent percentages of absolute alcohol, so that the number opposite to which the index stops, when the liquor in the cylinder over the lamp boils briskly, denotes the percentage of alcohol in it.

Dr. Ure introduced another form of instrument (*fig.* 773). It is thus described by the inventor:—

It consists, 1, of a flat spirit-lamp A, surrounded by a saucer for containing cold water to keep the lamp cool, should many experiments require to be made in succession; 2, of the boiler B, which fits by its bottom cage C, upon the case of the lamp. At the point C, is seen the edge of the damper-plate for modifying the flame of the lamp, or extinguishing it when the experiment is completed. D is the thermometer, made with a very minute bore, in the manner of the Rev. Mr. Wollaston's instrument for measuring the height of a mountain by the boiling point of water on its summit. The bottom of the scale in the ebullition thermometer, is marked P for proof on the left side, and 100 (of proof spirit) on the right side. It corresponds to 178·6 Fahr. very nearly, or the boiling point of alcohol of 0·920 specific gravity. The following table gives the boiling points corresponding to the indicated densities:—

Temp. Fahr.	Specific Gravity		Temp. Fahr.	Specific Gravity	
178·6	0·9200	P.	185·6	0·3665	50 U. P.
179·75	0·9321	10 U. P.	189·0	0·9729	60 ,,
180·4	0·9420	20 ,,	191·8	0·9786	70 ,,
181·0	0·9516	30 ,,	196·4	0·9850	80 ,,
183·4	0·960	40 ,,	202·0	0·992	90 ,,

The above table is the mean of a great many experiments. When alcohol is stronger than 0·92, or the excise proof, its boiling point varies too little with its progressive increase of strength to render that test applicable in practice. In fact, even for proof spirits, or spirits approaching in strength to proof, a more exact indication may be obtained by diluting them with their own bulk of water, before ascertaining their strength and then doubling it.

The boiling point of any alcoholic liquor is apt to rise if the heat be long continued, and thereby to lead into error in using this instrument. This source of fallacy may be in a great measure avoided by adding to the liquor in the little boiler about a teaspoonful (thirty-five grains) of common culinary salt, which has the curious effect of arresting the mercury in the thermometer at the true boiling point of the spirit, wine, or beer, to enable a correct reading to be had. The small measure marked M holds the requisite quantity of salt.

The thermometer is at first adjusted to an atmospheric pressure of 29·5 inches. When that pressure is higher or lower, both water and alcohol boil at a somewhat higher or lower temperature. In order to correct the error which would hence arise in the indications of this instrument under different states of the weather, a barometrical equation is attached, by means of the subsidiary scale E, to the thermometer D.

Having stated the principles and the construction of the ebullition alcoholometer, I shall now describe the mode of its application.

First.—Light the spirit-lamp A.

Second.—Charge the boiling vessel B, with the liquid to be tested (to within an inch of the top), introducing at the same time a paper of the powder; then place the vessel B (the damper-plate being withdrawn) on to the lamp A.

Third.—Fix the thermometer D on the stem attached to B, with its bulb immersed in the liquid. The process will then be in operation.

The barometrical scale indicated on the thermometer is opposite the mean boiling point of water. Prior to commencing operations for the day, charge the boiler B with water only, and fix the instrument as directed; when the water boils freely, the mercury will become stationary in the stem of the thermometer, opposite to the true barometrical indication at the time. Should the mercury stand at the line 29·5 this will be the height of the barometer, and no correction will be required; but should it stand at any other line, above or below, then the various boiling points will bear reference to that boiling point.

In testing spirituous or fermented liquors of any kind, when the mercury begins to rise out of the bulb of the thermometer into the stem, push the damper-plate halfway in its groove to moderate the heat of the flame. When the liquor boils freely the mercury will become stationary in the stem; and opposite to its indication, on the left, the underproof percentage of spirit may be read off at once, if the barometer stand that day at 29·5 inches; while on the right-hand scale, the percentage of proof spirit is shown; being the difference of the former number from 100. The damper-plate is to be immediately pushed home to extinguish the flame.

The alcoholometer will by itself only indicate the percentage of alcohol contained in any wine; but, by the aid of the hydrometer, the proportionate quantity of saccharum in all wines may be readily and easily determined. The hydrometer will show the specific gravity of the liquid upon reference to table No. 1, annexed. In testing a sample of wine, first take the specific gravity, and suppose it to be 989, then charge the boiler of the alcoholometer with the wine, as directed, and at the boiling point it indicates the presence of alcohol at 69·6 per cent.$^{\text{u.p.}}$, whose specific gravity will be found to be 979; deduct that gravity from the gravity of the bulk, or 989, and 10 will remain, which 10 degrees of gravity, upon reference to the wine table, will be found to represent 25 lbs. of saccharine or extractive matter in every 100 gallons, combined with $30\frac{4}{10}$ths gallons of proof spirit.

Sikes's hydrometer will only show the specific gravity of liquids lighter than water (or 1,000), and for wines in general use, the gravities being lighter than that article, will answer every purpose; but there are wines whose gravities are heavier than water, such as mountain, tent, rich Malagas, lachrymæ Christi, &c., to embrace which additional weights to the hydrometer will be required, as for cordialised spirits, &c. In testing a sample of rich mountain, its specific gravity was found to be 1032, or 39° heavier than water; that wine at the boiling point indicated the alcohol 72·5 per cent.$^{\text{u.p.}}$; but 980 specific gravity deducted from 1039 leaves 39° of specific gravity; against 59 of the wine tables will be found 147·5 or 147½ lbs. of saccharine or extractive matter, combined with 27½ gallons of proof spirit to every 100 gallons.

Should the barometer for the day show any other indication above or below the standard of 29·5, the thermometer scale will then only show the apparent strength, and reference must be had to the small ivory indicator, E, it being the counterpart of the barometrical scale of the thermometer; thus, should the barometer indicate 30, place 30 of the indicator against the boiling point of the liquid, and opposite the line of 29·5 will be found the true strength.

Example 1.—Barometer at 30.—Suppose the mercury to stop at the boiling point 72$^{\text{u.p.}}$, place 30 of the indicator against 72 on the thermometer, and the line of 29·5 will cut 69·6$^{\text{u.p.}}$, the true strength.

Example 2.—Barometer at 29.—Suppose the mercury to stop at the same point, 72$^{\text{u.p.}}$, place 29 of the indicator against 72 on the thermometer, and the line of 29·5 will cut 74·3$^{\text{u.p.}}$, the true strength.

For malted liquors.—To all brewers and dealers in fermented liquors, this principle, by its application, will supply a great desideratum, as it will not only show the alcohol created in the wort by the attenuation, as well as the original weight of the wort prior to fermentation, but it will indicate the value of malt liquors in relation to their component parts. It will likewise be a ready means of testing the relative value of worts from sugar compared with grain, as well as being a guide to the condition of stock beers and ales.

To ascertain the strength of malt liquors and their respective values, the instrument has been supplied with a glass saccharometer, testing-glass, and slide-rule. Commence by charging the testing-glass with the liquid, then insert the saccharometer, to ascertain its present gravity or density per barrel, and at whatever number it floats, that will indicate the number of pounds per barrel heavier than water.

Example 1.—Suppose the saccharometer to float at the figure 8, that would indicate 8 lbs. per barrel; then submit the liquid to the boiling test, with the salt as before directed, and suppose it should show (the barometrical differences being accounted for) 90$^{\text{u.p.}}$, that would be equivalent to 10 per cent. of proof alcohol. Refer to the slide-rule, and place A on the slide against 10 on the upper line of figures, and facing B on the lower line will be 18, thus showing that 18 lbs. per barrel have been decomposed to constitute that percentage of spirit; then, by adding the 18 lbs. to the present 8 lbs. per barrel, the result will be 26 lbs., the original weight of the wort after leaving the copper.

Example 2.—The saccharometer marks 10 lbs. per barrel, and at the boiling point it indicates 88$^{\text{u.p.}}$, equivalent to 12 gallons of proof spirit per cent.; place A against 12, and opposite B will be 21½ lbs. per barrel, when, by adding that to the 10 lbs. present, 31½ lbs. will be the result.

To ascertain the relative value.—Suppose the price of the 26 lbs. of beer to be 36*s.* per barrel, and the 31½ lbs. beer to be 40*s.* per barrel, to ascertain which beer will be the cheapest, place 26 on the opposite side of the rule against 36, and opposite 31½ lbs. will be 43*s.* 7*d.*, showing that the latter beer is the cheapest by 3*s.* 7*d.* per barrel.

By taking an account of the malt liquors by this instrument prior to stocking, it may be ascertained at any time whether any alteration has taken place in their condition, either by an increase of spirit by after-fermentation and consequent loss of sugar, or whether, by an apparent loss of both, acetous fermentation has not been going on towards the ultimate loss of the whole.

This instrument will likewise truly indicate the quantity of spirit per cent. created

No. 1.

Table of Specific Gravities, by Sikes's Hydrometer, adapted to Field's Patent Alcoholometer for Cordialised Spirits.

The foregoing Table, which shows the Specific Gravity on the bulk of the mixture, bears reference to the Table (No. 2) of the Alcoholometer following.

in distillers' worts, whether in process of fermentation or ready for the still; the only difference will be in the allowance on the slide-rule.

N.B.—The saccharometers applicable to the foregoing rules for beer, ales, &c., have been adjusted at the temperature of 60° Fahrenheit, and will be found correct for general purposes; but where extreme minuteness is required, the variation of temperature must be taken into account; therefore, for every 10° of temperature above 60, $\frac{3}{10}$ths of a pound must be added to the gross amount found by the slide-rule; on the contrary, for every 10° below 60, $\frac{3}{10}$ths of a pound must be deducted.

For cordialised Spirits.—The operation in this instance is somewhat different from that of beers, which have the alcohol created in the original worts; whereas, in cordialised spirits, gins, &c., the alcohol is the original, and the saccharine matter, or sugar, is an addendum.

No. 2.

Table showing the lbs. of Sugar per Gallon in Cordialised Spirits, with Per Centages to be added to the identical Strength, per the Alcoholometer.

If 100 gallons of spirits are required at a given strength, say 50 per cent. under proof, 53 gallons of proof spirit, with the addition of 50 gallons of water, would effect that object, and upon testing it by the alcoholometer, it would be found as correct as by the hydrometer. But in cordialising spirits it is different, for to the 50 gallons of proof spirit 50 gallons of sugar and water would be added, thereby rendering the hydrometer useless, except for taking the specific gravity of the bulk, and according to the quantity of sugar present, so a relative quantity of water must have been displaced; and as the sugar has no reducing properties, the alcoholometer will only show the strength of the cordial in relation to the water contained in it, as the principle indicates, irrespectively of saccharine or extractive matter.

Suppose, in making 100 gallons of cordial at $50^{u.p.}$, 3 lbs. of sugar are put to the gallon, or 300 lbs. to the 100 gallons, that 300 lbs., displacing $18\frac{67}{100}$th gallons of water, only $31\frac{33}{100}$th gallons of water instead of 50 have been applied; the sugar, without reducing properties, making up the bulk of 100 gallons, which is meant to represent 50 per cent.$^{u.p.}$.

The alcoholometer will only show at the full point of ebullition the alcoholic strength in relation to the water in the 100 gallons of the mixture, or 35 per cent.$^{u.p.}$, leaving 15 per cent. to be accounted for on the bulk.

As the quantity of sugar present must be determined before that percentage can be arrived at, a double object will be effected by so doing, namely eliciting in all instances the quantity of sugar present, as well as the percentage of spirit to be accounted for.

Example 1.—In taking the specific gravity of a cordial, suppose it to be found 1076, then submit the liquid to the boiling point, and having ascertained the percentage of alcohol, and it proves to be $35^{u.p.}$, the specific gravity of alcohol at that strength will be found to be 956; deduct 956 from the specific gravity of the bulk, 1076, and 120 will remain; refer that to its amount on the head line of the table No. 1, namely, 120, under which will be found 3, representing 3 lbs. of sugar to the gallon; and by running the eye down the column table No. 2 to opposite the alcoholic strength indicated ($35^{u.p.}$), will be found 14·9, which represents the percentage of water displaced by the sugar, and which amount of 14·9, added to the 35 per cent. ascertained, makes the total upon the bulk 49·9 per cent.$^{u.p.}$, with 3 lbs. of sugar to the gallon.

For Gins, &c.—Example 2.—In taking the specific gravity, suppose it to be found 957; then submit to the boiling point, and it proves to be $14^{u.p.}$, whose specific gravity is 937, which, deducted from 957, leaves specific gravity 20; on the head-line of table No. 2, under 20, will be found 8 oz., or ½ lb. of sugar to the gallon, and on running the eye down to opposite $14^{u.p.}$, will be found 3·0, which, added to the 14, makes the total on the bulk 17 per cent.$^{u.p.}$, with 50 lbs. of sugar to the 100 gallons.

To chemists for their tinctures, &c., this instrument will be found essentially useful.

N.B.—Care must be taken that the mercury is entirely in the bulb of the thermometer before it is fixed on the stem for operation, and in all cases (except for water) the salt must be used.

ECLOGITE. See Eklogite.

EDDOES. A plant (*Arum esculentum*) which is found in most tropical climates, and cultivated for food. It contains 63 parts of matter soluble in water, and 37 parts insoluble. It ranks with the potato as an article of nutrition.

EDENITE. A variety of hornblende, occurring at Edenville, New York.

EDGE TOOLS; more properly *cutting tools*, of which the chisel may be regarded as the type. Holtzapffel, whose book on 'Mechanical Manipulation' is the best to be found in any language, divides cutting tools into three groups: namely, paring tools, scraping tools, and shearing tools.

First. Paring or splitting tools, with thin edges, the angles of which do not exceed sixty degrees, one plane of the edge being nearly coincident with the plane of the work produced (or with the tangent in circular work). These tools remove the fibres principally in the direction of their length, or longitudinally, and they produce large coarse chips, or shavings, by acting like the common wedge applied as a mechanical power.

Secondly. Scraping tools, with thick edges, that measure from sixty to one hundred and twenty degrees. The planes of the edges form nearly equal angles with the surface produced, or else the one plane is nearly or quite perpendicular to the face of the work (or becomes as a radius to the circle). These tools remove the fibres in all directions with nearly equal facility, and they produce fine dust-like shavings by acting superficially.

Thirdly. Shearing, or separating tools, with edges of from sixty to ninety degrees generally duplex, and then applied on opposite sides of the substances. One plane of each tool, or of the single tool, coincident with the plane produced.

Mr. James Bouydell introduced a process which professed to produce cheap edge tools of excellent quality, He welded iron and steel together in such a manner that when cut up to form edge tools, the steel constituted a thin layer to form the cutting edge. He piled a slab or plate of steel upon two or more similar plates of iron; heated it in a furnace to a good welding heat, and then passed it between grooved or other suitable rollers to convert it into bars; the steel being in a thin layer either on one of the outer surfaces of the bar, or between two surfaces of iron, according to the kind of tool to be made therefrom. The bars thus produced were cut up and manufactured into the shape of the desired articles by forging. If the cutting edge was to extend but a short distance, the steel was applied only near one edge of the pile. The compound bars which have the steel on one side are suitable for chisels and other tools, which have a cutting edge on one side, the iron being ground away when making or sharpening the tool. See CUTLERY; STEEL.

EDULCORATE (*Edulcorer*, Fr.; *Aussüssen*, Ger.) is a word introduced by the alchemists to signify the sweetening, or rather rendering insipid, of acrimonious pulverulent substances, by copious ablutions with water. It means, in modern language, the washing-away of all particles soluble in water, by agitation or trituration with this fluid, and subsequent decantation or filtration.

EFFERVESCENCE. (Eng. and Fr.; *Aufbrausen*, Ger.) When gaseous matter is suddenly extricated with a hissing sound during a chemical mixture, or by the application of a chemical solvent to a solid, the phenomenon, from its resemblance to that of simmering or boiling water, is called effervescence. The most familiar example is afforded in the solution of sodaic powders; in which the carbonic acid gas of bicarbonate of soda is extricated by the action of citric or tartaric acid.

EFFLORESCENCE (Eng. and Fr.; *Verwittern*, Ger.) is the spontaneous conversion of a solid, usually crystalline, into a powder, in consequence either of the abstraction of the combined water by the air, as happens to the crystals of sulphate and carbonate of soda; or by the absorption of oxygen and the formation of a saline compound, as in the case of alum schist, and iron pyrites. Saltpetre appears as an efflorescence upon the ground and walls in many situations.

EGGS. The eggs of birds become useful in many processes of manufacture. They consist of four parts:—

1. The *shell*, consisting of—

Carbonate of lime	89·6
Phosphate of lime and magnesia	5·7
Animal matter and sulphur	4·7

2. *A membrane* (*membrana putaminis*) which lines the shell, which analysis shows to be composed of—

Carbon	50·7
Hydrogen	6·6
Nitrogen	16·8
Oxygen and sulphur	26·0

3. *The white.* Albumen, a colourless liquid, enclosed in large cells formed of a thin membrane.

4. *The yolk*, or *vitellum.* Surrounded by the albumen; also enclosed in a membrane.

The albumen, or white-of-egg, is used for numerous purposes in the arts. It contains carbonates in variable quantity, albumen, a small quantity of fat, glucose, and extractive matter.

The yolk of birds' eggs consists mainly of fat and pigment. See Watts's 'Dictionary of Chemistry.'

Eggs, non-incubated, respire, giving off water and carbonic acid, and absorbing oxygen, so that the air confined at the broad end of the egg is richer in oxygen than the external air. This indicates the method to be adopted in the preservation of eggs, viz., to fill the pores of the shell, so as to prevent entirely the osmose force to which this process of respiration belongs. If the eggs are dipped into melted tallow or wax, or into a cream of freshly-slaked lime, this is effected. Dipping eggs into a strong brine is said to be effectual; the effects are similar in either case. The trade in eggs is large.

The *Importation* of eggs in the last five years was as follows:—

Year	Great hundreds	Computed value
		£
1868	3,199,742	1,009,285
1869	3,684,772	1,126,853
1870	3,590,352	1,102,080
1871	3,351,106	1,265,484
1872	4,650,676	1,837,886

EGGS, HATCHING. See Incubation, Artificial.

EGG-APPLES. The edible fruit of *Solanum ovigerum* and *S. Melongena.*

EGYPTIAN JASPER. Rolled pebbles of brown jasper from the Valley of the Nile. They are cut and polished as ornamental stones.

EHLITE. A hydrated phosphate of copper, occurring generally in reniform and botryoidal masses. It takes its name from one of its localities—Ehl, near Linz, on the Rhine. According to the analyses made by Bergemann, this mineral contains vanadium, and it has hence been sometimes called phosphovanadate of copper.

EHRENBERGITE. A mineral found as a deposit in trachyte in the Siebengebirge. It was examined by Ehrenberg, after whom it was named. It contains silica and alumina, and, according to Bischof and Schnabel, water extracts from it chlorine, sulphuric acid, and magnesia, while hydrochloric acid extracts both iron and manganese. Its composition is very variable.

EIDER-DOWN is so called because it is obtained from the *Eider*-duck.

EIDER-DUCK. *Sometaria.* There are two species of these ducks, abundant in the frozen regions of the North, especially in Iceland, Lapland, Greenland, Spitzbergen, Baffin's Bay, and Hudson's Bay. To the inhabitants of these countries these birds are exceedingly valuable. They build their nests among precipitous rocks, and the female lines them with fine down plucked from her breast, among which she lays her five eggs. The natives of the districts frequented by the eider-ducks let themselves down by cords among the dangerous cliffs, to collect the down from the nests. They also catch the hen bird while she is sitting, and pluck the down. When brought to market the down is in balls, weighing from three to four pounds, and not much larger than a man's fist. But the down is so fine and elastic that when opened and held near a fire to expand, one ball would fill a quilt five feet square. See Swan's Down.

EISENKIESEL. A German name for ferruginous quartz, sometimes used for convenience by English mineralogists.

EJOO. *Saguerus Rumphii.* A vegetable fibre possessing considerable strength. See Fibres.

EKLOGITE. A rock composed of green smaragdite, in which red garnets are embedded. When polished, it forms a beautiful stone for ornamental purposes. It is found in the Sau Alp, in Styria; and at Münchberg, in the Fichtelgebirge.

ELÆIS. A genus of palm-trees, containing one or two species which grow in tropical Africa and America. The oil-palm, or *Elæis guineensis*, is a native of the western coast of Africa.

The oil resides in the fleshy portion of the fruit, which is about the size of pigeons' eggs, ovate, somewhat angular, deep orange-yellow, collected in beads. They have a thin epicarp, a fibrous, oily, yellow sarcocarp, which covers and closely adheres to the hard stony putamen or endocarp, within which is the seed. The oil is obtained from the sarcocarp, and in this respect resembles that of the olive. It is obtained either by expression, or by boiling the fruit with water, when the oil separates and rises to the surface. It is imported principally from Cayenne and the coasts of Guinea. It is, when freshly imported, of the consistence of tallow, of an orange colour, possesses the smell of violets, and fuses at about 80° F. It speedily becomes rancid, and decomposes with liberation of glycerine and the fatty acids, and as this change progresses, its fusing-point gradually rises till it sometimes even reaches 97° F. It is composed principally of a peculiar fat, *palmitin*, and a little oleine and colouring-matter. It is used in the manufacture of soap and candles, and is imported in very large quantities. The following is a general outline of the treatment of palm-oil at Price's Candle Company's works. (See 'Pharmaceutical Journal,' vol. xv. p. 264.) The crude palm-oil is melted out of the casks in which it has been imported, and allowed to remain in a melted state in large tanks until the mechanical impurities have settled to the bottom. The clear oil is then pumped into close vessels, where it it is heated and exposed to the action of sulphuric acid. The glycerine and fatty acids are thereby separated, and the colouring-matter and impurities are carbonised and partly rendered insoluble. The mixture has now a greyish-brown colour, and is washed with water to remove the acid. From the washed product, distillation now separates the mixed fatty acids (palmitic and palm-oleic acids), as a white crystalline fat, while the residuum in the still is converted into a fine hard pitch. This pitch is fit for any of the purposes for which ordinary pitch is applicable. The mixed fatty acids may be made directly into candles, or they may be separated by hydraulic pressure, aided, if necessary, by heat. This effects the separation of the liquid part (oleic acid), which, after purification, is fit for burning in lamps and other purposes. The hard cake left in the presses is nearly pure palmitic acid; it is brilliantly white, not at all greasy, and has a melting point of 135° to 138°. It is fit for the manufacture of the finest candles, either alone or in admixture with the stearine of the cocoa-nut oil.

Palm-oil often requires to be bleached for its various uses, and there are several processes used to effect it, viz. chlorine, powerful acids, and the combined influence of air, heat, and light.

M. Bohl has bleached palm-oil by heating it quickly to 464° F., and keeping it at that temperature for a few minutes, without the aid of light or air. And he says this process has been carried on for some time in a factory. The heating of the palm-oil is effected as rapidly as possible in cast-iron pans; it is kept for ten minutes at the temperature of 464° F., and the bleaching is complete. Ten or twelve hundredweight of palm-oil may be conveniently heated in one pan, which, however, must only be two-thirds full, as the oil expands greatly by the heat. It must be covered with a well-fitted cover, which prevents inconvenience from the disagreeable vapours which arise. This answers better on the large scale than on the small. By this process it acquires an empyreumatic odour, which disappears after a little time, and the original odour of the palm-oil returns.

The yellow fat which is used to grease the axle-trees of the railway carriages is prepared with a mixture of palm-oil and tallow, with which is mixed a little soda-lye. (*Gerhardt.*)

For the properties of *palmitin* and *palmitic acid*, see PALMITIC ACID.

Of palm-oil our *Imports* have been :—

ELŒOMETER. A variety of hydrometer which is sometimes used for detecting adulterations in fixed oils by their specific gravity, and by their different rates of expansion by heat. The determinations by this instrument are not, however, to be strictly relied on.

ELAINE (called also OLEINE) is the name given by Chevreul to the thin oil, which may be expelled from tallow and other fats, solid or fluid, by pressure either in their natural state or after being saponified, so as to harden the *stearine.* It may be extracted also by digesting the fat in seven or eight times its weight of boiling alcohol, specific gravity 0·798, till it dissolves the whole. Upon cooling the solution the stearine falls to the bottom, while the elaine collects in a layer, like olive-oil, upon the surface of the supernatant solution, reduced by evaporation to one-eighth of its bulk. If this elaine be now exposed to a cold temperature, it will deposit its remaining stearine, and become pure. Braconnot obtained it by exposing olive-oil to a temperature of about 21° F. in order to cause the congelation of the margarine or stearine (?). The elaine was a greenish-yellow liquid; at 14° F. it deposited a little margarine. See OILS and STEARINE.

ELASTIC BANDS. (*Tissus élastiques*, Fr.; *Federharz-zeige*, Ger.) See CAOUTCHOUC and BRAIDING MACHINE.

ELASTIC BITUMEN, called also *mineral caoutchouc* and *elaterite*, was first observed in Derbyshire, in the forsaken lead-mine of Odin, by Dr. Lister, in 1673, who called it a subterranean fungus. It was afterwards described by Hatchett. The analysis of this variety, by Johnston, gave the following as its composition :—

Carbon 85·47 . . . . . . Hydrogen 13·28.

Two descriptions of elastic bitumen were analysed by M. Henry fils (‘*Ann. des Mines*’). He states the English to have been in brown masses, slightly translucid, of a greenish colour, soft, elastic, burning with a white flame, and giving off a bituminous odour, and of specific gravity 0·9 to 1·23, and obtained from Derbyshire.

The French elastic bitumen generally resembled the English, excepting that it was opaque, and floated on water. It was discovered at the coal-mines of Montrelais.

	English	French
Carbon	0·5225	0·5826
Hydrogen	0·0742	0·0489
Nitrogen	0·0015	0·0010
Oxygen	0·4011	0·3675
	1·0000	1·0000

Elastic bitumen is found in soft, flexible masses at Castleton in Derbyshire. See BITUMEN.

ELASTICITY. The property which bodies possess of occupying, and tending to occupy, portions of space of determinate volume, or determinate volume and figure, at given pressures and temperatures, and which, in a homogeneous body, manifests itself equally in every part of appreciable magnitude (*Nichol*). The examination of this important subject in Kinetics does not belong to this work. A few remarks, and some explanations, only are necessary.

Elastic Pressure is the force exerted between two bodies at their surface of contact.

Compression is measured by the diminution of volume which the compressible (elastic) body undergoes.

The *Modulus* or *Coefficient of Elasticity* of a liquid is the ratio of a pressure applied to, and exerted by, the liquid to the accompanying compression, and is therefore the reciprocal of the compressibility. The quantity to which the term *Modulus of Elasticity* was first applied by Dr. Young, is the reciprocal of the extensibility or longitudinal pliability. (See the Edinburgh Transactions, and those of the Royal Society, for the papers of *Barlow, Maxwell,* and *Rankine,* and the British Association Reports for those of *Fairbairn, Hodgkinson,* &c.)

L refers to rods cut lengthwise with the grain,
R to those cut in a direction radial, and
T to those tangential to the annual rings.

Various tables, showing the elasticity of metals, glass, &c., have been constructed, and will be found in treatises on mechanics. The following notices of the mechanical properties of woods may prove of considerable interest. The experiments were by Chevandier and Wertheim.

Rods of square section 10 mm. in thickness and 2 m. in length were prepared, being cut in the direction of the fibres, and the *velocity of sound* in them was determined by the longitudinal vibrations, *their elasticity* from their increase in length, and *their cohesion* by loading them to the point of rupture. Small rods were cut in planes perpendicular to the fibre grain (in directions radial and tangential to the rings of growth) and their elasticity and sound velocity were measured by the lateral vibrations. It was thus again established, that the coefficients of elasticity, as deduced from the vibrations, come out higher than those derived from the elongation.

ELATERITE. See Elastic Bitumen.

ELATERIUM. A peculiar extract obtained from the juice of the wild cucumber. (*Mormordica elaterium.*) It owes its properties to a crystallisable principle called *Elaterin.*

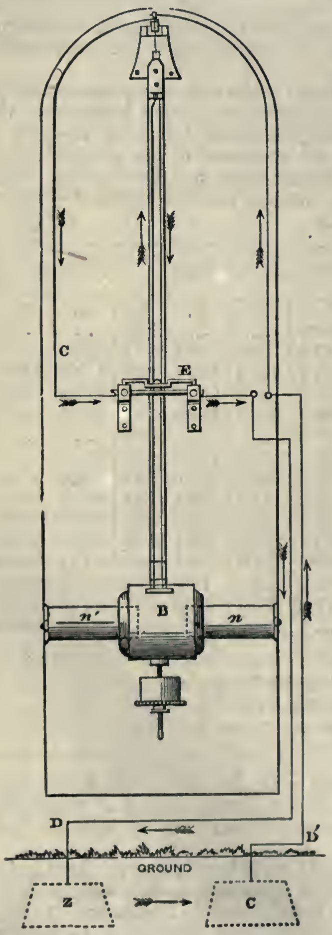
ELAYL. See Olefiant Gas.

ELDER. (*Sureau,* Fr.; *Holunder,* Ger.) *Sambucus nigra.* Pith-balls for electrical purposes are manufactured from the pith of the elder-tree, dried. The wood is employed for inferior turnery-work, for weavers' shuttles, netting-pins, and shoemakers' pegs. Its elasticity and strength render it peculiarly fitted for these latter purposes. The flowers of the elder are largely collected for distillation, yielding the well-known elder-flower water; 9 pounds of flowers distilled with 4 gallons of water give 3 gallons of the fragant distillate; they are also heated in lard for making elder-ointment. The berries or fruit of the elder are employed for making one of the truly British wines.

ELECTIVE AFFINITY. (*Wahlverwandtschaft,* Ger.) See Decomposition; Equivalents.

ELECTRIC CLOCKS. The application of electricity as a motive power to clocks, and as a means of transmitting synchronous signals or time, is naturally intimately connected with the attempts (not yet realised in an economic point) to apply it as a motive power to machinery, and with its application, so fully realised to telegraphy proper (see article Electro-Telegraphy); and it has grown up side by side with the latter. Prof. Wheatstone's attention was directed to it in the very early days of telegraphy. Without entering upon the history of electric clocks, it will suffice to describe two principles on which they have been constructed, and which are best known: Bain's and Shepherd's. In the former, electricity maintains the pendulum in motion, and the pendulum drives the clock-train; in the latter, the motion of the pendulum is maintained by electricity, but the clock-train is driven by distinct currents, sent to it by means of pendulum contacts.

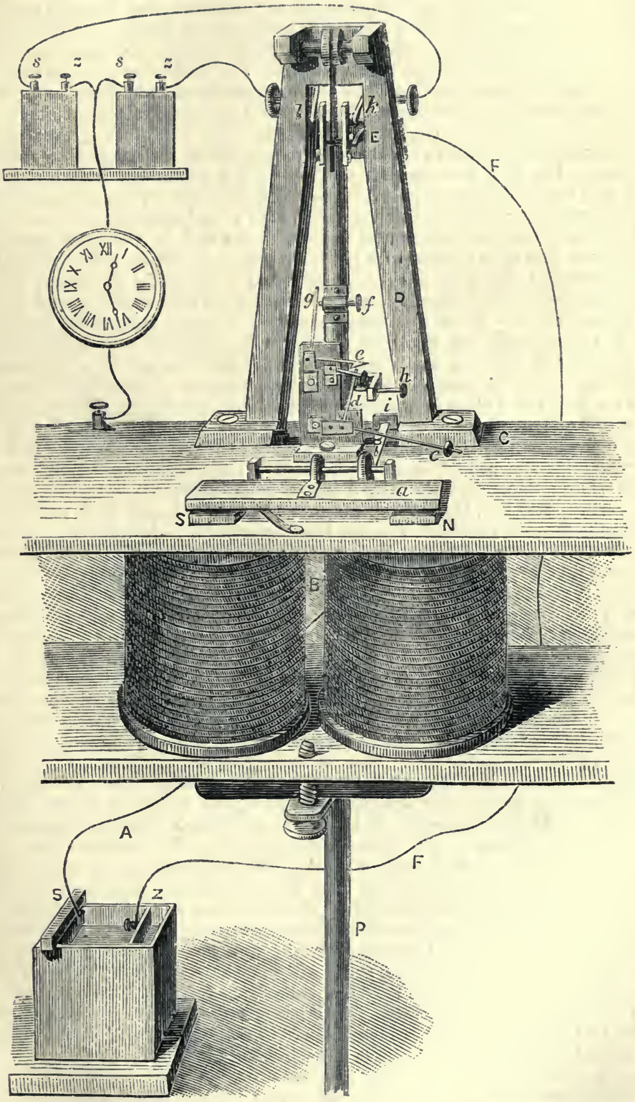
774



The bob of Bain's pendulum consists of a coil of wire, wound on a bobbin with a hollow centre. The axis of the bobbin is horizontal. Bar magnets, presenting similar poles, are fixed on each side of the coil, in such a position that, as the pendulum oscillates right and left, the poles on either side may enter the coil of wire. It is one of the laws of electric currents, when circulating in a helix, or spiral, or coil, or even in a single ring, that each face of the coil presents the characters of a magnetic pole; of a south pole, if the current circulates in the direction in which the hands of a watch move, of a north pole, if it circulates in the reverse direction. Things are so arranged in Bain's pendulum that a battery current is alternately circulating in and cut off from the coil. When the current is circulating, the coil has the character of a magnet, with a north end and a south end; if the permanent magnets present north poles, the north end of the coil-bob will be repelled from one of the magnets, while its south end will be attracted by the other magnet. This constitutes the impulse or maintaining power in one direction. Now the connections are such that, when the arc of vibration is complete and the pendulum ready for the return vibration, the pendulum rod pushes aside a golden slide, by which the electric circuit had been completed, and the current is cut off; the pendulum is thus able to make its return-vibration by mere gravity. It starts to repeat the above operations also by gravity; but, ere it completes the arc, the rod pushes back the slide, and again completes the electric circuit, and gives rise to a second impulse, and so on. A small amount of magnetic attraction is sufficient to supply the necessary amount of maintaining power. One pair of zinc-copper, buried in the moist earth, has been found ample.

In an ordinary clock, the train is carried by a weight or by a spring, and the time is regulated by the pendulum. In Bain's the time is regulated and the train is driven

775



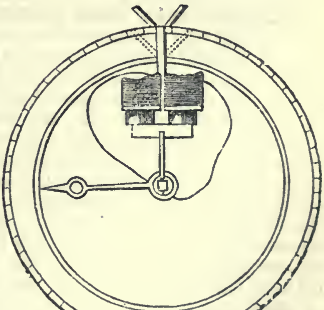
by the pendulum. The rod hangs within a crutch in the usual way; the crutch carries pallets of a particular kind, acting in a scape-wheel; and, from the latter, the motion is transmitted to a train of the usual character, but much lighter. For large clocks, Mr. Bain proposes a modification of the slide, which shall invert the current at each oscillation, so as to have attraction as a maintaining power in both oscillations. The general arrangement of the pendulum is shown in *fig.* 774. B is the pendulum bob, with its coil of wire, the ends of which pass up on either side of the rod. Z and C are the battery plates, with their attached wires D and D′. The arrows show the course of the voltaic current from the plate C by the wire D′, thence down the pendulum rod by the right-hand wire, through the coil B, up by the wire on left side of rod, then by the wire C, along the slide at E, and by the wire D to the zinc plate Z. When the slide E is in position, the circuit is complete, and the bob is attracted by the *n* pole of one of the magnets, and repelled by the *n′* pole of the other. When the slide is displaced, the attraction ceases, and the pendulum is left to the mere action of gravity.

Shepherd's electric clock has a remontoir escapement. There is no direct connection between the electric force and the pendulum, or between the pendulum and the clock-train. The attractive power, derived from the electric current, is simply employed to raise the same small weight to the same height; and the clock-train is carried by the attractive force derived from electric currents, whose circuits are completed by the pendulum touching contact springs. The pendulum is thus protected from the influence of change in the force of the current, or from irregular resistances in the train. *Fig.* 775 is a perspective view of this pendulum, with batteries, S Z, attached, and the clock connections and those of its batteries, *s z*, *s z*, shown. The electricity leaves the pendulum battery by the wire A, and returns to it by the wire F. There is only one break in this circuit, namely, at E, which is a slender spring faced with platinum, that is in contact with platinum on the pendulum at the extreme of its right vibration, but at no other time. The wire A reaches the pendulum from the battery by the coils B, the plate C, and the frame D; the wire F goes direct from the spring E to the zinc Z. From this arrangement, it happens that every time the contact at E is completed, the iron core, of which the ends N S are visible, contained within the coils B, becomes a magnet, and when the contact at E is broken, the magnetism ceases. The poles N S have, therefore, a power alternately to attract and to release *a*, which is a plate or armature of soft iron, moving on an axis, as shown in the figure, and to which is attached a bar *b*, with a counterpoise *i*. We have said that the office here of the electric force is merely to raise a weight; the fall of the weight maintains the pendulum in motion. When the armature *a* is attracted, the lever *b* is raised; this raises the wire *c* into a horizontal position, and its other part *d* into a vertical position; the latter is caught and retained by the latch or detent *e*; so that when the magnetic attraction ceases, the counterpoise *i* descends with the lever *b*; and so the armature *a* leaves the electro-magnet N S. But the wire *d* remains vertical, and its other part with the small weight *c* remains horizontal. Now, when the pendulum makes its left-hand oscillation, the point of the screw *f* impinges upon the stem *g*, and carries it a little to the left; this raises the detent *e*, and liberates the piece *d c*, which descends into its original position by gravity; the small ball *c* adds to its weight. In descending, the vertical piece *c* strikes against the point of the screw *h*, and gives a small impulse to the pendulum P. The ball *c* is not larger than a pea, and its fall is not an eighth of an inch; but the impact is sufficient to keep the pendulum in motion; and it is constant, being this same body falling through the same space; and is independent of any variation in the battery power, which latter is only concerned in raising the ball. The arc of the pendulum's vibration is regulated by adjusting the small ball to a greater or less distance from the centre. Provision is thus made for maintaining the pendulum in motion, and giving it an impact of constant value. If this arrangement is in connection with a compensating mercurial pendulum, extreme accuracy of time-keeping is attained. The next step is to transfer the seconds thus secured to a dial or clock. The same movement of the keeper *a* with its counterpoise *i*, has sometimes been made to impart motion to the seconds wheel of a clock-train; but more commonly the clock train is distinct, as shown in the drawing, and is carried by a special electro-magnetic arrangement, in connection with separate batteries, *z s*, *z s*, the contacts of which are, however, under the control of the pendulum. Insulated springs, *k* and *l*, are fixed near the top of the rod; from *k* a wire leads to the silver *s*, of the left-hand battery; and from *l* another wire leads to the zinc *z*, of the right-hand battery. The other metals of the respective batteries are connected by a wire with an electro-magnet within the clock, the other end of the said electro-magnet being connected with the metal bed and frame of the pendulum. When, therefore, the pendulum oscillates to the right, the circuit is completed at *k*; and the current of the left-hand battery circulates from *s* through the wire *k*: and thence through the metal frame and by the wire to the clock, and so to the zinc *z*. When the oscillation is to the left, and *l* is in contact, the right-hand battery is in action, and the current circulates from *s*, through the clock, to the metal frame, and thence to *l* and to the zinc *z* of the battery. In one case, a voltaic current enters the clock by the wire shown below, and leaves it by the upper wire; and, in the other case, it enters by the upper and leaves by the lower wire. There is a double set of electro-magnets within the clock, showing four poles in all; there are also two magnetised steel bars, mounted see-saw fashion, with their poles alternate, and facing the four electro-magnetic poles. When the current enters the clock from below or in one direction, the bars oscillate this way; when it enters from above or in the reverse direction, they oscillate that way. They are both fixed at right angles to and upon the same axis; which axis carries a pair of driving pallets, that act on a scape-wheel. and so the clock-train is driven. It will be seen at a glance that two or more clocks may be connected in the same circuit, as readily as one; it being merely necessary in such case to modify the battery power, to correspond with the work to be done. For instance, three such clocks have been going for several years at Tonbridge by the same pendulum; several are actuated in like manner at the Royal Observatory, Greenwich. Nor is it necessary that the clocks should be in the same room with the pendulum, or in the same building, or even in the same parish. All the clocks above referred to, are variously distributed; and one of the Observatory clocks is six miles distant from its pendulum, being at the London Bridge Station of the South-Eastern Railway.

In cases where it has not been found convenient to drive the clock-train, especially in the case of a public one, the movement of which is heavy, great advantage has been derived for regulating the oscillations of the pendulum of the large clock, by means of electric currents, under the control of a standard pendulum. Mr. Jones has adopted this method, and it is likely to meet with much favour. The turret-clock, under this arrangement, is driven by weights in the usual way, and the time is regulated by a pendulum. The bob of the pendulum is placed under a condition analogous to that of Bain's (*fig.* 774), the permanent magnet, however, being attached to the pendulum, and the electro-magnet fixed facing it. If currents are made to circulate synchronously in the latter, by means of a standard pendulum, the oscillations of the pendulum of the turret-clock are constrained to accord with those of the standard, and a very perfect system of time-keeping is obtained. This is practised at Liverpool; and has been introduced at Greenwich.

Under the above arrangements the clock is controlled by the standard pendulum second by second, and the two keep time together throughout the day. There are cases in which it is sufficient, and also more convenient, to correct a clock once a day only by means of a telegraph-signal transmitted from a standard clock. This is managed in several ways. There is a clock at the Telegraph Office in the Strand; a good regulator, adjusted to gain a second or two during the twenty-four hours, and to stop at one P.M. A telegraph-signal is sent from the Royal Observatory precisely at one, that drops a time-ball at the Strand office, which, in falling, starts the clock. At Ashford, seventy-three miles from Greenwich, there is an electric clock which has a gaining rate, and which is so constructed that the battery circuit is opened at one o'clock by means of pins and springs attached to the movement, and the clock therefore stops. At one P.M., Greenwich mean time, a signal is sent through the Ashford clock from the Royal Observatory, which starts it at once at true time. At the Post Office, Lombard Street, there is a clock which, in the course of the twenty-four hours, raises a weight. At noon a telegraph signal is sent from Greenwich, which passes through an electro-magnet; the latter attracts an armature of soft iron and liberates the ball, which falls, and in falling it encounters a crutch or lever, attached to the seconds-hand, and thrusts it this way or that, as the case may be; but so as to bring it to sixty seconds on the dial, and thus to set the clock right.

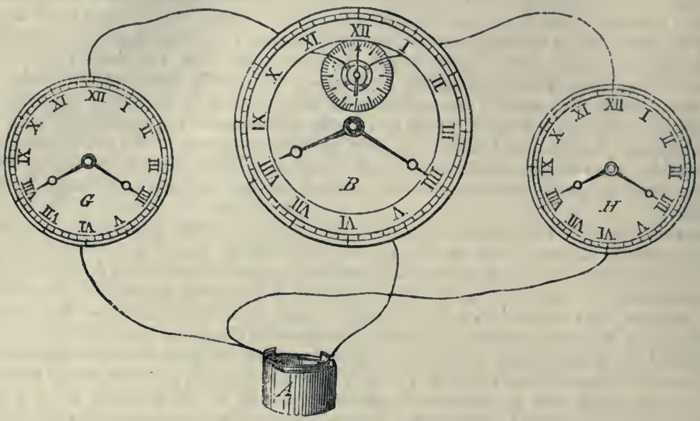
776



Intermediate between the one method of sending a signal every second to regulate a clock, and the other method of sending it once a day, we have the following arrangement of Bain's for sending it once an hour. *Fig.* 776 shows the arrangement, with part of the dial removed, to show the position of the electro-magnet. The armature is below; it carries a vertical stem terminating above in a fork. Its ordinary position is shown by the dotted lines. The minute hand (partly removed from the cut) carries a pin on its back surface. When the hand is near to sixty minutes, and an electric current is sent through the magnet, the armature is attracted upwards and the fork takes the position shown by the full lines at the top of the dial, and, in doing so, it encounters the pin and forces the hand into the vertical position, and sets the clock to true time, providing the signal comes from a standard clock, or is sent by hand at true time. A dial of moderate character keeps so near to time that once or twice a day would be, for all common purposes, often enough to correct it.

Fig. 777 is an arrangement of Bain's, by which a principal clock, showing seconds, sends electric currents at minute intervals to other clocks, and causes the hands to move minute by minute. A is a voltaic battery; B is the principal clock, which may be an electric clock or not at pleasure; G and H are two out of many subordinate clocks. The seconds hand of the principal clock completes a voltaic circuit twice (for the case of two clocks) during the minute; at the thirty seconds for the clock G, and at the sixty seconds for the clock H. The clock H shows time in leaps from one minute to the next; and the clock G from one half minute to the next half minute. As many more contacts per minute may be provided for the seconds-hand of the prime clock as there are subordinate clocks.

777



Next akin to the time signals above described, and which act automatically upon clocks, either to drive the clock-train or to correct the clock errors, are mere time signals, which are extensively distributed throughout the country by the ordinary telegraph wires, and are looked for at the various telegraph stations, in order to compare the office dials with Greenwich mean time, and to make the necessary correction; they are also re-distributed by hand the moment they appear, through sub-districts branching from junction-stations. Large black balls, hoisted in conspicuous stations, are also dropped daily by electric currents in various places, for the general information of the public, or of the captains of ships.—C. V. W.

ELECTRICITY FOR BLASTING *in Mines and Quarries.* Professor Hare was the first who entertained this idea, but Mr. Martin Roberts devised the following process. In order not to be called upon to make afresh a new apparatus for each explosion, Mr. Roberts invented cartridges, which may be constructed beforehand. With this view, two copper-wires are procured, about a tenth of an inch in diameter, and three yards in length, well covered with silk or cotton tarred, so that their insulation may be very good. They are twisted together (*fig.* 778) for a length of six inches, care being taken to leave their lower extremities free, for a length of about half an inch (separating them about half an inch), from which the insulating envelope is removed, in order to stretch between them a fine iron wire, after having taken the precaution of cleaning them well. The upper extremities of the two copper-wires are likewise separated, in order to allow of their being placed respectively in communication with the conductors, that abut upon the poles of a pile. The body of the cartridges is a tin tube, three inches long, and three quarters of an inch in diameter, the solderings of which are very well made, in order that it may be perfectly impermeable to water. A glass tube might equally well be employed, were it not for its fragility, which has caused a tin tube to be preferred. The system of copper-wires is introduced into the tube, fixing them by means of a stem that traverses it at such a height that the fine iron wire is situated in the middle of the tin tube, so arranged that the ends of the copper-wire do not anywhere touch the sides of the tube (*fig.* 779). The cork is firmly fixed at the upper extremity of the tube with a good cement. Mr. Roberts recommends for this operation, a cement composed of one part of bees'-wax and two parts of resin; the tube is then filled with powder by its other extremity, which is likewise stopped with a cork, which is cemented in the same manner. *Fig.* 780 indicates the manner in which the cartridge is placed in the hole, after having carefully expelled all dust and moisture; care must be taken that the cartridge is situated in the middle of the charge of powder that is introduced into the hole. Above the powder is placed a plug of straw or tow, so as to allow between it and the powder a small space filled with air; and above the plug is poured dry sand, until the hole is filled with it. The two ends of the copper-wires that come out of the cartridge are made to communicate with the poles of the pile, by means of conductors of sufficient length, that one may be protected from all dangers arising from the explosion of the mine.

M. Ruhmkorff, and after him M. Verdu, have successfully tried to substitute the induction-spark for the incandescence of a wire, in order to bring about the ignition of the powder. This process, besides the considerable economy that it presents—since instead of from fifteen to twenty Bunsen's pairs, necessary for causing the ignition of the wire, it requires but a single one for producing the induction-spark—possesses the advantages of being less susceptible of derangement. Only it was necessary to contrive a plan to bring about the ignition of the powder; in fact, it happens that when by the effect of the length of the conductors that abut upon the mine, the circuit presents too great a resistance, the induction-spark is able to pass through the powder without inflaming it. M. Ruhmkorff has conceived the happy idea of seeking for a medium, which, more easily inflammable by the spark, may bring about the ignition of the powder in all possible conditions. He found it in Statham's fuzes, which are prepared by taking two ends of copper-wire covered with ordinary gutta-percha; they are twisted (*fig.* 781), and the ends are bent so as to make them enter into an envelope of vulcanised (sulphured) gutta-percha, which has been cut and drawn off from a copper-wire that had been for a long time covered with it. Upon this envelope a sloping cut *a*, *b*, is formed; and after having maintained the extremities of the copper-wires at about the eighth of an inch from each other, their points are covered with fulminate of mercury, in order to render the ignition of the powder more easy. The cut is filled with powder, and the whole is wrapped round with a piece of caoutchouc tube *c*, *d*, or else it is placed in a cartridge filled with powder.

In the Statham fuzes, it is the sulphide (sulphuret) of copper adhering to the wire, produced by the action of the vulcanised gutta-percha which is removed from the copper-wire that it covered, which by being inflamed under the action of the induction-spark brings about an explosion. But it is necessary to take care when the fusee has been prepared, as we have pointed out, to try it in order to regulate the extent of the solution of continuity. It might, in fact, happen that while still belonging to the same envelope of a copper-wire, the sheath of a vulcanised gutta-percha with which the fusee is furnished, may be more or less impregnated with sulphide of copper; now, if the sulphide of copper is in too great quantity, it becomes too good a conductor, and prevents the spark being produced; if, on the contrary, it is not in a sufficiently large quantity, it does not sufficiently facilitate the discharge.

The first trials on a large scale of the application of the process that we have just described were made with Ruhmkorff's induction apparatus, by the Spanish colonel, Verdu, in the workshops of M. Herkman, manufacturer of gutta-percha covered wire, at La Villette, near Paris. Experiments were made successively upon lengths of wire of 400, 600, 1,000, 5,000, and up to 26,000 mètres (of 3·28 feet each); and the success was always complete, whether with a circuit composed of two wires, or replacing one of the wires by the earth; two ordinary Bunsen's pairs were sufficient for producing the induction-spark with Ruhmkorff's apparatus. Since his first researches with M. Ruhmkorff, M. Verdu has applied himself to fresh researches in Spain; and he was satisfied, by many trials, that of all explosive substances, not any one was nearly so sensitive as fulminate of mercury; only, in order to avoid the danger that arises from the facility of explosion of this compound, he takes the precaution of introducing the extremity of the fusees into a small gutta-percha tube, closed at the end. After having filled with powder this species of little box, and having closed it hermetically, the fuzes may be carried about, may be handled, may be allowed to fall, and even squeezed rather hard, without danger. The elastic and leather-like nature of gutta-percha, which has been carefully softened a little at the fire, preserves the fulminate from all chance of accident. We may add, that with a simple Bunsen's pair, and by means of Ruhmkorff's induction apparatus, M. Verdu has succeeded in producing the simultaneous explosion of six small mines, interposed in the same circuit at 320 yards from the apparatus. He has not been beyond this limit; but he has sought for the means of acting indirectly upon a great number of mines, by distributing them into groups of five, and by interposing each of these groups in a special circuit. The fusees of each group are made to communicate by a single wire, one of the extremities of which is buried in the ground, and whose other extremity is near to the apparatus. On touching the induction apparatus successively with each of the free ends that are held in the hand, which requires scarcely a second of time, if there are four wires, that is to say, four groups and consequently twenty mines, twenty explosions are obtained simultaneously at considerable distances. There are no limits either to the distance at which the explosion may take place, or to the number of mines that may be thus made to explode.

The following account of experiments on the application of permanent magnets to the explosion of charges and to submarine operations, is from a memoir by Professor Abel, F.R.S. The ignition of gunpowder by the direct magneto-electric current, though well known to be practicable, has never yet been applied to military or industrial operations, and no satisfactory experiments appear to have been made, before those undertaken at Woolwich, showing its practical applicability to these purposes.

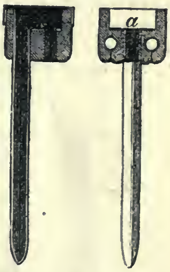
In the first experiments on this application of the magneto-electric current, a very large powerful magneto-electric machine was employed, which had been constructed by Mr. Henley (and had been exhibited by him at the Paris Exhibition in 1855). The principle of this instrument was precisely the same as that of the machine devised by Mr. Wheatstone, for ringing magneto-electric bells. Its armature, instead of being rotated, was suddenly detached from the magnet by means of a lever. It was soon established by a few experiments that, even with this instrument, gunpowder itself could not be ignited with any degree of certainty. Results obtained with Statham's and other fuzes, though superior to those furnished by gunpowder alone, were still far from satisfactory. The first efforts were therefore directed to the discovery of a suitable agent to serve as a perfectly certain medium (or priming material) for effecting the ignition of charges by means of the magneto-electric machine. For this purpose, a variety of compounds and mixtures of a more or less sensitive character were prepared for trial with the magnet.

Many of these compositions furnished results to a certain extent favourable, a number of fuzes, primed with them, having been fired in succession with the magnet, and from two to four charges in one circuit having been ignited, in a very few instances. But no perfect certainty of discharge was attained with any one of the materials used; the attempt to fire a fuze being frequently unsuccessful, while no difference between it and a successful fuze, containing the same composition, could be detected by careful examination.

Some successful results, obtained accidentally with one of the experimental compositions, which had become damp by exposure to air, led to a trial of the effect of moisture in promoting the ignition of but slightly sensitive compositions; and it was ultimately found that the impregnation of ordinary gunpowder with a small amount of moisture (by an expedient similar in principle to one adopted with considerable success by Captain Scott, R.E., in connection with charges to be fired by the induction coil-machine), rendered its ignition by means of the magnet a matter of certainty.

Some important precautions were, however, indispensable to the attainment of this definite result. If the slightly-damp powder was employed in a finely-divided condition, it very frequently became caked between the wire-terminals in the fuze, and the current would then pass through the composition without igniting it. This was found to take place occasionally, even when the powder was employed in its original granular condition. Several attempts were made to overcome this difficulty by modifying the form and position of the terminals or poles in the fuze, and I at last contrived a perfectly successful arrangement, in which only the *sectional surfaces* of the terminals, consisting of fine copper-wire (0·022 inch diameter), were exposed to the interior of the fuze (see *a*, *fig.* 782), so as not to project at all. The prepared gunpowder, therefore, simply *rested* upon the surfaces, and a perfect uniformity in the action of the fuze was attained. The priming composition consisted of fine-grain gunpowder, which had been soaked in an alcoholic solution of chloride of calcium, of a strength sufficient to impregnate the grains with from one to two per cent. of that salt. The prepared powder was exposed to the air for a short time, to permit of a sufficient absorption of moisture by the deliquescent salt. Upwards of 500 quill-fuzes (of the description employed for firing guns), primed with the prepared gunpowder, and fitted with the arrangement of the terminals above referred to (*fig.* 782), were fired with the larger lever-magnet. The failures did not amount to more than 3 per cent., and were all proved to be due to defective manufacture. In the experiments with these fuzes, one or two simple rheotomic arrangements were successfully employed for effecting the rapidly successive discharge of a series of fuzes.

782



The above fuze was found to be easy of manufacture and permanently effective. While, however, it presented a certain means of effecting the ignition by the aid of a powerful magnet, of single charges, or of a large number, to be fired in moderately rapid succession, it was inapplicable to the ignition with certainty of more than one charge in circuit. After a great number of experiments, I at length succeeded in the production of a priming material for the fuze, which greatly exceeded in sensitiveness any of the other compositions hitherto tried.

The new priming composition consisted of a very intimate mixture of sub-phosphide of copper, chlorate of potassa, and levigated coke, the latter substance being employed to add to the conducting power of the mixture, which was found otherwise insufficient.

In the course of experiments subsequently carried on with fuzes which contained this composition, it was found that a slight residue, consisting principally of the coke employed, occasionally remained on the surfaces of the terminals in the fuze, after its discharge, and by forming a good conducting link between them, interfered with any future effects of the magnetic current in other directions, by the establishment of a complete circuit. This obstacle to the perfect success of the composition was entirely removed by the substitution, for the coke, of another material, more easily acted on by the chlorate of potassa, and answering equally well as a conducting medium; namely, the sub-sulphide of copper. No instance has occurred in the discharge of several thousand fuzes, primed with the mixture of sub-phosphide and sub-sulphide of copper with chlorate of potassa, in which the terminals have not been found quite free from adherent residue, after the ignition.

The sub-phosphide of copper, which is produced at an elevated temperature, is a compound of very stable character, and the mixture of the three constituents is quite as unalterable as the explosive mixtures which are in general use for the preparation of percussion caps, &c. The stability of the mixture has already been submitted to very satisfactory tests. Fuzes primed with it have been found to have lost none of their delicacy and certainty, when tried more than two years after preparation.

The sub-phosphide of copper, intimately blended with chlorate of potassa, forms a mixture in a high degree sensitive to the effect of heat, and possessed, at the same time, of some power of conducting electricity. With the employment, however, of magneto-electric machines of comparatively low power, and in cases where the resistance to be overcome by the current is considerable, this conducting property is not sufficient to insure the ignition of the mixture by assisting the passage of the current across the interruption in the metallic circuit (i.e. across the small distance between the terminals of the wire in the fuze). It must be borne in mind that the striking-distance, or the space between the terminals across which the current from even a powerful magneto-electric machine will leap, is very small. With the large lever-magnet the spark could only be produced when the wires were almost in contact. Since, however, it is indispensable to the proper insulation of the wires in the fuze-arrangement, that the terminals should be at least one-sixteenth of an inch apart, it will be readily understood how essential to success, in operations with these machines, it is that the priming material should possess considerable conducting power. Hence the necessity of increasing the conducting power of the mixture of sub-phosphide of copper and chlorate of potassa : a result which, it has been already stated, was obtained in the first instance by the employment of finely-levigated coke, and afterwards by the substitution of sub-sulphide of copper for that substance. Many experiments were of course required to determine the proportions in which it was advisable to employ the conducting constituent, so as to facilitate the passage of the current through the mass as far as possible, without interfering too much with the sensitiveness of the explosive mixture, or producing an almost perfectly continuous connection between the two poles in the fuze, and thus promoting the passage of the current so greatly as to prevent the ignition of the composition.

The fuzes contrived by me for use with magneto-electric apparatus are of two kinds, the one being adapted for mining purposes and the other for firing cannon. The fuze for mining purposes, *fig.* 783, consists of:—

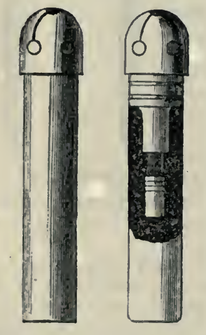
a. A head for receiving the wires which connect the fuze with the magnet and the earth, *fig.* 784.

b. Of the insulated wires, with the terminals of which the priming material is in close contact.

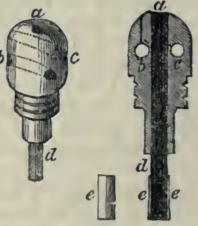
c. Of a small cartridge or charge of powder, enclosing the terminals, upon which the sensitive composition rests.

The wooden fuze-head contains three perforations (*a a*, *b b*, *c c*, *fig.* 784); the one, passing downwards through the centre, receives about two inches of double insulated wire, *d*. The other two perforations, which are parallel to each other on each side of the central one, and at right angles to it, serve for the reception of the circuit-wires. The arrangement for securing the connection of these with the insulated wires in the fuzes is as follows :—

783



784



785

The piece of double-covered wire above referred to, is originally of a sufficient length to allow of the gutta-percha being removed from about 1½ inch of the wires. These bare ends of the fine wires, which are made to protrude from the top of the fuze-head *a*, *fig.* 784, are then pressed into slight grooves in the wood provided for their protection, and the extremity of each is passed into one of the horizontal perforations in the head, in which position it is afterwards fixed by the introduction into the hole of a tightly-fitting piece of copper tube, so that the wire is firmly wedged betweeen the wood and the exterior of this tube, and is thus at the same time brought into close contact with a comparatively large surface of metal. It will be seen that it is only necessary to fix one of the circuit-wires into each of these tubes in the opposite sides of the fuze-head, in order to ensure a sufficient and perfectly distinct connection of each one of them with one of the insulated wires in the fuze.

The phosphide-of-copper fuze for firing cannon, *fig.* 785, differs somewhat in construction from the mining fuze. The head is somewhat longer, and of such a form that the double-covered wires are completely enclosed in it, the lower extremity of its central perforation still remaining free to receive the top of the quill or copper-tube, which is charged with gunpowder in the same manner as the ordinary tube arrangement for firing cannon.

The plan originally suggested by M. Savare, of arranging the charges in divided circuits was next tried, and furnished far more successful results. The simultaneous ignition of twenty-five charges was repeatedly effected; and forty charges were similarly exploded on several occasions. These results were all obtained with the large magnet constructed by Henley, the current being established by rapidly separating the armature from the poles by means of a lever. By a simple arrangement for shifting the connection of the main wire with the exploded charges from them to a second series, similarly arranged, twenty-five were almost simultaneously ignited on allowing the armature to return to the poles of the magnet.

The system of firing charges by means of magneto-electricity, with the aid of the phosphide-of-copper fuze, having been thus far successfully developed, a series of experiments was instituted at Chatham, for the purpose of thoroughly testing its certainty and applicability in the field, and subsequently for ascertaining the extent to which it admitted of application to the explosion of submarine charges. These experiments extended over a period of six months, and were performed under various conditions of weather. It will readily be understood that the best and most simple method of connecting the fuzes, enclosed in the charges, with the branch-wires and the earth, of arranging the experimental charges for explosion, and of carrying out the various small but essential details involved in the operations, were only gradually arrived at; and that, consequently, in many of the first experiments, which were only partially successful, the failures were traced to causes unconnected with the efficiency of the magneto-electric apparatus, or the fuze. It would be superfluous to enter into details with regard to those preliminary experiments, however important they were at the period of the investigation; the description of the operations at Chatham will therefore be confined to those which were carried on according to the plan which was ultimately proved to be most efficient. The magneto-electric apparatus employed in all the field experiments was Mr. Wheatstone's arrangement of six small magnets, the whole apparatus having been enclosed in a box, so that the only exposed portions were the binding screws for the attachment of the wires, a handle for setting the armatures in motion, and a key, by the depression of which, at a given signal, the circuit could be completed.

To employ the instrument at any moment, only the following operations were necessary: the insulated wire and the copper wire passing to the earth were fixed to the apparatus by means of binding screws: the instrument was raised from the ground by being placed on its packing-case; at that height, a man could operate with it when in a kneeling posture. At the signal 'Ready' the handle was turned with one hand, so as to cause the armatures to revolve with the greatest possible velocity, whilst the other hand was pressed against one corner of the instrument close to the key, so as to steady the box and to be ready, at the signal 'Fire,' to depress the key with the thumb.

The connection of the instrument with the earth was effected as follows: a moderately clean spade was selected from among those used by the men in digging holes for the charges. One end of a piece of stout copper-wire was placed under the edge of the spade, so that, when the latter was firmly forced into the ground, the wire was pressed by the earth on both sides against the iron surface. The protruding wire was wound once or twice round the bottom of the spade handle, and then attached to the binding screw of the magnet.

The gutta-percha covered wire used in the experiments having been in occasional service at Chatham for some years, the coating had sustained some injury in two or three places. Such defects were protected from possible contact with the earth by means of waterproof cloth or sheet India-rubber. The total length of wire used was 881 yards, of which 600 were extended, lying along the ground.

To the extremity of the covered wire a number (from 12 to 25) of pieces of similar insulated wire, varying in length between three and six yards, and serving to connect it with the individual charges, were attached in the following manner: about six inches of the extremity of the main wire and of each of the branch wires were laid bare and cleansed; the end of the former was then surrounded with those of the latter (placed in an opposite direction) and the whole tightly twisted together by means of pliers, so as to be brought thoroughly in contact with each other and with the main wire. The twisted wires were then bound round with moderately fine copper-wire, which was made to bring every portion of the exterior of the bundle into connection. The joint was made rigid with pieces of stick tied against it, and the whole securely enveloped in a piece of waterproof cloth or canvas, to protect it from damp and contact with the earth.

These connections, though of a very rough description and most readily prepared by any soldier, were thoroughly effectual. No instance occurred, in the whole of the experiments, of the failure of a charge, which could be attributed to an imperfect connection of its branch wire with the main wire.

The following was the method adopted for connecting the fuzes with their respective branch wires and with the earth :—

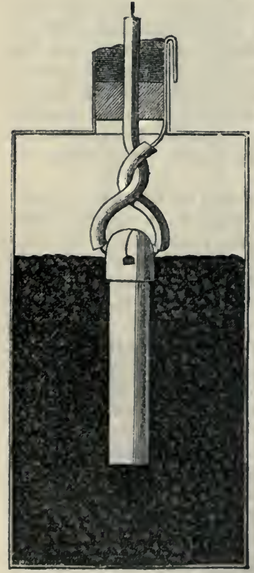
The fuzes, as they were manufactured, were always fitted with two pieces of covered wire twisted together, *fig.* 786, which were tightly fixed into their proper positions by forcing a short pin of copper-wire into the holes of the fuze-head. They were thus ready for insertion into the bag or other receptacle containing the charge of gunpowder, the ends of the covered wires protruding from the opening of the latter to a convenient distance for effecting the junction with the branch and earth-wires. The extremities of one of the fuse-wires and of a branch wire (from both of which the gutta-percha was removed to a distance of about two inches) were connected by hooking them firmly one in the other with pliers (in the manner shown in *fig.* 787). A piece of fine copper binding wire was then twisted over the whole of the connection, and the joint was finally enclosed in a small wrapping of oiled canvas, in a manner similar to that adopted at the principal junction with the main wire.

786

787

The extremity of the other fuze-wire was attached to an uncovered copper-wire, of sufficient length to bring the whole of the charges into connection with each other in this manner. The wire was fixed in a convenient position by being twisted round short stakes or pickets driven into the ground, and its extremities were buried in the earth, being attached either to spades, as already described, or to zinc plates about eight inches square.

788



The experiments instituted at Chatham with the object of applying the magneto-electric current to the ignition of *submarine* charges were attended with greater difficulties than those which served to test the system in its application to land operations; nevertheless, the results ultimately attained were also of a character to lead to definite and favourable conclusions.

The method of establishing the connections of a charge with the wire and the earth differed naturally in some respects from the mode of proceeding already described. The charges of powder were contained in canisters of block tin carefully soldered so as to be watertight.[1] The fuze, with two wires attached as before, the one a few inches longer than the other, was inserted into the charge, and fixed in its proper position in the canister by means of a loose-fitting bung, (see *fig.* 788) pushed a little distance into the neck, and cut out on one side, so as to admit of the passage of the longer insulated wire, while the bare part of the shorter wire was firmly pressed by the cork against the inside of the neck. The latter was then completely filled up with melted gutta-percha, and the extremity of the short uncovered wire was bent back over its side, so as to be in close contact with the metal surface. In this manner, the enclosed fuze was brought into good metallic connection with the wet earth, or water, by which the canister was surrounded.

The insulated wire, projecting from the mouth of the canister, was connected with one of the branch wires in the manner already described; but in order thoroughly to protect the connection from the water, in which it would become immersed, a piece of

---

[1] Any vessels of this material, such as turpentine cans, may be employed, provided they be perfectly coated inside with marine glue, or some other description of varnish.

vulcanised India-rubber tubing, of suitable length, and a tin tube, rather longer and wider than the latter, were slipped on to the branch wire, before it was joined to the fuze-wire, and, when the junction had been effected, the India-rubber tube was pulled over it, and tied very firmly at both ends on to the gutta-percha covering of the wires, *fig.* 789. A small quantity of a cement (consisting of bees'-wax and turpentine) was

789

rubbed in between the latter and the ends of the India-rubber tube, so as thoroughly to ensure the exclusion of water, and finally the tin tube was pulled over the joint, and fixed (by compressing the ends) for the purpose of imparting rigidity to the junction, and thus protecting it from injury by any sudden twist or strain. By these arrangements, when carried out with moderate care, the perfect exclusion of water from the charge and from its connection with the branch wire was effected.

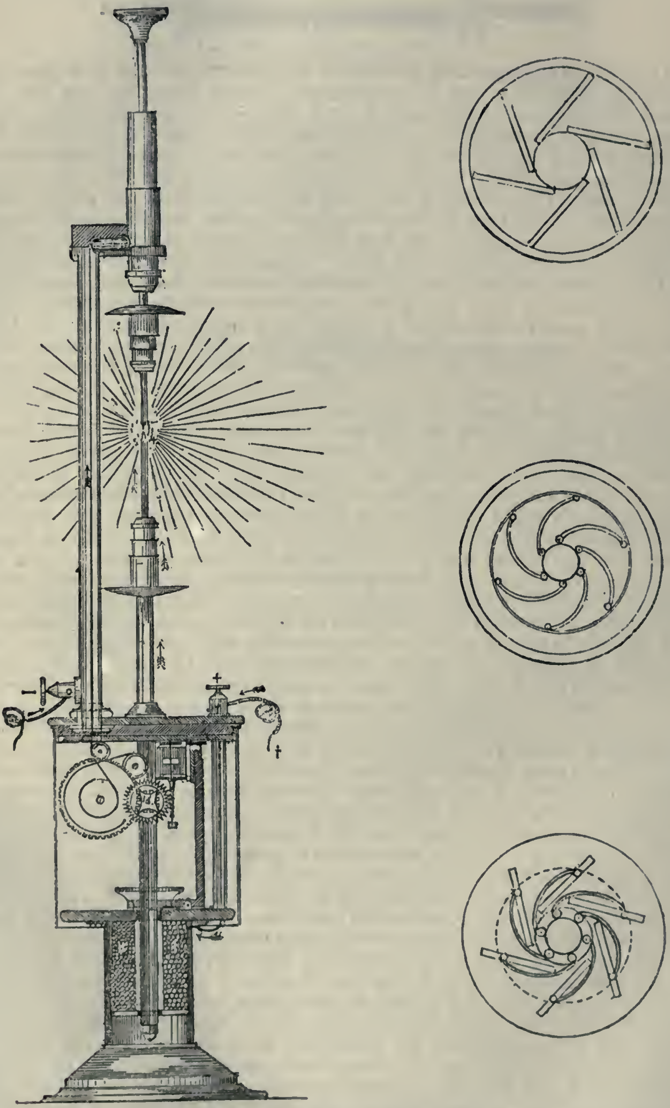
The first trials of these charges were made in a shallow canal with a mud bottom, and from which, at the time of experiment, the water was receding so rapidly, that before the whole of the charges had been immersed, several of them were exposed to view, being partly imbedded in the mud. Twenty-five charges were arranged, of which thirteen were exploded, though less rapidly than in the experiments on land. On the next occasion, when twenty-five charges were entirely surrounded by water (simply resting upon the firm bed of a pond of some depth), only four of the charges were exploded. Several other attempts were made to fire a smaller number of (ten and five) charges similarly immersed, but in every instance only four were ignited. A careful examination into the cause of the invariable explosion of so comparatively limited a number of charges under water led to the following explanation:

It will be remembered that the explosion of numerous charges in a divided circuit by the magneto-electric apparatus with revolving armatures is effected by the action of an exceedingly rapid succession of currents. The rapidity with which they follow each other, however great, cannot equal that with which the terminals of a fuze, enclosed in a small charge, under water, come into contact with the latter after the explosion. The instant this occurs, a complete circuit is established through the water, and any further action of the current is at once arrested. By the time, therefore, that four charges had been ignited in extremely rapid succession, so as to be apparently exploded at once, a sufficient interval of time had in reality elapsed to allow the water to re-occupy the space filled for a brief period by the gaseous products of the first explosion, and thus to rush in upon, and complete the circuit with, the terminals of the fuze. It appears probable that, with the employment of larger charges of powder (about eight ounces was the quantity exploded in each charge) when the volume of water displaced by the explosion would be more considerable, a great number of charges would be exploded before the circuit could be completed by the water.

ELECTRIC LIGHT. Various attempts have been made, from time to time, to employ electricity as an illuminating power; but hitherto without the desired success. The voltaic battery has been employed as the source of electricity, and in nearly all the arrangements, the beautiful arc of light produced between the poles, from the points of the hardest charcoal, has been the illuminating source. One of the great difficulties in applying this agent arises from the circumstance that there is a transference of the charcoal from one pole to the other, and consequently an alteration in the distance between them. This gives rise to considerable variations in the intensity and colour of the light, and great want of steadiness. Various arrangements, many of them exceedingly ingenious, have been devised to overcome these difficulties.

The most simple of the apparatus which has been devised is that of Mr. Staite, which has been modified by M. Archereau. Two metal columns or stems, to which any desired form can be given, are connected together by three cross pieces, so as to form one solid frame; one of these cross pieces is metallic, namely the one which occupies the upper part of the apparatus; the others must be of wood. These latter serve as supports and points of attachment to a long bobbin placed parallel to the two columns and between them, and which must be made of tolerably thick wire, in order that the current, in traversing it without melting it, may act upon a soft iron rod placed in the interior of the bobbin. This iron rod is soldered to a brass stem of the same calibre, and of the same length, carrying at its free extremity a small pulley. On the opposite side the iron carries a small brass tube, with binding screws, into which is introduced one of the carbons, when the entire rod has been placed in the interior of the bobbin. Then a cord fixed to the lower cross piece, and rolling over a pulley of large diameter, is able to serve as a support to the moveable iron rod, running in the groove of the little pulley. For this purpose, it only requires that a counterpoise placed at the end of the cord shall be enabled to be in equilibrio with it. The metal cross piece which occupies the upper part of the apparatus, carries a small brass tube, which descends perpendicularly in front of the carbon that is carried by the electro-magnetic stem, and into which is also introduced a carbon crayon. By means of a very simple adjustment, this tube may besides be easily regulated, both for its height and for its

790



direction; and consequently the two carbons may be placed very exactly above one another. The apparatus being adjusted, we place one of the two metal columns of the apparatus in connection with one of the poles of the pile, and cause the other pole to abut upon the copper-wire of the bobbin (one end of which is soldered upon its socket). The current then passes from the bobbin to the lower carbon by the rod itself that supports it, and passing over the interval separating the two carbons, it arrives at the other pole of the pile by the upper cross piece of the apparatus and the metal column, to which one of the conducting wires is attached.

So long as the currrent is passing and producing light, the bobbin reacts upon the iron of the electro-magnet rod, which carries the lower carbon and attracts it on account of the magnetic reaction that solenoids exercise over a moveable iron in their interior. It is this which gives to the carbons a *separation sufficient for the luminous effect.*

But immediately the current ceases to pass, or is weakened, in consequence of the consumption of the carbons, this attraction ceases, and the moveable carbon, acted on by the counterpoise, is found to be drawn on and raised until the current passes again; equilibrium is again established between the two forces, and the carbons may be employed again. Thus, in proportion as the light tends to decrease, the counterpoise reacts; and this it is that always maintains the intensity of the light equal.

M. Breton has an apparatus which differs somewhat from the above, and M. Foucault has also devised a very ingenious modification.

M. Duboscq has made by far the most successful arrangement (*fig.* 790), for a description of which we are indebted to De la Rive's 'Treatise on Electricity,' translated by C. V. Walker.

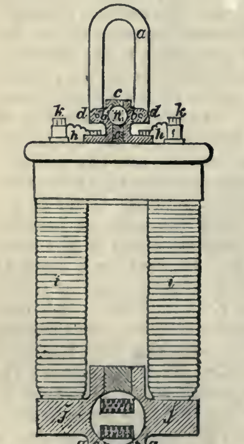
The two carbons, between which the light is developed, burn in contact with the air, and shorten at each instant; a mechanism is consequently necessary, which brings them near to each other, proportionally to the progress of the combustion; and since the positive carbon suffers a more rapid combustion than the negative, it must travel more rapidly in face of this latter; and this in a relation which varies with the thickness and the nature of the carbon. The mechanism must satisfy all these exigencies. The two carbons are unceasingly solicited towards each other, the lower carbon by a spiral spring, that causes it to rise, and the upper carbon by its weight, which causes it to descend. The same axis is common to them.

The galvanic current is produced by a Bunsen's pile of from 40 to 50 elements: it arrives at the two carbons, as in apparatus already known, passing through a hollow electro-magnet, concealed in the column of the instrument. When the two carbons are in contact, the circuit is closed, the electro-magnet attracts a soft iron, placed at the extremity of a lever, which is in gear with an endless screw. An antagonist spring tends always to unwind the screw as soon as a separation is produced between the two carbons; if it is a little considerable, the current no longer passes, the action of the spring becomes predominant, the screw is unwound and the carbons approach each other until the current, again commencing to pass between the two carbons, the motion that drew them towards each other is relaxed in proportion to the return of the predominance of the electricity over the spring; the combustion of the carbons again increases their distance, and with it the superior action of the spring; hence follows again the predominance of the spring, and so on. These are alternatives of action and reaction, in which at one time the spring, at another time the electricity, has the predominance. On an axis, common to the two carbons, are two pulleys: one, the diameter of which may be varied at pleasure, communicates by a cord with the rod that carries the lower carbon, which corresponds with the positive pole of the pile; the other, of invariable diameter, is in connection with the upper or negative carbon. The diameter of the pulley, capable of varying proportionately to the using of the carbon, with which it is in communication, may be increased from three to five. The object of this arrangement is to preserve the luminous point at a convenient level, whatever may be the thickness or the nature of the carbons. It is only necessary to know that at each change of kind or volume of the carbon, the diameter of the pulley must be made to vary. This variation results from that of a moveable drum, communicating with six levers, articulated near the centre of the sphere; the moveable extremity of the six arms of the lever carries a small pin, which slides in cylindrical slits. These slits are oblique in respect of the sphere; they form inclined planes. A spiral spring always rests upon the extremity of the levers; so that if the inclined planes are turned towards the right, the six levers bend towards the centre, and diminish the diameter. If, on the contrary, they are turned towards the left, the diameter increases, and with it the velocity of the translation of the carbon, which communicates with the pulley. We may notice, in passing, that this apparatus is well adapted to the production of all the experiments of optics, even the most delicate; and that, in this respect, it advantageously supplies the place of solar light.

Mr. (now Justice Sir William) Grove calculated, some years ago, that for acid, zinc, wear and tear, &c. of batteries, a light equal to 1,444 wax candles could be obtained for about 3*s.* 6*d.* per hour. The cost of the light employed for about five minutes at Her Majesty's Theatre, as an incident in the ballet, which was obtained by employing 75 cells of Callan's battery of the largest size, was said to be 2*l.* per night. In this calculation we expect we have not a fair representation of all the conditions. To obtain a light for ten minutes, a battery as large must be used as if it were required to be maintained in activity for hours—and probably the batttery was charged anew every evening. There can be no doubt but the cost of light or of any other *force* from electricity, with our present means of producing it, must be greatly in excess of any of our ordinary means of producing illumination. For a consideration of this subject, see Electro-motive Engines. Mr. Grove proposed a light which should be obtained from incandescent platinum, but the objection to this was, that after a short period, the platinum broke up into small particles, the electric current entirely disintegrating the metal. Mr. Way exhibited a very continuous electric light, produced from a constant flow of mercury rendered incandescent by the passage of the electric current. The light obtained by the action of a magneto-electric engine, especially in the form employed by Mr. Holmes, is not by any means so expensive as the electric light obtained from the voltaic battery. After the first cost of the machine, the only cost of importance is the mechanical power produced by a small steam-engine. The following is perhaps the most important advance which has been made in the direction of the useful application of electrical power.

Wilde's Magneto-Electric Machine.—The principle of this apparatus, which has been invented by Mr. Wilde of Manchester, for the purpose of obtaining the electric light more promptly and of higher density than had hitherto been done, consists in directing a current of electricity from an electro-magnetic machine armed with permanent magnets, so as to excite a still more powerful electro-magnet. This electro-magnet is again used by Mr. Wilde as the basis of a still larger electro-magnetic machine, in which induction currents are generated by its agency. The electric current is obtained by the well-known means of causing the rotation of an armature close to the poles of a permanent magnet, this electric current being made to pass round an electro-magnet, which causes it to produce a far greater amount of magnetism than was possessed by the first magnet. If, again, the amount of magnetism thus obtained is passed round a still larger electro-magnet, we should produce a vastly greater development of electric force; therefore, by the application of sufficient power to rotate the several armatures, there seems to be no limit to this multiplication of force, excepting the excessive heat developed by the rotation of the armatures and the intensity of the light produced. The construction of this machine will be more readily understood by the annexed diagram (*fig.* 791), representing an end view. At *a* are sixteen permanent horse-shoe magnets, which are bolted on to a hollow magnetic cylinder, *b c b*, composed of brass and iron, and so arranged that the iron portions of it, *b b*, are screwed on to the respective poles of the magnets at *d*, separated from each other by the brass pieces *c*, and forming one entire north pole and one entire south pole to the sixteen magnets. The armature *n*, which is made to revolve in close proximity to the interior of this cylinder, in suitable bearings at the extremities, consists of a cylinder of cast iron on which is wound, in direction of its length, about fifty feet of insulated copper wire one-eighth of an inch in diameter, and is bound round with brass rings, in order that the centrifugal force caused by the rapid rotation may prevent the wires from flying out of position; the inner extremity of this wire is fixed in good metallic contact with the armature, the other end being connected with the insulated half of a commutator which is placed on one end of the armature. The armature is made to revolve at the rate of 2,500 revolutions per minute, by a driving band working on a pulley attached to the other end of the armature. During each revolution of this armature two waves of electricity, moving in opposite directions, are induced in the insulated copper-wire surrounding the armature; the rapid succession of the alternating waves thus generated at the rate of 5,000 per minute, are converted by means of the commutator into an intermittent current moving in one direction only, which is conducted along the wires.

791



The electro-magnetic machine by which the light is produced is of precisely the same construction as the magneto-electric machine above described, except that instead of the permanent magnets *a*, an electro-magnet *i* is substituted; this electro-magnet is formed of two rectangular plates of rolled iron, 36 in. in length, 26 in. in width, and 1 in. in thickness; they are bolted parallel to each other, to the magnetic cylinder *j*, which is similar in construction but of larger dimensions to that described above. These plates are connected together at their upper extremities by a cross piece formed of two thicknesses of the same iron; around the sides of this electro-magnet is coiled an insulated conductor 3,300 feet long, consisting of a bundle of seven No. 10 copper-wires, laid parallel to each other and bound with a double covering of linen tape; the extremities of this conductor are connected with the studs *k k*, thereby connecting them with the wires *h h*. The currents of electricity which produce the light are taken from steel collars by means of springs *g g*, thence to the studs at *l l*, from which they can be conveyed by conductors to any required place. The power necessary to work such a machine as this is derived from a seven-horse engine, at a cost for coal of one halfpenny per hour. In addition to this must be added the expense of the carbon rods for the lamps, which will be about ten inches per hour, worth perhaps a penny. The total cost of working, including interest on the cost of purchase of machines, expense of maintenance and repairs, would be perhaps about 4*d*. or 8*d*. per hour. The light produced is estimated to have an intensity equal to 6,000 wax candles. A more detailed account of this machine will be found in the 'Quarterly Journal of Science,' No. XII. October 1866.

Mr. Wilde has lately introduced some improved apparatus for the production of light of great intensity. His machine, as recently employed, consists of two parts—an electro-magnetic induction machine for producing the electricity, and an arrangement for regulating the light produced by the current, and projecting it upon distant objects.

The electro-magnetic induction machine is founded upon a new and somewhat paradoxical principle discovered by Mr. Wilde—that magnets and electric currents indefinitely weak can produce magnets and currents of indefinite strength. The machine consists of a circular or cylindrical framing of cast iron, round the interior of which are arranged a number of electro-magnets at equal angular distances from each other. A cast-iron disc is mounted on a driving shaft, running bearings fitted to each side of the framing, and carries a number of armatures revolving before the electro-magnets. A slight charge of magnetism is imparted to the electro-magnets before the machine is used for the first time by transmitting a momentary current through the wires surrounding the iron cores, or by touching their extremities with the poles of a permanent magnet. This initial charge is always retained by the electro-magnets, and is the basis of the augmentations of the electricity and magnetism produced by the rotations of the armatures. As the armatures revolve they become slightly magnetised in their passage between the poles of the electro-magnets, generating weak currents in the insulated wires surrounding them. These currents are transmitted by means of a commutator through the wires surrounding the electro-magnets, so as to increase their magnetism, until, by a series of actions and reactions of the armatures and electro-magnets on each other, the magnetism is exalted to the highest degree of intensity and the most powerful currents of electricity are produced. A small fraction of the current thus produced is sufficient to sustain the power of the electro-magnets, while the major portion of the current produces the light. The machine is 28 in. high, 34 in. in length, and 21 in. in diameter. Its weight is 11 cwt. About four-horse power is required to drive it a velocity of 600 revolutions per minute, and this driving power is obtained from the fly-wheel of a small steam-engine. At this velocity the current will fuse an iron wire 6 ft. long and 0·05 in. in diameter, and will burn 'carbons' half an inch square. In this machine the alternating current is used for producing the light, past experience in lighthouse illumination having proved it to be greatly superior to the direct or continuous current, since it has the important advantage of consuming the carbons equally, and thus always retains the luminous point in the focus of the optical apparatus used in connection with the machine. The alternating current also dispenses with commutators, and the destructive spark on the rubbing surfaces is also avoided when the light may be accidentally extinguished, or when the circuit becomes broken from any other cause. The carbons as they consume are made to approach each other by means of a right- and a left-handed screw, the screws being made to act independently of each other, so as to allow of the adjustment of the carbons to the focus of the optical apparatus used for projecting the light. The regulator with its carbon points is placed in the focus of a catadioptric lens, which parallelises the divergent rays of the light into a single beam of great intensity.

This machine has been introduced to the Admiralty by Mr. Wilde, and the following account of some experiments made at Portsmouth, on board the 'Comet,' with a view to test the power of this electric light as a means of detecting the advance of torpedos, or anything indeed, at night, over the sea, is quoted from the 'Times' of February 23, 1874:—

'The Naval Torpedo Committee have given the subject of attack by torpedo boats at night upon ships at anchor considerable attention, and have proved by experimental practice that in the majority of instances the torpedo attack upon the ship must be successful. The "Monarch," one of the ships experimented upon, was anchored at Spithead, and on one occasion was considered to have been made almost impregnable against any attack by a strong crinoline framework of booms and spars built up round her, supplemented by her boats rowing guard round her within hailing distance. The ship had also the advantage of knowing that a boat torpedo attack would be made upon her, and the time when the attack might be expected. Notwithstanding these important advantages in the ship's favour the torpedo boats—steam pinnaces—burst through the "Monarch's" cordon of guard boats, got over the difficulty of the projecting crinoline spar defence, and struck the frigate with their dummy torpedoes. These results proved that any vessel lying at anchor at night must be fatally deficient in her defensive powers in a want of means for searching with lightning quickness and distinctness the surface of the water to a considerable distance around the ship.

'To supply this want effectually, Mr. H. Wilde, of Manchester, some time since submitted to the Admiralty a proposition for the use of one of his electro-magnetic induction machines, fitted with a proper apparatus for projecting the beam of light produced upon distant objects. One of these machines has been fixed on board the "Comet," twin screw gun vessel at Portsmouth (one of the short and light draught-boats carrying one 18-ton gun on a rising and lowering platform, on the Armstrong-Rendell plan), and was tested during the nights of Thursday and Friday, under the supervision of Captain Boys, commanding the "Excellent" gunnery establishment, and members of the Naval and War Office Torpedo Committee, with the most complete success.

'On Thursday the "Comet" left Portsmouth Harbour for the eastern entrances to Spithead, from the Channel, at about 8 P.M.; but half an hour before leaving a first experiment was made with the machine and its projector lens in throwing the beam of light round the upper part of Portsmouth Harbour. The results were startling. The gunnery ship "Excellent," with her tenders and the boats alongside and at the boom-ends, the long lengths of the sea-wall enclosing the dockyard extension works, the mud-banks—it being nearly low water—the "Asia" and the vessels about her, and further away into Fareham Creek, Her Majesty's yacht "Victoria and Albert," the "Glatton" monitor, and the few men-of-war boats moving about between the ships at the time, all stood out with wonderful distinctness as the electric light touched them. But, beyond all the others, the "Glatton," in her French-grey paint, given her as an invisible dress at certain distances by daylight, shone out in weird splendour. It needed no subsequent experiment to prove that a vessel painted in neutral colour must stand out very much more distinctly under the influence of the electric light than another vessel at the same distance, and painted with the ordinary black coating of our broadside ironclads. When the "Comet" subsequently left the harbour and had taken on board the members of the Torpedo Committees off Southsea, she steamed to a position off Brading and the east end of the Isle of Wight, and anchored, attacks being then made upon her by two steam-pinnace torpedo boats, from directions, of course unknown on board the "Comet." When the boats had been away a certain time the electric light was brought into play, its beam sweeping the surface of the water, and in each instance discovering the torpedo boats before they could lessen a mile's distance between them and the "Comet." Discovered at such a distance, their attack, of course, was considered to have utterly failed.

'On Friday the "Comet" was anchored in Stoke's Bay, near the west end of the measured mile, and buoyed off for the speed trials of Her Majesty's ships. Captain Boys and the members of the Torpedo Committees made a number of experiments with the light, upon which official reports will be made, as will also be done with the experiments conducted on the previous day. If we knew, which we do not, the exact details of all these experiments, comment upon them here would be out of place as anticipating the reports to be yet made by Captain Boys and the members of the committees. What was evident to all afloat and on the look-out for the trial of the new light on the nights of Thursday or Friday was that its power was immense, and of this we may speak freely and yet briefly. On Friday, as on Thursday, no boat could approach the light within a mile without being at once discovered, and the grey or white painted steam-pinnace was always much more prominently and longer in view under the light than the other in its coat of black paint. In a boat at 2,000 yards distance from the "Comet," and with the beam of light brought to bear upon the boat, the "Times" could be read with the greatest ease.'

For a description of Gramme's Magneto-electric machine, see ELECTRO-MOTIVE ENGINES.

ELECTRIC TELEGRAPH. See ELECTRO-TELEGRAPHY.

ELECTRIC WEAVING. M. Bonelli devised a very beautiful arrangement, by which all the work of the Jacquard loom is executed by an electro-magnetic arrangement. The details of the apparatus would occupy much space in the most concise description, and as the invention has not passed into use, although M. Froment has modified and improved the machine, we must refer those interested in the subject to the full description given in De la Rive's 'Treatise on Electricity' by Walker.

ELECTRO-GILDING BATH. See CYANIDES.

ELECTRO-METALLURGY. The art of working in metals was carried on exclusively by the aid of fire until the year 1839. At that epoch a new light dawned upon the subject; considerable interest was excited in the scientific world, and much astonishment among the general public by the announcement that electricity, under proper management, and by most easy processes, could supersede the furnace in not a few operations upon metals; and that many operations with metals, which could scarcely be entertained under the old condition of things, might be placed in the hands of a child, when electricity is employed as the agent.

Public attention was first directed to the important discovery by a notice that appeared in the 'Athenæum' of May 4, 1839, that Professor Jacobi of St. Petersburg had 'found a method of converting any line, however fine, engraved on copper, into a relief, by galvanic process.' Jacobi's own account of the matter was that, while at Dorpat, in February 1837, prosecuting his galvanic investigations, a striking phenomenon presented itself, which furnished him with perfectly novel views. Official duties prevented his completing the investigation, thus opened out to him, during the same year; and it was not until October 5, 1838, that he communicated his discovery, accompanied with specimens, to the Academy of Sciences at St. Petersburg; an abstract of which paper was published in the 'German News' of the same place on October 30 of the same year. And in a letter of Mr. Lettsom, dated February 5, 1839, the nature of the discovery is thus given in the following March number of the 'Annals of Electricity.' Speaking of a recent discovery of Professor Jacobi's, he says, 'He observed that the copper deposited by galvanic action on his plates of copper could by certain precautions be removed from those plates in perfect sheets, which presented in relief most accurately every accidental indentation on the original plate. Following up this remark, he employed an engraved copper-plate for his battery, caused the deposit to be formed on it, and removed it by some means or other; he found that the engraving was printed thereon in relief (like a woodcut) and sharp enough to print from.' This paragraph does not appear to have caught the eye of the public so readily as the briefer note that appeared a couple of months later in the 'Athenæum.'

On May 8, or four days after the appearance of the notice in the 'Athenæum,' Mr. Thomas Spencer gave notice to the Polytechnic Society of Liverpool that he had a communication to make to the society relative to the application of electricity to the arts. He subsequently desired to communicate the result of his discoveries to the British Association, whose meeting was at hand; but, for some cause, which does not appear, the communication was not made; and it eventually was made public, as at first proposed, through the Polytechnic Society of Liverpool, on September 12, 1839. In the meantime, namely on May 22, Mr. C. J. Jordan, referring to the notice in the 'Athenæum,' wrote to the 'Mechanics' Magazine' that, at the commencement of the summer of 1838, he had made 'some experiments with the view of obtaining impressions from engraved copper-plates by the aid of galvanism.' His letter describing this process appears in the number for June 8. It occurred to him, from what he had gathered from previous experience, that an impression might be obtained from an engraved surface; and so it was, 'for on detaching the precipitated metal, the most delicate and superficial markings, from the fine particles of powder used in polishing to the deeper touches of a needle or graver, exhibited their correspondent impressions in relief with great fidelity.'

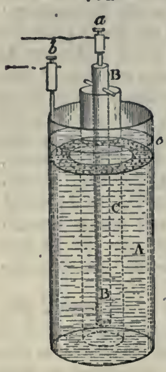
Mr. Spencer in his communication, besides noticing the fidelity with which the traces on an original plate were copied, recorded the case of a copper-plate that had become covered with precipitated copper, excepting in two or three places, where by accident some drops of varnish had fallen; whence it occurred to him, and experiment confirmed his conjecture, that a plate of copper might be varnished, and a design made through the varnish with a point, and copper might be deposited upon the metal at the exposed part, and thus a raised design be procured.

In the 'Philosophical Magazine' for December, 1836, Mr. De La Rue, after describing a form of voltaic battery, refers to the well-known condition on which the properties of the battery in question mainly depend, that 'the copper-plate is also covered with a coating of metallic copper, which is continually being deposited;' and he goes on to describe that 'so perfect is the sheet of copper thus formed, that being stripped out, it has the counterpart of every scratch of the plate on which it is deposited.' Daniell himself, whose battery is here in question, noticed as he could not fail to do in common with all who had employed his battery to any extent, the same peculiarities; but it does not appear that either he or De La Rue, or any one else, to whom the phenomenon presented itself before Jacobi, Jordan, or Spencer, caught the idea of its applicability in the arts. It would also appear that the impression came with the greater vividness to the two latter; for, while but little time seems to have been lost to them in realising their idea, twenty long months elapsed between the time when the 'perfectly novel views' first presented themselves to Professor Jacobi, and the time when his 'well-developed galvanic production' was communicated to the

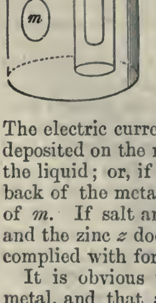
Imperial Academy of Sciences. But, on the other hand, neither Mr. Jordan nor Mr. Spencer appears, as far as we are aware, to have been so sensible of the importance of the results to which they had arrived as to have taken any steps to secure them as an invention or to publish them, until their attention was roused by the previous publication of the successes of Jacobi.

Jacobi's 'Galvano-plastik,' Smee's and also Shaw's 'Electro-metallurgy,' Walker's 'Electrotype Manipulation,' four well-known works on the subject before us, present the different names under which the art is known; and from which it is gathered that metals may become, as it were, plastic under the agency of galvanic electricity, and may be worked and moulded into form. Voltaic pairs are described in general terms in the article on Electro-Telegraphy. The particular voltaic pair which led to the discoveries now before us, here requires special notice; because, on the one hand, while in use for other purposes, it was the instrument which first directed attention forcibly to the behaviour of metals under certain conditions of electric current; and, on the other hand, it has been itself extensively used in electrotype operations. Professor Daniell first described his mode of arranging a voltaic pair, in the 'Philosophical Transactions,' for 1836. *Fig.* 792 shows one cell complete of Daniell's combination, which from its behaviour is called a constant battery. A is a copper vessel; B a rod of zinc, contained in a tube C of porous earthenware. The liquid within the tube C is salt and water, in which case the zinc is in its natural state; or, sulphuric acid and water, in which case the zinc is amalgamated; the latter arrangement being the more active of the two. The liquid in the outer vessel A, consists of crystals of sulphate of copper, dissolved in water. At *c* is a perforated shelf of copper below the surface of the liquid, upon which are placed spare crystals of sulphate of copper, which dissolve as required, and serve to keep up the strength of the solution in proportion as the copper already there is extracted by the voltaic action hereafter to be described. *a* and *b* are screws, to which wires may be attached, in order to connect up the cell and convey the current from it into any desired apparatus. Certain chemical changes take place when this instrument is in action: oxygen, from the water within the porous tube, combines with zinc, making oxide of zinc, which enters into combination with sulphuric acid, producing as a final result sulphate of zinc; hydrogen is liberated from water in the outer cell, and itself liberates oxygen from oxide of copper, and combines with it producing water, and leaving copper free. As far as the metals are concerned, zinc is consumed *from* the rod B, at the one end, and copper is liberated *upon* the plate A, at the other end. These actions are slow and continuous; and the copper, as it is liberated atom by atom, appears upon the inner surface of the cell; and after a sufficient quantity has been accumulated, may be peeled off or removed; when it will be found to present the marks and features of the surface from which it has been taken, and which, as we have already said, arrested the attention of many into whose hands this instrument fell. A slight modification of the above arrangement gives us a regular electrotype apparatus. The cell *c* in this arrangement (*fig.* 793), is of glass or porcelain, or gutta-percha, filled as before with a saturated solution of sulphate of copper, to which a little free acid is generally added; it is provided with a shelf or other means of suspending crystals of sulphate of copper. A zinc rod *z* is placed in a porous tube *p*, as already described; and *m*, the other metal of the voltaic pair, is suspended in the copper solution and connected with the zinc *z* by the wire *w*. The electric current now passes; zinc is consumed, as in *fig.* 792, but copper is now deposited on the metal *m* front and back, and on as much of the wire *w* as may be in the liquid; or, if Mr. Spencer's precaution is taken of varnishing the wire and the back of the metal *m*, all the copper that is liberated will be accumulated on the face of *m*. If salt and water, or very weak acid water, is contained in the porous tube *p*, and the zinc *z* does not considerably exceed in size the metal *m*, the conditions will be complied with for depositing copper in a compact reguline form.

792



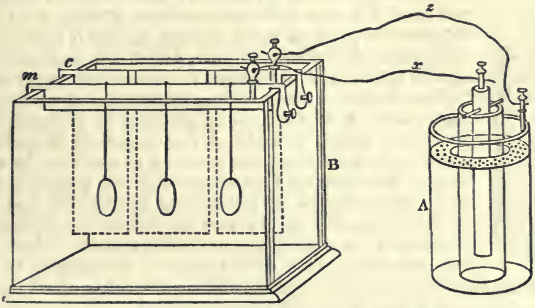
793

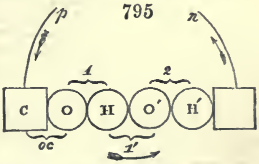


It is obvious that, with this arrangement, *m* may be a mould or other form in metal, and that a copy of it may be obtained in copper. Fusible metal, consisting of 8 parts of bismuth, 4 of tin, 5 of lead, and 1 of antimony; or 8 parts bismuth, 3 tin, and 5 lead, is much used for taking moulds of medals. The ingredients are well melted together and mixed; a quantity sufficient for the object in view is poured upon a slab or board and stirred together till about to set; the film of dross is then quickly cleared from the surface with a card, and the cold medal is either projected upon the bright metal, or being previously fitted in a block of wood is applied with a sudden blow. Moulds of wax or stearine variously combined, or more recently and better in many cases, moulds of gutta-percha, are applicable to many purposes. But, as none of these latter materials conduct electricity, it is necessary to provide them with a conducting surface. Plumbago or black-lead is almost universally employed for this purpose; it is rubbed over the surface of the mould with a piece of wool on a soft brush, care being taken to continue it as far as to the conducting wire, by which the mould is connected with the zinc. With moulds of solid metal, the deposit of copper commences throughout the entire surface at once; but, with moulds having only a film of plumbago for a conductor, the action commences at the wire and extends itself gradually until it has been developed on all parts of the surface.

The nature of the electro-chemical decompositions that are due to the passage of voltaic currents through liquids, especially through liquids in which metal is contained in certain forms, can be best understood by studying the arrangement that is most commonly used in the arts, wherein the voltaic apparatus, from which the electric current is obtained, is distinct and separate from the vessel in which the electro-metallurgical operations are being brought about. Such an arrangement is shown in *fig.* 794, where A is a Daniell's cell, as in *fig.* 792; and B a trough filled with an acid solution of sulphate of copper; *m* is a metal rod, on which the moulds are hung; and *c* a metal rod, upon which plates of copper are hung facing the moulds; the copper-plates are connected by the wire *z* with the copper of the battery cell, and the moulds by the wire *x* with the zinc rod. The voltaic current is generated in the cell A, and its direction is from the zinc rod, through the solutions to the copper of the cell; thence by the wire *z* to the plates of copper *c*; through the sulphate solution to the moulds *m*; and thence by the wire *x* to the zinc rod. In this arrangement, no shelf is necessary in the trough B for crystals of sulphate of copper to keep up the strength of the solution; for the nature of the electro-chemical decompositions is such, that in proportion as copper is abstracted and deposited upon the moulds *m*, other copper is dissolved into the solution from the plates *c*. Water is the prime subject of decomposition. It is a compound body, consisting of the gases oxygen and hydrogen, and may be represented by *fig.* 795, where the arrows show the direction in which the current, by the wire *p*, enters the trough B of *fig.* 794, by the plate of copper *c*, and passes through the water in the direction shown, and leaves it after traversing the mould by the wire *n*. Two atoms of water O H and O′ H′, as bracketed 1 and 2, are shown to exist before the electric current passes; and two atoms, one of water H O′ (bracketed 1′), and one of oxide of copper *o c*, exist after the action. On the one hand, an atom of copper C has come into the solution; and, on the other hand, the atom of hydrogen H′, belonging to the second atom of water, is set free and rises in the form of gas. The explanation is to show that oxygen is liberated where the current enters, and combines there in its nascent state with *copper*; it would not have combined, for instance, with gold or platinum. We might easily extend this symbolical figure, and show how that, when free sulphuric acid is in the solution, the oxide of copper on its formation combines with this acid to produce the sulphate of copper required; and how, when free sulphate of copper

794



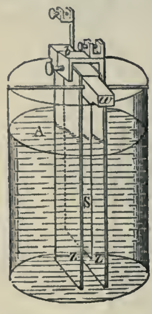


is present, the hydrogen, instead of being freed in the form of gas, combines with oxygen of the oxide of copper, and liberates the metal, which in its nascent state is deposited on the mould, and produces the electrotype copy of the same. One battery cell is sufficient for working in this way in copper; it is increased in size in proportion to the size of the object operated upon. And, although for small subjects, such as medals, a vertical arrangement will act very well; for large objects, it has been often found of great advantage to adopt a horizontal arrangement, placing the mould beneath the copper-plate. The varying density of a still solution in the vertical arrangement is not without its effect upon the nature of the deposit, both on its character and its relative thickness. This has been in some instances obviated, and the advantage of the vertical method retained by keeping the solution in motion, either by stirring or by a continuous flow of liquid.

We have described principally Daniell's battery as the generating cell in electro-metallurgical operations; but Mr. Smee's more simple arrangement of platinised silver and zinc, excited with diluted sulphuric acid, has been found in practice more economical and convenient.

Fig. 796 is a Smee's cell; a vessel of wood, glass, or earthenware, contains diluted sulphuric acid, one part of acid in eight or ten of water; a platinised silver plate s, sustained by a piece of wood *w*, is furnished with a plate of zinc, z z, on each side, so as to turn to useful account both sides of the silver plate. The zinc plates are connected by the binding screw *b*. Platinisation consists in applying platinum in fine powder to the metallic surface. When hydrogen is liberated by ordinary electric action upon a surface so prepared, it has no tendency to adhere or cling to it; but it at once rises, and in fact gets out of the way, so that it never, by its presence or lingering, interferes with the prompt and ready continuance of the electric action; and in this way the amount of supply is well kept up.

796



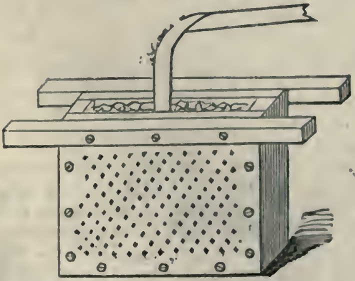
Platinisation is itself another illustration of working in metal by electricity. A few crystals of chloride of platinum are dissolved in diluted sulphuric acid. A voltaic current is made to enter this solution by a plate of platinum and to come out by a silver plate. Two or three Daniell's or Smee's cells are necessary for the operation. The chloride of platinum is decomposed, and the metal is deposited upon the silver plate; not, however, in the reguline compact form, as in the case of copper, but in a state of black powder in no way coherent. This affords also an illustration of the different behaviour of metals under analogous circumstances. Copper is of all metals the most manageable; platinum is among the more unmanageable.

Mr. C. V. Walker has, with great advantage, substituted graphite for silver. The material is obtained from gas retorts, and is cut into plates a quarter of an inch thick, or thicker, when plates of a larger size are cut. He platinises these plates in the usual way as above described, and deposits copper on their upper parts, also by electrotype process, and solders a copper slip to the electrotype copper, in order to make the necessary connection.

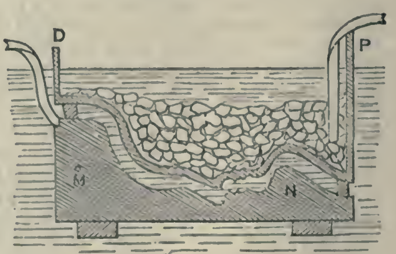
Utilisation of Copper Scraps in Electro-Plating.—The following description of M. C. Guérin's method of utilising scraps of copper, in lieu of plates, as a soluble anode in electro-plating, has been published by the 'Scientific American.' By this process the inventor utilises cuttings and other scraps, previously-deposited films, and, in a word, all the metal which would be otherwise thrown aside as useless for such a purpose.

Fig. 797 is a representation of the receptacle used for holding the copper scraps. It is simply a prismatic box about 1½ in. broad, sustained in the bath by the two longitudinal rods shown at the top. The acting sides are pierced each with about 100

797



798



holes, of 0·1 in. in diameter, per 16 square inches, and are of oak or beech wood, and about 0·2 in. thick. Before it is put together, the apparatus is plunged in a bath of melted wax, and is covered with several coats of gum-lac varnish, in order to protect the parts from the action of the acid, brass screws being used to connect it.

The following practical hints will be of use in selecting scraps to fill the receptacle:—Choose pieces free from solder or rivets of brass or iron. Flatten out with a hammer such bits as are curled up, and divide with shears those of irregular form, so that all may fit closely upon each other. With these, pack the receptacle as uniformly as possible. For the band of copper, which serves as a conductor, choose a long piece, so that it may bury anew in the mass as its lower end becomes dissolved. Every four or five days stir the pieces vigorously with a brass rod.

The soluble anode, in its rectangular form as before described, acts as a plate, and hence gives proofs of unequal thickness; but if the active surface of the receptacle, instead of being flat, be so disposed as to form a sort of counterpart, following the contour of the mould, the deposit will have a uniform thickness. This is illustrated in *fig.* 798.

M N is the mould in section; over it, at a distance of 0·3 in., is arranged a gutta-percha box D P, of which the bottom is perforated with a large number of small holes. This box first has its bottom covered with linen cloth, and is then filled with copper scraps, and the copper conducting band is inserted.

In order to localise or concentrate the galvanic action at certain places, it is only necessary to heap up the copper pieces at the desired points; and conversely, when a part has become covered with a deposit of sufficient thickness, it is obviously unnecessary to employ the protecting coverings of wax or gutta-percha ordinarily used with plate anodes. The mode of forming the gutta-percha counterpart consists in coating the interior of the mould with several layers of fine thin plaster for a thickness of 0·3 in. This is allowed to harden. Into the hollow cast the gutta-percha, softened by warm water, is pressed by the hand, so as to cause it to conform to the indentations of the plaster, care being taken to keep it of uniform thickness. After cooling, it is easily removed, and after perforation is ready for use as above described. It is of course a reduced copy of the interior of the mould.

With the exception of silver and gold, copper is the metal which has been most extensively worked by these electro-metallurgical processes.

Seals are copied by obtaining impressions in sealing-wax, pressing a warm wire into the edge for a connection; rubbing black-lead over the wax to make the surface conducting; fastening a slip of zinc to the other end of the wire; wrapping the zinc in brown paper, and putting the whole into a tumbler containing sulphate of copper, a little salt-water having been poured into the brown paper cell.

Plaster-of-Paris medallions may be saturated with wax or stearine, and then treated, if small, like seals; if large, in a distinct trough, as in *fig.* 794. In this case the copy is in intaglio, and may be used as a mould for obtaining the facsimile of the cast. More commonly, the cast is saturated with warm water, and a mould of it taken in wax, stearine, or gutta-percha. This is treated with black-lead, and in other respects the same as seals.

Woodcuts are treated with black-lead, and a copper reverse is deposited upon them. This is used as a mould to obtain electrotype duplicates, or as a die for striking off duplicates.

Stereotype plates are obtained in copper by taking a plaster copy of the type, treating it plaster fashion, depositing a thin plate of copper upon it, and giving strength by backing up with melted lead.

Old brasses may be copied by the intervention of plaster.

Embossed cards or paper may be copied by first saturating with wax and then using black-lead.

Fruit may be copied by the intervention of moulds, or may be covered with copper. *Leaves, twigs,* and *branches* may have copper deposited upon them. The same for *statuettes, busts,* and *statues.*

Leaves and flowers are furnished with a conducting surface by dipping them into a solution of phosphorus in bisulphide of carbon, and then into a solution of nitrate of silver. Silver is thus released in a metallic state upon their surface.

Plaster busts, &c., have been copied in copper, by first depositing copper on the plaster prepared for this operation; when thick enough, the original bust is destroyed, the copper shell is filled with sulphate of copper, as in *fig.* 794, and copper is deposited on its inner surface till of sufficient thickness; the outer shell is then removed.

Tubes and *vessels* of capacity do not appear to have been profitably multiplied by electrotype.

Plates have been prepared for the *engraver* to work on by depositing copper on polished copper-plates, and removing the deposits when thick enough.

For the multiplication of *engraved copper-plates*, the electrotype process has been very extensively adopted. A reverse of the plate is first obtained by the deposition of copper; this serves as a mould, from which many copies of the original plate are obtained by depositing copper upon it, and then separating the two. The mode practised by the Duke of Leuchtenberg is to print from an engraved plate on very thin paper with a mixture of resin of Damara, red oxide of iron, and essence of turpentine. While the impression is wet, the paper face downwards is pressed upon a polished plate of copper. When dry the paper is washed away, and the impression remains. An electrotype copy from this is obtained in intaglio, and is fit for the use of the printer.

Galvanography is a picture drawn originally in varnish on the smooth plate, and then treated in a similar way to the above.

The *plates* on rollers used by *calico printers* have been multiplied like engraved plates.

Glyphography is a name given by Mr. Palmer to his process. He blackens a fair copper-plate with sulphuret of potassium, covering it uniformly with a coating of wax and other things, then draws the design through the wax with fine tools. From the plate thus prepared, an electrotype is taken in the usual way, and is backed up and mounted as an electro-glyphic cast to print from as from a wood-block. For a *stereoglyphic* cast to work from as a stereotype-plate, a plaster copy is taken of the original drawing, the high lights are cut out, and then an electrotype copy is made.

Electro-tint is done by drawing with wax or varnish any design on a fair copper-plate, and making an electrotype copy for the printer's use.

Fern-leaves, &c., are copied by being laid on a sheet of soft gutta-percha, pressed into the surface by a smooth plate to which pressure is applied, and then removed in order to subject the gutta-percha mould to the electrotype process. This is NATURE PRINTING, which see.

MM. Auer and Worring have copied *lace, embroidery*, flowers, leaves of trees, entire plants, fossils, insects, &c., in their natural relief, by laying the objects upon a plate of copper, after having soaked them in spirits of wine and turpentine so as to fix them. A plate of clean lead is laid over, and, on being pressed, an intaglio copy is produced on it of the object. From this an electrotype is obtained.

Undercut medallions, &c., are copied in elastic moulds made of treacle and glue in the proportions of 1 to 4. Masks and busts may also be obtained in such moulds.

Electro-cloth was made by saturating the fibre of canvas or felt, making it conducteous in the usual way; it was proposed in place of tarpaulins as a water-tight cover.

Retorts and *crucibles*, &c., of glass or porcelain, have been successfully coated with electrotype copper by first varnishing or otherwise preparing the surface to retain the black-lead, and then treating them as usual.

Soldering copper surfaces has been accomplished by galvanic agency. The ends to be united are placed together in the solution of sulphate of copper, and connected with the battery as for ordinary deposition. Parts not included in the process are protected off by varnish; copper is then deposited, so as to unite the separate pieces into one.

Iron may be coated with *copper*. But here a new feature comes into view. Sulphuric acid leaves the copper of the sulphate, combines with iron, and deposits copper on its surface without the aid of the voltaic apparatus. The iron surface is imperfectly covered with copper, and no firm perfect deposit occurs. In order to obtain solid deposits of copper on iron, it is necessary to use a solution that has no ordinary chemical reaction upon iron. Cyanide of copper is used, which may be obtained by dissolving sulphate of copper in cyanide of potassium. This solution requires to be raised to and retained at a temperature not greatly below 200°, in order to give good results.

Electro-zincing is applied to surfaces of iron, in order to protect them from corrosion. A solution is made of sulphate of zinc, which is placed in a trough B, *fig.* 794. Two or three battery cells are required. The iron to be zinced is connected with the zinc end of the battery, and a plate of zinc with the copper end.

Voltaic brass does not appear to have been obtained in a solid distinct form, but has been successfully produced as a coating upon a copper surface. Separate solutions are made of sulphate of copper and of sulphate of zinc in cyanide of potassium. The two solutions are then mixed, and placed in a decomposing trough. Two or three cells of a battery are used, and a brass plate connected with the copper end. An electrotype copper medal or other prepared surface is connected with the zinc. Brilliant and perfect brass soon appears, and will deposit slowly for some hours; but after a while, the character of the solution changes, and copper appears in place of brass.

This hasty glance at the leading applications of this art will give an idea of its utility. It also comes into play in cases where least suspected. Pins were tinned by electrotype long before the art was known. Brass pins are thrown into solution of tin in cream of tartar, and are unchanged; but when a lump of tin is thrown among them, a voltaic pair is formed, and tin is deposited on all the heap. Any stray pins detached from the mass, escape the influence.

Space would fail us were we to go through the list of crystalline and of simple bodies formed by these processes; as for instance, octahedral crystals of protoxide of copper; tetrahedral crystals of proto-chloride of copper; octahedral crystals of sulphide of silver; crystals of subnitrate of copper; bibasic carbonate of copper, and others too numerous to name, have all been formed by slow voltaic actions. The alkaline metals, potassium, sodium, &c., were first obtained by Davy in the galvanic way; magnesium, barium, aluminium, calcium, &c., are obtained by M. Bunsen by operating upon the chlorides of these metals either in solution or in a state of fusion.

Electro-etching is produced at the place where the current *enters* the decomposing trough, as at the copper-plates *c* of *fig.* 794. A plate of copper is prepared as if for the graver; its face is then covered with an etching ground of asphalte, wax, black pitch, and burgundy pitch; and its back with varnish. The design is then traced through the etching ground with a fine point; the plate is then placed in the trough B, containing either sulphate of copper or simply diluted sulphuric acid, and connected with the copper of the battery. After a few minutes it is removed, and the fine lines are stopped out with varnish; it is then replaced, and again, after a few minutes is removed, and the darker shades are stopped out; the parts still exposed are again subjected to the action, and the etching is complete. When the ground is removed, the design will be found etched upon the copper-plate ready for the printer.

Daguerreotype etching is a delicate operation, and requires much care. The solution employed by Professor (now Sir W.) Grove was hydrochloric acid and water in equal parts, and a battery of two or three cells.

Platinized silver is used in face of the daguerreotype, instead of copper. The result comes out in about half a minute. An oxy-chloride of silver is formed, and the mercury of the plate remains untouched.

A *Photo-galvano-graphic* Company was formed in London for carrying out the process of Paul Pretsch. He made solutions of bichromate of potash in glue-water, or in solution of gelatine, instead of in pure water. He then treated the glass or plate with these, and in the usual way took a picture. He washed the gelatine picture with water, or solution of borax or carbonate of soda, which left the picture in relief; when developed, he washed with spirits of wine, and obtained a sunk design. The surfaces thus prepared, or moulds made from them, were placed in a galvano-plastic apparatus for obtaining an engraved plate from which to print. The process was not, commercially, successful. See PHOTO-GALVANOGRAPHY.

The Duke of Leuchtenberg prepares a plate for etching by leaving the design on the ground, and removing the ground for the blank parts. When his electrotype operation is complete, the design is in relief instead of being in intaglio as in ordinary etching.

Metallo-chromes consist of thin films of oxide of lead, deposited sometimes on polished plates of platinum, but most commonly on polished steel plates. The colours are most brilliant and varied. Nobili is the author of the process.

A saturated solution of acetate of lead is prepared and placed in a horizontal trough. Three or four battery cells are required. A steel plate is laid in the acetate of lead with its polished surface upward, and is connected with the copper of the battery. If a wire is connected with the zinc end of the battery, and held over the steel plate in the solution, a series of circles in brilliant colours, arise from the spot immediately beneath the wire, and expand and spread, like the circles when a stone is thrown into a pond. Silver-blond is the first colour; then fawn-colour, followed by the various shades of violet, and indigoes and blues; lake, bluish lake, green and orange, greenish violet, and passing through reddish yellow to rose-lake, which is the last colour in the series.

According to the shape of the metal by which the current enters—be it a point, a slip, a cross, a concave, or a convex disc—so is the form of the coloured figure varied. And if, in addition to this, a pattern in card or gutta-percha is cut out and interposed between the two surfaces, the action is intercepted by the portions not removed, and the design is produced on the steel plate, in colours, that may be greatly varied, according to the duration of the experiment. The different colours are due to the different thicknesses of the thin films of peroxide of lead.

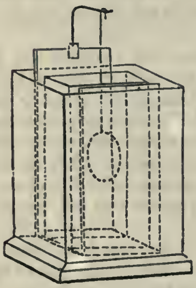
M. Becquerel proposed the deposit of peroxide of lead, and also the red peroxide of iron, for protecting metals from the action of the atmosphere. For the latter, protosulphate of iron is dissolved in ammonia solution, and operated upon by two or three batteries.

The most important application of electro-metallurgy in the arts has been for *plating* and *gilding*, which is most extensively carried on both at home and abroad. Results that were unattainable, and others attainable only at great cost, are readily produced by this mode of manipulating. The liquids most in use are the cyanide solutions, first introduced by Messrs. Elkington. They are prepared in various ways. Cyanide of potassium is added carefully to dilute solution of nitrate of silver; and the white deposit of cyanide of silver is washed, and then dissolved in other cyanide of potassium; or lime-water is added to the nitrate solution, and the brown deposit of oxide of silver is washed, and, while moist, is dissolved in cyanide of potassium; or common salt is added to the nitrate solution, and the white deposit of chloride of silver is washed and dissolved in cyanide of potassium. Or a solution of cyanide of potassium is placed in the trough B, *fig.* 794, and the current from three or four cells is passed into it from a silver plate at *c*, which combines with and is dissolved in the liquid, converting it into a cyanide of silver solution. To prevent silver being abstracted by deposition at *m*, as the current leaves the trough, the metal at *m* is placed within a porous cell of cyanide solution, so as to limit the action.

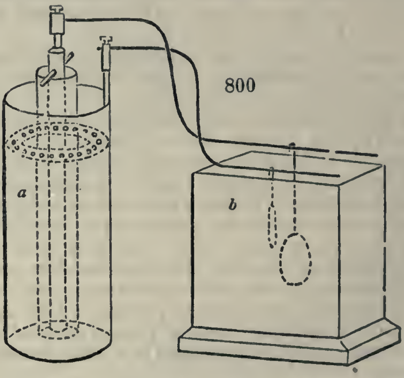
Gold solution is obtained by dissolving the anhydrous peroxide of gold in cyanide of potassium, or by treating chloride of gold with cyanide of potassium, or by using a gold plate and a voltaic current with a solution of cyanide of potassium in the same way as described for silver, and allowing the action to continue until the solution is sufficiently strong of gold. With these solutions electro-plating and gilding are readily accomplished. There are other solutions more or less valuable, which will be found in the books that treat upon the subject.

Fig. 799 shows a single-cell arrangement for plating. The zinc is outside, and is bent to embrace both sides of the porous cell. The article to be plated is within this cell, because, being the vessel of smaller capacity, less of the more valuable silver solution is required, and there is less of loss or waste. The same holds good in a greater degree of gold. In a few minutes the article is covered with silver. If a few drops of sulphuret of carbon are added to the silver solution, the silver is deposited bright. Gold does not come down quite so rapidly as silver.

799



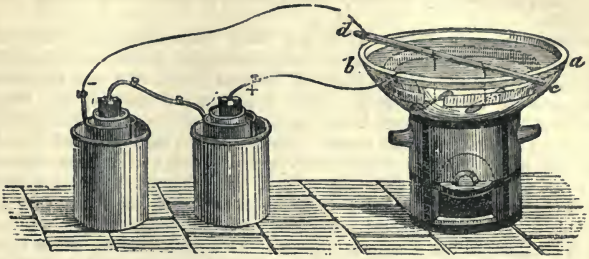
800



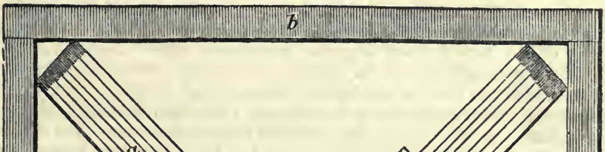
Except for mere experiment, these operations are better accomplished, and with less waste, by using distinct batteries, as *a*, *fig.* 800, the solution of gold or silver being in a distinct trough *b*, plates of silver or gold, as the case may be, being suspended in front of the article to be coated. One or two cells, according to the result required, are used for plating; and three or four for gilding. But gilding is never so well accomplished as it is with hot solutions. The modes of keeping solutions hot vary with circumstances, and with the extent of the operations. *Fig.* 801 is an arrangement for operations on a small scale. The vessel *a b*, containing the gold solution, rests over a small stove or spirit-lamp. The objects to be gilt are suspended by wires to the conducting rod *d*, in connection with the zinc end of the battery; and the gold wire or plate *c* is connected with the other end. A temperature of from 100° to 200° is desirable; the higher temperatures require fewer battery cells; with the highest, one will suffice. The solution, of course, evaporates under the influence of heat; and distilled water must be added to supply the loss, before each fresh operation.

Plating and gilding are successfully, and, in point of economy, advantageously, carried on at Birmingham, in more than one manufactory, by means of magneto-electricity. In the article on ELECTRO-TELEGRAPHY will be found a description of this form of electric force, and the means by which it is produced. An electro-magnet is

801



802



set in motion in front of the poles of a permanent magnet, in such a manner that the soft iron core of the electro-magnet becomes alternately a magnet and not a magnet: in the act of becoming a magnet, it raises up a current in one direction in the wire with which it is wound; in the act of ceasing to be a magnet, it raises up a current in the reverse direction. The ends of the wire are led away and insulated. The instrument is fitted with a commutator, so adjusted that it collects the currents from the ends of the wire, and guides them in a uniform direction into the vessel that contains the solution and articles to be gilded or plated. In practice, a single machine consists of many electro-magnets grouped together, and many powerful magnets for exciting them; by which means a continuous flow of a large amount of electricity is obtained. *Fig.* 802 is an illustration of such an arrangement as adapted by Mr. Woolrich: *a a a a* are four clusters of permanent steel magnets, seen from above; *b b b b b* is the frame-work of the machine; *c c c c* are four bars of soft iron, wound with large size insulated copper-wire; *d* is a circular disc, on which they are mounted, and which rotates on a vertical axis, of which *f* shows the upper end; *e* is the commutator, from which two wires are led off to the solution to be operated upon. The permanent magnets are U-shaped; one pole only of each bundle is visible; the other is beneath the disc *d*, and its freight of electro-magnets *c c*, &c. The axis is set in rotation by a strap passing over the drum of a shaft of the steam-engine, that does the ordinary work in a factory; and the disc carries the electro-magnets between the poles of the permanent magnets, and exposes them to the most favourable action of these poles. The number of coils and magnets varies in proportion to the work required. By this arrangement, not only does each coil pass under the influence of many magnets, but each magnet acts successively on many coils; and a proportionate supply of electricity is the result.

Electro-Deposition of Iron. This has been often attempted, without much success until recently. A process has now been discovered which answers admirably.

This new process has been perfected by M. Eugène Klein, who is at the head of the chemical department in the Imperial State paper manufactory in St. Petersburg. Many difficulties have arisen and have been successfully surmounted in developing this process to its present practical issue. Attempts were made to effect the object so far back as the year 1846, but which were unsuccessful, and it was about twenty years before the problem was definitely solved. The importance and reality of the progress, however, are now unquestionable, and an extended knowledge of the process must inevitably lead to its general adoption. At the present time we believe its application is confined to the Russian Imperial State paper works, where it has been in active operation for some time, the iron plates replacing those of copper for bank-note printing and for other similar purposes. The application of the invention, however, extends to all the other branches of the art of electrotyping.

From a paper upon the present subject, read by the late Prof. Jacobi before the Academy of Sciences in Russia, in 1868, it appears that in the previous year M. Feuquières sent to the Paris Exhibition some specimens of iron electrotype which presented a fair appearance as regarded surface, but still were inferior to those produced by M. Klein in the year following. M. Feuquières does not appear to have published the process by which he obtained his results, and he moreover only spoke of it with the greatest reserve. Professor Jacobi, however, states, on the authority of Professor Varrentrapp of Brunswick, that the process and the bath employed differ essentially from those of M. Klein, whose results may be considered as being perfectly independent.

Referring to the process of electrotyping in iron, Professor Jacobi observes that the good quality of the iron deposit depends principally upon the greater solubility of the anode. The augmentation of its surface not having produced the desired effect, M. Klein conceived the idea of combining the anode of iron with another of copper. The Professor varied this combination by replacing the copper with horn-charcoal, which gave more powerful results. The effects of this combination were thus rendered complete, the negative metal combined with the iron in the same bath formed a duplicate layer, which worked as a cathode opposite the iron, and as an anode by its combination with the copper-wire, or the positive pole of the pile which furnished the principal current. The surface of this electrode consequently disengaged hydrogen and oxygen simultaneously, which combined in the proportions which form water. The surplus hydrogen freely disengaged itself, or produced a polarisation of the electrotype. If, observes the Professor, the oxygen is most abundant, and if the electrotype consisted of an inoxidisable substance, such as horn-charcoal, it would also have disengaged gas, and have given a feeble polarisation. If, however, the electrotype is oxidisable like copper, it will be oxidised and dissolved. By immersing a galvanometer in the circuit, Professor Jacobi has observed the deviation of the needle diminish by degrees whilst the current was very feeble, and it became perfectly still after the force of the current had been increased to a certain degree. At length, passing that degree, the Professor noted that the deviation again became inconstant. By means of the galvanometer, therefore, it becomes easy to so regulate the current as to disengage neither the oxygen nor the hydrogen from the cathode.

So far Professor Jacobi. Turning now to a letter from M. Klein, which was placed before the Russian Academy of Sciences in 1868, we have recorded the methods employed by him in the production of iron electrotype. M. Klein saw M. Feuquières' specimens at the Paris Exhibition, and, encouraged by Professor Jacobi, he, on his return to St. Petersburg in October 1867, renewed his attempts to electrotype in iron. The scientific interest which attached to the new development, and the eminently useful applications of which he saw it was susceptible, especially in the departments of engraving and printing, stimulated M. Klein, and in the early part of 1868 he had accomplished his object. The medals produced in the early part of M. Klein's researches showed, on their reverse, porosities and deep hollows which penetrated nearly through the thickness of the deposit. These cavities were also observable in great numbers in the productions of M. Feuquières. In M. Klein's later specimens these singular cavities—which probably proceeded from bubbles of gas—entirely disappeared, and their reverses are no way inferior to those of copper specimens produced under the best conditions. The starting point of M. Klein was the steeling of engraved copper-plates, which process was effected in a bath composed of the chlorates of ammonia and iron, to which he added a small proportion of glycerine, Those however, who have paid attention to this steeling process, have had occasion to remark that in giving the deposit of iron a greater thickness, the surface cracked, and the deposit detached itself from the cathode in excessively brittle flakes. It became necessary, therefore, to employ baths of two different classes, composed of sulphate of iron and sulphate or chlorate of ammonia. Finally, M. Klein devised three baths, after the formula $FeO, SO^3 + NH^4O, SO^3 + 6HO$. The first bath consists of a concentrated solution of crystals of this double salt. The second bath was composed by mixing the concentrated solution of each of these two salts in the proportions of their equivalents. At length M. Klein obtained the third bath by taking a solution of sulphate of iron, precipitating the iron by carbonate of ammonia, and dissolving the precipitate by sulphuric acid, getting rid of all excess of acid. In preparing the baths of the second class, M. Klein, as we have stated, mixed the solutions of chlorate of ammonia and sulphate of iron in the proportions of their equivalents. Another method employed is to dissolve in a solution of iron as much chlorate of ammonia as it will readily absorb at a temperature of about 66° Fahr. All these baths were concentrated as highly as they could be. As an anode, M. Klein employed iron plates giving a surface about eight times that of the copper cathode. In using a Daniell battery for the decomposition, the deposit was formed in twenty-four hours upon the whole of the cathode. The deposit, however, was full of flaws, and was easily detached and broken up into fragments. As it often happens that the solution of sulphate of copper improves by use, M. Klein hoped that the iron solutions would act in a similar manner. He therefore continued the experiments for several days, without, however, obtaining any better results. Under the advice of Professor Jacobi, instead of a pair of Daniell cells for each of the five stages of decomposition, he then employed four pairs of feebler Meidinger cells, uniting them in series with the five stages of decomposition. This arrangement was found to give a smaller development of hydrogen at the cathodes, and better final results. The deposits, however, were not yet perfect, some exhibiting porosity, and others being furrowed.

Conceiving from previous experience that this was due to acidification of the bath, M. Klein tested it, and found a very decided acid reaction. He attributed this acidification to the circumstance that the quantity of iron deposited on the cathode was greater than that dissolved by the anode. It was, therefore, necessary to give the anode a greater degree of solubility, and as that could only be effected by increasing its area, M. Klein conceived the idea of placing in the bath a plate of copper and uniting it with the iron. The result of this combination was very remarkable; not only were the baths of the first class rendered neutral after several hours, but the deposits became much more uniform. Their colour was a dull grey; they adhered perfectly to the cathode without warping or cracking in any part. During the first 24 hours the surfaces remained perfectly even; but afterwards they began to exhibit minute cavities similar to the appearances often produced upon galvanic deposits of copper. These cavities, however, rarely penetrated to the depth of the deposit. Their production is attributed to the superabundant disengagement of gas on the surface of the cathode. It probably happens that these bubbles attach themselves strongly enough to hinder the formation of the deposit. If the energy of the current becomes too great, these annoying phenomena are produced more frequently. By reducing this energy in the process, and having only an imperceptible disengagement of gas, by diminishing the concentration of the bath, or augmenting the resistance of the solid portions of the circuit, the formation of these cavities entirely disappeared, and the beautiful results to which we have already referred have been obtained. A microscopical examination of the reverses of the deposits produced by M. Klein's final process fails to discover any porosity or irregularity in the specimens.

On leaving the bath the iron is as hard as tempered steel and very brittle. Reheated to a dull red heat it loses much of its sharpness and hardness. Heated to a cherry-red, it becomes malleable and may be engraved as easily as soft steel. If the deposits are produced in good condition and annealed uniformly and with the necessary precautions, they are neither subject to warp nor bend. There is no contraction, but on the contrary, a slight degree of expansion, almost imperceptible however. Owing to the necessity of having bank-note and similar plates identical in every respect, it is of the first importance that they should not be distorted, nor have their dimensions altered in the process of annealing. It appears that the galvanic deposit of iron has not only permanent magnetism, but that, like soft iron, it receives the magnetism of position.

We have now reviewed both the failures and the successes of M. Klein. Of the importance of the practical application of the process there can be no doubt whatever. By replacing plates of copper by those of iron greater facilities will be afforded for producing publications, works of art, and especially bank-notes and cheques. Iron electrotype plates are found to be almost indestructible. They not only can be printed from an almost unlimited number of times; but they are better calculated than those of copper to withstand those inevitable accidents constantly occurring in printing establishments. Printers are sometimes obliged to set aside as useless their best plates, which are often damaged by a grain of sand, or by a chance knot in the paper. These accidents not only involve the expense of renewing the plates, but sometimes occasion interruptions and delays in works of a very pressing nature. These are some amongst the many advantages which may be expected to accrue from the introduction of iron electrotype.'

ELECTRO-DEPOSITION OF NICKEL. 'It is only within the last few years that nickel-plating has been brought prominently into notice but Mr. Smee, in his "Elements of Electro-metallurgy," published in 1852, has the following on the subject:—'The nitrate and sulphate of nickel, the ammonio-nitrate, and sulphate of nickel, the nickelo-cyanide of potassium, but especially the chloride of nickel, require consideration. The nitrate is very soluble, but the metal has no great inclination to be precipitated, for the hydrogen appears rather to prefer being evolved than to reduce the metal. The sulphate of nickel is also used as a double salt, and the metal is reduced more readily from it than from the nitrate. It is best reduced by the compound battery process with a platinum positive pole, though a nickel positive pole may be employed. The solution of either nitrate or sulphate combined with alkalis, those of ammonia deserving the preference, ought to be as strong as possible. The chloride forms an excellent material for precipitation, by means of a nickel positive pole with one or two batteries. The nickel so deposited has a peculiar white, brilliant lustre, looking almost like glass. The deposit is so beautiful when removed from the negative pole that it forms a great contrast to the common nickel metal, and no person would ever suppose that there was any similarity of composition between that substance, still less identity. For practical purposes the chloride is first, and next to it is the sulphate for the reguline deposit." Several processes for nickel-plating have been patented within the last four years, but it is difficult to see how the inventors can claim any right to more than the exclusive use of some probably immaterial detail. Napier coated articles with nickel in 1847; and although there have doubtless been improvements in the various methods, it will be seen from the extract from Smee above quoted, that it is only some special detail of the process that can be claimed. In one of the latest of these patents, taken out in the United States this year, the inventor claims a solution of either of the soluble salts of nickel, which must be free from potash, soda, lime, alumina, or nitric acid, the said solution to be perfectly neutral. M. Becquerel, however, states that potash in no way affects the deposition of the nickel, the double sulphate of nickel and potash being as useful as the double sulphate of nickel and ammonia. The batteries in use for nickel-plating are, we believe, principally the Smee and the Bunsen with their modifications, although the Daniell and the Grove elements are also suitable; but the chief requirement from the battery is a uniform and unchanging current perfectly free from variation. Napier says it is indispensable that the battery should be so arranged that the quantity of electricity generated should correspond with the extent of surface to be coated; and it appears to us that Napier is correct in this, but we take from Dr. Feuchtwanger the details of the apparatus employed in an extensive nickel-plating establishment in the United States. The plating-trough consists of a large wooden box 5 ft. 6 in. long, 2 ft. wide, and 14 in. deep, lined with asphaltum varnish. (We have reason to believe that good dry oak is the best wood of which to make the troughs used in electro-plating: other woods will answer, but oak is both cheapest and best in the long run.) The capacity of this vat is about 70 gallons, the liquid consisting of hot water, to each gallon of which three quarters of a pound of the double sulphate of nickel and ammonia is allowed. The battery consists of six zinc plates, 9 × 10 in., well amalgamated, and six carbon plates of the same dimensions. The box containing these is lined with lead, and holds ten gallons of water, to which 20 ozs. of sulphuric acid are added. This battery is said to remain in active operation for two weeks, the zinc plates needing no re-amalgamation for four months. The articles to be plated are suspended from copper and brass wires stretched across the vat, and require from 6 to 10 hours' immersion. The battery is kept constantly at work; as soon as one set of articles is plated another replaces it. According to Dr. Feuchtwanger, the plating solution must be kept neutral, litmus-paper being frequently used, and if acid is present caustic ammonia must be added till the liquid is brought to the normal state, the tendency being to work acid. It is also necessary, of course, to replace the consumed salts. If chloride of nickel and ammonia is used, the proportions are four ounces of the salt to a gallon of water. Dr. Feuchtwanger also describes what he terms "a simple nickel-plating apparatus;" but his account is not so explicit as may be deemed needful. However, the apparatus consists of a "bath or vat containing the usual nickel solution of double salt (the sulphate, we presume), three quarters of a pound to the gallon of hot water; five gallons is to be applied to the porous cell which contains the amalgamated zinc pole, three inches broad, seven inches deep, and seven inches long; but touching within one-half of an inch all around from the cell. The copper-wire is connected to hold suspended the articles, such as faucets, pistols, or other ware to be plated with nickel; the operation goes on at once and deposits the metallic nickel from its solutions in the space of three or four hours." It must be acknowledged that the details here given are not of the clearest kind, and some portions of the apparatus appear to have been forgotten. Mr. Beardslee, whom Dr. Feuchtwanger says is the veteran nickel-plater of the States, gave the latter valuable information. Mr. Beardslee finds the best results to be given by the chloride of nickel and a certain quantity of ammonia. He uses the chromium negative plate battery in two cells. The amount of battery-power required for a given amount of work should be in zinc surface equal to the surfaces to be coated at one time. The surface of a nickel anode should never be less than the surface to be coated. "The anode surface for a nickel solution may be much greater than the surface to be coated; and more and better work will be the result." A nickel solution of 40 gallons requires 10 anodes of 6 × 12 in. and so in proportion to the greater or less quantity of gallons. The nickel anodes are connected to the chromium or carbon plates of the battery (Mr. Beardslee prefers chromium); the articles to be coated with the zincs. In the small way Mr. Beardslee employs in one gallon of the nickel solution a nickel anode of 4 × 6 in., with two one-gallon cells of the chromium negative plate battery; and he states that the chloride solution works better when it exhibits an acid reaction. Possibly, however, Stolba's method is the simplest of all, and is easily applicable. To some chloride of zinc add double the quantity of water, boil and add hydrochloric acid slowly till the precipitate is re-dissolved. A very little zinc powder is added, and in a few minutes the vessel is coated with zinc wherever the liquid touches it. The nickel salt (either the chloride or sulphate) is then added in sufficient quantity to turn the liquid of a greenish tint. The articles are then introduced with some cuttings of zinc; the whole being boiled for about 15 minutes, when the coating will be found complete. It is scarcely necessary to say that whatever process is employed, the surfaces to be coated must be perfectly clean, which is best secured by dipping in acid; and when they are plated they must be washed with hot water and polished with cloth buffs and crocus, rouge, or other polishing powder. By means of the thin coating of nickel, articles of iron and steel are prevented from rusting, while those of brass, copper, lead, or zinc, are preserved from tarnish; nickel-plating, too, has the advantage over silver-plating that it lasts four times as long and costs about one-fourth, while it is less liable to lose its polish.'

Electro-deposition of nickel has been effected from several of the salts of nickel in solution; but, until recently, the process has not been worked commercially. The Plating Company working Brookes' patent have been eminently successful by the following processes: which we copy from their Specification of Patents:—

'The solutions from which nickel has been heretofore most successfully deposited are the chloride of nickel, the cyanide of nickel and potassium, the double sulphate of nickel and ammonia, and the double chloride of nickel and ammonium. The inventor of the recently-patented process believes the chloride is the best, but the deposits obtained from it are very far from what is required for the general purposes to which the electro-deposition of this metal may be applied. As this solution is ordinarily prepared, it is a good conductor of electricity as compared with most liquids, and the nickel is deposited from it freely, but in a spongy, brittle condition, and more or less mixed with the peroxide of nickel, which gives it a brownish appearance. The deposit has also a great tendency to accumulate on the edges of the plate on which it is made in nodules or warty protuberances. Therefore, although the deposits may be obtained of considerable thickness, they are practically useless for electrotyping or electro-plating. Moreover, a portion of the electricity is expended in forming a sub-chloride of nickel, which falls to the bottom of the vessel as an insoluble precipitate. In consequence of this, the solution is soon exhausted, both of nickel and chlorine, and the process of deposition stops. Even when the solution is formed in the best-known manner, by subliming a pure nickel-chloride, the deposited metal, though free from the oxide, and therefore white, is deposited in the brittle, warty condition, accompanied with the precipitation of sub-chloride. The double cyanide of nickel and potassium is a poor conductor of electricity, and requires high battery-power. With a low battery-power very little metal can be deposited, and that little is accompanied with the deposition of peroxide of nickel to such an extent as to be black or nearly black. With a high battery-power a film of white nickel may be obtained, but not thick enough to satisfy the ordinary requirements of electro-plating.

'Neither of these solutions gives for any great length of time the full equivalent of metal for the electricity employed; and, so far as the patentee has been able to discover, these two solutions are inherently incapable of giving a coherent, tenacious, flexible metal, such as is required in the arts of electrotyping and electro-plating. Of the other two solutions named, the inventor believes that, before his improvements, the best results were obtained from the double chloride of nickel and ammonium, but the metal deposited from it is of such a character as to be worthless when deposited to any appreciable thickness. It is accompanied with the deposit of peroxide, and is therefore brown or black. It is extremely liable to split up into thin scales, which may be rubbed off even with the hand. This want of coherence and tenacity unfits it for the requirements of the arts. The metal deposited from the double sulphate of nickel and ammonia is substantially the same as the above, but it is not so easily obtained. If, with these solutions, a battery-power is used of an intensity of two Grove cells, or thereabouts, a white deposit may be obtained of considerable thickness, but still with such a tendency to split up in scales that it is practically useless, and neither solution gives the full equivalent due to the current.

'It has been discovered, however, that the difficulties attending the use of these last-named solutions, and the character of their deposits, are not inherent in the nature of the solutions, but are due to the modes of preparing them, or to the presence in minute quantities of certain substances which are generally employed in making them, or in the reduction of the nickel used in making them. In order, therefore, to prepare these solutions in such a manner as to give the results reached, it is necessary to adopt processes in their preparation and observe precautions which shall either dispense with the use of these substances altogether or shall effectually remove them if they are employed.'

The patentee then proceeds to give the following directions:—'In preparing this solution, I prefer the use of pure nickel; but commercial nickel may be used. Commercial nickel almost always contains more or less of the re-agents employed in the purification or manufacture of the metal, such as sulphate of lime, sulphide of calcium, sulphide of sodium or potassium, chloride of sodium, and alumina. When any of these substances are present it is necessary to remove them; this can be done by melting the nickel, or by boiling it in water containing at least 1 per cent. of hydrochloric acid. The boilings must be repeated with fresh acid and water until the waste-waters give no indication of the presence of lime when treated with oxalate of ammonia. When the metal is purified by melting, the foreign substances collect on the top of the melted metal in the form of a slag, which can be removed mechanically. If the nickel contains zinc it should be melted, in order to volatilise the zinc and drive it off. The crucible in such case must not be closed so tightly as to prevent the escape of the zinc fumes. If copper, arsenic, or antimony is present in the nickel it can be removed after the nickel is dissolved by passing sulphuretted hydrogen through the solution. The acid to be used in dissolving the metal consists of one part strong nitric acid, six parts muriatic acid, and one part water. Nitric acid or muriatic acid may be used separately, but the above mixture is preferred. A quantity of this acid is taken, sufficient to dissolve any given amount of the metal, with as little excess of the former as possible; a gentle heat is all that is required. The resulting solution is then filtered, and to prepare the solution of the double sulphate of nickel and ammonia, a quantity of strong sulphuric acid, sufficient to convert all the metal into sulphate, is added, and the solution is then evaporated to dryness. The mass is then again dissolved in water, and a much smaller quantity than before of sulphuric acid is added, and the whole again evaporated to dryness, the temperature being raised finally to a point not to exceed 650° Fahr. This temperature is to be sustained until no more vapours of sulphuric acid can be detected. The resulting sulphate of nickel is pulverised and thoroughly mixed with about $\frac{1}{50}$th of its weight of carbonate of ammonia, and the mass again subjected to a gradually-increasing temperature, not to exceed 650° Fahr. until the carbonate of ammonia is entirely volatilised. If any iron is present, the most of it will be converted into an insoluble salt, which may be removed by filtration. The resulting dry and neutral sulphate of nickel is then dissolved in water by boiling, and if any insoluble residue remains, the solution is filtered. From the weight of the nickel used before solution, the amount of sulphuric acid in the dry sulphate can be calculated. This amount of sulphuric acid is weighed out, diluted with four times its weight of water, and saturated with pure ammonia or carbonate of ammonia; the former is preferred. This solution, if it is at all alkaline, should be evaporated until it becomes neutral, to test-paper. The sulphate of ammonia of commerce may likewise be used, but pure sulphate of ammonia is to be preferred. The two solutions of the sulphate of nickel and sulphate of ammonia are then united and diluted with sufficient water to leave 1½ oz. to 2 ozs. of nickel to each gallon of solution, and the solution is ready for use.

'In preparing the solution of the double chloride of nickel and ammonium, the nickel is to be purified and dissolved in the same manner as is described for the previous solution, and it is to be freed from copper and other foreign matters in the same manner. The solution is then to be evaporated to dryness; it should be made as nearly anhydrous as possible. The salt is then placed in a retort and heated to a bright red heat. The salt sublimes and is collected in a suitable receiver, the earthy matter being left behind. The salt thus purified is dissolved in water, and to the solution is added an equivalent quantity of pure chloride of ammonium. The solution is then ready for use: it may have a specific gravity of 1050 to 1100.'

Of these two solutions the inventor much prefers the double sulphate, as it gives a softer metal, which can be polished, or otherwise worked more readily than that obtained from the double chloride solution. The double sulphate solution has this important advantage over any other solution, that it gives a deposit with a smooth surface, which can be polished with comparatively little labour. When the process is properly conducted, the deposit can be made much thicker than is ordinarily required for plating other metals before it acquires a rough or matted surface. With a metal so hard as nickel this is a matter of great importance.

The Specification of the Patent and the Disclaimer and Memorandum of Alteration of The Plating Company (Limited) to Brookes' patent give still further directions for securing the purity of the nickel solution. These are points, however, to which those only who are likely to carry out the electro-deposition of nickel on a large scale need attend, and to such the papers referred to are always available.

Having prepared the solutions and anodes, nickel may be readily deposited; but, in order to carry on the deposition continuously, it is necessary to observe certain precautions.

First. The use of a battery of too high an intensity must be avoided; an intensity of two Smee's cells is sufficient. A high intensity decomposes the solution and liberates free ammonia, thus rendering the solution alkaline, and impairing its value. Whenever the smell of free ammonia arises from the decomposing cell, the operator may be sure that the solution is being injured. It is important that the depositing shall not be forced by the use of too strong a current.

Second. It is important that great precaution should be used to prevent the introduction into the solution of even minute quantities of potash, soda, or nitric acid. When an article to be coated is cleaned in acid or alkaline water, or is introduced into it for any purpose, the greatest care must be taken to remove all traces of these substances before the article is introduced to the nickel solution, as the introduction of the most minute quantities of acids or alkalis will surely be injurious.

Third. The anode of the depositing cell—a nickel plate of the utmost purity--of copper, or alloyed with a little iron to secure the precipitate, should present a surface to the action of the solution somewhat larger than the surface upon which the deposit is being made, particularly in the double sulphate solution. The reason is that nickel dissolves so slowly that if the exposed surface is not larger than the surface on which the deposit is made, the solution will not keep saturated. On the other hand, if the anode is very much larger than the positive pole, it tends to give a deposit of black powder.

Fourth. With solutions and anodes thus prepared and used, the deposition of nickel can be carried on continuously, and almost as surely and certainly as the deposition of copper from the common sulphate solution, though the limits of the battery-power which may be used are narrower. The metal deposited is compact and tenacious. It may be deposited of nearly uniform thickness over any surface, however large. The deposited metal is capable of being annealed by a heat below a low red heat; it then becomes flexible, malleable, and ductile, either to furnish effectual protection to the metal on which it is deposited, or to be removed and used separately from the surface on which it may be deposited. Thus electro-type plates of nickel may be produced, either as copies of irregular surfaces which it is desired to reproduce, or as plain sheets of nickel, which, after being annealed, may be rolled, hammered, or spun into a variety of forms or articles.

Far more extensive use has been made of these properties in America than in this country. There it is used for carriage and harness fittings, for guns and pistols, for various scientific instruments, and for numerous domestic utensils and articles of furniture from fenders to flat-irons. For brass and iron fittings on board ship, and for lever handles of engines of all kinds it is especially adapted, and for the metals mentioned in all places where they are liable to oxidation or corrosion. The process is, we believe, carried on in London on an extensive scale, but one establishment, or even half-a-dozen, cannot supply the needs of the public when the value of the process becomes better known. even if they can keep pace with the present demand. Without doubt many improvements upon the process introduced by Prof. Boettger in 1843 will be introduced as soon as the utility of nickel-plating becomes known.

ELECTRO-MOTIVE ENGINES. The following remarks on this subject are an abstract of a communication read by the editor to the Institution of Civil Engineers, for which they awarded him their Telford Medal.

Numerous electro-magnetic machines have been made, but a few only of these require to be described. In 1832, Salvatore dal Negro published an account of the attempts made by him in this direction. As Dal Negro's engine was of a very simple and effective kind, the Professor's description of it may be quoted:—'As I had been successful in producing temporary magnets of very great power, with very small electro-motors, I endeavoured to apply this power to moving machinery. I will now briefly state by what means I endeavoured to set a lever in motion. I first used a magnetic steel bar, placed vertically between one end of a temporary magnet. The bar vibrated from the attractions and repulsions which took place between its north pole and the north and south poles of the electro-magnet. In the same way a motion may be effected in a horizontal plane. I also set in motion a similar bar, by allowing a piece of iron, set free from the magnet at the moment when its power became = 0 to fall on one of its ends, after this it was immediately re-attracted. This can be effected in two ways: the one may be employed when a quick motion is to be produced, and the second when a greater force is wanted; in the first case the weight falls only just out of the power of the magnet's attraction, and the instant the weight has fallen upon the bar, or lever, it is re-attracted by the magnet that the action may be repeated: it is always small in comparison with that which the magnet cannot support whilst in contact. In the second case the whole weight which the magnet can carry is employed, and use is made of the force which draws it to the magnet.' Upon this was founded several other attempts, particularly one by Dr. Schulthess, who was so satisfied with the result, that he wrote in 1833:—'If we consider that electro-magnets have already been made, which were capable of carrying 20 cwts., and that there is no reason to doubt that they may be made infinitely more powerful, I think I may boldly assert that electro-magnetism may certainly be employed for the purpose of moving machines. Professor Bottò, of Turin, also employed 'a lever put in motion (in the manner of a metronome) by the alternating of two fixed electro-magnetic cylinders, exerted on a third moveable cylinder, connected with the lower arm of the lever, the upper part of which maintains a metallic wheel, serving in the ordinary way, as a regulator in a continuous gyratory motion.' It will be evident to any one who has observed the motion of many of the electric clocks, that this is in several respects similar to the pendulous motions adopted.

In 1835, the late Prof. Jacobi, of St. Petersburg, published an account of his experiments, which were carried out on a large scale, regardless of cost, at the expense of the Emperor Nicholas. His first idea was to employ the attractive and repellant powers of magnetic bars, so that he might obtain an advancing and receding motion, which could be easily changed into a continuous circular motion. A great many machines have been made upon this principle; but Jacobi alone, as far as can be learned, has pointed out the true cause of their failure. 'We know,' he says, 'the ill effects of shocks in the movements of machines, but there is here another inconvenience which is not simply mechanical. The soft iron, by these repeated shocks and vibrations, gradually acquires at the surface of contact the nature of steel; there will be a considerable permanent magnetism, and the transient magnetic force which alone produces the movement, will be weakened in proportion. A number of experiments, which I have made upon the magnetic force of a bar of soft iron, bent into a horseshoe form, has shown me the great disadvantage of often-repeated shocks, proceeding from the sudden contact of the armature.'

Jacobi, finally setting aside all oscillating motions, produced a machine giving continuous circular motion, by fixing eight electro-magnetic bars on a disc, moveable round an axis—and eight fixed bars similarly arranged upon a fixed platform. The arrangement of the bars admitted of much variety, provided it was exactly symmetrical, and that it allowed the poles to approach each other as nearly as possible. Arrangements were made, with much ingenuity, by which the poles of the magnets were inversed directly, and so that inversion should take place precisely at that point where the bars were opposite each other. One hundred and forty-four inversions in the second were readily effected, and Jacobi declared it would be easy with his apparatus to change, or to completely interrupt, the electric current one thousand or more times in a second.

A machine constructed upon this principle was, at the desire and at the cost of an Imperial Commission, put on board a ten-oared shallop, equipped with paddle-wheels, to which the electro-magnetic machine communicated motion. The boat was 28 feet long, and 7½ feet in width, and drew 2½ feet of water. In general, there were 10 or 12 persons on board, and the voyage on the Neva was continued during several entire days. By these experiments Jacobi was led to the conclusion that a battery of

20 square feet of platinum would produce power equivalent to one horse; and the vessel went at the rate of four miles an hour. In 1839, Jacobi tried another experiment, with a battery of 64 platinum plates, each having 36 square inches of surface; when the boat, with a party of 14 persons on board, went against the stream at the rate of three miles an hour.

In 1837, Mr. Thomas Davenport, of the United States, constructed a rotary engine, in which permanent and electro-magnets were employed. Mr. Taylor, in 1839, patented an electro-magnetic engine, both in America and in this country, the principal novelty in which was, that instead of changing the poles of the magnets, the electric action was, at fixed rapid intervals, entirely suspended. In 1837, Mr. Davidson, of Edinburgh, constructed an engine, in which he produced motion by simply suspending the magnetism, without a change of the poles. Mr. Robert Davidson placed an electro-magnetic locomotive on the Edinburgh and Glasgow Railway; the carriage was 16 feet long and 6 feet broad, and weighed about 5 tons. All the arrangements appear to have been very complete, but when put in motion on the rails, it was not possible to obtain a greater speed than four miles an hour.

Professor Page's electro-magnetic engine was for some time looked upon as a triumph. The fundamental principle of it is thus described:—'It is well known that when a helix of suitable power is connected with the poles of a battery in action, an iron bar, within it, will remain held up by the induced magnetism, although the helix be placed in a vertical position; and if the bar is partly drawn out of the helix by the hand, it goes back with a spring, when the hand lets go its hold. This power —the action of the helix upon the metallic bar within it—is the power used in Page's engine.' Professor Page exhibited one of his engines, of between 4 and 5 horse-power, at the Smithsonian Institution; the battery to operate with being contained within a space of 3 cubic feet. It was a reciprocating engine of 2-feet stroke, and the whole, including the battery, weighed about one ton. Professor Page stated that the consumption of 3 lbs. of zinc per day would produce one horse-power. This statement requires further investigation.

Many similar attempts have been made to construct effective machines to be moved by the power of the voltaic battery. Among others, Mr. Henley constructed an electro-magnetic engine of considerable power for Mr. Talbot, and another for Professor Wheatstone. In these there were many ingenious mechanical arrangements, invented to overcome some of the difficulties hitherto encountered; but the physical conditions were similar to those already described. Mr. Talbot's engine was 3 ft. 6 ins. long, and 2 ft. 6 ins. wide; when excited by a Grove's battery, consisting of four cells with double plates of zinc, 9 ins. by 6½ ins., platinum plates 9 ins. by 5½ ins., excited by diluted sulphuric acid in the proportions of 1 to 4, and concentrated nitric acid, it drove a lathe, with which was turned a gun-metal pulley, 5 ins. in diameter; but in three quarters of an hour the battery was quite exhausted.

Mr. Hjörth, a few years since, exhibited in London a large machine, constructed somewhat on the principle of Page's; this, however, failed to produce any great mechanical effect, and it appears to have been abandoned. Dr. Lardner stated, in 1851, that M. Gustave Froment, of Paris, was using, with much advantage, an electro-magnetic engine in his workshops for turning lathes, planing machines, &c. Its use, however, appears to have been abandoned, on account of the great cost of the battery power.

Hankel and Fessel, on the Continent, the Rev. James William M'Gauley, Dr. Kemp, and others, in Great Britain, have, at different times, excited much attention by the ingenious machines which they have constructed.

Notwithstanding these numerous trials, and, connected with them, an almost infinite amount of experiment, it does not appear that any satisfactory explanation has ever been given of the causes which have led to the abandonment of the idea of employing electricity as a motive power. It was mainly with the view of directing attention to these causes, that the essay read was written.

Electro-magnetism undoubtedly affords an almost unlimited power. An electro-magnet may be constructed which shall have a lifting power equal to many tons. It is probable, that there are limits beyond which it would not be possible to increase the power of electro-magnets; those limits have not yet been reached; but supposing them to be attained, there is nothing to prevent the multiplying of the number of electro-magnets in the arrangements. It may be stated, in connection with this part of the subject, that from experiments made with Hearder's magnetometer, it appears that the development of magnetism in iron observes some special peculiarities. These may be thus stated:—With the same electro-magnet there is, as the voltaic pairs in the battery are increased, a gradual increase of magnetic force. With from one to seven elements there appears an average excess of 31 lbs.; after this point, with the increase of battery power, by the addition of pair after pair of zinc and platinum elements, the production of power bears a decreasing ratio to the power employed, and at last, the addition of five elements was not found to produce an increase of effect equivalent to the value of one element. In all experiments, therefore, on electro-magnetic machines, the experimentalist has first to determine the utmost power which the soft iron is capable of assuming, in relation to—1st, the number of coils of wire on the iron; and 2nd, the number of elements employed in the exciting source—the voltaic battery. The length of the iron and its thickness are also points demanding special considerations from the constructor of an electro-magnetic machine.

There remains now to examine the production of the power, Electro-Magnetism.

The electro-mechanician is dependent upon his battery, in the same way as a steam engineer is dependent upon his fire and his boiler, for the production of mechanical effect.

Voltaic batteries vary in their effects, and hence arise statements which differ widely from each other, as to the result obtained, by the destruction (? change of form) of a given quantity of metal in the battery.

Dr. Botto states, that 45 lbs. of zinc, consumed in a Grove's battery, are sufficient to work a one-horse power electro-magnetic engine for twenty-four hours.

Mr. Joule says the same results would have been obtained, had a Daniell's battery been used, by the consumption of 75 lbs. of zinc.

It is impossible, on the present occasion, to enter into the theory of the voltaic battery, or to describe the varieties of arrangement which have been adopted for generating (developing) electrical force in the form of a current, with the greatest effect, at the smallest cost.

On this point the evidence of Jacobi may be quoted:—'With regard to the magnetic machine, it will be of great importance to weaken the effects of the counter current, without at the same time weakening the magnetism of the bars. It is the alternate combination of the pairs of plates in the voltaic pile, which permits us to increase the speed of rotation at will. We know the magnetic power of the current is not sensibly augmented by increasing the number of the pairs of plates, but the counter current is considerably weakened by its being forced to pass through a great many layers of liquid. In fact, on using twelve voltaic pairs, each, half a square foot, instead of four copper troughs, each with a surface two square feet, which I had hitherto used, the speed of rotation rose at least 250 or 300 revolutions in a minute.'

Mechanical force, whether obtained in the form of man-power, horse-power, steam-power, or electrical power, is the result of a change of form in matter. In the animal, it is the result of muscular and nervous energy, which is maintained by the due supply of food to the stomach. In the steam-engine, it is the result of vapour-pressure, which is kept up by the constant addition of fuel to the fires, under the boilers. In the magnetic machine, it is the result of currents circulating through wires, and these currents are directly dependent upon the chemical change of zinc or of some other metal in the battery. Then,

Animal-power depends on food.
Steam-power depends on coal.
Electrical power depends on zinc.

An equivalent of coal is consumed in the furnace—that is, it unites its carbon with oxygen to form carbonic acid, and its hydrogen with oxygen to form water, and during this change of state the quantity of heat developed has a constant relation to the chemical action going on.

Mr. Joule has proved by a series of most satisfactory experiments, that: 'The quantity of heat capable of increasing the temperature of a pound of water by one degree of Fahrenheit's scale is equal to, and may be converted into, a mechanical force capable of raising 838 lbs. to the perpendicular height of one foot.'

Mr. J. Scott Russell has shown that in the Cornish boilers, at Huel Towan and the United Mines, the combustion of one pound of Welsh coal evaporates of water, from its initial temperature, 10·58 lbs. and 10·48 lbs. respectively. 'But,' says Mr. Joule, 'we have shown that one degree is equal to 838 lbs. raised to the height of one foot. Therefore the heat evolved by the combustion of one pound of coal is equivalent to the mechanical force capable of raising 9,584,206 lbs. to the height of one foot, or to about ten times the duty of the best Cornish engines.'

Such are the conditions under which heat is employed as a motive power. An equivalent of zinc is acted on by the acid in the cells of the battery, and is oxidised thereby. In this process of oxidation a given quantity of electricity is set in motion; but the quantity available for use falls very far below the whole amount developed by the oxidation of the zinc. The electricity, or electrical disturbance, is generated on the surface of the zinc; it passes through the acidulated fluid to the copper plate or platinum plate, and in thus passing from one medium to another it has to overcome certain mechanical resistances, and thus a portion of the force is lost. This takes place in every cell of the voltaic arrangement, and consequently the proportion of zinc which is consumed, to produce any final mechanical result, is considerably greater than it should be theoretically.

Joule gives as the results of his experiments, the mechanical force of the current produced in a Daniell's battery as equal to 1,106,160 lbs. raised one foot high, per pound of zinc, and that produced in a Grove's battery as equal to 1,843,600 lbs. raised one foot high, per pound of zinc.

It need scarcely be stated, that this is infinitely above what can be practically obtained. A great number of experiments, made by the Author some years since, enabled him to determine, as the mean average result of the currents, produced by several forms of battery-power, that one grain of zinc, consumed in the battery, would exert a force equal to lifting 86 lbs. one foot high. Mr. Joule and Dr. Scoresby thus sum up a series of experimental results: 'Upon the whole, we feel ourselves justified in fixing the maximum available duty of an electro-magnetic engine, worked by a Daniell's battery, at 80 lbs. raised a foot high, for each grain of zinc consumed.' This is about one-half the theoretical maximum duty. In the Cornish engines, doing the best duty, one grain of coal raised 143 lbs. one foot high. The difference in the cost of zinc and coal need scarcely be remarked on. The present price of the metal in sheets is 28*l.* per ton, and coal can be obtained, including carriage to the engines, at less than 1*l.* per ton; and the carbon element does two-thirds more work than can possibly be obtained from the metallic one.

By improving the battery arrangements, operators may eventually succeed in getting a greater available electrical force. But it must not be forgotten, that the development of any physical force observes a constant law. Whether in burning coal in the furnace, or zinc or iron in the battery, the chemical equivalent represents the theoretical mechanical power. Therefore, the atomic weight of the carbon-atom being 6, and that of the zinc-atom being 32, it is not practicable, under the best possible arrangements, to obtain anything like the same mechanical power from zinc which can be obtained from coal. Zinc burns at an elevated temperature; in burning a pound of zinc there should be obtained, as heat, the same amount of mechanical power which is obtained as electricity in the battery. The heat being more easily applied as a prime mover, it would be far more economical to burn zinc under a boiler, and to use it for generating steam-power, than to consume zinc in a voltaic battery for generating electro-magnetical power.

With the advance of our knowledge some of the difficulties may be overcome. An important and substantial step in advance has been made in practical electricity by M. Gramme, of Paris, who substitutes a rotatory for a reciprocating motion in the mechanical arrangement employed in the production of an electrical current. Hitherto magneto-electric machines have acted upon a principle analogous to that of the ordinary pump, and the current produced has consequently been intermittent in its character. The new machine acts in a similar manner to the rotary pump, and, like that apparatus, gives a continuous stream, and with a very small expenditure of power, while the great drawback to other systems, self-heating, is in it scarcely appreciable, It is, moreover, the first recorded instance of a perfectly continuous magneto-electric current having been obtained on a practical scale, and the circumstance derives additional interest from the fact that the inventor is from the ranks of mechanical workers in electrical science, and not a highly-educated electrician. Had he been one, the probability is that the present apparatus would never have been invented by him, for to obtain a continuous stream an electrician would have followed a course of experiment and inductive reasoning which would have landed him in an entirely opposite direction. Even M. Gramme's explanation of the reasons operating to produce the results he has achieved are at variance with several known facts in electrical science, and with the views entertained by electricians upon the subject. The production of the apparatus is therefore to be attributed more to intuition on the part of its inventor than to the study and practical application of the laws which govern the artificial production of electrical currents. The machine by means of which this important improvement is effected is composed of three rings of soft iron encircled with an endless coil of copper-wire. Each of these rings is made to rotate between the two poles of a strong electro-magnet. The magnets are vertical cylinders of soft iron 3 ft. 6 in. high by 3½ in. in diameter, and are coiled round with insulated copper-wire. They are connected at the top by a square cast-iron plate, and at the bottom are let into a base-plate 2 ft. 8 in. square. In operation the half of each ring which is in proximity with the north end of the magnet takes south polarity, while the opposite half near to the south end takes north polarity. The two neutral points of the system are equi-distant on each side. The rings or bobbins are rotated on a horizontal axis, and when they are set in motion their polarity remains unchanged in position with regard to the operator. The action is therefore equivalent to the coils alone being rotated over a stationary ring-shaped magnet. The effect of this is to produce currents in the two halves of each ring in opposite directions between its two neutral points. At these points, however, contacts are placed, which touch in succession a series of studs connected, at regular intervals, with the wire-coil. Thus the opposite currents in the two halves of each ring, instead of neutralising each other, unite and form a single current. The machine requires a very small amount of force to drive it—much less than one horse-power being ample—and it produces a very intense and steady flow of light. With this apparatus some interesting experiments have lately been made by Mr. Robert Sabine at the works of Messrs. Whieldon and Cooke, in the Westminster-bridge Road, where the machines are being manufactured. It was shown that the current is producible in large quantities, at a much cheaper rate, and of greater constancy than by galvanic batteries. A further superiority over the batteries was also demonstrated in the fact that the resistance remains the same no matter at what speed the machine is driven, within reasonable limits. Therefore, by driving it at double speed twice as much electromotive force is obtained, which represents, therefore, more than twice as much current. In the experiments the machine was driven at a speed of about 320 revolutions per minute, and the first object of the exhibitors was to show the power developed by the system. In the next place a length of 10 ft. of platinum-wire was made red-hot in a few seconds. This experiment was afterwards repeated with a chain of about the same length and composed of alternate links, six inches long, of silver and platinum. While the platinum rapidly became red-hot, and remained so, the silver never became more than inconveniently heated. The light-producing power of the apparatus was then exhibited from the rear portion of Messrs. Whieldon's works. The light was produced in the usual way from carbon points and condensed in a concave reflector, which threw the rays down a by-street on to premises in the York Road, a long distance off, and which were brilliantly lighted up. The light was very intense and remarkably steady, and would doubtless have fallen brightly on the Thames Embankment had not the rays been intercepted by the York Road premises. After the light had been exhibited for some time, the experimenters illustrated the power of the current to fuse metals. This was done in the interior of the building, and platinum, aluminium, silver, magnesium, strontium, metallic sodium, and steel were successively and successfully burnt, the spectrum of each being thrown on a screen. The invention will undoubtedly prove of great importance, for use in lighthouses and for metallurgical purposes, as well as on shipboard, owing to the portability of the apparatus, the small space it occupies, and the slight power required to drive it. It has already been in use for some time past with the best results at the electro-plating works of Messrs. Christofle and Co., of Paris, and is at present under trial by the Postal Telegraph Department. Messrs. Whieldon and Cooke have constructed a machine which has been employed for exhibiting a light in the clock-tower of the Houses of Parliament during the sittings of the House, so that the public had an opportunity of judging of its merits. This application of the electric light has not at present (1874) been adopted, why, we know not. M. Gramme certainly deserves credit for this most important contribution to applied science, by means of which he has practically solved the problem of the production of cheap dynamic electricity.

ELECTRO-PLATING AND GILDING IRON. Professor Wood, of Springfield, Massachusetts, in a paper, which he has communicated to the 'Scientific American,' recommends the following as useful recipes for the electro-metallurgist. He says, 'I believe it is the first time that a solution for plating direct on iron, steel, or Britannia metal has been published. In most of the experiments I have used Smee's battery; but for depositing brass I prefer a battery fitted up as Grove's, using artificial graphite—obtained from the inside of broken coal-gas retorts—in the place of platinum. With one large cell (the zinc cylinder being 8 by 3 inches, and excited with a mixture of one part sulphuric acid and twelve parts water, the graphite being excited with commercial nitric acid) I have plated six gross of polished iron buckles per hour with brass. I have also coated type and stereotype-plates with brass, and find it more durable than copper-facing.

'*To prepare Cyanide of Silver.*—1. Dissolve 1 oz. of pure silver in 2 oz. of nitric acid and 2 oz. of hot water, after which add 1 quart of hot water. 2. Dissolve 5 oz. of the cyanide of potassium in 1 quart of water. To the first preparation add by degrees a small portion of the second preparation, until the whole of the silver is precipitated, which may be known by stirring the mixture and allowing it to settle. Then drop into the clear liquid a very small quantity of the second preparation from the end of a glass rod: if the clear liquid is rendered turbid, it is a proof that the whole of the silver is not separated; if, on the other hand, the liquid is not altered, it is a proof that the silver is separated. The clear liquid is now to be poured off, and the precipitate, which is the cyanide of silver, washed at least four times in hot water. The precipitate may now be dried and bottled for use. *To prepare Cyanide of Gold.*—Dissolve 1 oz. of fine gold in 1·4 oz. of nitric acid and 2 oz. of muriatic acid; after it is dissolved add 1 quart of hot water, and precipitate with the second preparation, proceeding the same as for the cyanide of silver. *To prepare Cyanides of Copper and Zinc.*—For copper, dissolve 1 oz. of sulphate of copper in 1 pint of hot water. For zinc, dissolve 1 oz. of the sulphate of zinc in 1 pint of hot water, and proceed the same as for cyanide of silver. The electro-plater, to insure success in plating upon all metals and metallic alloys, must have two solutions of silver; the first to whiten or fix the silver to such metals as iron, steel, Britannia metal, and German silver; the second to finish the work, as any amount of silver can be deposited in a reguline state from the second solution. *First, or Whitening Solution.*—Dissolve 2½ lbs. (troy) of cyanide of potassium, 8 oz. carbonate of soda, and 5 oz. cyanide of silver in one gallon of rain or distilled water. This solution should be used with a compound battery, of three to ten pairs, according to the size of the work to be plated. *Second, or Finishing Solution.*—Dissolve 4½ oz. (troy) of cyanide of potassium, and 1½ oz. of cyanide of silver, in 1 gallon of rain or distilled water. This solution should be used with one large cell of Smee's battery, observing that the silver plate is placed as near the surface of the articles to be plated as possible.—N.B. By using the first, or whitening solution, you may insure the adhesion of silver to all kinds of brass, bronze, red cock-metal, type-metal, &c., without the use of mercury, which is so injurious to the human system. *To prepare a Solution of Gold.*—Dissolve 4 oz. (troy) of cyanide of potassium, and 1 oz. of cyanide of gold, in 1 gallon of rain or distilled water. This solution is to be used warm (about 90° Fahr.) with a battery of at least two cells. Gold can be deposited of various shades to suit the artist, by adding to the solution of gold a small quantity of the cyanides of silver, copper, or zinc, and a few drops of the hydro-sulphuret of ammonia.'

ELECTRO-PLATING BATH. See CYANIDES.

ELECTRO-SORTING APPARATUS. M. Froment devised an apparatus for the separation of iron from matters by which it may be accompanied. The apparatus consists of a wheel carrying on its circumference eighteen electro-magnets. The iron ore, reduced and pulverised, is spread continually upon one of the extremities of a cloth drawn along with it, and passed under the electro-magnets in motion. The iron in the ore which has of course been brought into a magnetic state by any of the processes by which this may be effected, is separated by the magnets, and the impurities carried onward. See De la Rive's 'Electricity.'

ELECTRO-TELEGRAPHY. The simultaneous appearance of the electric spark at the respective ends of a long conducting wire forcibly arrested the attention of electricians in the early days of the science.

A series of remarkable experiments were made by Dr. Watson, commencing on July 14th, 1747; when he passed an electric discharge from the Thames bank at Westminster to the opposite bank at Lambeth, by means of a wire suspended to Westminster Bridge. He continued his researches; and, on August the 5th of the following year, he arranged 12,276 feet of wire at Shooter's Hill, the beginning, the middle, and the end of which were led into the same apartment. He discovered that the electric signs at the middle of the wire coincided in time with the discharge at the two ends, proving that the passage, at least in such a length of wire, was instantaneous. In reference to these results, Professor Muschenbroeck wrote to Dr. Watson: 'Magnificentissimis tuis experimentis, superasti conatus omnium,' Dr. Franklin made similar experiments in 1748 across the Schuylkill at Philadelphia, and in the next year Du Luc repeated them across the Lake of Geneva.

The idea of applying this property to the transmission afar of telegraph signals proper was an early and natural result of these discoveries. But many onward steps were necessary before the idea could assume any definite form; and further advances in knowledge were essential before the idea could be realised.

Locked up, as it were, in all bodies, is a large store of electric force, the equilibrium of which is disturbed in a greater or less degree by a variety of causes, some extremely simple, others more complex; and, according as one or other cause is in operation, the conditions under which the electric force is manifested vary; some conditions being very unfavourable, and others very favourable to the object in view.

The rapidity with which electric force traverses conductors depends upon the circumstances under which the conductors are placed; in the case of wire suspended in the air, the electric force has little else to do than to travel onward and be discharged from the far end of the wire; in the case of buried wire, it has to disturb the electric equilibrium of the gutta-percha as it travels onward, and thus suffers considerable retardation. The greatest recorded velocity of a signal through a suspended copper telegraph wire is 1,725,800 miles per second, by M. Hipp; the lowest velocity through a buried copper-wire, 750 miles per second by Faraday. Intermediate velocities are recorded, for which the nature of the wire or the conditions under which it was placed were different. Wheatstone found the velocity of electricity under different conditions from the above to be 288,000 miles per second. His wire was copper, and was wound on a frame. The electricity that was employed by Mr. Wheatstone in these experiments was obtained from the friction of glass against an amalgam of tin. The various velocities are due partly to the conditions under which the conducting wire is placed, and partly, no doubt, to the varied properties of electricity from various sources.

Electricity is obtained from other sources than friction with so much greater facility, and in forms so much more applicable and manageable for telegraphic purposes, that frictional electricity has not been applied in real practice. It must not, however, be passed over in this place, because one of the earliest telegraphs, perhaps the very first in which a long length of wire was actually used, was actuated by this form of electricity. In February 1753 a writer, dating from Renfrew, and signing himself 'C. M.' wrote to the Scot's Magazine on 'An expeditious mode of conveying intelligence.' The method proposed differed in no respect from that adopted by Dr. Watson, frictional electricity being employed, and the signals being the movements of pith-balls. He, however, proposed the use of bells, upon which the electrified balls were to strike, and thus, he says, the experimentalist 'will inform his correspondents by the sound what wires have been touched; and thus by some practice, they may come to understand the language of the chimes in whole words, without being put to the trouble of noting down every letter.'

Lesage, we are informed by Moigno, in his '*Télégraphie Electrique*,' erected at Geneva in 1774 a line of twenty-four insulated metallic wires, insulated from each other, each wire being connected at its farthest end with a pith-ball electrometer, which corresponded to one of the letters of the alphabet. Lomond, in 1787, employed a single electroscope, and by arranging a system of signals given by the divergence of the pith-balls, transmitted intelligence by means of a single wire. This was seen by Arthur Young, and described by him in his 'Travels in France.' In 1816 Mr. Ronalds established, in the grounds attached to his residence at Hammersmith, eight miles of wire suspended by silk to dry wood, besides 175 yards of buried wire in glass tubes embedded in pitch and enclosed in troughs of wood. He obtained his electricity from a common electrical machine, and his signals from the motion of light bodies, balls of elder-pith, produced under circumstances analogous to those to which we have already referred. At the far end of his telegraph wire two pith-balls were suspended close together. Electricity applied at the home end of the wire at once diffused itself throughout the conducting system, including the pair of light balls. Just as we have seen gold-leaf recede after having approached rubbed amber, and acquired an electric charge, so the pith-balls, each being charged with electricity, derived from the same source, recede from each other; and this in obedience to the fundamental laws of static electricity, for which we must refer readers to treatises on the subject. Here, then, we have one solitary signal. The manner in which Mr. Ronalds turned it into language was ingenious. He pressed time into his service, and by combining time and motion he obtained a language. He provided a clock movement at each station; the clocks were so regulated as to be synchronous in their movements; each of them carried, in lieu of a hand, a light disc, having the letters of the alphabet and other signals engraved on it. The disc was hidden by a screen, in which was *one* opening. It is obvious that if the clocks were started together, and had uniform rates, the same letter at the same time would be visible through the opening in each screen; and letter by letter would pass seriatim and simultaneously before the respective openings. If absolute uniformity is difficult for long periods, it is practicable for shorter. The sender of a message watched the opening of his screen; the moment the letter approached that he desired to telegraph he charged the wire with electricity, and the balls at the far station moved; the letter then visible there corresponded with the one at the home station, and was read off. The sender watched till the next letter he required came round, and so on.

Let us now pass on to some of the leading features of electro-telegraphy, as it has been realised of late years, and to a description of some of the telegraph instruments that are most in use.

Chemical action is the most fertile source of electricity. If a silver fork and a steel knife are connected together by a piece of wire, and the fork is thrust into a piece of meat, say a hot mutton-chop, the moment an incision is made in the meat with the knife, electricity will pass along the wire and continue to do so while the above disposition of things remains. Upon the proper test being applied, the electricity is readily detected. This is the *current form* of electricity. The amount of force in circulation in this particular combination is not very great, and its power of travelling to a distance is not very high, but still it is quite capable of producing good signals, on a delicate arrangement of the needle instrument—the galvanometer, with which we are now so familiar.

The amount of electricity obtained by means of chemical action is increased to the required extent by a judicious selection of the two metals forming the galvanic series and of the liquid or liquids in which they are immersed. Zinc is invariably used as one of the metals. Copper, silver, and platinum or graphite (gas carbon) is selected for the other. When the two metals are immersed in the same liquid, a mixture of sulphuric acid with salt-water, or fresh, is employed. When two liquids are used, they are separated by a porous partition; the zinc is usually placed in the sulphuric acid solution, and the other metal in a solution varying with the nature of the arrangements proposed. Zinc is naturally soluble in the acid solution in question; and would therefore waste away and be consumed at the expense also of the acid, unless precautions were taken to make it resist the ordinary action of the solvent. When zinc is dissolved in mercury it is not attacked, under ordinary circumstances, by sulphuric acid solution. Hence the plate of zinc employed in all good Voltaic combinations, as they are called after Volta, into which this acid, in a free state, enters, are protected by being well amalgamated, that is, they are dipped in a strong acid mixture and well washed; and are then dipped into a mercury bath, and are placed aside to drain. The operation is generally repeated a second time; and, in the best arrangements, the further precaution is taken of standing the zinc plate, while in the acid water, in some loose mercury, placed either in the bottom of the containing vessel, or in a gutta-percha cell: by the latter arrangement, mercury is economised. In single-liquid arrangements, it is desirable to select a metal that is not attacked by the acid. Copper has been extensively used, and is very valuable; but it possesses the defect of being slowly attackable. The waste, however, that it suffers in itself from this cause, is of small moment compared with certain secondary results, which terminate in the consumption of the acid and the zinc, and the destruction of the functions of the apparatus. Gold or platinum are free from these defects, but are too costly. Silver is to a great extent free from them, and has been much and successfully used, especially when platinised, that is, having its surface covered with finely-divided powder of platinum. The accumulated carbon from gas-retorts, cut into plates, and similarly treated, forms, with amalgamated zinc, one of the cheapest and most effective combinations. See Galvanism of Plates.

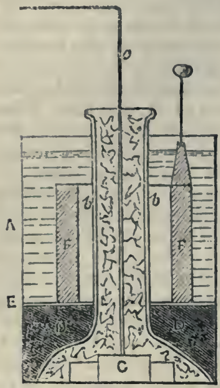
After the discovery of the electrical pile by Volta, and after Nicholson and Carlisle had shown that water could be decomposed by the electric current produced by the chemical action in the battery, Herr S. T. Sömmering communicated a system of telegraphing, in 1808, to the Academy of Sciences at Munich. A series of twenty-four wires were arranged to correspond with the letters of the alphabet, and ten to correspond with numerals. One end of each wire being furnished with a gold point was brought into a tube of water. When contact was made by the other end of one of the wires with the pile or battery, a bubble of gas appears in the water of one of the glass tubes. Thus, by a little careful arrangement, it was possible to convey intelligence from one point to another by the decomposing power of the galvanic battery.

A single pair of plates, no matter what their character, is unable to produce a force that can overcome the resistance of a wire of any length, and produce an available result at a distant station; and hence a series of pairs of plates are employed in the telegraphic arrrangements. E (*fig.* 804) represents a common mode of arranging a series of pairs of plates. It consists of a wooden trough made water-tight, and divided into water-tight cells. The metals are connected in pairs by copper bands; each pair is placed astride over a partition, and all the zincs face one way. When the plates (copper and zinc) are placed in, and the cells are filled up with pure white sand, and the acid water poured in, we have the very portable battery that was originally used by Mr. Cooke, and is still much employed. When batteries of a higher class are employed, the cells are distinct pots or jars; and great precautions are taken to prevent any conducting communication existing between the neighbouring cells, save by means of the copper band. In the trough form there is a leakage and loss of force from cell to cell. The c, or copper, is the positive end of such a series, and the z, or zinc, the negative; and both are in a condition to discharge, either each to the other, by means of a wire led from one to the other, or each to the earth, one by a wire leading to the earth at the place where the battery stands, and the other by a long wire (say a telegraph wire), leading to the earth at a distant place. The resistance to be overcome is, in the former case, less; and the current of force in circulation is proportionately greater.

It is not practical or expedient in a work of this character to enter into any detailed description of all the varieties of galvanic battery which have been employed. A few only can be named. For use with the needle telegraph the *sand battery* is very commonly employed. This consists simply of amalgamated zinc and copper plates, the spaces between them being filled with sand moistened with dilute sulphuric acid. These batteries are usually arranged in boxes of one dozen elements; they remain tolerably constant for some weeks without attention and are readily recharged.

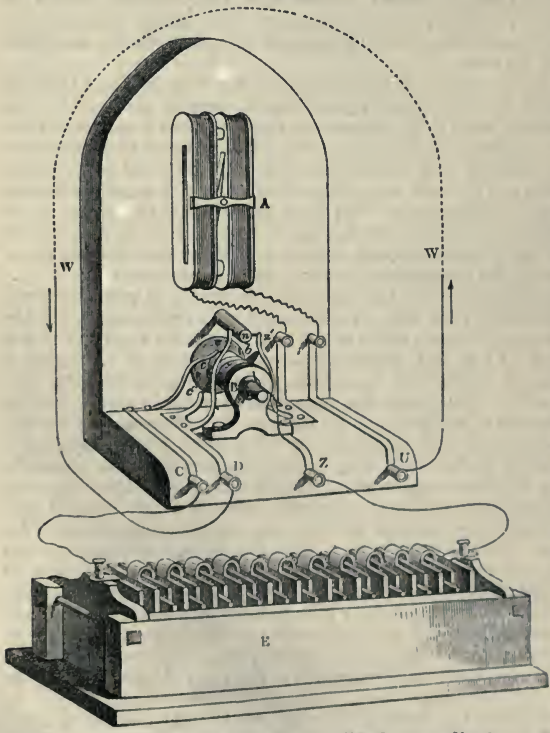
The Marié-Davy battery is much used in France. A zinc plate is immersed in pure water—in practice the zinc cylinders are packed in wet sponge—and carbon plates in porous cylinders are immersed in a paste of proto-sulphate of mercury and water. This battery requires very little attention, and it is said to retain its original force for six months.

803



Meidinger produced a modification of Daniell's battery, which was charged with a solution of Epsom salts and sulphate of copper. This has, however, given way to the battery of Siemens and Halske, in which the peculiarity is the use of paper-pulp, in addition to the porous earthenware diaphragm, to prevent the mixing of the fluids too readily. Into a glass jar A A, *fig.* 803 is placed a cross-shaped plate of copper C, united to a copper-wire *c*, which rises above the jar. Over this is placed a porous earthenware cylinder *b b*, widened out at the bottom into a bell shape. Between this porous bell and the glass jar, paper-pulp D, saturated with a quarter of its weight of sulphuric acid, which converts it into a gelatinous mass, and then worked up with four times its weight of water is pressed so as to form a compact mass; this about half fills the jar, and upon it is placed an annular disc of brown paper or of cotton cloth E E. The zinc cylinder F F, cast with a neck which rises above the fluid, rests upon this disc, reaching to within an inch of the top of the jar. Crystals of sulphate of copper are dropped into the porous cylinder, and then both compartments are filled to the same height with water, which may be fresh or acidulated. This battery only requires to be supplied with sulphate of copper from time to time, and water added to supply the waste by evaporation. It has been found that at the end of six months the electro-motive force was ninety per cent. of what it was originally.

804

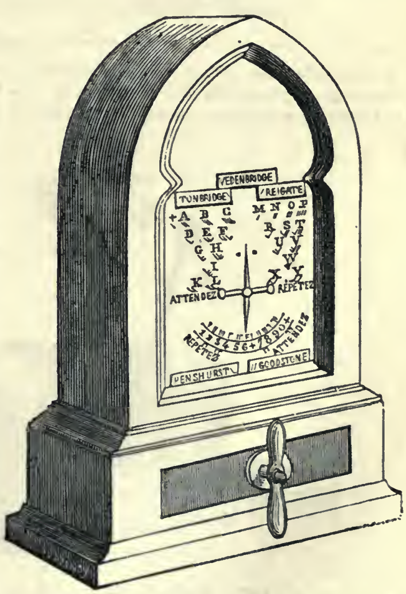


Under whatever circumstances a wire takes part in promoting the discharge of a voltaic apparatus, the whole of the said wire is in a condition to indicate the presence of the force that is pervading it; and as the force may be presented to the wire in either of two directions, that is to say, the copper or the zinc, namely, the positive or the negative end of the battery, may be presented to the given end of the telegraph wire, the relative condition of the wire will be modified accordingly. Not only can the direction of this current-force be inverted at pleasure, but it can be maintained for any length of time, great or small, and in either direction. This is accomplished by various mechanical arrangements, which are the keys, commutators, or handles of the various telegraph instruments, and are often the only parts presenting any complexity about them. In *fig.* 804, the source of electricity, E, we have already described; the test-instrument for the abnormal state of the wire, that is to say, the telegraph proper, is the part A. The complex part, consisting of springs, cylinders, and studs, shown below A, is nothing more than the necessary mechanical arrangement for directing at pleasure the current from the battery E, in either direction through the wire, and through the part A. By following the letters in the order here given, the course of the current may be traced from its leaving, say the positive or copper end of the battery, till its return to the zinc or negative end; C *c′* D W W U A Z′ *b* B Z. If a companion instrument were in any part of the circuit of the wire W W, it would correspond in its signals with the home instrument, *fig.* 804.

In 1820 Oersted of Copenhagen made the capital discovery that a magnetic needle suspended in the neighbourhood of a wire, through which a current of electricity was passing, was deflected from its position of rest, the angle of deflection varying with the amount of electricity passing along the wire. Ampère found the law by which this influence was governed, numerous investigators continued the inquiry with more or less success, and eventually Michael Faraday, by a series of the most perfect inductive experiments which adorn the annals of British science, made the two discoveries of Volta-electric induction and of magneto-electricity. These completed the series which were necessary for the full development of electro-telegraphy, and it only remains for us now to deal with the practical application of those great laws to which we have alluded.

One of the properties possessed by a wire, during the discharge of a voltaic battery is to deflect a magnetised needle. If the needle and the wire are parallel in the normal state of the wire, the needle is deflected this way or that, when the wire is in the abnormal state; and if the needle is very delicate, and a large enough amount of electricity is circulating through the wire, the needle will reach the maximum deflection of 90°. This is an extreme case, and cannot be approached in practice. Indeed, the deflection of any ordinary needle, under the action of an ordinary telegraph wire, would not be appreciable. But, as *every* foot of the wire has the *same* amount of reaction, we have merely so to arrange things that many feet shall be made to react upon the needle at the same time, and thus the effect is multiplied in proportion to the length of wire so concentrated. This is managed by covering a considerable quantity of fine wire with silk or cotton, and winding it on a frame A (*fig.* 804), suspending the needle within the frame. Such an instrument is called, from its properties, a *multiplier*. It is seen at a glance that the wire of the multiplier is an *addition* over and above the length of the actual telegraph wire required for reaching the distant station, and thus it practically increases the distance to be traversed. The multipliers commonly used add a resistance equal to six or seven miles of telegraph wire.

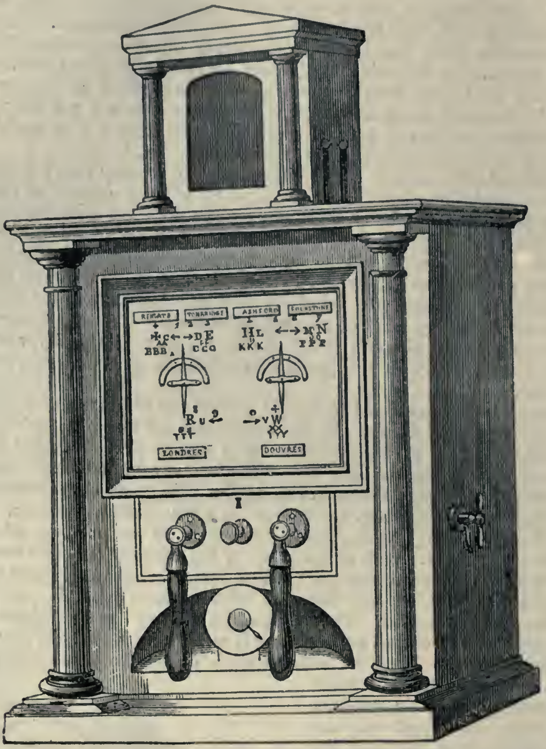
805



Let us now turn to the face of the instrument. Here we have a dial and an index, which is on the same axis as the magnetised needle above described, capable of being deflected to the right or left, and limited in its motion by ivory pins. We have a handle for working the mechanical part so connected that, as it moves to the right, it directs a current into the wire such that the needle moves to the right, and *vice versâ*. An alphabet is constructed from the combination of these two elementary motions, one or more of either or both kinds of deflection being used for the various letters, as shown on the engraved dial. This is Cooke and Wheatstone's single-needle instrument, *fig.* 805.

The form and character of their double-needle instrument is shown in *fig.* 806. It is precisely a duplicate of the former: two handles, and their respective springs, studs, and cylinders, two multipliers, and two magnetised needles, with their external indexes, and two telegraph wires. One battery, however, is sufficient. One

806



or more of either or both kinds of deflection of either or both needles, according to the code engraved on the dial, constitutes the alphabet. This instrument is very extensively employed; messages are sent by it with extreme rapidity.

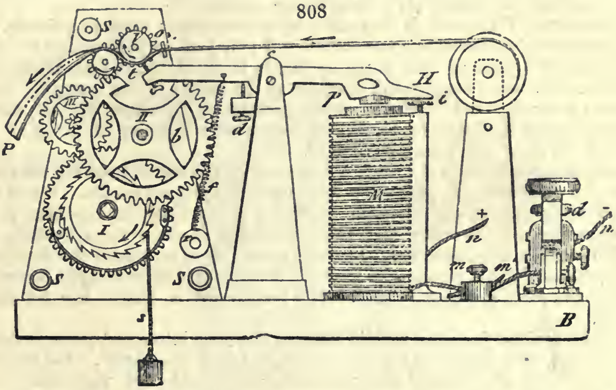
807

Another property possessed by a wire conveying a current is that of converting soft iron, for the time, into a magnet. The attractive power, which can thus be given to, and withdrawn from, the soft iron at pleasure, is turned to useful account, either in producing direct mechanical action, or in liberating the detents of a clock movement. Here also the effect of the solitary wire is inappreciable, and many convolutions around the iron are necessary in order to obtain a useful result.

The simplest application of this principle is shown in *fig.* 807. Here are two brass reels, filled with cotton-covered copper-wire in one length. They are hollow, and a U-shaped bar of iron passes through them, presenting its ends at the face turned toward us in the drawing. This bar becomes magnetic,—forms what is called an *electro-magnet* every time and as long as an electrical current circulates in the wire; and its ends become respectively north and south poles. A narrow plate of iron, an *armature*, as it is termed, is mounted on pivots in front of the ends or poles of the magnet; it carries a vertical stem upon which the hammer is fixed. Every time the iron bar is magnetic the armature is attracted, and the hammer strikes the bell. The spring or contact-maker for introducing the current of electricity into the circuit, is shown in front on the right-hand side. This is Mr. Walker's bell for signalling railway trains from station to station. The language consists of one or more blows. One, two, and three blows are the signals for common purposes, half a dozen blows is the limit. The acknowledgment of a signal is its repetition. By a simple arrangement of an index, that moves in fellowship with the hammer, the eye, as well as the ear, may read the bell signals.

Fig. 808 shows another application of the direct action of an electro-magnet in producing telegraph signals. It is Morse's printing telegraph, very generally used in America, and to no small extent in Europe. The coils of wire are shown at M, the armature at H, fixed at one end of the lever *p*, which is itself carried on centres at *c*. The range of motion here is small in order to produce rapid utterance; it is regulated by the screws *d* and *i*. The reaction of the spiral spring *f* restores the lever to its normal position each time the magnetism ceases. The signals consist of dots or dashes, variously combined, made by the pointed screw *t* upon the slip of paper P, running from the drum at the right in the direction of the arrows; a few such signals are shown upon the end of the paper slip. We have described the telegraph proper, which is seen to be extremely simple. The only parts at all complex are, as with the needle instruments already described, the mechanical parts, namely, the train of wheels for carrying on the paper band, and the key or contact-maker, not shown in the figure. The amount of pressure required from the point *t* in order to produce a mark, is such that it cannot conveniently be produced by the magnetic attraction, derived from a current of electricity that has come from a far distant station in order to circulate in the coils of wire M. This difficulty does not prevail in the signal-bells, *fig.* 807, which are, at most, not required to be more than eight or ten miles apart, and in which also momentum can be and is accumulated so as to conspire in producing the final result. Morse has, therefore, had recourse to a *relay*, as he calls it. This, in principle, is pretty much the same thing as the instrument itself; but it has no heavy work to do, no marks to make; it has merely to act the part of a contact-maker or key; it can hence be made very delicate, so as to act well by such currents as would not produce any motion in the instrument itself. The batteries which furnish the electricity for doing the actual printing work in Morse's telegraph are in the same station with the instrument itself. The office of the relay is to receive the signals from afar, and to make the necessary connections with the local battery and instrument so as to print off the signals on the paper in the usual way. It is obvious that the motions of the instrument and the relay are sympathetic, and that what a trained eye can read off from the one a trained ear can read off from the other. The relays are constructed with much finer wire than is required for the instrument itself, so that the current circulating in them, although very low in force, is multiplied by a very high number, and becomes equal to the delicate duty required of it.

808



It is, we hope, now understood, that, whatever form the needle telegraph may take it consists essentially of a magnetic needle, which is deflected by an electric current passing through considerable lengths of wire carefully coiled around it. Several attempts have been made to render these instruments in the highest degree sensitive to electrical influences. Professor Weber employed a galvanometer the magnetic needle of which is a circular steel mirror reflecting the divisions of an illuminated scale placed at some distance from it, into a telescope through which the observer reads off the deflections of the mirror. Sir William Thomson has greatly improved upon Weber's instrument. He employs a mirror whose weight does not exceed a few grains, and he dispenses with the telescope by throwing a spot of light directly upon the scale and lessening its distance. For all measurements in which the instrument serves as a galvanoscope, and when the readings are not very different in value, Sir W. Thomson's instrument is superior to Weber's.

Mr. Sabine, in his work on the Electric Telegraph, remarks: 'Mr. Becker has given it a very convenient form, by fixing the coil in the back of a brass barrel or cylinder, in the front of which a glass plate enables the interior to be seen from before, and prevents dust and currents of air getting to the needle.

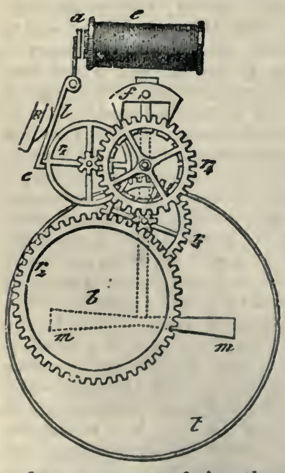
'In the centre of the coil is suspended by a fine cocoon fibre, in a frame, a small silvered mirror[1] of microscope glass, between $\frac{1}{2}$ and $\frac{1}{4}$ of an inch diameter. A little magnet, made of a piece of thin watch-spring, is fastened to the back or silvered side of the glass, and, being magnetised, operates as the needle of the system. Above the brass barrel a vertical rod carries a curved permanent adjusting magnet, and a rack and pinion enables the latter to be turned horizontally to bring the point of light to any part of the scale which may be desired.

'The adjusting magnet is elevated or depressed on the vertical rod for the purpose of increasing or decreasing the directing force upon the magnet needle. When the ends of the adjusting magnet coincide with the poles of the earth's magnetism, it adds to the directive force of the latter, and the instrument becomes proportionally unsensitive. The magnet may, however, be turned round, so as to oppose the directive force of the earth, and in this position be lowered towards the mirror, until it very nearly neutralises the earth's directive force. The instrument so placed has its maximum sensibility.

'The scale, divided from the middle towards the ends into equal parts, is fixed upon a wooden stand, at a distance of two or three feet from the mirror. Behind the scale is a paraffin lamp, whose light falls through an adjustable slit underneath on to the mirror, which reflects it back upon the scale; and, in order that the point of light shall be as well defined as possible, a small plano-convex lens is placed before the mirror, through which the rays converge into a focus, throwing a sharp image of the slit upon the scale.

'Mr. Darley has made some of these instruments for the measurements of the Atlantic cable, and has substituted a plano-convex lens silvered on the curved side, for the mirror in Professor Thomson's instrument dispensing of course with the lens in front.'

809



We may here refer to the case of another bell or alarum, in which the magnetic attraction derived from the current that arrives, is not equal to the mechanical work of striking a blow and sounding a bell; but which is able to raise a detent, that had restrained a train of wheels; and so allow the mechanism of the latter to do the work required. This arrangement is shown in Cooke and Wheatstone's alarum, *fig.* 809; *t* is the bell; *m m*, is the double-headed hammer, which is in fact the pendulum, attached to the pallets *f*, which work in a scape-wheel hidden in the figure, and in gear in the usual way with a coiled spring in the box *b*, by the train r_4, r_1, r_3, r_2. The electro-magnetic part here, as in other instruments, is simple enough; *a c* is a lever moving on a centre above *l*, having at one end an armature *a*, facing the poles of the electro-magnet *e*; and at the other end *c*,

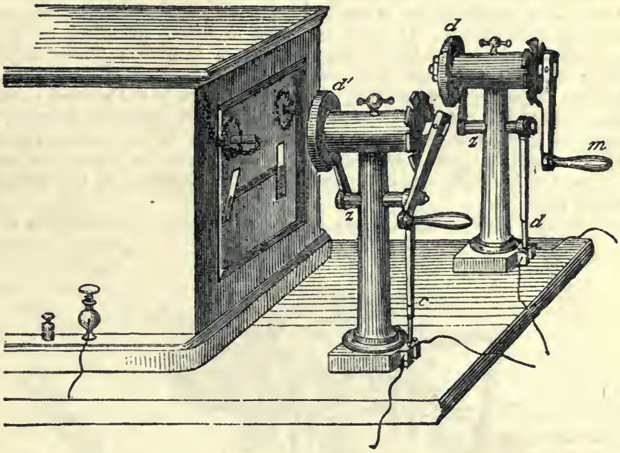
---

[1] The process of depositing metallic silver upon glass is as follows:—(A) Dissolve 10 parts of nitrate of silver in 50 parts of water, and neutralise with (about) 6 parts of liquor ammonia; add to this a solution (B) of 1 part of tartaric acid in $4\frac{1}{2}$ parts of water, and dilute the whole (A + B) with 500 parts of water. The things to be silvered should be placed conveniently in a vessel, the solution poured in, and then put away in a quiet place for a few hours, at a temperature of from 40° to 50° C. When silvered they may be washed by a gentle stream of water, dried, and varnished with a solution of amber in chloroform.

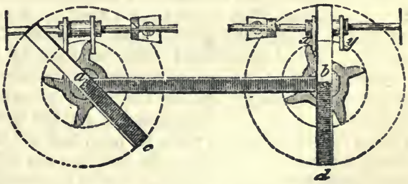
a hook which faces the wheel r_1, and by catching in a notch on its circumference, keeps the train at rest. But when a current circulates through the coils *e*, the armature is attracted, the hook is raised, the train is liberated, and the pendulum-hammer vibrates and strikes a succession of blows. R is a support carrying a small spring, which reacts on the lever, and restores it to its normal position when the magnetism ceases. This alarum is used for calling the attention of telegraph clerks. It requires a little attention to keep up the proper adjustment between the spring on the one hand, and the magnetic attraction on the other.

The telegraph originally adopted and still largely used by the French Administration, is somewhat akin to the alarum just described. It has a train of wheels, a scape-wheel with four teeth, and a pair of pallets. There is, however, no pendulum; but the pallets are connected with the armature of an electro-magnet, in such a manner that, for each attraction or repulsion of the armature, the scape-wheel is liberated half a tooth; for an attraction and a repulsion a whole tooth; so that four successive currents, producing of course four consecutive attractions and repulsions, produce a whole revolution of the scape-wheel. The axis of the latter projects through the dial of the instrument (*fig.* 810), and carries an arm *a* or *b* (*fig.* 811), which, following the motion of the wheel, is able to assume eight distinct positions. The apparatus is generally double, as shown in the figure; and the signals are made up of the various combinations of the eight positions of each of the two arms. The arm is half black, the other half white. The position of the black portion is read off; the white portion is merely a counterpoise. When only one half of the dial, or one index is in use, the combinations are shown by producing with the one index successively the positions of the two, whose combination makes the signal, always giving first the position of the left-hand index, then that of the right. The handles shown in front are the contact-makers; and are so constructed that the position of the arm on the dial coincides with the position given to the handle. *Fig.* 811 is a front view of the two arms; part of the dial is supposed to be removed, so as to expose the four-toothed-wheel already mentioned, and the pallets *x* and *y*; which, in their movement to and fro, allow of the semi-tooth advances of the wheel.

810



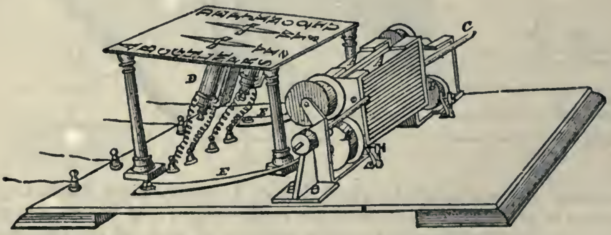
811



In these various applications of the electro-magnet, the armature has been of soft iron, and the only action of the electric-magnet has been to attract it. It has been withdrawn from the magnet after the electricity has ceased to circulate, either by its own gravity, by a counterpoise, or by a reacting spring. We now come to a telegraph that is well known and much used, Henley's magneto-electric telegraph, in which there is no reacting spring; and in which the movement or signal is produced by the joint action of attraction and repulsion; and the return to its normal state by the same joint action. Each pole of Henley's electro-magnet has a double instead of the single termination that we have been considering in all preceding cases. A piece of soft iron, like a crescent, is screwed upon each of the poles; the horns or cusps of the respective crescents are facing and near to each other; and a magnetised steel needle is balanced between them. This arrangement is somewhat like the following (|). So long as no current is circulating in the coils of the electro-magnet, the crescents are impassive soft iron, and no one point of either of them has more tendency than any other point to attract either end of the magnetised needle that is between them. But while a current is circulating, one of the crescents is endowed with north magnetic polarity, which is especially developed at its horns, and the other with south polarity. Suppose the horns of the right-hand crescent are north poles, those of the left south poles, and the top end of the needle is north. Four forces will conspire to move the needle to the left. Its top will be attracted by the left-hand crescent and repelled by the right; its bottom will be repelled by the left, and attracted by the right. When this current ceases to circulate, the simple attraction between the magnetised needle and the soft iron of the crescent tends to retain it in a deflected position. This tendency is increased by a little residual magnetism, that is apt to remain in the best iron, notwithstanding every care in its preparation. In order, therefore, to restore the needle to its normal position, a short quick current in the reverse direction is given. These instruments are single or double. Only one kind of deflection of the needle is available for actual signals; the other motion being merely the return to the normal state. The single-needle alphabet is composed of deflections of a short or a long duration; these are produced by holding on the current for an instant or for more than an instant; and the various combinations of short and long correspond to Morse's dot-and-dash system. The double-needle alphabet consists of combinations of the deflection of either or both needles.

Fig. 812 shows Henley's instrument; and, in completing the description of it, we have to describe another source of electric current to which no allusion has been hitherto made. The electricity here employed is obtained neither by friction nor by chemical action, but by means of magnetism *and* motion. If a piece of metal is moved in the presence of a magnet, or a magnet is moved in presence of a piece of metal, a current of electricity is generated in the metal. The results are multiplied when the metal is a coil of covered wire; so that we have here the converse of the electro-magnet; in the one case electricity had produced magnetism, in the other magnetism produces electricity; hence the name *magneto-electric* telegraph. We have here a powerful set of steel magnets A A, all the north ends pointing in one direction, and bound together with a plate of iron, and all the south ends similarly arranged in the other direction. Facing each end, but not quite in front when at rest, is an electro-magnet proper, B B, consisting of the U-shaped iron rod and the coil of covered wire, as described in *fig.* 807. Each electro-magnet is mounted upon an axis. C is a short lever or key; on depressing this the electro-magnet moves from its normal position in a region of lesser magnetic force, into a new position in the region of greatest magnetic force, and thus is the double condition, enunciated above, complied with; the copper-wire is moved in the presence of a magnet, and this under the most favourable conditions; and the U-iron, rising from a feeble to a strong magnet, its lines of magnetic force move in presence of the copper wire. Just as a current, *coming* from a long distance, had to be received in Morse's arrangement (*fig.* 808) in an electro-magnet of a long coil of fine wire, so as to be much multiplied in order to do its work, so here a magneto-electric current, that has to be *sent* to a long distance, must be

812

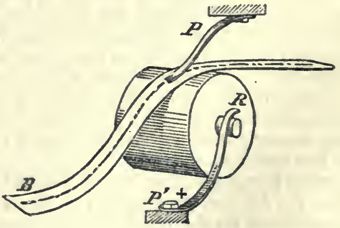


generated in a long coil of very fine wire in order to have electro-motive force sufficient to overcome the resistance opposed to it. In like manner the electro-magnets of the instrument D, in which it is received at the far-off station, have the same multiplying characteristics. The magneto-electric current exists only during the motion of the electro-magnet in front of the steel magnets, and this motion must be rather brisk, or the change of place is slow and the current feeble; but the current ceases with the motion. The needle, however, remains deflected from causes to which we have already referred, and if the hand is raised gently, so that the coils return slowly to their normal position, the needle will remain deflected; but, if the hand is so removed that the coils return quickly from the region of greatest to one of lesser magnetic force, a reverse current of lesser force than the original is generated, which releases the needle from its deflected position and restores it to its normal place, ready for making the next signal. In a recent form of this instrument Mr. Henley has obviated the necessity of moving the electro-magnets, still retaining the same fundamental principles. He uses a set of large U-shaped permanent magnets, and places the electro-magnet in the space between the branches of the permanent magnet, and so that the four poles of the two magnets, the permanent and the electro, shall be flush with each other or in the same plane. A couple of iron armatures are mounted on a disc in front of the magnets. The disc has a motion on a centre; the armatures are curved or crescent-shaped. Their form is so adjusted to the relative positions of the poles of the respective magnets that, in their normal or ordinary position, one crescent connects the N. pole of the magnet with one, say the *upper* pole of the electro-magnet, and the other crescent connects the S. pole of the permanent magnet with the *lower* pole of the electro-magnet. On pressing a key the disc moves, and the armatures so change in position that the N. pole of the magnet is connected with the *lower*, and the S. pole with the *upper* poles of the electro-magnet. By this arrangement the polarity of the electro-magnet is reversed at pleasure; and in its transition from being a magnet with poles in one direction, to becoming a magnet with poles in the reverse direction, an electric current is generated in the wire with which it is wound, and the direction of the current is this way or that according as the transition is from this direction of polarity to that. This form of magneto-electric machine allows of larger electro-magnetic coils being used, and gives the manipulator comparatively very little weight to move in signalling.

We have shown how an electric current generates magnetism, and how magnetism generates another electric current; it would follow logically that one electric current should therefore generate another electric current; for the magnetism produced by a current circulating in one wire, must have *all* the properties of magnetism, and among them, that of producing another current in another wire; and so it is. A few convolutions of a large-sized wire are coiled round an iron rod; and outside the larger wire is a very great length of finer wire. The current from the battery is called the *primary* current in this arrangement; and the moment it begins to circulate in the large wire, it magnetises the iron and generates a current, called *secondary*, in the fine wire, which is able to penetrate to a very great distance. When the primary current ceases, magnetisation ceases, the lines of magnetic force disappear, and a reverse secondary current is produced. This was the method proposed for obtaining the secondary current for traversing the Atlantic Ocean from Ireland to Newfoundland. The large wire is not necessarily first coiled on; in the coils for the Transatlantic telegraph it was coiled outside. Nor is the presence of iron essential to obtaining secondary currents.

It will have been noticed in all the arrangements which have hitherto been described, that the signals are produced by motions—that the electric current on reaching the far station is multiplied by being directed through many convolutions of wire, and is made to act upon either a piece of soft iron or a piece of magnetised steel, and to move them, the motion being turned to account directly, or by the intervention of mechanism. We have yet another property of electricity, that has been very successfully applied to the production of telegraphic signals by Mr. Bain, in his *electro-chemical* telegraph. If a current of electricity is led into a compound fluid body, say into water, by one wire and out of it by another wire, the body is decomposed into its constituent elements, one of which, the oxygen in the case in question, makes its appearance at one wire, and the other, the hydrogen, makes its appearance at the other wire. The same holds good with bodies of a more complex

813



character in solution in water. The compound selected by Mr. Bain is ferrocyanide of potassium. With a solution of this, he saturates a long ribbon of paper, similar to that employed in Morse's telegraph. He causes the paper B (*fig.* 813) to pass over a drum of brass R, between the metal of R and an iron point or stylus P. The electric current enters the apparatus by the point P, passes through the solution of ferrocyanide of potassium, with which the paper B is saturated, and out by the spring P′, which is in metallic contact with the drum R. Decomposition takes place, and the well-known ferrocyanide of iron (Prussian blue) is formed at the point of contact of the iron stylus P with the paper, the iron of the compound being supplied by the stylus itself. The paper is carried on by ordinary mechanism; and a dot-and-dash alphabet is formed, according to the duration of contacts at the sending station. There is a single-wire and a double-wire code; and the signals appear as deep blue marks upon the paper. Supplies of paper saturated with the solution are kept in reserve. This is unquestionably a telegraph of extreme simplicity. It has been employed with much success.

Mr. Whitehouse prepared for the Atlantic Telegraph a system in which motion and chemical action each play their part. The secondary currents that he employed were not able to produce the chemical decomposition that he requires for his signals. He therefore received them in a very sensitive relay, either an electro-magnet or a multiplier. The relay was a contact-maker, and connected the necessary number of local batteries with the printing apparatus, which consists of a ribbon of paper, saturated with a chemical solution and passing between a drum and a steel point.

We should exceed our limits were we to attempt the description of some of the many other forms that have been proposed. The above are good illustrations of the leading principles, and are all in successful use. Some telegraphs will print in ordinary characters; this result is only attained by much complexity, and its value is more than questionable, it being as easy to learn a new code as a new alphabet; telegraph clerks read their signals as readily as they read ordinary writing or printing, and they acquire their knowledge in a very short time. Hence probably it is that telegraphs to print in ordinary characters are but little known in real practice; nevertheless, some very promising instruments of the class have been produced by House, and especially one more recently by Hughes, both of the United States.

The following remarks on printing telegraphs have been handed to us, and we give them insertion as they appear to point to an improved system:—

'The needle and bell instruments, however, have hitherto transmitted messages with far greater rapidity than has been possible by the ink writer; but the advantage of a system which is self-recording recommends itself to all, inasmuch as, without some record, it is impossible to trace an error to its source, either at the sending or receiving station.

'The ink-writer now in use by the Telegraph Department of the Post Office, can only record the telegraphic signals by breaking a line formed longitudinally, on a band of paper, the operator, whether skilful or unskilful, breaking that line where he pleases into the requisite "dots" and "dashes." Thus, apart from the time occupied in writing or drawing the "dashes"—which, being formed of strokes three times the length of the strokes forming the "dots," require three times longer to draw them than the "dots"—a certain amount of skill is needed to work the instrument, and, of course, accuracy is not insured. Indeed, a short "dash" followed by a long "dot" may be read either as two dashes or two dots.

'Attempts to remedy this confusion have been made by Mr. Herring, who has endeavoured to unite the chief advantages of the Morse ink-writer, which was the favourite instrument of the Electric Company, with the speed of the bell-instrument, which was an equal favourite with the Magnetic Company; and, without necessitating any new method of sending or receiving messages, but simply by substituting for the double bell a printing instrument, he appears to have perfectly succeeded. Instead of wasting the currents upon merely fleeting appeals to the eye by needle, or to the ear by bell, or adopting an uncertain and tedious method of writing the signs in ink, he has contrived a telegraph printing instrument, whereby the signs may be instantaneously stamped in printing ink, on the paper, with their actual types, thus insuring positive correctness. This instrument which costs very little more than that now used by the Telegraph Office, has been described by Mr. Scudamore as 'much superior to the numerous methods which have been brought forward from time to time during the last twenty years,' and he adds, that it 'admits of the signs being produced faster and in less compass.

'The telegraphic instrument invented by Mr. Herring was so constructed as to produce the dot and the dash of the Morse code in such a manner that one could never be mistaken for the other. This was effected by the use of two distinct levers: an arrangement which also permitted the dash to be made vertical, instead of horizontal, and to be produced instantaneously, instead of by continued pressure, thus saving the time of the operator, and diminishing the length of the message slip.

'In this instrument the slip of paper, on which the message is received, is made to travel by clockwork in the ordinary way. It passes directly over a metallic disc, placed transversely to the course of the slip, revolving on an axis, and dipping into an ink well; over the paper is a lever, terminating in a broad style, placed vertically above the disc, so that the descent of the lever compresses the slip of paper between the disc and the style. This lever is double, in the sense that its central portion, carrying the central portion of the style, can be acted upon either independently of the lateral portions, or together with them. In the former case, only the narrow central portion of the style descends, and the slip of paper is pressed upon the inking disc at only a single point of contact, which produces a dot. In the latter case, the style descends as a whole, and, having a concave edge, it presses the paper into contact with the disc, by more or less of this edge, thus producing a vertical dash. There is an adjusting screw, by which the paper may be raised or lowered at pleasure, and by which means the contact-surface, and hence the boldness of the mark, may be increased or lessened at the pleasure of the operator. The pressure of the style stops for the moment the revolution of the inking disc, upon the immediate recommencement of which the ink supply depends. The inventor has, therefore, placed upon the axle of the disc a box containing a spiral spring, so arranged that, when the disc itself is checked, the power of the clockwork coils the spring. The moment the disc is released the coiled spring gives the necessary impulse to produce immediate revolution.

'The operator is furnished with two keys, one of which commands the central or dot portion of the lever, the other the lever as a whole. One, therefore produces the dot and the other the dash, and no mistake can occur between the two, except by the use of the wrong key. The printing is remarkably clear, distinct, and compact, and gives a legibility to the messages which no other modification of the Morse system has at present attained. The instrument is worked with a double current, like that used for the double bell, with the great advantage over the latter that the signals are printed and permanently recorded, instead of being fleeting impressions upon the ear of the recipient.'

The adoption of Mr. Herring's printing instrument would at once admit of the registration of telegrams, an advantage which is so much needed, but at present denied. By simply starting the instrument at the sending station, a perfect fac-simile might be retained of the message as recorded at the distant receiving station; and as the width of the telegraph paper slip is just half the diameter of the ordinary post-office letter-stamp, the two ends of the message slip laid side by side might be impressed with the town and date in the usual way, and thus the slip itself would become of legal importance. Not only would the address be registered, as in the case of a letter, but also the actual communication itself. A solicitor or a broker, sending a registered telegram, would virtually receive from the Department a certified copy of his letter; and this being handed to him in an envelope on which the key to the code was printed, which is extremely simple, he would at once be enabled to satisfy himself of its correctness, and to put it away as usual with his letters.

Another, and a very great advantage would be gained in adopting a similar course in case of pressure at any terminal station. The Telegraph Department only undertakes to transmit messages upon the understanding that it 'is not liable for losses incurred through the incorrect transmission, delay, or non-delivery of telegrams.' It is nevertheless urged by postal facilities to avoid delay in delivery, and, probably, nothing tends more to delay than doubts and errors in transmission, which, at, present necessitate repeating the message back again, thus consuming the time twice over, not only of the wire, but of the clerks at both stations; and delay once arising, especially if aggravated by a little extra business, causes hurry, confusion, and liability to an increase of error. At such a time, relief might be instantly afforded by delivering a few of the message slips with the printed key, and the business of the office would then proceed in the usual way, and with accustomed quietness, without any excuse for either error or delay.

In case of need, as, for instance, when required to telegraph in cipher for the Government, it would be possible, by Mr. Herring's invention, to make an addition to the ordinary signs 'dot and dash.' Two other signs, which might be sent by the same single wire, could be introduced by means of two extra levers and styles working over the same inking disc, and operated by a second battery, stronger than that used for the dot and dash. Thus, with four signs, any requisite number of combinations might be devised capable of insuring secrecy, certainty, and speed.

The following table has been drawn out as an illustration of the codes of some of the chief instruments that have been the subject of this article. It shows the number and nature of the signals (deflections, dots, dashes) for producing the name of the great discoverer of electro-magnetism, which is the foundation of electro-telegraphy.

The figures on the right show the number of marks or signs used in printing the same word in each kind of telegraph.

The *Rheo-electro-static* system of telegraphy was first described by M. Botto, in 1848. It is applicable to some, but not to all forms of telegraph. It has been applied on the South-Eastern Railway to the signal bells (*fig.* 814), for the purpose of reducing the amount of battery power required under other circumstances to be maintained. The wire, by which a pair of bells are connected, is in its normal state in permanent connection with the similar pole, say the positive, of batteries of equal power at the respective stations, so that two currents of equal power are opposed to and balanced against each other. Under these circumstances, the wire is in a null, or rheo-electrostatic state; neither current circulates. If the connection of one of the batteries is reversed, so that its negative pole is presented to the wire, then the currents of both batteries are in the same direction, and they circulate as one current, equal in value to the combined force of the two batteries. The application is obvious; that, whereas, under the ordinary system, a *whole* battery, of force sufficient to traverse the distance and do effective work, must be at each station, under this system only *half* such battery is necessary at each station for producing the same effective work. Also, if a little more battery power is placed at each station than is necessary for the actual work required, signals of higher power are obtained under common circumstances; and also the equilibrium of the two opposed currents may be disturbed at any place between the two stations, and signals may be made by merely making a connection between the line-wire and the earth; because the negative pole at each station is fitted up in permanent connection with the earth; and, as the positive poles are in like connection with the line-wire, each battery current is made to circulate through its own signal-bell every time the earth and line-wire are placed in connection. By this means the guard of a train can make signals of distress to the nearest station without the aid of portable apparatus. Considerable care is required to obtain good communication with the earth on the open railway for making distress signals, or otherwise the discharge is imperfect, and no signal is made. Fish-jointed rails are very valuable for this purpose; in their absence, especially at embankments, metal must be buried for the purpose at intervals in the moist earth, and a wire attached for use. Contact springs on the telegraph poles are proposed.

Telegraph wires are suspended to poles by insulators of earthenware, glass, or porcelain; the material and shape varying according to the experience of the engineer and the length of line to be insulated. In very short lengths, the battery power required for overcoming the resistance is not great; it will therefore not overcome the resistance of an insulator of moderate quality, and escape to the pole and thence to the earth; but the battery power required to overcome the resistance of very great lengths of wire is equally able to overcome the resistances presented by inferior insulators, and to escape in considerable quantities at every pole; so that the force which reaches the far station would not be equal to its work. It is for these long lines that the greatest ingenuity has been expended in constructing insulators. Fine porcelain is most in favour from its presenting a very smooth surface, and being less hygrometric than glass; and it is distorted into most mysterious-looking shapes in order to present as great a distance, and one as much sheltered as possible, between the part with which the line-wire is in contact, and the part that is in contact with the pole.

814

Telegraph signals pass with far less rapidity through buried and through submarine wires than along the ancient aërial wires. The slow travellings mentioned above were through wires of this kind. We must refer to treatises on Electricity for full details of the conditions presented by a telegraph cable. In practice it is found that on first sending a signal into a submerged wire, the electricity is delayed on its road, in order to produce a certain electrical condition upon the surface of the gutta-percha that is in immediate contact with the conducting wire. Nor is this all; before a second distinctive signal can be sent, it is necessary that the condition produced by the first signal shall be destroyed; and this is an operation requiring even more time than was consumed in the mere act of producing it. These two classes of retardation, especially the latter, were largely manifested in the Atlantic cable; and have called forth all the ingenuity of electricians in order to mitigate or to modify them.—C.V.W.

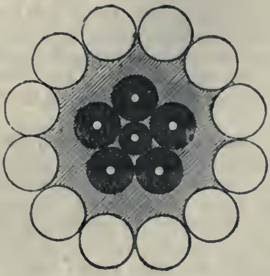
815

Fig. 814 represents the cable that has been lying in the British Channel between Dover and Calais, since September 1851. It contains four No. 16 copper-wires, each wire being doubly covered with gutta-percha. The four wires are then twisted into a rope; and the rope is thickly covered, first with hempen yarn, tarred, and finally with a jacket of ten No. 1 iron-wires. The cable is shown in perspective and in section. *Fig.* 815 shows the perspective and section of the Irish, a single-wire cable. It consists of a single central conductor, of one No. 16 copper-wire, doubly covered with gutta-percha, then with hempen yarn as before; and finally with a protecting jacket of ten No. 8 iron-wires. The Calais cable weighs 7 tons per mile; the Irish 2 tons per mile.

The first practical experiment with deep-sea telegraphs appears to have been made by Mr. Brett in 1850. This was a gutta-percha covered copper-wire sunk between Dover and Calais, which failed on the first day. In 1851, a cable consisting of four covered copper-wires was sunk across the Channel, which is still working. In 1853, Messrs. Newall made a line seventy miles long between Dover and Ostend. In this cable the conducting wires were increased to six.

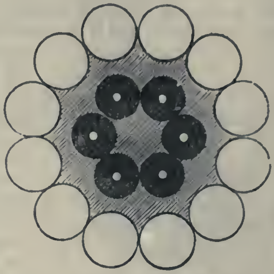
The Dover and Ostend cable was laid on May 6, 1853. This cable (*fig.* 816) is 70 miles long; it is composed of six copper-wires, insulated by a coating of gutta-percha, which are essentially the electrical cable, and these are secured by an armour of twelve iron-wires. The whole rope was capable of sustaining a strain of about 50 tons; it weighed 7 tons per mile, making a total weight of nearly 500 tons. It was made by Newall and Co., in 100 days, its cost being 33,000*l*. It required 70 hours to coil it into the ship, and it was submerged in the sea, from Dover to Ostend, in 18 hours. The arrangement of the inner wires did not prove entirely satisfactory.

816



Cable from Dover to Ostend
(1853. Length 70 miles),
and Zuyder Zee, 5 miles.

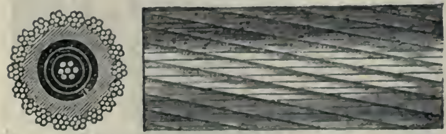
817



From Port Patrick to Donaghadee
(1853. Length 25 miles),
and Spezzia to Corsica, 110 miles.

After the success in sinking the Dover and Ostend cable, Messrs. Newall and Co. commenced laying a cable from Donaghadee, in Ireland, to Port Patrick, in Scotland, across the Irish Channel. This cable was of the same weight and size as *fig.* 816, but the conducting wires were differently arranged, as seen in *fig.* 817. The drawings given are of the natural size. This cable was made in twenty-four days, and at a cost of 13,000*l*. The Mediterranean cable is of the same construction as that across the Irish Channel, and was laid in 1854. This line runs from Spezzia to the Island of Corsica. Over this there is a land-line extending to the Straits of Bonifacio, where a short submarine line of 7 miles runs to the Island of Sardinia. Across this island there is a line 203 miles long, terminating at Cape Spartivento. The telegraphic communication between the Island of Sardinia and Africa seems to have been surrounded with great difficulties. Two attempts were unsuccessful; but the third proved, by its success, that perseverance accompanied by judgment usually attains the end desired. This cable, also made by Messrs. Newall, was composed of 4 sets of conducting wires, and these, in the deep-sea portion, were protected by 18 iron-wires, while the shore-end was surrounded by 12 much stouter wires. The shore-cable was 6 miles in length. The distance between Cape Spartivento in Sardinia, and Bona on the African coast, is 125 miles. Messrs. Newall and Co. also made the cable which unites Malta and Corfu with Sardinia. The electrical cord in this cable is composed of 7 small wires twisted together and insulated by a thick layer of gutta-percha. The deep-sea portion is protected by 18 small iron-wires; while the shore-end is covered by an armour of 10 stout iron-wires, and which is consequently much heavier than the deep-sea cable. The weight of the deep-sea section of this cable is 1,960 lbs. per mile, and its total cost was 125,000*l*. These may be regarded as typical examples of nearly all the submarine electrical cables which have been laid.

818



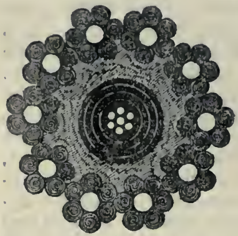
The Atlantic Cable, 1858. Length 1670 miles.

It becomes necessary to give a little more in detail the description of the Atlantic cable of 1858 (*fig.* 818). The electrical conductor was a copper strand, consisting of 7 wires—6 laid round 1, forming in fact, as far as electricity is concerned, only 1 wire. This weighed 107 lbs. per nautical mile of 2,028 yards. It was carefully insulated with gutta-percha, laid on in 3 coatings, and weighing 261 lbs. per nautical mile. Eighteen strands of charcoal iron-wire—each strand composed of 7 wires, 6 laid round 1—laid spirally round the core. This was, however, previously padded with a serving of hemp, saturated with a mixture of Stockholm tar. The weight of this cable in air was 20 cwts. per nautical mile, while in water it was only 13·4 cwts. This made it equal to 4·85 times its weight in water; or capable of bearing its own weight in a little less than 5 miles deep of that fluid. Its breaking strain was estimated to be 3 tons 5 cwts. This enterprise failed from causes which were foretold. Before the cable left this country it was imperfect; it had been carelessly kept, and greatly injured by the cutting-out of pieces while in Keyham yard, so that its power of carrying an electrical current was reduced to a minimum.

The unfortunate failure of this enterprise—in which both Europe and America were equally interested—led to considerable discussion, and to a careful examination of all the conditions which were supposed to influence such electric cords. All the laws regulating the flow of an electrical wave were re-examined by some of our best electricians, and many previous conclusions received some correction. It had been supposed that an insulated submarine wire conducts according to a different law from that of a suspended circuit. This difference was thought to depend upon a system of induced earth currents influencing the submerged wire, which would not influence a wire when suspended in the air. A simple example to render this clear to the non-scientific reader may be necessary. If a wire insulated by means of gutta-percha, or any other non-conducting substance, is connected, so as to complete the circuit, with the two ends of a voltaic battery, a current is said to flow through it. This means that an electrical wave of motion is propagated along it in a given direction. If another copper-wire is placed near it—though not in contact with either it or the battery—another current, or wave, is generated, that is, *induced*, in it. This induced current interferes, to a greater or less extent, with the primary current; and where great lengths of cable are concerned it becomes an element of serious consideration. If a coated wire is placed on the earth, and an electrical current is established in it, the earth acts the part of the second wire, and induction is developed on its surface. Mr. S. A. Varley has examined this problem with much care, and has arrived at the following conclusions. In a suspended wire the insulatory medium of the air takes the place of the gutta-percha of the submarine circuit. The earth, which is the nearest conductor, is a considerable distance off, and is only on one side of the wire; therefore, but little induction can take place between the wire and the earth. Nevertheless, induction to a certain extent does take place, and it can be detected with delicate apparatus in circuits of very moderate lengths. If the distance between the wire and the earth is decreased, induction will be developed more strongly, and the wire could be brought down step by step, until the condition of a submarine circuit would be approached, where the earth surrounds the wire on all sides, and is only separated from it by the thickness of one-eighth or three-sixteenths of an inch of gutta-percha, a substance possessing, moreover, specifically a much greater inductive capacity than air. It, therefore, appears that the conditions are precisely the same, only differing in degree. It is, nevertheless, evident from this, that a submarine wire is placed under circumstances of greater difficulty than those which surround an aërial wire. This difficulty increases with the length of the wire, retardation becoming more and more powerful as the distance through which the wave has to move is extended. A submarine cable may be regarded as a Leyden jar, and the telegraphic indications are analogous to the discharges of a coated glass. An impulse is given by making a connection with a voltaic battery at one end of a wire suspended in air—and it indicates telegraphically by producing magnetic disturbance at the other—and a succession of impulses will rapidly give a succession of indications. Now, in an insulated submarine wire this is not exactly what takes place. A distinction has to be drawn between the simple arrival of a current—which may be regarded as instantaneous—and the production of a telegraphic signal. After having charged the wires sufficiently to develope an appreciable current, owing to the wire taking some time to empty itself, if currents are sent in succession with any rapidity, they will blend into one another, and, instead of getting a series of distinct impulses at the further extremity, a continuous undulating wave will be obtained. This sluggishness has been obviated, to a great extent, in circuits of moderate length, by employing opposite currents of electricity in succession. The effect of this is to absorb the preceding wave, and to neutralise it much more quickly than would be the case if the wire were left to discharge itself in the usual way. In a suspended wire, as there is but little induction, there can be no accumulation of static charge worth noticing; whereas a submarine wire, unless attention be paid to this, becomes useless for telegraphy.

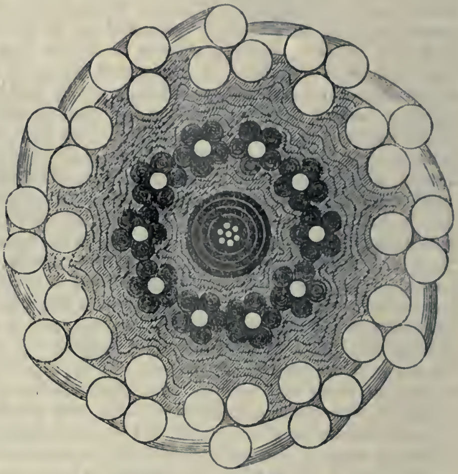
The electric conductor of the Atlantic cable is formed of 7 wires, 6 around 1 (*fig.* 819). Seven wires are used rather than 1 to give greater freedom to the electricity in passing by presenting a more extensive surface to it. There are mechanical reasons also why a band of wires is preferable to one wire. The most serious accident that can happen to a submerged wire is its severance. Copper-wire cannot always be depended upon to present the same amount of strength in every part. It frequently happens that an inch, or even a less portion of a wire, is crystalline, and therefore liable to break in being coiled. By using 7 sections instead of 1, the probability of a fatal breach of continuity is greatly reduced. It is scarcely to be expected that 7 weak places would occur at the same spot, and, if a single wire were broken, it would not interfere, to any sensible degree, with the passage of the current. In constructing the Atlantic cable, however, the utmost care prevailed in every department. Every portion of the copper-wire was submitted to exact examination, and no wire was used which possessed a lower conducting power than 85 per cent. of that of pure copper. The insulation of this conductor was thus effected. The centre wire of the copper strand was first covered with 'Chatterton's compound' (that is, gutta-percha rendered viscid with Stockholm tar). This first coating was so thick that, when the other six wires forming the strand were laid spirally around it, every interstice became filled and air excluded. The mechanical solidity of the core thus formed was very great, This cable is nearly 3 times as heavy as the old Atlantic conductor, its weight being 300 lbs. to the nautical mile against 107 lbs. The complete exclusion of air, which is a most important object, is believed to be effected by this arrangement. The conductors of some cables have suffered from their being to some extent loose with their insulating covering. The core being thus formed, next received another coating of Chatterton's compound, which quickly solidified, and thus thoroughly protected the whole. It was then surrounded with a coating of the purest gutta-percha, which was pressed round it in a plastic state, by means of a very accurate die, and sheathed the core in a continuous tube. Over this was again laid another coating of Chatterton's compound, for the purpose of effectually closing up any pores or flaws which may have escaped detection in the gutta-percha tube. To this covering succeeds a second tube of gutta-percha, then another coating of Chatterton's compound, and so on alternately until the wire was covered with 4 coatings of gutta-percha and 4 of the compound. This being completed, it weighs 400 lbs. to the nautical mile. It is well known that the insulating power of gutta-percha sensibly decreases by heat. The whole of the conductor was immersed in water of a temperature of 75° Fahr., in which it remained for 24 hours, and during that time it was constantly submitted to electrical tests. The core, after having been subjected to this and other tests to prove the perfect character of its insulation, was then submitted to the process of being protected by its iron-wire armour.

819



Section of the Atlantic Cable, 1865.

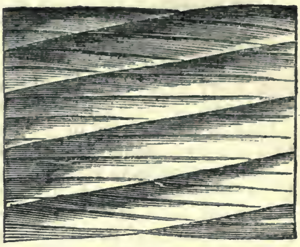
820



The Atlantic Cable—Shore-End, 1865.

Jute, which had been submitted to the action of catechu, in order to preserve it from decay, was very carefully wrapped round the core, and as fast as the wrapping proceeded, it was coiled in water. If the water at any time penetrated to the wire, it would at once conduct away the electric current to the earth, and the loss of insulation would be at once detected. This wrapping of jute is surrounded by 10 wires manufactured from homogeneous iron; each separate wire being itself, in the first instance, covered with tarred Manilla yarn, by which the iron was protected, and the specific gravity of the mass lessened. By a very ingenious arrangement, which our space will not allow us to describe, the 10 wires covered with the tarred Manilla hemp are spirally wound round the core, and the deep-sea cable is completed. The section and side-view of the electric cable will be fully understood by reference to *figs.* 819 and 821. As the-shore end of any cable is more exposed to the action of the waves than those parts are which remain in a state of rest at the bottom of the deep sea, it becomes necessary to give this portion a greatly-increased degree of protection. *Fig.* 820, which is of the exact size of the shore-end of the Atlantic cable, will fully illustrate the conditions of this portion. The core was formed by the main cable, which was wrapped with a serving of yarn to a size sufficient to receive round it 12 strands of iron wire, each strand being composed of 3 galvanised iron-wires, each of which being nearly a quarter of an inch in diameter; the weight of the completed shore-end was nearly 20 tons to the mile. Its diameter is 2½ inches, but at its junction with the main cable it is made to taper down to the size of the latter by a gradual diminution in diameter extending over 500 yards. This shore-end was laid out for about 28 miles from the coast of Valentia Island, when it reached water of the depth of 100 fathoms. From Hope's Content, Newfoundland, about 8 miles of shore-cable only would have been required.

821



Side view of the Atlantic Cable.

The weight of the deep-sea cable—according to the Company's statement—in air was 35 cwts. 3 qrs. per nautical mile of 2,028 yards. Its weight in water, 14 cwts. to each nautical mile, or equal to 11 times its weight in water per knot; that is to say, it will bear its own weight in 11 miles deep of water. Its breaking strain was 7 tons 15 cwts. The length of cable shipped was 2,300 nautical miles; the actual distance from the point of departure, Valentia, on the West of Ireland, to the point Heart's Content, in Trinity Bay, Newfoundland, on which it was to have been landed, being 1,670 nautical miles.

As every one knows, this great experiment failed, the cable breaking when the Great Eastern had reached the mid-Atlantic. Another experiment was made in 1866, and the result has proved in the highest degree satisfactory. Not only has the new cable been securely lowered to its ocean-bed in the depths of the Atlantic, but the old cable has been recovered and repaired, and we have now several electrical nerves uniting the new with the old continents. These electric cables have now been for some time in constant use, and their powers of transmitting electric currents appear to improve.

It is not necessary in this place to notice the various electrical cables which now girdle the earth. There are a few points, however, which are of sufficient interest to find a place in these volumes. The condition of the cable in the ship is one of these. For the following remarks we are indebted to Mr. Robert Sabine's excellent work on 'Electro-Telegraphy':—

'At present, all cables of any importance are sent to sea in water-tanks on board the transport ships. The tanks are circular, with as large a diameter and as high as the room of the ship will allow between the bottom of the tank and the deck; they are made of plates of iron, riveted together, caulked, and painted with red lead to prevent rusting. There are usually two such tanks, the forehold and afterhold, on board a cable ship. In the centre of each tank a hollow cone of iron is erected, and above this a series of rings of 2-inch round iron, which are lowered in the tank as the cable is paid out, are suspended for guiding the cable as it leaves the tanks, and preventing it flying out by centrifugal force, and going into kinks. On leaving the tanks, the cable passes through the rings in the circular space between them and the top of the cone, which it rubs against continually. The friction which the cable exerts against the sides and bottom of the trough assists the breaks in preventing its too rapid egress from the ship.

'No good electrical measurements are possible during the passage out on account of the motion of the ship, and the difficulty of keeping the apparatus dry; the measurements which are made are only of value qualitatively and approximately in the event of a fault occurring. The electrical conditions of the cable are, however, always kept under surveillance.

'Messrs. Siemens have constructed a galvanometer purposely for use on board ship. It consists of an astatic system of magnetic needles on a vertical bar, moving in stone pivots, and surmounted by an aluminium pointer. Each needle turns in the centre of an independent coil of wire. Above the glass cover of the dial-plate is a tall rod of brass carrying a horizontal adjusting magnet, which, in different positions and at different distances from the magnet system, increases or diminishes its directive force, and with this the sensibility of the instrument.

'Professor Thompson has succeeded in eliminating the directive force of the earth's magnetism entirely from his marine galvanometer by surrounding it with a heavy armour of soft iron, which gives it the advantage of retaining its constant of sensibility and zero point in whatever position the ship's head may be put; he also keeps his mirror magnet steady by suspending it to a tightly-drawn cocoon fibre.

'The measuring apparatus on board does not materially differ from that used on shore, only, where it is possible, it is made simpler. On the sea everything is damp, and with a dampness caused by the particles of salt water carried by the wind; these particles of water are conductors, and provide a short circuit for the current to earth from every corner of the apparatus. Therefore, the fewer the pieces used, the fewer the chances are that the "subtle fluid" departs from the way it should go.

'Before commencing to pay out a cable, and while the ship is quiet in harbour, careful measurements are made of its insulation, copper resistance, and temperature.

'In commencing to pay-out a cable, one end of the shore-cable is put upon the land and carried into the station. The ship pays this out to the end, when it is joined to the middle-cable, or to the deep-sea-cable if no middle-cable is employed. At this point, the officer of the ship takes the bearings carefully in his nautical way, and the telegraph engineer takes his bearings in a less scientific and much simpler way. These consist in rough sketches of marked points on the coast. The line which a church makes with a hill, or two hills together, or an inlet with a hill behind should be carefully noted. There are very few coasts which do not present such inequalities as to enable the engineer to find lines between distant objects. Of these lines two at least should be noted, if possible making an angle of 90° with each other; and the objects noticed on the land should be, one as near to the water and the other as far from it as the nature of the coast permits. In the long run, this method is the most valuable, and enables the engineer to return at any time to the exact locality of the point, in case he may want to pick it up.

'From this point begins the most difficult and risky part of submarine telegraphy. The manufacture requires a constant supervision and care; it has, however, the advantages of terra-firma, and any accident may be repaired, because the essential element —time, is to be had; but the laying demands untiring courage and caution, and that, because when once under way, there is no stopping without danger to the cable, notwithstanding the innumerable casualties which invariably attend a sea voyage.'

In his new book on telegraphy ('Traité sur le Télégraphie') M. du Moncet says that in order to lay a cable successfully the speed of the ship should be precisely that of the outlying cable. Unfortunately for the telegraph engineer, this physicist's ideas of the sea bottom do not correspond with the reality. Instead of being level like a street, it is found that as great irregularities occur in the earth under the water, as in the earth above it. The sea has its mountains, its valleys, its precipices, as well as the dry land, and over these mountains, and across these valleys, and up and down these precipices, the cable must be laid, and not hung from peak to peak like a tight rope. It must everywhere rest upon the bottom; if not, it must sooner or later break by its own weight between the points of suspension, or abrade against the rocks until it is cut through.'

The following conclusions appear to have been arrived at by those connected with the working of the Atlantic electric cable: 1st, That an insulated submarine wire conducts according to a different law to that of a circuit suspended in air; 2nd, That the rate at which a voltaic signal travels along a wire is not affected by the intensity of the battery; and 3rd, that magneto-electric induced currents have the property of travelling much faster than voltaic ones, and increase in the rapidity of travelling, when their intensity is increased. Mr. Samuel Alfred Varley, in a paper read before the Institution of Civil Engineers, makes the following remarks on these points:—

'In examining these conclusions, it has first to be considered whether the conditions of a submarine circuit and of a suspended one are different. In a suspended wire, the insulating medium of the air takes the place of the gutta-percha of the submarine circuit. The earth, which is the nearest conductor, is a considerable distance off, and is only on one side of the wire; therefore, but little induction can take place between the wire and the earth. Nevertheless, induction to a certain extent does take place, and can be perceived in circuits of very moderate length. The author has noticed indications of it in a circuit 60 miles long, and he feels confident that, with delicate apparatus, it could be perceived in much shorter circuits. If the distance between the wire and the earth is decreased, induction will be developed more strongly, and the wire could be brought down, step by step, until the condition of a submarine circuit would be approached, where the earth surrounds the wire on all sides, and is only separated from it by the thickness of $\frac{1}{8}$th or $\frac{3}{16}$ths of an inch of gutta-percha, a substance possessing, moreover, specifically a much greater inductive capacity than air. It therefore appears that the conditions are precisely the same, only differing in degree.

'In a Leyden jar, the inner and outer coatings are perfectly insulated one from the other. If they were not insulated, there could be no statical charge, as is well understood by all electricians. Induction, therefore, involves insulation. But in a submarine circuit this is not the case. If the wire was disconnected at the further extremity from the telegraph instrument, and was sealed up with gutta-percha, the conditions would be nearly the same. In practice, however, it is quite open through the instrument to the earth, and the resistance opposed by the very long length of wire is the only insulation between the inner and outer coatings; for it unites both, being in connection with the earth at both ends. It is, therefore, evident that, if the wire offers no resistance, there will be no insulation, and, as a consequence, no induction to retard the passage of the current. It is also equally plain, that precisely in proportion to the resistance which the wire opposes, provided always the insulating medium is of the same thickness, will induction manifest itself, and retardation be experienced. There is also another difference between a Leyden jar and a submarine circuit. The Leyden jar is charged uniformly all over, whilst in a submarine wire, the tension of the charge varies in different portions of the circuit, being at its maximum at the end where contact with the battery is made, and gradually vanishing to nothing at the further extremity.

'The fact has already been adverted to, that if a battery capable of developing, when in short circuit, a much greater quantity of electricity than it does when connected through a fine wire, is connected through a long wire of small dimensions, the quantity evolved through one length of this fine wire will be twice the amount of that evolved through double the length. From this it appears that double the length of wire opposes the same resistance to a given quantity of electricity, as a wire of half this length does to double that quantity of electricity. Hence, any length of wire opposes an infinitely small amount of resistance to an infinitely small quantity of electricity. An idea seems to prevail, that if the wire becomes attenuated at any one spot, the conducting power of the whole circuit will be brought down to that of a wire of no greater thickness than it is at the attenuated portion. It will be at once seen, from what has just been said, that this cannot be the case, but that the effect will be precisely the same as increasing the length of the circuit. For if the circuit is attenuated, say throughout a mile of its length, to half its normal diameter, it will possess, in this space, only one-fourth of the sectional area; consequently, it will oppose 4 times as much resistance as a mile of wire of its original size. In other words, this mile will oppose as much resistance as 4 miles of any other portion of the circuit. If the resistance offered by 1 mile of the circuit, is put down as 1, then the resistance opposed by the attenuated mile would be 4; and if the normal resistance, or 1, is subtracted from this, there will remain 3, as the excess of resistance over what it should be, owing to this attenuation. The effect will therefore be the same, as increasing the length of the circuit by 3 miles. It seems surprising that this should have escaped observation, for if true the conducting power of the whole circuit would be brought down to that of a wire of no greater diameter than that made use of in the coils of the instruments, which may be considered simply as a continuation of the cable, and is only about one-eightieth of an inch in diameter. Electricity flowing through a long circuit which is attenuated at one portion, may be compared to water flowing through a long tube of small dimensions, and therefore opposing a great amount of friction to the passage of the water. If the tube is indented at any one part, it will decrease the flow to a certain extent, but not nearly so much as if the bore of the pipe was reduced throughout its length to the same size as it is where indented.

'Incidentally connected with, and following as a natural sequence to what has just been said, is the bearing and the value of the resistance opposed by the coils of the telegraph instrument. If an electro-magnet is enveloped with a single convolution of wire, and a battery is connected with it, there will be little resistance to the free passage of the electricity, as owing to the short length of wire, but very little magnetism will be developed. Under such conditions, with a great expenditure of battery power, a very small equivalent of magnetic force will be obtained. If the number of convolutions be increased until the resistance opposed by the greater length of wire begins sensibly to reduce the dynamic quantity flowing, the magnetic force will then be found to be increased proportionately to the number of convolutions, less certain other considerations, which need not now be entered upon, and with actually less expenditure of battery power. Resistance encountered and overcome, under these conditions, implies so much work done; and the larger the proportion of it in the instruments, relatively to that opposed by the cable, the more economically will the electricity be expended. If the cable is supposed to offer 10 times the resistance of that opposed by the coils of the telegraph instrument, which is nearly the case in some printing circuits of 200 miles in length, the whole of the cable, as well as the coils, will be rendered magnetic. Ten-elevenths of the magnetism will be developed in the cable itself, where it will be useless, and one-eleventh only in the coils of the apparatus, where it will be available as a motive force. But, if the coil-wires are increased in length, so as to oppose a resistance equal to 40 miles of the cable, an amount of magnetism equal to one-fifth of that developed in the cable, instead of one-tenth, as in the former instance, will now be developed in the telegraph instrument, if the same quantity of electricity as in the former case is forced through. Hence, the reason is apparent, why such fine wire, and so great a length of it, is found to answer best for the coils of telegraphic apparatus. In practice, there is of course a limit, to which the coil-wire may be increased in length, or be diminished in sectional area, with advantage.

'These are not new facts, for the bearing of the resistance in the coils, to that opposed by the cable itself, is pretty well understood and appreciated by many electricians; but it is believed that attention has not been publicly directed to it before. The remarks which are constantly made show that it is not so well comprehended as it should be. When it was urged upon the projectors of the Atlantic cable that attenuation at any one portion of the cable would seriously decrease the conducting power of the whole throughout, it was put to the test of a practical experiment. Finding it did not perceptibly affect the working, it was accounted for, not from the reasons here given, but from its being at the attenuated portion, a Leyden arrangement of smaller dimensions. This shows that the idea, that reduction at one spot is tantamount to reduction throughout, is entertained by some, whose practical experience deservedly gives weight to their opinions. In the work before alluded to it is said, "The fact is, that this fear of the conducting wire of the cable being telegraphically disabled by attenuation, is based upon the notion that the insulated strand is to act as a *simple conductor*, and not as an *inductively charged Leyden jar*. It may be, and probably is true, that a simple conductor transmits an electrical current with a facility which is in a measure proportioned to its capacity at the smallest part of its length; the entire conductor being virtually reduced in its dimensions to the standard of this smallest part. But it is not true that the transmitting power of an insulated submarine wire, which is virtually a Leyden jar, and open to inductive charges, is modified, from the same cause, to anything like the same extent. Here the induction, which has taken a mischievous part in producing retardation of electrical movement in coated wires, turns round and makes amends for its interference, by causing small and easily-laid wires to be more manageable for submarine telegraphy than large ones could be."

'The next point for consideration is, what will be the action of a galvanic battery when connected to send a current on a long submarine circuit? The wire and the earth being only separated by the thin layer of gutta-percha, induction can readily take place between them; whilst the wire itself opposes a very great resistance to the flowing of the large quantity of fluid which the battery can generate, and wants to force through. As the wire offers but little resistance to a small quantity of electricity, a small amount will travel through almost instantly, the wire being statically charged at the same time; and as the wire becomes more and more highly charged, so will the stream flow out, in larger and larger quantities, at the further extremity.

'It has been already shown that induction manifests itself in proportion to the resistance offered by the wire, other circumstances being the same, and that a wire offers comparatively speaking, no resistance to very small amounts of electricity. This, at first sight, might lead to the idea, that if very sensitive instruments could be employed, supposing the wire to be perfectly insulated, as the induction would be less, the signals would be passed through more quickly, or, in other words, that increasing the delicacy of the instrument would be the same thing as magnifying the wire. A little reflection will, however, show the fallacy of such a supposition, for in proportion as the wire opposes less resistance, so will the tension of the current be lowered, and therefore it will possess a proportionately smaller amount of energy to urge forward the current. If the diameter of the cable is increased to double the size, it will then possess four times the sectional area, and consequently have four times the conducting power of a wire of half this diameter. But the outside surface, on which induction depends, will, at the same time, be doubled, and hence there will be twice the inductive force. Nevertheless, there will be a gain; for if, in the original wire, the resistance was one, and the induction one also, in the wire of twice the diameter, although the inductive force would be two, the resistance of the wire would be brought down to one fourth, the relative balance of the forces being reduced one half. Therefore, there would be a proportionate gain in favour of rapidity of conduction, and as doubling the diameter of the wire has reduced the retarding induction, one-half signals might be expected in this case to travel twice as fast. Supposing four cables to be ranged side by side, it is evident they will oppose one-fourth less resistance than one would do; and, consequently, the same tension of current would force four times the dynamic quantity of electricity through as would be forced through one alone. Signals would not, however, be passed more quickly through the four cables than through one cable, for, although the resistance has been reduced to one-fourth, the induction has been quadrupled at the same time, which will exactly counterbalance the smaller resistance. If the cables are merged into one, the case will then be altered, for the surface will at once be brought down to one-half, and therefore there will only be half the amount of induction to retard the rapidity of signalling, whilst the conducting power will remain the same as it was before. As the outer surface of the gutta-percha does not increase so rapidly as its substance, there will be a gain on that head, for if the conductor is $\frac{1}{10}$th of an inch in diameter, and it is coated to the depth of $\frac{1}{10}$th of an inch with gutta-percha, making a total diameter of $\frac{3}{10}$ths of an inch, the united exterior surface of four such cables would be 3·6 square inches, but if the four conductors are merged into one, the exterior surface will be 1·2 square inch, or less than half the exterior surface of the four cables, in the proportion of 4 to 6.

'The next question which has to be considered is whether the rate of transmission of signals is affected by increasing the number of cells, when a voltaic battery is employed. The author is of opinion that this would be the case. It has already been explained how the wave of electricity rises and falls on connecting and disconnecting a battery from a submarine circuit. The effect of a higher intensity would be to raise the wave to its maximum height more quickly, and as the arrival of the current takes place at the instant when the wave has risen sufficiently high at the further extremity to record itself on the instrument, and not at the time it actually begins to flow, this height would be attained more quickly, and signals also would be obtained sooner. An experiment made by the Atlantic Telegraph Company seems inadvertently to prove the truth of this reasoning. A Lilliputian battery of seven cells, reduced to the smallest dimensions, having been connected to a cable 600 miles long, the signals occupied $\frac{9}{10}$ths of a second in arriving. This battery was then disconnected, and another joined up in its place, but of twelve cells, and with a much larger extent of surface in each cell, when signals arrived in $\frac{44}{100}$ths of a second. This great difference of speed is almost in regular proportion to the number of cells employed. Had the signals, in the case of the battery of seven cells, occupied $\frac{7}{10}$ths, instead of $\frac{9}{10}$ths of a second in arriving, the speed would have been exactly in proportion to the number of cells, one cell taking $\frac{49}{10}$ths, seven cells occupying $\frac{7}{10}$ths, and twelve cells a little more than $\frac{4}{10}$ths of a second in arriving. When it is remembered that no two cells of batteries differently constructed will have precisely the same intensity, even supposing these minute differences of time were quite accurately recorded, there would still be reasons sufficient to account for the irregularity. It should be mentioned that this experiment is stated to be given in order to show that increasing the battery surface alone, affects the rate of transmission. No explanation of how it does this is attempted, and the difference in the intensity of the two batteries seems to have been overlooked as a matter of no importance. The author believes the increase of rate to have been chiefly due to the larger number of cells employed in the second part of the experiment, and not so much to the increased surface. He has already explained the conditions under which an increased battery-surface would raise the tension of the current, and so increase the rapidity of signalling. In this experiment the tension of the currents used was so low, and the resistance opposed by the 600 miles of wire so great, that it is probable a very much smaller dynamic quantity was generated through the whole length of the wire than even the Lilliputian battery would generate through a circuit of nominally no resistance. If this was the case, increasing the battery surface only, without adding to the series, would have but little effect in increasing the quantity flowing. The experiment, therefore, as a trial of the effect of large battery-surface alone, cannot be considered a fair one. Attention has been drawn to it here, as it may help to throw some light upon the matter under consideration.'

The following note of a gold-leaf electrometer, and the introduction of an induction coil, promises to give increased sensibility. It is the invention of Mr. Highton, who introduces an induction coil, the especial object of which is to multiply the current at the receiving end of a telegraphic line. This recording instrument is also a novelty, and consists of a strip of gold-leaf, about an inch and a half in length, and weighing $\frac{3}{1000}$th parts of a grain, suspended between the two poles of an electrometer. Near the leaf is a magnet which causes the leaf to be deflected, either to the right hand or to the left, according as a positive or negative current is brought into action. The vibrations of the leaf are magnified by an ordinary magic-lantern arrangement, and are thrown on a screen, from which they are read off by the operator.

ELECTRO-TINT. The art of preparing tinted plates by the action of electricity on copper. One process consists in putting a perfectly clean copper plate into a solution of acetate of lead, and making it one of the terminal poles of a voltaic battery, the other pole being a piece of pure lead dipping into the solution. Tints of the most exquisite character and colour can, by a little careful manipulation, be thus produced.

ELECTROTYPE. See Electro-Metallurgy.

ELECTRUM, or **ELECTRON.** Amber was so called by the Greeks, and from it we derive our word 'electricity.' The Romans used the term at first, for a compound of gold and silver, which was of the colour of amber; subsequently it was applied to a definite mixture of gold and silver, used for coins.

Native alloys of gold and silver are now called electrums, when they contain sufficient silver to make their colour lighter, and their specific gravity less than that of gold. According to Klaproth, electrum is composed of gold 64, silver 36. Hausmann applied the term to all native alloys that contain from 20 to 50 per cent. of silver.

A base metal in modern use has received the name of electrum. It is an alloy of copper, zinc, and tin, with sometimes nickel.

ELEMENTS. This name is now given to bodies which have not been reduced to any more simple form of matter than that in which we find them. The elements of the ancients, *air*, *fire*, *earth*, and *water*, had quite a different meaning from the elements of the modern chemist; so had the *salt*, *sulphur* and *mercury* of the early alchemists. In their philosophy those terms represented the ultimate forms into which matter could be resolved, or out of which all matter could be created. The number of elements at present known is 63:—

Table of Chemical Elements.

Aluminium
Antimony
Arsenic
Barium
Bismuth
Boron
Bromine
Cadmium
Cæsium
Calcium
Carbon
Cerium
Chlorine
Chromium
Cobalt
Copper
Didymium
Erbium
Fluorine
Glucinum
Gold
Hydrogen
Indium
Iodine
Iridium
Iron
Lanthanum
Lead
Lithium
Magnesium
Manganese
Mercury
Molybdenum
Nickel
Niobium
Nitrogen
Osmium
Oxygen
Palladium
Phosphorus
Platinum
Potassium
Rhodium
Rubidium
Ruthenium
Selenium
Silica
Silver
Sodium
Strontium
Sulphur
Tantalum
Tellurium
Thallium
Thorinum
Tin
Titanium
Tungsten
Uranium
Vanadium
Yttrium
Zinc
Zirconium

A list of the more important of these elements, with their symbols and atomic weights, will be found under the article Atomic Weights.

For a full examination of the laws regulating the chemical relations of these bodies, their atomic constitution, &c. see Watts's 'Dictionary of Chemistry.'

ELEMI. This appears to be the resinous product of various terebinthinous trees. The Edinburgh College states it to be a 'concrete resinous exudation from one or more unascertained plants.' And the London Pharmacopœia describes it as a concrete turpentine derived from an unknown plant. In the former edition *Amyris Elemifera* was named as the plant producing this resin. This error was due to Linnæus, who confounded under one name two distinct plants. The larger quantities of elemi come to us from the Dutch settlements through Holland. It is imported in '*the lump*,' and in masses weighing from one to two pounds, each enveloped in a palm-leaf. Elemi is employed in making lacquer. See Varnish.

ELEPHANTS' TUSKS. See Ivory.

ELEPHANTS' URINE. The celebrated Indian yellow, or *Purree*, is said to be a mixture of the earthy phosphate and urea deposited from this.

ELEUTRIATE. (*Soutirer*, Fr.; *Schlemmen*, Ger.) When any insoluble powder, such as chalk, is diffused through a large body of water, and then allowed to subside slowly, of course the larger particles will by their gravity be the first to subside. If then the supernatant liquor is poured off, or better, if drawn off by a siphon, the finer powder will be collected in the next vessel; and by repeating this process an impalpable powder may be obtained. This process is called *Eleutriation.*

ELEVATORS FOR MINES. Under this name Messrs. Alexander Alison and John Shaw have patented an arrangement for 'Raising water and minerals from collieries and mines, and for other purposes.' There is much ingenuity in the arrangements proposed, which are in point of fact modifications of the systems adopted by the Pneumatic Despatch Company. The principle involved will be sufficiently understood from the following description, taken from the Specifications of the patentees:—A cylinder or tube is placed in the shaft which rises a few feet above the top of it, and reaches to a few feet below the bottom of the mine; this cylinder is made of malleable or cast iron, or other suitable metal or material, and of a diameter according to the weight of minerals, water, or other substances to be lifted. In this cylinder or tube a double-headed piston works, and between the two heads of the piston a fixed or moveable receiver, or barrel, or waggon is placed, which holds the mineral or water to be raised.

An air-pump worked by a steam-engine or water-wheel, or other power, is used for forcing air down the shaft in a tube, which air passes into the cylinder below the under piston head. Forcing only may be used, but exhausting and forcing may be used in conjunction. When the load is put in at the bottom, a valve is opened so that the air is introduced under the piston, which with its load then rises to the top; on arriving at the top the load is removed, and on an escape-valve at bottom being opened, the piston descends, and the air which escapes ventilates the mine. This elevator not only acts as an elevator and ventilator, but provides a safe and expeditious mode of conveying workmen up and down the shaft.

The other improved elevator may be described thus:—Air is forced by an air-pump, worked by steam or other power, down a tube into one or more cisterns in the bottom of the shaft, into which the water of the mine runs. The water is in this way forced up to the surface through another tube. The cistern or cisterns are fitted with self-acting valves, which open and shut by means of a float. As the air escapes from the bottom this elevator acts as a ventilator as effectually as the one previously described. See MAN-ENGINE.

ELIASITE. An ore of uranium. A mineral allied to pitchblende, but differing from it widely in its large proportion of water and lower specific gravity (4·086 to 4·237).

It occurs with fluor, dolomite, quartz, &c., at the Elias mine, Joachimstal (whence its name), in large flattened pieces, sometimes half an inch thick, of a dull reddish-brown colour, approaching to hyacinth-red on the edges.

It is subtranslucent, with a greasy subvitreous lustre, and affords a dull streak, varying from wax-yellow to orange. Hardness between calcite and fluor spar.

It is composed of peroxide of uranium, 61·33; alumina, 1·17; peroxide of iron, 6·63; protoxide of iron, 1·09; lime, 3·09; magnesia, 2·20; oxide of lead, 4·62; silica, 5·13; carbonic acid, 2·52; phosphoric acid, 0·84; water, 10·68: Total, 99·30.

Before the blowpipe it affords a reaction like pitchblende; it is decomposed by muriatic acid.—H.W.B.

ELIQUATION. The separation of lead and silver from copper, the agent for doing this being lead. The copper containing silver was melted with a certain portion of lead, and cast into discs. These discs were exposed to a temperature sufficiently high to melt the lead. This metal then *liquated,* or separated from the copper, carrying the greater portion of the silver with it. The process is seldom now employed.

ELIXIR OF VITRIOL. A preparation of sulphuric acid, with some aromatics.

ELM. (*Ulmus,* Lat.; *Orme,* Fr.; *Ulme,* Ger.) Of this European timber tree there are five species. The *Ulmus campestris,* the English Elm, is regarded in this country as one of the finest of European deciduous trees for park scenery; it lives for upwards of 200 years, forming a remarkably straight tall trunk. The quality of timber depends a good deal on the soil in which it is grown, being always best on a dry, loamy soil, with plenty of air. The *Ulmus montana,* is the Mountain, Scotch, or Wych Elm: the trunk is not so lofty nor the wood so heavy as the English Elm; and though coarse-grained, is very highly prized by shipbuilders and cartwrights. It possesses great longitudinal adhesion, and is consequently one of our stiffest and straightest timbers. These woods are not liable to split; they bear the driving of nails or bolts better than any other timber, and are exceedingly durable when constantly wet. They are therefore much used for the keels of vessels, and for wet foundations, waterworks, piles, pumps, and boards for coffins. On account of its toughness, it is selected for the naves of wheels, and for the gunwales of ships.

ELVANITE. A quartziferous porphyry, forming the typical rock of the Cornish Elvans.

ELVANS. Granitic and felspathic porphyritic rocks, which are frequently found traversing both the granite and slate rocks.

'The elvans or veins of quartziferous porphyry—that is, a granular crystalline mixture of felspar and quartz, which are common both in Cornwall and Devon, and near the granite of the south-east of Ireland—are probably in reality granite veins, or veins proceeding from a granitic mass.'—*Jukes.*

'When these *granite veins* are of a large size they are termed *Elvan courses*; indeed, this is the only distinction between these two forms of elongated masses of granitic rock. In composition these elvans are either shorl rock, eurite, felsparite, or even varieties of fine-grained granite.'—*Boase.*

ELYTRA. The horny wing-cases of beetles, formed by the anterior wings becoming hardened, and therefore useless for flight. The brilliantly-coloured and iridescent elytra of some beetles are used for ornamental purposes.

EMAIL OMBRANT. A process which consists in flooding coloured but transparent glazes over designs stamped in the body of earthenware or porcelain. A plane surface is thus produced, in which the cavities of the stamped design appear as shadows of various depths, the parts in highest relief coming nearest the surface of the glaze, and thus having the effects of the lights of the picture. This process was introduced by the Baron A. De Tremblay of Rubelles, near Melun.

ÉMAUX CLOISONNÉS. See ENAMELS.

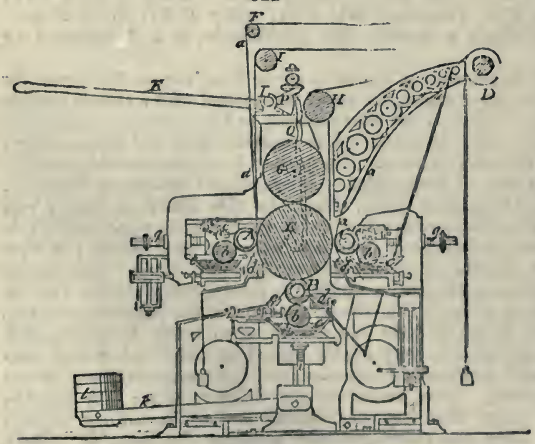
EMBALMING. (*Embaumement*, Fr.; *Einbalsamirung*, Ger.) An operation employed by the ancients to preserve human bodies from putrefaction. From their using *balsams* in the process, the name was derived. See DISINFECTION; PUTREFACTION.

EMBOLITE. A chloro-bromide of silver found in Chili and Mexico. It varies in colour from an asparagus green to an olive green, is perfectly malleable, and of resinous lustre. The ratio of the chlorine to the bromine appears to vary indefinitely, those varieties which are of a yellow or of a deep green tint being the richest in bromine. The name is derived from ἐμβόλιον, *intermediate*, in allusion to the mineral being intermediate in chemical composition between the chloride and the bromide of silver.

EMBOSSING. One of the plans introduced for EMBOSSING CLOTH by machinery which appears to be the most effective, is that of Mr. Thomas Greig, of Rose Bank, near Bury. This machine is thus constructed:—

Figs. 822, 823 represent three distinct printing cylinders of copper, or other suitable material, A, B, C, with their necessary appendages for printing three different colours upon the fabric as it passes through the machine; either of these cylinders, A, B, or C, may be employed as an embossing cylinder, without performing the printing process, or may be made to effect both operations at the same time.

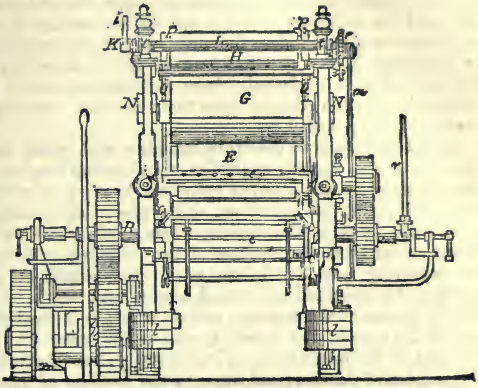
822



The fabric or goods to be operated upon being first wound tightly upon a roller, that roller is to be mounted upon an axle or pivot, bearing in arms or brackets at the back of the machine, as shown at D. From this roller the fabric *a*, *a*, *a*, *a*, is conducted between tension rails, and passed under the bed cylinder or paper bowl E, and from thence proceeds over a carrier roller F, and over steam-boxes not shown in the drawing, or it may be conducted into a hot room, for the purpose of drying the colours.

The cylinders A, B, and C, having either engraved or raised surfaces, are connected with feeding rollers *b*, *b*, *b*, revolving in the ink or coloured troughs *c*, *c*, *c*; or endless felts, called sieves, may be employed, as in ordinary printing machines, for supplying the colour, when the device on the surface of the cylinders is raised; these cylinders may be furnished with doctors or scrapers when required, or the same may be applied to endless felts.

823



The blocks have adjustable screws *g*, *g*, for the purpose of bringing the cylinders up against the paper bowl with any required degree of pressure; the cylinder B is supported by its gudgeons running in blocks, which blocks slide in the lower parts of the side frames, and are connected to perpendicular rods *i*, having adjustable screw nuts.

The lower parts of these rods bear upon weighted levers *k*, *k*, extending in front of the machine; and by increasing the weights *l*, *l*, any degree of upward pressure may be given to the cylinder B.

The colour boxes or troughs *c*, *c*, *c*, carrying the feeding rollers *b*, *b*, *b*, are fixed on boards which slide in grooves in the side frames, and the rollers are adjusted and brought into contact with the surface of the printing cylinders by screws.

If a black cloth should be required to be introduced between the cylindrical bed or paper bowl E, and the fabric *a*, *a*, *a*, as the ordinary felt or blanket, it may, for printing and embossing cotton, silk, or paper, be of linen or cotton; but if woollen goods are to be operated upon, a cap of felt, or some such material, must be bound round the paper bowl, and the felt or blanket must be used for the back cloth, which is to be conducted over the rollers H and I.

For the purpose of embossing the fabric, either of the rollers A, B, or C, may be employed, observing that the surface of the roller must be cut, so as to leave the pattern or device elevated for embossing velvets, plain cloths, and papers; but for woollens the device must be excavated, that is, cut in recess.

The pattern of the embossing cylinder will, by the operation, be partially marked through the fabric on to the surface of the paper bowl E; to obliterate which marks from the surface of the bowl, as it revolves, the iron cylinder roller G is employed; but as in the embossing of the same patterns on paper, a counter roller is required to produce the pattern perfectly, the iron roller is in that case dispensed with, the impression given to the paper bowl being required to be retained on its surface until the operation is finished.

In this case the relative circumferences of the embossing cylinder, and of the paper bowl, must be exactly proportioned to each other; that is, the circumference of the bowl must be equal, exactly, to a given number of circumferences of the embossing cylinder, very accurately measured in order to preserve a perfect register or coincidence, as they continue revolving between the pattern on the surface of the embossing cylinder and that indented into the surface of the paper bowl.

The axle of the paper bowl E, turns in brasses fitted into slots in the side frames, and it may be raised by hand from its bearings, when required, by a lever *k*, extending in front. This lever is affixed to the end of a horizontal shaft L, L, crossing the machine seen in the figures, at the back of which shaft there are two segment levers P, P, to which bent rods Q, Q, are attached, having hooks at their lower ends, passed under the axle of the bowl. At the reverse end of the shaft L, a ratchet-wheel *r*, is affixed, and a pall or click mounted on the side of the frame takes into the teeth of the wheel *r*, and thereby holds up the paper bowl when required.

When the iron roller G, is to be brought into operation, the vertical screws *t*, *t*, mounted in the upper parts of the side frames, are turned, in order to bring down the brasses N, which carry the axle of that roller and slide in slots in the side frames.

The cylinders A, B, and C, are represented hollow, and may be kept at any desired temperature during the operation of printing, by introducing steam into them; and under the colour boxes *c*, *c*, *c*, hollow chambers are also made for the same purpose. The degree of temperature required to be given to these must depend upon the nature of the colouring material, and of the goods operated upon. For the purpose of conducting steam to these hollow cylinders and colour boxes, pipes, as shown at *v*, *v*, *v*, are attached, which lead from a steam-boiler. But when either of these cylinders is employed for embossing alone, or for embossing and printing at the same time, and particularly for some kinds of goods where a higher temperature may be required, a red-hot heater is then introduced into the hollow cylinder in place of steam.

If the cylinder B is employed as the embossing cylinder, and it is not intended to print the fabric by that cylinder simultaneously with the operation of embossing, the feeding roller *b* must be removed, and also the colour box *c*, belonging to that cylinder; and the cylinders A and C are to be employed for printing the fabric, the one applying the colour before the embossing is effected, the other after it. It is, however, to be remarked, that if A and C are to print colours on the fabric, and B to emboss it, in that case it is preferred, where the pattern would allow it. A and C are wooden rollers, having the pattern upon their surfaces, and not metal, as the embossing cylinders must of necessity be.

It will be perceived that this machine will print one, two, or three colours at the same time, and that the operation of embossing may be performed simultaneously with the printing, by either of the cylinders A, B, or C, or the operation may be performed consecutively by the cylinders, either preceding or succeeding each other.

The situations of the doctors, when required to be used for removing any superfluous colour from the surface of the printing cylinder, are shown at *d*, *d*, *d*; those for removing any lint which may attach itself, at *e*, *e*, *e*. They are kept in their bearings by weighted levers and screws, and receive a slight lateral movement to and fro, by means of the vertical rod *m*, which is connected at top to an excentric, on the end of the axle of the roller H, and at its lower end to a horizontal rod mounted at the side of the frame; to this horizontal rod arms are attached, which are connected to the respective doctors; and thus, by the rotation of the excentric, the doctors are made to slide laterally.

When the cylinders A, B, or C, are employed for embossing only, those doctors will not be required. The driving power is communicated to the machine from any first mover through the agency of the toothed gear, which gives rotatory motion to the cylinder B, and from thence to the other cylinders A, and C, by toothed gear shown in *fig.* 822.

EMBOSSING LEATHER. Beautiful ornaments in basso-relievo for decorating the exteriors or interiors of buildings, medallions, picture-frames, cabinet work, &c., have been made by the pressure of metallic blocks and dies, by M. Claude Schroth. The dies are made of type-metal, or of the fusible alloy with bismuth, called d'Arcet's. The leather is beaten soft in water, then wrung, pressed, rolled, and fulled, as it were, by working it with the hands till it becomes thicker and quite supple. In this state it is laid on the mould, and forced into all its cavities by means of a wooden, bone, or copper tool. In other cases, the embossing is performed by the force of a press. The leather, when it has become dry, is easily taken off the mould, however deeply it may be inserted into its crevices, by virtue of its elasticity.

EMBOSSING WOOD. (*Bossage*, Fr.; *Erhabenes Arbeit*, Ger.) Raised figures upon wood, such as are employed in picture-frames, and other articles of ornamental cabinet work, are usually produced by means of carving, or by casting the pattern in plaster of Paris, or other composition, and cementing, or otherwise fixing it on the surface of the wood. The former mode is expensive; the latter is inapplicable on many occasions. The invention of Mr. Streaker may be used either by itself, or in aid of carving, and depends on the fact, that if a depression be made by a blunt instrument on the surface of the wood, such depressed part will again rise to its original level by subsequent immersion in the water.

The wood to be ornamented having been first worked out to its proposed shape, is in a state to receive the drawing of the pattern; this being put on a blunt steel tool, or burnisher, or die, is to be applied successively to all those parts of the pattern intended to be in relief, and, at the same time, is to be driven very cautiously, without breaking the grain of the wood, till the depth of the depression is equal to the intended prominence of the figures. The ground is then to be reduced by planing or filing to the level of the depressed part; after which, the piece of wood being placed in water, either hot or cold, the part previously depressed will rise to its former height, and will then form an embossed pattern, which may be finished by the usual operations of carving. See CARVING BY MACHINERY.

Another process which may be regarded either as carving or embossing wood, is that patented by Messrs. A. S. Braithwaite and Co.

Oak, mahogany, rose-wood, horse-chestnut, or other wood, is steeped in water for about two hours; and the cast-iron mould containing the device is heated to redness, or sometimes to a white heat, and applied against the wood, either by a handle, as a branding iron, by a lever press, or by a screw press, according to circumstances; the moulds are made by the iron-founder from plaster casts of the original models or carvings.

Had not the wood been saturated with water, it would be ignited, but until the moisture is evaporated, it is only charred; it gives off volumes of smoke, but no flame. After a short time the iron is returned to the furnace to be re-heated, the blackened wood is well rubbed with a hard brush to remove the charcoal-powder, which being a bad conductor of heat, saves the wood from material discoloration; and before the re-application of the heated iron, the wood is again soaked in water, but for a shorter time, as it now absorbs moisture with more facility.

The rotation of burning, brushing, and wetting is repeated ten or twenty times, or upwards, until, in fact, the wood fills every cavity in the mould, the process being materially influenced by the character and condition of the wood itself, and the degrees to which heat and moisture are applied. The water so far checks the destruction of the wood, or even its change of any kind, that the burned surface, simply cleaned by brushing, is often employed, as it may be left either of a very pale or deep brown, according to the tone of colour required, so as to match old carvings of any age; or a very little scraping removes the discoloured surface. Perforated carvings are burned upon thick blocks of wood, and cut off with the circular saw.

EMBROIDERING MACHINE. (*Machine à broder*, Fr.; *Steckmaschine*, Ger.) —This art has been from the earliest times a handicraft employment, cultivated on account of its elegance by ladies of rank. But M. Heilmann, of Mulhouse, invented a machine of a most ingenious kind, which enables a female to embroider any design with 80 or 140 needles as accurately and expeditiously as she formerly could do with one. A brief account of this remarkable invention will therefore be acceptable to many readers. It was first displayed at the National Exposition of the Products of Industry in Paris for 1834. 130 needles were occupied in copying the same pattern with perfect regularity, all set in motion by one person.

Several of these machines are now mounted in France, Germany, and Switzerland, and, with some modifications, in Manchester, Glasgow, and Paisley.

The price of a machine having 130 needles, and of consequence 260 pincers or fingers and thumbs to lay hold of them, is 5,000 francs, or 200*l.* sterling; and it is estimated to do daily the work of fifteen expert hand embroiderers, employed upon the ordinary frame. It requires merely the labour of one grown-up person and two assistant children. The operative must be well taught to use the machine, for he has many things to attend to: with the one hand he traces out, or rather follows the design with the point of the pantograph; with the other he turns a handle to plant and pull all the needles, which are seized by pincers and moved along by carriages, approaching to and receding from the web, rolling all the time along an iron railway; lastly, by means of two pedals, upon which he presses alternately with the one foot and the other, he opens the 130 pincers of the first carriage, which ought to give up the needles after planting them in the stuff, and he shuts with the same pressure the 130 pincers of the second carriage, which is to receive the needles, to draw them from the other side, and to bring them back again. The children have nothing else to do than to change the needles when all their threads are used, and to see that no needle misses its pincers.

This machine may be described under four heads: 1. the structure of the frame; 2. the disposition of the web; 3. the arrangement of the carriages; and 4. the construction of the pincers.

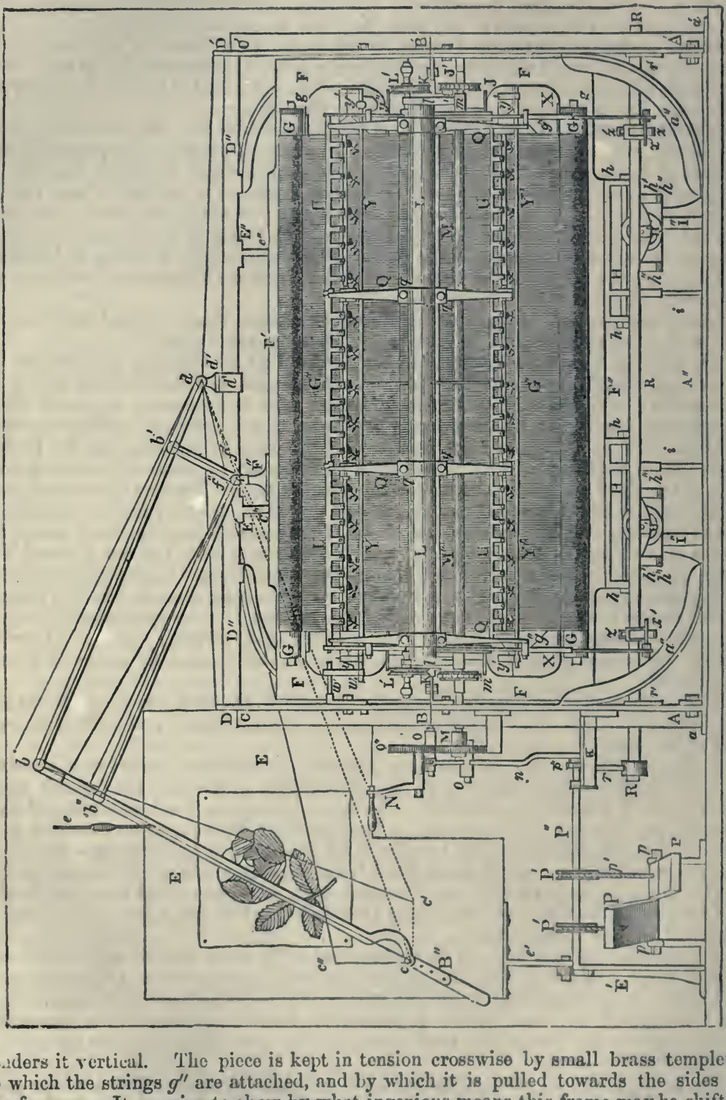
1. *The structure of the frame.*—It is composed of cast iron, and is very massive. *Fig.* 824 exhibits a front elevation of it. The length of the machine depends upon the number of pincers to be worked. The figure here given has been shortened considerably, so that the drawing might be brought within the page, but the other proportions are not disturbed. The breadth of the frame ought to be the same for every machine, whether it be long or short, for it is the breadth which determines the length of the thread to be put into the needles, and there is an advantage in giving it the full breadth of the model machine, fully 100 inches, so that the needles may carry a thread at least 40 inches long.

2. *Disposition of the piece to be embroidered.*—We have already stated that the pincers which hold the needles always present themselves opposite to the same point, and that in consequence they would continually pass backwards and forwards through the same hole, if the piece was not displaced with sufficient precision to bring successively opposite the tips of the needles every point upon which they are to work a design, such as a flower.

The piece is strained perpendicularly upon a large rectangular frame, whose four sides are visible in *fig.* 824; namely, the two vertical sides at F F, and the two horizontal sides, the upper and lower at F′ F″. We see also in the figure two long wooden rollers G and G, whose ends, mounted with iron studs, are supported upon the sides F of the frame, so as to turn freely. These form a system of beams, upon which the piece destined to receive the embroidery is wound and kept vertically stretched to a proper degree, for each of these beams bears upon its end a small ratchet wheel g, g;

the teeth of one of them being inclined in the opposite direction to those of the other. Besides the system of lower beams, there is another of two upper beams, which is however but imperfectly seen in the figure, on account of the interference of other parts in this view of the machine. One of these systems presents the web to the inferior needles, and the other to the upper needles. As the two beams are not in the same vertical plane, the plane of the web would be presented obliquely to the needles were it not for a straight bar of iron, round whose edge the cloth passes, and which renders it vertical. The piece is kept in tension crosswise by small brass templets, to which the strings g'' are attached, and by which it is pulled towards the sides of the frame F. It remains to show by what ingenious means this frame may be shifted in every possible direction. M. Heilmann has employed for this purpose the pantograph which draughtsmen use for reducing or enlarging their plans in determinate proportions.

824



$b\,b'\,f''\,b''$ (*fig.* 824) represent a parallelogram, of which the four angles b, b', f', b'', are jointed in such a way that they may become very acute or very obtuse at pleasure, while the sides of course continue of the same length; the sides $b\,b'$ and $b\,b''$ are prolonged, the one to the point d, and the other to the point c, and these points c and d are chosen under the condition that in one of the positions of the parallelogram, the line $c\,d$ which joins them passes through the point f; this condition may be fulfilled in an infinite number of manners, since the position of the parallelogram remaining the same, we see that if we wished to shift the point d further from the point b', it would be sufficient to bring the point c near enough to b'', or *vice versâ*; but when we have once fixed upon the distance $b'\,d$, it is evident that the distance $b''\,c$ is its necessary consequence. Now the principle on which the construction of the pantograph rests is this: it is sufficient that the three points d, f, and c be in a straight line, in one only of the positions of the parallelogram, in order that they shall remain always in a straight line in every position which can possibly be given to it.

We see in the figure that the side $b\,c$ has a handle B″ with which the workman puts the machine in action. To obtain more precision and solidity in work, the sides of the pantograph are joined, so that the middle of their thickness lies exactly in the vertical plane of the piece of goods, and that the axes of the joints are truly perpendicular to this plane, in which consequently all the displacements are effected. We arrive at this result by making fast to the superior great cross-bar D″ an elbow-piece d'', having a suitable projection, and to which is adapted in its turn the piece d', which receives in a socket the extremity of the side $b\,d$; this piece d' is made fast to d'' by a bolt, but it carries an oblong hole, and before screwing up the nut, we make the piece advance or recede, till the fulcrum point comes exactly into the plane of the web. This condition being fulfilled, we have merely to attach the frame to the angle f of the parallelogram, which is done by means of the piece F″.

It is now obvious that if the embroiderer takes the handle B″ in his hand and makes the pantograph move in any direction whatever, the point f will describe a figure similar to the figure described by the point c, and six times smaller, but the point f cannot move without the frame, and whatever is upon it, moving also. Thus in the movement of the pantograph, every point of the web describes a figure equal to that described by the point f, and consequently similar to that described by the point c, but six times smaller; the embroidered object being produced upon the cloth in the position of that of the pattern. It is sufficient therefore to give the embroidering operative who holds the handle B″ a design six times greater than that to be executed by the machine, and to afford him at the same time a sure and easy means of tracing over with the point c, all the outlines of the pattern. For this purpose he adapts to c, perpendicularly to the plane of the parallelogram, a small style terminated by a point c', and he fixes the pattern upon a vertical tablet E, parallel to the plane of the stuff and the parallelogram, and distant from it only by the length of the style $c\,c''$; this tablet is carried by the iron rod e', which is secured to a cast-iron foot E′, serving also for other purposes, as we shall presently see. The frame, loaded with its beams and its cloth, forms a pretty heavy mass, and as it must not swerve from its plane, it needs to be lightened, in order that the operative may cause the point of the pantograph to pass along the tablet without straining or uncertainty in its movements. M. Heilmann has accomplished these objects in the following way. A cord e attached to the side $b\,c$ of the pantograph passes over a return pulley, and carries at its extremity a weight which may be graduated at pleasure; this weight equipoises the pantograph, and tends slightly to raise the frame. The lower side of the frame carries two rods H and H, each attached by two arms $h\,h$, a little bent to the left; both of these are engaged in the grooves of a pulley. Through this mechanism a pressure can be exercised upon the frame from below upwards which may be regulated at pleasure, and without preventing the frame from moving in all directions, it hinders it from deviating from the primitive plane to which the pantograph was adjusted. The length of the rods H ought to be equal to the amount of the lateral movement of the frame. Two guides $i\,i$, carried by two legs of cast iron, present vertical slits in which the lower part of the frame F′ is engaged.

3. *Disposition of the carriages.*—The two carriages, which are similar, are placed the one to the right, and the other to the left of the frame. The carriage itself is composed merely of a long hollow cylinder of cast iron L, carrying at either end a system of two grooved castors or pulleys L′, which roll upon the horizontal rails K; the pulleys are mounted upon a forked piece l', with two ends to receive the axes of the pulleys, and the piece l' is itself bolted to a projecting car l cast upon the cylinder.

This assemblage constitutes, properly speaking, the carriage, resting in a perfectly stable equilibrium upon the rails K, upon which it may be most easily moved backwards and forwards, carrying its train of needles to be passed or drawn through the cloth.

M. Heilmann has contrived a mechanism by which the operative without budging from his place, may conduct the carriages, and regulate as he pleases the extent of their course, as well as the rapidity of their movements. By turning the axes M″ in the one direction or the other, the carriage may be made to approach to, or recede from the web.

When one of the carriages has advanced to prick the needles into the stuff, the other is there to receive them; it lays hold of them with its pincers, pulls them through, performs its course by withdrawing to stretch the thread, and close the stitch, then it goes back with the needles to make its pricks in return. During these movements, the first carriage remains at its post waiting the return of the second. Thus the two chariots make in succession an advance and a return, but they never move together.

To effect these movements M. Heilmann has attached to the piece O′ made fast to the two uprights A C and A D of the frame, a bent lever *n o n′ n″*, moveable round the point *o*; the bend *n′* carries a toothed wheel O′, and the extremity *n″* a toothed wheel O″; the four wheels M, M′, O′, and O″, have the same number of teeth and the same diameter; the two wheels O′ and O″ are fixed in reference to each other, so that it is sufficient to turn the handle N to make the wheel O″ revolve, and consequently the wheel O′; when the lever *n o* is vertical, the wheel O′ touches neither the wheel M nor the wheel M′; but if it be inclined to the one side or the other, it brings the wheel O′ alternately into gear with the wheel M or the wheel M′. As the operative has his two hands occupied, the one with the pantograph, and the other with the handle of impulsion, he has merely his feet for acting upon the lever *n o*, and as he has many other things to do, M. Heilmann has adapted before him a system of two pedals, by which he executes with his feet a series of operations no less delicate than those which he executes with his hands.

The pedals P are moveable round the axis *p*, and carry cords *p′* wound in an opposite direction upon the pulleys P′; these pulleys are fixed upon a moveable shaft P″ supported upon one side by the prop E′, and on the other in a piece K attached to the two great uprights of the frame. In depressing the pedal P (now raised in the figure), the upper part of the shaft P″ will turn from the left to the right, and the lever *n o* will become inclined so as to carry the wheel O′ upon the wheel M′, but at the same time the pedal which is now depressed will be raised, because its cord will be forced to wind itself upon its pulley, as much as the other cord has unwound itself; and thus the apparatus will be ready to act in the opposite direction when wanted.

4. *Disposition of the pincers.*—The shaft L′ carries, at regular intervals of a semi-diameter, the appendages *q q* cast upon it, upon which are fixed, by two bolts, the curved branches Q destined to bear the whole mechanism of the pincers. When the pincers are opened by their appropriate leverage, and the half of the needle, which is pointed at each end, with the eye in the middle, enters the opening of its plate, it gets lodged in an angular groove, which is less deep than the needle is thick, so that when the pincers are closed, the upper jaw presses it into the groove. In this way the needle is firmly held, although touched in only three points of its circumference.

Suppose now, that all the pincers are mounted and adjusted at their proper distances upon their prismatic bar, forming the upper range of the right carriage. For opening all the pincers there is a long plate of iron, U, capable of turning upon its axis, and which extends from the one end of the carriage to the other. This axis is carried by a kind of forks which are bolted to the extremity of the branches Q. By turning that axis the workman can open the pincers at pleasure, and they are again closed by springs. This movement is performed by his feet acting upon the pedals.

The threads get stretched in proportion as the carriage is run out, but as this tension has no elastic play, inconveniences might ensue, which are prevented by adapting to the carriage a mechanism by means of which all the threads are pressed at the same time by a weight susceptible of graduation. A little beneath the prismatic bar, which carries the pincers, we see in the figure a shaft Y, going from one end of the carriage to the other, and even a little beyond it; this shaft is carried by pieces *y* which are fixed to the arms Q, and in which it can turn. At its left end it carries two small bars *y′* and *w′*, and at its right a single bar *y′*, and a counterweight (not visible in this view); the ends of the two bars *y′* are joined by an iron wire, somewhat stout and perfectly straight. When the carriage approaches the web, and before the iron wire can touch it, the little bar *w* presses against a pin *w′*, which rests upon it, and tends to raise it more and more. In what has preceded we have kept in view only the upper range of pincers and needles, but there is an inferior range quite similar, as the figure shows, at the lower ends of the arms Q. In conclusion, it should be stated, that the operative does not follow slidingly with the pantograph the trace of the design which is upon the tablet or the picture, but he must stop the point of the style upon the point of the pattern into which the needle should enter, then remove it, and put it down again upon the point by which the needle ought to re-enter in coming from the other side of the piece, and so on in succession. To facilitate this kind of reading off, the pattern upon the tablet is composed of right lines terminated by the points for the entrance and return of the needle, so that the operative (usually a child) has continually under her eyes the series of broken lines which must be followed by the pantograph. If she happens to quit this path an instant, without having left a mark of the point at which she had arrived, she is under the necessity of looking at the piece to see what has been already embroidered, and to find by this comparison the point at which she must resume her work, so as not to leave a blank, or to repeat the same stitch.

Explanation of Figure.

A, lower cross bars, which unite the legs of the two ends of the frame.

a, the six feet of the front end of the frame.

a′, the six feet of the posterior end of the frame.

a″, curved pieces which unite the cross bars A″ to the uprights.

B″, handle of the pantograph.

b, *b*′, *b*″, three angles of the pantograph.

c, point of the side *b b*″ on which the point is fixed.

C″, point of the pantograph.

D″, cross bar in form of a gutter, which unites the upper parts of the frame.

d, fixed point, round which the pantograph turns.

E, tablet upon which the pattern to be embroidered is put.

E′, support of that tablet.

e, cord attached at one end to the side *b c* of the pantograph passing over a guide pulley, and carrying a weight at the other end.

e′, iron rod by which the tablet E is joined to its support E′.

F, F, uprights of the cloth-carrying frame.

F′, F′, horizontal sides of the same frame.

G, four roll beams.

G″, the piece of cloth.

g″, the strings, which serve to stretch the cloth laterally.

This machine has not been applied for embroidering nets or muslins, as these fabrics are not sufficiently close to hold the needles; it has been hitherto used for embroidering cloth for vests and other purposes, and silk for ladies' dresses. We learn, however, that some very satisfactory experiments have been made by the Messrs. Houldsworth of Manchester, which promise to lead to the successful application of these machines to the finer description of fabrics.

EMERALD. (*Émeraude*, Fr.; *Smaragd*, Ger.) A precious stone of a pure green colour, ranking in value next to the oriental ruby and sapphire. Although susceptible of a fine polish, its hardness is considerably inferior to that of most other gems, being indeed but little higher than that of quartz. Its specific gravity is also remarkably low, not exceeding 2·75. The mineral occurs crystallised in regular six-sided prisms, more or less modified on the edges and angles, and offering a tolerably easy cleavage parallel to the basal plane. Heated before the blowpipe it loses its transparency, and at a higher temperature fuses to a vesicular glass; whilst with borax it forms a transparent bead of a fine green colour. It is quite unaffected by acids.

The chemical composition of the emerald, and its relation to the beryl and aquamarine, were first determined, in 1797, by Vauquelin, whose analyses showed it to be a silicate of alumina, combined with a silicate of a peculiar earth, called glucina or beryllia. The most recent analyses of the typical emerald from Muzo, are those by M. Lewy, of which the following is the mean:—

Silica	67·9
Alumina	17·9
Glucina	12·4
Magnesia	0·9
Soda	0·7

Slight traces of sesquioxide of chromium are included in this analysis, but, according to Vauquelin's experiments, the amount of this chromic oxide may rise as high as 3·5 per cent.

Since this oxide is well known to communicate a fine green tint to glass, the colour of the emerald was naturally referred to its presence; but this opinion was contradicted a few years ago by M. Lewy, who maintained that the extremely minute trace of chromic oxide which he found in the emerald would be utterly inadequate to produce the intense green colour: moreover, according to his researches, the gem entirely loses its colour at a dull red heat, whilst those minerals that are truly coloured by chromium are unaffected in this respect by temperature. In his experiments the loss on ignition amounted to nearly 2 per cent., of which 0·12 consisted of a hydrocarbon, derived probably from the associated organic remains; and since the amount of this hydrocarbon was found to be greatest in those stones that possess the deepest colour, Lewy was induced to regard this organic compound as the true colouring agent in the gem; comparing it with chlorophyll, or the green colouring matter of plants, a compound well known to possess intense tinctorial power.

Soon after its announcement, this opinion was called in question by the experiments of Hofmeister on the Salzburg emerald; and it was further controverted by the researches of Wöhler and Gustav Rose on the emerald of Muzo. The latter chemists showed not only that the colour of the emerald is unaffected by ignition, but also that the amount of chromic oxide present in a given emerald is quite competent to impart an intense green colour to a quantity of glass equal to that of the mineral from which the oxide was derived. The subsequent researches of Boussingault also confirmed the opinion that the emerald is coloured by oxide of chromium; and the yet more recent investigations of Dr. Greville Williams lead to the same conclusion. The latter chemist has found that certain colourless beryls may contain as large a proportion of carbon as is to be found in the richest-tinted emeralds, and that the Muzo emerald may bear a bright red heat without loss of colour. He also finds that on fusing the emerald an opalescent green glass is first formed, but that this, on prolonged heating, becomes transparent and almost colourless. The density and hardness of the emerald are diminished by fusion.

Dr. Greville Williams's experiments are of so much interest that we give his own account of them:—

'I have carefully repeated and extended those experiments (those of Hofmeister). The emeralds employed were *cañutillos* (finely-crystallised emeralds) from Santa Fé de Bogotà. The following values were obtained in a determination of their specific gravities before fusion:—

No. of Experiment	W.	W′.	*t.*	*st.*	D.
1	4·4964	2·8293	16·5°	·998921	2·69
2	4·4961	2·8294	17·0°	·998841	2·69
3	1·6655	1·0486	16·0°	·999002	2·70

The formula used was:—

$$D = st\,\frac{W}{W - W'}.$$

W is the weight in air; W′ the weight in water; *st* the specific gravity of water at *t*°; *t* the temperature of the water; D the specific gravity.

'One of the above emeralds was exposed for three hours in a platinum crucible to a bright reddish-yellow heat. At the end of the operation it was opaque at the edges, but the green colour was not destroyed. This experiment completely confirms those of Wöhler and Rose, and Hofmeister. It is, I think, quite evident that no organic colouring matter could withstand such a temperature for so long a time.

'The announcement by Lewy, that the depth of colour of emeralds is in proportion to the amount of carbon present, made it appear improbable that beryls contained that element. The power of this colouring matter to resist a red heat having, however, made me inclined to disconnect the question of colour from that of the presence of carbon, I made experiments to determine whether beryls contained that element, and, if so, to what amount.

'An experiment made at this stage of the enquiry showed that the beryl analysed contained the same amount of carbon as Lewy's emerald. To settle the question definitely, as to the presence of carbonic anhydride, I burnt 1·2 grm. of beryl in a platinum boat in a current of oxygen. The water produced was absorbed by sulphuric acid; the carbonic anhydride was received in a Geissler's potash tube containing lime-water. Carefully-purified oxygen was allowed to stream through the lime-water to prove its freedom from carbonic anhydride. The beryl was then heated to redness in the stream of gas, and in a few seconds the lime-water became milky; thus not only proving the presence of carbon in a colourless beryl, but, taken in conjunction with the quantitative determination, showing conclusively that the depth of colour is not, in this class of stones, in the ratio of the amount of carbon present.

'But it was still possible that the carbon might have been derived from the decomposition of a carbonate in the beryl. To settle this question, I arranged an apparatus in which, in a current of pure air passing through lime-water, a finely-levigated beryl was boiled with dilute sulphuric acid. No carbonic anhydride was evolved. It was, therefore, evident that the carbon found in the beryl did not proceed from the decomposition of a carbonate.

'Five milligrammes of charcoal treated in the same way, produced a milkiness in all the lime-water bulbs in four minutes. In another experiment, after the usual precautions, 53 milligrammes of graphite were acted on. In four minutes the first bulb, in eight minutes the whole of the bulbs, were rendered milky.

'The above experiments show, therefore, that the beryl (experiment on one which was from Ireland) contains carbon, not in the state of a carbonate, but in a condition which is more slowly attacked than either free charcoal or graphite; and it is, I think, probably in the form of diamond, as has been shown to occur with the water contained in artificially-crystallised boron.

'The presence of carbon in beryls does not appear to be invariable. After repeated experiments upon another large beryl from Haddam County, North America, I was unable to satisfy myself that it contained carbon. It is true there were traces found in the experiment, but they were so minute that they might have been due to organic dust accidentally present.

'The next point I wished to ascertain was the relation borne by the quantity of carbon in the Irish beryl, to that in the emerald. Minute precautions were necessary, since 1 grm. of the beryl or emerald only yielded 3 milligrammes of carbonic anhydride.

Experiment 1.	0·9725 grm.	beryl gave	0·0030	CO^2	and	0·0131	H^2O
„ 2.	1·0082 „	„ „	0·0031	„		0·0174	„
„ 3.	1·1690 „	emerald	0·0030	„		0·0140	„

Expressed per cent.:—

	Irish Beryl		Emerald	Lewy's Emerald (Mean.)
	I.	II.		
Carbonic anhydride	0·31	0·31	0·26	0·28
Water	1·32	1·73	1·20	1·89.'

Among the ancients the emerald was very highly esteemed, being ranked by Pliny next to the diamond and pearl. During the middle ages it maintained a very high position; but on the discovery of the Peruvian mines, in the middle of the sixteenth century, it suffered a sudden reduction in value, from which it has never entirely recovered. A stone of 4 grains' weight is said to be worth from 4*l.* to 5*l.*; one of 8 grains, 10*l.*; one of 15 grains, being fine, is worth 60*l.*; one of 24 grains fetched, at the sale of M. de Drée's cabinet, 2,400 francs, or nearly 100*l.*

From the descriptions of the *smaragdos*, or emerald of the ancients, it is evident that they confounded under this name a number of green minerals differing widely from each other in general characters; such, for example, as malachite, chrysoprase, green fluor-spar, amazon-stone, and even green glass. The true emeralds of the ancients were probably in great part derived from Mount Zabara, in Upper Egypt, where the old workings were discovered some years back by the French traveller M. Cailloud, and were re-opened by Mohammed Ali; but the emeralds obtained being only of poor quality, the operations were soon suspended.

For many years past, the emerald has been obtained almost exclusively from the famous mine of Muzo, a large open excavation on the eastern cordillera of the Andes, 75 miles N.N.W. of Santa Fé de Bogotà. It there occurs, associated with crystals of iron pyrites and the rare mineral parasite, in veins of calcareous spar traversing a black bituminous limestone, containing ammonites and other fossils, apparently of lower cretaceous age. When first removed from the rock, the emeralds are excessively fragile; and numbers of them crack spontaneously, in spite of careful protection from the sun. The emeralds are indeed so rarely free from flaws that they are often imitated in fictitious gems.

The Muzo mines were leased, in 1864, to a French Company, in consideration of an annual payment to the Government of Columbia of about 3,000*l.* The workings are conducted under the direction of M. Lehmann, and the emeralds which are obtained are sent direct to Paris. The present agreement expires this year—1874—and it is understood that it will not be renewed.

A fine crystal of Muzo emerald, 2 inches long, exhibited in the Great Exhibition of 1851, is now in the cabinet of the Duke of Devonshire; it measures across its three diameters 2¼ in., 2⅕ in. 1⅞in., and weighs 8 oz. 18 dwts.: owing to flaws, it is but partially fit for jewellery.

Emeralds of less beauty, but larger than the South American gems, occur in Siberia. One specimen in the Imperial Russian collection measures 14½ inches long and 12 broad, and weighs 16¾ lbs. troy; another is 7 inches long and 4 inches broad, and weighs 6 lbs. troy. The Siberian emerald occurs near Ekaterinburg, embedded in mica-slate. A similar rock forms the matrix of the emerald found in the Habachthal, in Salzburg. From this locality some interesting specimens were exhibited in the Austrian Department of the International Exhibition of 1862. These were stated to be found in a steep cliff, at an altitude of 8,700 feet. Masses of rock containing emeralds having fallen into the neighbouring valley, this locality was discovered, and it is now worked by the possessor, S. Goldschmidt of Vienna.

The *Oriental Emerald* is an Indian Stone, entirely distinct from the common emerald described in this article; it is, indeed, a green transparent variety of corundum, differing, therefore, from the sapphire and ruby only in colour. From its extreme rarity, and its great hardness, the oriental stone is very highly prized, although far inferior in point of colour to the common emerald.

EMERALD COPPER. Dioptase, a hydrous silicate of copper See Copper.

EMERALD GREEN. Scheele's arsenical green. See Copper.

EMERALD NICKEL. A native hydrocarbonate of nickel. See Nickel.

EMERALDINE. See Aniline Green.

EMERY (*Émeri*, Fr.; *Schmergel*, Ger.). This mineral was long regarded as an ore of iron, and was called by Haüy, *fer oxide quartzifère*. It is, however, a massive granular, or compact variety of corundum, more or less impure. It is very abundant in the island of Naxos, at Cape *Emeri*, whence its name. From this place it is imported in large quantities. It is said to be found in Jersey; it occurs, though rare, in Spain, Poland, Saxony, Sweden, Persia, and a few other places. Its colour varies from red brown to dark brown: its specific gravity is about 4; it is so hard as to scratch quartz and many precious stones.

We have accounts of emery discoveries in the United States, but nearly all that is used at present in the arts comes from Turkey, near ancient Smyrna. Dr. Lawrence Smith, an American geologist, made a discovery of a deposit of emery while residing in Smyrna, and he made an examination of the locality in 1847. Dr. Smith having reported his discoveries to the Turkish Government, a commission of enquiry was instituted, and the business soon assumed a mercantile form. The monopoly of the emery of Turkey was sold to a mercantile house in Smyrna, and since then the price has diminished in the market.

The following analyses are quoted by Dana, from an elaborate paper by J. Lawrence Smith, in the 'American Journal of Science':—

	Hardness, Sapphire being 100	Specific Gravity	Alumina	Peroxide of iron	Lime	Silica	Water
Kulah . . .	57	4·28	63·50	33·25	0·92	1·61	1·90
Samos . . .	56	3·98	70·10	22·21	0·62	4·00	2·10
Nicaria . . .	55	3·75	71·06	20·32	1·40	4·12	2·53
Kulah . . .	53	4·02	63·00	30·12	0·50	2·36	3·36
Gumuch . .	47	3·82	77·82	8·62	1·80	8·13	3·11
Naxos . . .	46	3·75	68·53	24·10	0·86	3·10	4·72
Nicaria . . .	46	3·74	75·12	13·06	0·72	6·88	3·10
Gumuch . .	42	4·31	60·10	33·20	0·48	1·80	5·62
Kulah . . .	40	3·89	61·05	27·15	1·30	9·63	2·00

Valuable deposits of corundum, a purer form of alumina than emery, have recently been discovered in the United States. The following description of the Corundum of North Carolina, Georgia, and Montana, is by Mr. J. Lawrence Smith:—

'The corundum formations in North Carolina and Georgia are the second in importance in the United States that have been brought to my notice; and the one in North Carolina is by far the most interesting in this country, and perhaps of any yet known, in the extent of the formation, the distribution of the corundum, and the purity of the mineral.

'This mineral was first discovered in North Carolina in 1846—about the time I was engaged in developing the geology of emery in Asia Minor and the Grecian Archipelago; and upon communicating to American geologists my discoveries in relation to the associate-minerals of the emery in Asia Minor, and directing them to search for the same in connection with the corundum found in different parts of America, the same associates were discovered in connection with the North Carolina corundum as well as that from other localities.

'At this time there had been discovered but one detached block, but no other specimen could be found in that locality. There the matter rested until 1865, when Mr. C. D. Smith (to whom I am indebted for valuable information contained in this paper), assistant of Professor Emmons, geologist of North Carolina, had brought to him by one of the inhabitants of the country west of the Blue Ridge Mountains a specimen of rock which was recognised as being corundum, and on visiting the spot this geologist discovered the corundum *in situ*, and a number of specimens were collected. Since that time public interest has increased in relation to this substance, and it has been discovered in such quantities as to make it an object of interest to the arts as a substitute for emery, and very rapidly other localities were brought to light along a distance of forty miles.

'The colours of the corundum as found along this zone of outcrops are blue, grey, pink, ruby, and white. Sometimes it has broad cleavage faces, and then again it occurs in hexagonal prisms. One hexagonal prism weighed over three hundred pounds. There is a difference in the cleavage and the associate-minerals at different localities.

'In the development in North Carolina the corundum occurs in chrysolite or serpentine rocks, and outside of serpentine it has not been found. These chrysolite rocks belong to a regular system of dykes, which have been traversed for the distance of about one hundred and ninety miles. This system of dykes lies on the north-west side of the Blue Ridge, and has a strike parallel to the main mass of the ridge, and has an average distance from the summit of the ridge of about ten miles. It continues this strike to the head of the Little Tennessee River, say from Mitchell to Macon County, one hundred and thirty miles. Here the ridge curves around the head of the Tennessee, and falls back about ten miles to the north-west. In conformity with this elbow in the ridge, the disturbing force shifts to the north-west and re-appears at Buck's Creek, having the same relative position to the Blue Ridge.

'The serpentine appears at intervals along this whole line of one hundred and ninety miles. There is a corresponding system of dykes traversing the southern slope of the Blue Ridge, but not so regular and compact as the system on this north-west side, nor are the outcrops so frequent. The main mass of the ridge bears no evidence of having been disturbed at all, at least none has been found. From Mitchell County to Macon the serpentine is usually enclosed in a hard crystalline gneiss, which bears rose-coloured garnets, cyanite, and pyrite. After its shifting to the right it occurs in hornblendic beds and gneiss. At Buck Creek and thence south-westward the hornblende beds assume very large proportions, and instead of common felspar have in them albite, making an albitic syenite. At Buck Creek (which is named Cullakenih) the chrysolite covers an area of about three hundred and fifty acres. One or two observers have fallen into the error of confounding the two dyke systems, whereas they have no connection whatever. According to them the northern system cuts through the Blue Ridge at right angles, and then turns back on the opposite side of the ridge. Now there are no such phenomena connected with these outcrops. They evidently belong to separate systems. The outcrops along the northern system occur at intervals ranging from one to fifteen miles. The belt or zone along which these outcrops occur never exceeds four miles in width on the northern side of the ridge. On the opposite side the system is not so well defined, and the outcrops are rarer.

'Upon these serpentine beds there exist chalcedony, chromite on some of them, chlorite, talc, steatite, anthophyllite, tourmaline, emerylite, epidote on some of them, zoisite, and albite, with occasionally asbestus and picrolite, as also actinolite and tremolite. The corundum at some places seems to occur mostly in ripidolite in fissures of the serpentine. At Cullakenih the corundum with its immediate associates is in chlorite, except the red variety, which is in zoisite, containing a minute quantity of chrome.

'Throughout all the range of rocks for the great extent referred to, corundum forms a geognostic mark of this chrysolite rock, just as it does of the calcareous rock bearing corundum described by me in Asia Minor. They belong to the same geological epoch, and overlie the gneiss.

'The closest investigation shows that the chrysolite in North Carolina takes the place of calc-rock in Asia Minor; that these are invariably the gangue-rock in the two different quarters of the globe; but as remarked above, the contiguous rock shows them both to be of the same geological period, overlying directly the primary rocks; and both of them are also identical geologically with the Chester emery-formation of Massachusetts.

'While all the localities of corundum and emery I have examined exhibit certain marked and prominent characteristics common to them all, and evince unmistakeable evidence of geological identity, yet each locality has its peculiar characteristics. In all cases, however, the masses of corundum give evidence of having been formed by a process of segregation, as described in my memoir on the Asia Minor emery.

'In Asia Minor the Gumuch-dagh emery has but little black tourmaline associated with it, and instead chloritoid in crystals or lamellæ; also its disapore is rare, but when found is prismatic, affording the finest perfect crystals yet seen, from which M. Dufrénoy made his last study of the crystallography of this mineral; and the emery is associated with calcareous rock overlying gneiss. The Kulah emery from the same part of the world is equally in calcareous rock, and has very little chloritoid or chloritic mineral associated with it.

'The Naxos and Nicaria emery of the Grecian Archipelago is also in connection with calcareous rock, but has no chloritoid associated with it, but in its place black tourmaline is abundant.

'While in the above localities the rock bearing the corundum is calcareous, that in Chester, Mass., has hornblendic gneiss immediately on one side of the vein, and is accompanied with a large amount of magnetic oxide of iron. Tourmaline also abounds in this corundum, and, like the Asiatic variety, it contains rutile, ilmenite, &c.'

The mining of emery in the East is of the simplest character. The natural decomposition of the rock in which it occurs facilitates its extraction. The rock decomposes into an earth, in which the emery is found imbedded. The quantity procured under these circumstances is so great that it is rarely necessary to explore the rock. The earth in the neighbourhood of the block is almost always of a red colour, and serves as an indication to those who are in search of the mineral. Sometimes, before beginning to excavate, the spots are sounded by an iron rod with a steel point, and when any resistance is met with, the rod is rubbed in contact with the resisting body, and the effect produced on the point enables a practised eye to decide whether it has been done by emery or not. The blocks which are of a convenient size are transported in their natural state, but they are frequently broken by large hammers; when they resist the action of the hammer they are subjected to the action of fire for several hours, and on cooling they most commonly yield to blows. It sometimes happens that large masses are abandoned, from the impossibility of breaking them into pieces of a convenient size, as the transportation, either on camels or horses, requires that the pieces shall not exceed 100 lbs. each in weight.

When reduced to a powder, emery varies in colour from dark grey to black. The colour of its powder affords no indication of its commercial value. The powder, examined under the microscope, shows the distinct existence of two minerals, corundum and oxide of iron. Emery, when moistened, always affords a very strong argillaceous odour. Its hardness is its most important property in its application to the arts, and was ascertained by Mr. Smith in the following manner:—Fragments were broken from the piece to be examined, and crushed in a diamond mortar with two or three blows of a hammer, then thrown into a sieve with 400 holes to the inch. The powder is then weighed, and the hardness tested with a circular piece of glass, about four inches in diameter, and a small agate mortar. The glass is first weighed, and placed on a piece of glazed paper; the pulverised emery is then thrown upon it at intervals, rubbing it against the glass with the bottom of the agate mortar. The emery is brushed off the glass from time to time with a feather, and when all the emery has been made to pass once over the glass, it is collected, and passed through the same operation three or four times. The glass is then weighed, again subjected to the same operation, the emery by this time being reduced to an impalpable powder. This series of operations is continued until the loss sustained by the glass is exceedingly small. The total loss in the glass is then noted, and when all the specimens of emery are submitted to this operation under the same circumstances, an exact idea of their relative hardness is obtained. The advantages of using glass and agate are, that the latter is sufficiently hard to crush the emery, and in a certain space of time to reduce it to such an impalpable state that it has no longer any sensible effect on the glass; and, on the other hand, the glass is soft enough to lose during this time sufficient of its substance to allow of accurate comparative results. By this method, the best emery was found capable of wearing away about half of its weight of common French window-glass.

In the ordinary process, the lumps of emery ore are broken up in the same manner as stone is for repairing macadamised roads, and into lumps of similar size. These lumps are then crushed under stampers, such as are used for pounding metallic ores, driven by water- or by steam-power. It is supposed that the stampers leave the fragments more angular than they would be if they were ground under runners, a mode which is sometimes employed. The coarse powder is then sifted through sieves of wire-cloth, which are generally cylindrical, like the bolting cylinders of corn-mills; but the sieves are covered with wire-cloth, which vary from ninety to sixteen wires to the inch. No. 16 sieve gives emery of about the size of mustard-seed; and coarser fragments, extending nearly to the size of pepper-corns, are also occasionally prepared for the use of engineers. The sieves have sometimes as many as 120 wires in the inch; but the very fine sizes of emery are most commonly sifted through lawn sieves.

The finest emery that is obtained from the manufacturers is that which floats in the atmosphere of the stamping-room, and is deposited on the beams and shelves, from which it is occasionally collected. The manufacturers rarely or never wash the emery; this is mostly done by the glass-workers, and such others as require a greater degree of precision than can be obtained by sifting.

The following table shows the number of wires usually contained in the sieves, and the names of the kinds respectively produced by them:—

	Wires.
Corn emery	16
Coarse grinding emery	24
Grinding emery	36
Fine grinding emery	46
Superfine grinding emery	53
Coarse flour emery	60
Flour emery	70
Fine flour emery	80
Superfine flour emery	90

Washing emery by hand is far too tedious for those who require very large quantities of emery, such as the manufacturers of plate glass and some others, who generally adopt the following method:—Twelve or more cylinders of sheet copper, of the common height of about two feet, and varying from about three, five, eight, to thirty or forty inches in diameter, are placed exactly level, and communicating at their upper edges, each with the next, by small troughs or channels; the largest vessel has also a waste-pipe near the top. At the commencement of the process, the cylinders are all filled to the brim with clean water; the pulverised emery is then churned up with abundance of water in another vessel, and allowed to run into the smallest or the three-inch cylinder, through a tube opposite the gutter leading to the second cylinder. The water during its short passage across the three-inch cylinder, deposits in that vessel such of the coarsest emery as will not bear suspension for that limited time; the particles next finer are deposited in the five-inch cylinder, during the somewhat longer time the mixed stream takes in passing the brim of that vessel; and so on. Eventually the water forms a very languid eddy in the largest cylinder, and deposits therein the very fine particles that have remained in suspension until this period; and the water, lastly, escapes by the waste-pipe nearly or entirely free from emery. In this simple arrangement, time is also the measure of the particles respectively deposited in the manufacture to which the emery is applied. When the vessels are to a certain degree filled with emery, the process is stopped, the vessels are emptied, the emery is carefully dried and laid by, and the process is recommenced.

Holtzapffel informs us that he has been in the habit, for many years, of employing emery of twelve degrees of fineness, prepared by himself by washing over.

For optical purposes, Mr. Ross mixes four pounds of the flour of emery of commerce, with one ounce of powdered gum-arabic, and then throws the powder into two gallons of clear water; and he collects the deposit at the end of 10″ and 30″, and 2′, 10′, 20′, and 60′, and that which is not deposited by one hour's subsidence is thrown away as useless for grinding lenses.

Emery paper is prepared by brushing the paper over with thin glue, and dusting the emery-powder over it from a sieve. There are about six degrees of coarseness. Sieves with thirty and ninety meshes per linear inch are in general the coarsest and finest sizes employed. When used by artisans, the emery-paper is commonly wrapped round a file or a slip of wood, and applied just like a file, with or without oil, according to circumstances. The emery-paper cuts more smoothly with oil, but leaves the work dull.

Emery-cloth only differs from emery-paper in the use of thin cotton cloth, instead of paper, as the material upon which the emery is fixed by means of glue. The emery-cloth, when folded around a file, does not ply so readily to it as emery-paper, and is apt to unroll. Hence smiths, engineers, and others, prefer emery-paper and emery-sticks; but for household and other purposes, where the hand alone is used, the greater durability of the cloth is advantageous.

Emery-sticks are rods of board about eight or twelve inches long, planed up square; or with one side rounded like a half-round file. Nails are driven into each end of the stick as temporary handles; they are then brushed over, one at a time, with thin glue, and dabbed at all parts in a heap of emery-powder, and knocked on one end to shake off the excess. Two coats of glue and emery are generally used. The emery-sticks are much more economical than emery-paper wrapped on a file, which is liable to be torn.

Emery-cake consists of emery mixed with a little bees'-wax, so as to constitute a solid lump, with which to dress the edges of buff and glaze wheels. The ingredients should be thoroughly incorporated by stirring the mixture whilst fluid, after which it is frequently poured into water, and thoroughly kneaded with the hands, and rolled into lumps before it has time to cool. The emery-cake is sometimes applied to the wheels whilst they are revolving; but the more usual course is, to stop the wheel and rub in the emery-cake by hand. It is afterwards smoothed down by the thumb.

Emery-paper, or patent razor-strop paper, is an article in which fine emery and glass are mixed with paper-pulp, and made into sheets as in making ordinary paper; the emery and glass are said to constitute together 60 per cent. of the weight of the paper, which resembles drawing-paper, except that it has a delicate fawn colour. The emery-paper is directed to be pasted or glued upon a piece of wood, and when rubbed with a little oil, to be used as a razor-strop.

In 1842, Mr. Henry Barclay took out a patent for a method of combining powdered emery into *discs* and *laps* of different kinds, suitable to grinding, cutting, and polishing glass, enamels, metals, and other hard substances. The process of manufacture is as follows:—Coarse emery-powder is mixed with about half its weight of pulverised Stourbridge loam and a little water or other liquid, to make a thick paste; this is pressed into a metallic mould by means of a screw-press, and after having been thoroughly dried, is baked or burned in a muffle or close receiver at a temperature considerably above a red heat and below the full white heat. In this case, the clay or alumina serves as a bond, and unites the particles very completely into a solid artificial emery-stone, which cuts very greedily, and yet seems hardly to suffer perceptible wear.

Superfine grinding-emery is formed into wheels exactly in the same manner as the above, but the proportion of loam is then only one-fourth instead of one-half that of the emery. Those emery-stones, which are of medium fineness, cut less quickly, but more smoothly than the above.

Flour-emery, when manufactured into artificial polishing stones, requires no uniting substance, the moistened powder is forced into the metal mould and fired; some portions of the alumina being sufficient to unite the whole. These fine wheels render the works submitted to them exceedingly smooth, but they do not produce a high polish on account of the comparative coarseness of the flour-emery.

A similar method has been adopted by Mr. F. Ransome—at the suggestion, we believe, of Mr. Bessemer—for the production of emery wheels, by a process similar to that employed for the production of artificial stone by the use of silicate of potash, as a cementing material for the finely-divided emery.

Under the name of 'metalline,' Messrs. Bond, Russell, and Fisher, of Newport, Monmouthshire, patented a preparation of blast-furnace slag, which they proposed to introduce as a substitute for emery. See CORUNDUM.

EMERYLITE. A micaceous mineral associated with the emery of Asia Minor. It is identical with *margarite.*

EMETINE. An organic bark obtained from the ipecacuanha root.

EMPATAGE. A French term for the combination of an alkali with the fatty acids.

EMPLECTITE. An ore of bismuth, called also *Tannenite.* See BISMUTH.

EMPYREAL AIR. The name given to oxygen gas shortly after its first discovery. Scheele, in his 'Experiments on Air and Fire,' says:—'Since this air (oxygen) is absolutely necessary for the generation of fire, and makes about one-third of our common air, I shall henceforth for shortness call it *empyreal air* (literally *fire-air*). The air which is unserviceable for the fiery phenomenon, and which makes about two-thirds of common air, I shall for the future call *foul air* (literally *corrupted air*).'—*Chemical Observations and Experiments on Air and Fire.* By Charles William Scheele. Translated by J. R. Forster, LL.D., F.R.S. 1780.

EMPYREUMA. The smell produced by fire applied to organic matters, chiefly vegetable, in close vessels. Thus, empyreumatic vinegar is obtained by distilling wood at a red heat, and empyreumatic oil from many animal substances in the same way.

EMULSIN. The vegetable albumen of the almond. See Watts's 'Dictionary of Chemistry.'

ENAMELS (*Émaux*, Fr.; *Schmelzglas*, Ger.) are varieties of glass, generally opaque or coloured, always formed by the combination of different metallic oxides, to which certain fixed fusible salts are added, such as the borates, fluates, and phosphates.

The ancients carried the art of enamelling to a very high perfection, and we occasionally find beautiful specimens of their work. Then, as at present, each artist made a mystery of the means that succeeded best with him, and thus a multitude of curious processes have been buried with their authors.

The enamel was applied to the metallic ground in several distinct ways, giving rise to very different kinds of enamel-work, which it is desirable to distinguish. In the process called *cloisonné enamelling*, the plan was to braze on to a plain surface of metal, the bars or *cloisons* which were intended to hold the coloured paste which was to be vitrified in the enamel furnace. The vases from China, probably some 500 or 600 years old, are enamelled by the true cloisonné process. After the sacking of the Summer Palace at Peking, large numbers of Chinese cloisonné enamels were brought to Europe, and the English market thus becoming glutted, they sold at prices very much lower than what they would have realised in the East. The cloisonné method was also much used in Mediæval Greek and Byzantine art, and fine examples are to be seen in the celebrated Pala d' Oro, or Altar-front, of the Church of St. Mark at Venice, in the crown of Charlemagne at Vienna, and in the shrine of the Magi at Cologne. Theophilus, who described the cloisonné process in the twelfth century, applied the term *electrum* to these enamels.

A similar yet distinct method is that known as *champ levé enamelling*. Here, instead of fillets of metal being soldered on to the metal ground, the field or ground itself is incised or hollowed out so as to leave the outline of the design in slender elevated bands of metal; the parts which are sunk, or in intaglio, are then filled in with enamel powder, which is vitrified in the furnace, and the surface is finally smoothed down by grinding and polishing. The difference, therefore, between the two processes is this: in the champ levé enamels the metallic fillets, or *cloisons*, forming the partitions between one colour and another, are part of the metallic plate itself, whilst in the cloisonné enamels they are separate bands of metal soldered on to the metallic plate. Champ levé enamels are generally executed in copper; the cloisonné often on gold. The art of champ levé enamelling was extensively practised at Limoges, in France, from the eleventh to the fourteenth century, especially for the decoration of ecclesiastical objects.[1]

Beautiful enamels of modern French workmanship are now produced, in which the enamel colours are surrounded by filigree work obtained by the electrotype process, and many pleasing designs result from the facilities thus afforded of producing this beautiful mixture of metal and enamel—the '*émaux cloisonnés à champ levé*.'

After the champ levé enamelling had long flourished at Limoges, a different and simpler method became popular. This was a method in which the subject was executed in slight relief, by a process of engraving or chasing, and the surface was then encrusted with *translucid* enamels of brilliant colours, through which the design on the subjacent metal was visible. The technicalities of this process were carefully described by Benvenuto Cellini in his 'Trattato dell' Oreficeria.'

Finally, the school of Limoges introduced the method of painting on an enamelled surface. The plate of metal, usually copper, is coated with an opaque white enamel ground, which is fired, and on this ground the design is then painted in enamel colours. All the later Limoges enamels are of this character. The old English enamels made at Battersea and at Bilston in Staffordshire were also produced by this process; snuff-boxes, patch-boxes, tea-caddies, candlesticks, &c., were made of enamelled copper, in the last century, and are now much prized. Modern enamel paintings are also examples of superficial enamelling, but are less popular now than they were some few years ago; the family of Bones for three generations were celebrated as enamel-painters, and Mr. Essex has also obtained reputation in this art. The kind of enamel used as a ground by the artist is known as 'Venetian white hard enamel,' and is composed of silica, borax, and binoxide of tin.

The Venetians are still in possession of the best enamel processes, and they supply the French and other nations with the best kinds of enamel, of every coloured shade.

Enamels are either transparent or opaque; in the former all the elements have experienced an equal degree of liquefaction and are thus run into crystal glass, whilst in the latter, some of their elements have resisted the action of heat, so that their particles prevent the transmission of light. This effect of opacity is produced particularly by the oxide of tin.

The simplest enamel, and the one which serves as a basis to most of the others, is obtained by calcining, first of all, a mixture of lead and tin, in proportions varying from 15 to 50 parts of tin for 100 of lead. The middle term appears to be the most suitable for the greater number of enamels; and this alloy has such an affinity for

---

[1] For the history of Enamelling, the reader may refer to Jules Labarte's 'Recherches sur la Peinture en Émail dans l'Antiquité et au Moyen Age.' Paris, 1856.

oxygen, that it may be calcined with the greatest ease in a flat cast-iron pot, and at a temperature not above a cherry red, provided the dose of tin is not too great. The oxide is drawn off to the sides of the melted metal, according as it is generated, new pieces of the alloy being thrown in from time to time, till enough of the powder be obtained. Great care ought to be taken that no metallic particles be left in the oxide, and that the calcining heat be as low as is barely sufficient; for a strong fire frits the powder, and obstructs its subsequent comminution. The powder when cold is ground in a proper mill, levigated with water, and elutriated. In this state of fineness and purity, it is called *calcine* or flux, and it is mixed with siliceous sand and some alkaline matter or sea-salt. The most ordinary proportions are, 4 of sand, 1 of sea-salt, and 4 of *calcine*. Chaptal states, that he has obtained a very fine product from 100 parts of calcine, made by calcining equal parts of lead and tin, 100 parts of ground flint, and 200 parts of pure sub-carbonate of potash. In either case, the mixture is put into a crucible, or laid simply on a stratum of sand, quicklime spontaneously slaked, or wood-ashes placed under a pottery or porcelain kiln. This mass undergoes a semivitrification, or even a complete fusion on its surface. It is this kind of frit which serves as a radical to almost every enamel; and by varying the proportions of the ingredient, more fusible, more opaque, or whiter enamels are obtained. The first of these qualities depends on the quantity of sand or flux, and the other two on that of the tin.

The sea-salt employed as a flux may be replaced either by salt of tartar, by pure potash, or by soda; but each of these fluxes gives peculiar qualities to the enamel.

Most authors who have written on the preparation of enamels, insist a great deal on the necessity of selecting carefully the particular sand that should enter into the composition of the frit, and they even affirm that the purest is not the most suitable. Clouet states, in the 34th volume of the 'Annales de Chimie,' that the sand ought to contain at least 1 part of talc for 3 of siliceous matter, otherwise the enamel obtained is never very glassy, and that some wrinkled spots from imperfect fusion are seen on its surface; and yet we find it prescribed in some old treatises, to make use of ground flints, fritted by means of salt of tartar or some other flux. It would thence appear that the presence of talc is of no use towards the fusibility of the silica, and that its absence may be supplied by increasing the dose of the flux. In all cases, however, we ought to beware of metallic oxides in the sand, particularly those of iron and manganese, which most frequently occur, and always injure the whiteness of the frit.

The frits for enamels that are to be applied to metallic surfaces require greater fusibility, and should therefore contain more flux; and the sand used for these should be calcined beforehand with one-fourth its weight of sea-salt; sometimes, indeed, metallic fluxes are added, as minium or litharge. For some metallic colours, the oxides of lead are very injurious, and in this case recourse must be had to other fluxes. Clouet states that he has derived advantage from the following mixtures, as bases for purples, blues, and some other delicate colours:—

Three parts of siliceous sand, one of chalk, and three of calcined borax; or, three of glass (of broken crystal goblets), one of calcined borax, one-fourth of a part of nitre, and one part of well-washed diaphoretic antimony. These compositions afford a very white enamel, which accords perfectly well with blue.

It is obvious that the composition of this primary matter may be greatly varied: but we should never lose sight of the essential quality of a good enamel; which is, to acquire, at a moderate heat, sufficient fluidity to take a shining surface, without running too thin. It is not complete fusion which is wanted, but a pasty state, of such a degree as may give it, after cooling, the aspect of having suffered complete liquefaction.

Dead-white Enamel.—This requires greater nicety in the choice of its materials than any other enamel, as it must be free from every species of tint, and be perfectly white; hence the frit employed in this case should be itself composed of perfectly pure ingredients. But a frit should not be rejected hastily because it may be somewhat discoloured, since this may depend on two causes; either on some metallic oxides, or on fuliginous particles proceeding from vegetable or animal substances. Now the latter impurities may be easily removed by means of a small quantity of peroxide of manganese, which has the property of readily parting with a portion of its oxygen, and of thus facilitating the combustion, that is to say, the oxidation of the colouring carbonaceous matter. Manganese, indeed, possesses a colouring power itself on glass, but only in its highest state of oxidisement, and when reduced to the lower state, as is done by combustible matters, it no longer communicates colour to the enamel combinations. Hence the proportion of manganese should never be in excess; for the surplus would cause colour. Sometimes, indeed, it becomes necessary to give a little manganese-colour (i.e. a pink tint) in order to obtain a more agreeable shade of white; as a little azure blue is added to linens, to brighten or counteract the dulness of their yellow tint.

A white enamel may be conveniently prepared also with a *calcine* composed of two parts of tin and one of lead calcined together; of this combined oxide, one part is melted with two parts of fine crystal and a very little manganese, all previously ground together. When the fusion is complete, the vitreous matter is to be poured into clear water, and the frit is then dried, and melted anew. The pouring into water and fusion are sometimes repeated four times, in order to secure a very uniform combination. The crucible must be carefully screened from smoke and flame. The smallest portions of oxide of iron or copper admitted into this enamel will destroy its value.

Some practitioners recommend the use of washed diaphoretic antimony (antimoniate of potash, from metallic antimony, and nitre deflagrated together) for white enamel; but this product cannot be added to any preparation of lead or other metallic oxides; for it would tend rather to tarnish the colour than to clear it up; and it can be used therefore only with ordinary glass, or with saline fluxes. For three parts of white glass (without lead) one part of washed diaphoretic antimony is to be taken; the substances are well ground together, and fused in the common way.

Blue Enamel.—This fine colour is almost always obtained from the oxide of cobalt or some of its combinations, and it produces it with such intensity that only a very little can be used, lest the shade should pass into black. The cobalt blue is so rich and lively that it predominates in some measure over every other colour, and masks many so that they can hardly be perceived; it is also most easily obtained. To bring it out, however, in all its beauty, the other colours must be removed as much as possible, and the cobalt itself should be tolerably pure. This metal is associated in the best known ores with a considerable number of foreign substances, as iron, arsenic, copper, nickel, and sulphur, and it is difficult to separate them completely; but for enamel blues, the oxide of cobalt does not require to be perfectly free from all foreign metals; the iron, nickel, and copper being most prejudicial, should be carefully eliminated. This object may be most easily attained by dissolving the ore in nitric acid, evaporating this solution to a syrupy consistence, to expel the excess of acid, and separate a portion of arsenic. It is now diluted with water, and solution of carbonate of soda is dropped slowly into it with brisk agitation, till the precipitate, which is at first of a whitish grey, begins to turn of a rose-red. Whenever this colour appears, the whole must be thrown on a filter, and the liquid which passes through must be treated with more of the carbonate of soda, in order to obtain the arsenate of cobalt, which is nearly pure. Since arsenic acid and its derivatives are not capable of communicating colour themselves, and as they moreover are volatile, they cannot impair the beauty of the blue, and hence this preparation affords it in great perfection.

Metallic fluxes are not the most suitable for this colour; because they always communicate a tint of greater or less force, which never fails to injure the purity of the blue. Nitre is a useful addition, as it keeps the oxide at the maximum of oxidation, in which state it produces the richest colour.

Yellow Enamel.—There are many processes for making this colour in enamel; but it is somewhat difficult to fix, and it is rarely obtained of an uniform and fine tint. It may be produced directly with some preparations of silver, as the phosphate or sulphate; but this method does not always succeed, for too strong a heat or powerful fluxes readily destroy it, and nitre is particularly prejudicial. This uncertainty of success with the salts of silver causes them to be seldom employed; and oxides of lead and antimony are therefore preferred, which afford a fine yellow when combined with some oxides that are refractory enough to prevent their complete vitrification. One part of white oxide of antimony may be taken with from one to three parts of white lead, one of alum, and one of sal-ammoniac. Each of these substances is to be pulverised, and then all are to be exactly mixed, and exposed to a heat adequate to decompose the sal-ammoniac. This operation is judged to be finished when the yellow colour is well brought out. There is produced here a combination quite analogous to that known under the name of Naples yellow.

Other shades of yellow may be procured either with the oxide of lead alone, or by adding to it a little red oxide of iron; the tints varying with the proportion of the latter.

Clouet says, in his 'Memoir on Enamels,' that a fine yellow is obtained with pure oxide of silver, and that it is merely necessary to spread a thin coat of it on the spot to be coloured. The piece is then exposed to a moderate heat, and withdrawn as soon as this has reached the proper point. The thin film of metallic silver revived on the surface being removed, the place under it will be found tinged of a fine yellow, of hardly any thickness. As the pellicle of silver has to be removed which covers the colour, it is requisite to avoid fixing this film with fluxes: and it ought therefore to be applied after the fusion of the rest. The yellows require in general but little alkaline flux, as they answer better with one of a metallic nature.

Green Enamel.—It is known that a green colour may be produced by a mixture of yellow and blue; but recourse is seldom had to this practice for enamels, as they can be obtained almost always directly with the oxide of copper; or, still better, with the oxide of chrome, which has the advantage of resisting a strong heat.

There are two oxides of copper, the suboxide of an orange colour, which communicates its colour to enamels, but it is difficult to fix; the protoxide is blue in the state of hydrate, but blackish-brown when dry, and it colours green all the vitreous combinations into which it enters. This oxide requires, at most one or two proportions of flux, either saline or metallic, to enter into complete fusion; but a much smaller dose is commonly taken, and a little oxide of iron is introduced. To 4 pounds of frit, for instance, 2 ounces of oxide of copper and 48 grains of red oxide of iron are used; and the ordinary measures are pursued for making very homogeneous enamel.

The green produced by oxide of chrome is much more solid; it is not affected by a powerful fire, but it is not always of a fine shade. It generally inclines too much to the dead-leaf yellow, which depends on the degree of oxygenation of the chrome.

Red Enamel.—We have just stated, that suboxide of copper afforded a fine colour when it could be fixed, a result difficult to obtain on account of the fugitive nature of this oxide; slight variations of temperature enabling it to absorb more oxygen. The proper point of fusion must be seized for taking it from the fire whenever the desired colour is brought out. Indeed, when a high temperature has produced peroxidation, this may be corrected by adding some combustible matter, as charcoal, tallow, tartar, &c. The copper then returns to its lower stage of oxidation, and the red colour which had vanished, reappears. It is possible, in this way, and by pushing the heat a little, to accomplish the complete reduction of a part of the oxide; and the particles of metallic copper thereby disseminated in a reddish ground, give this enamel the aspect of the stone called *aventurine.* The surest and easiest method of procuring suboxide of copper is to boil a solution of equal parts of sugar, and sulphate or rather acetate of copper, in four parts of water. The sugar takes possession of a portion of the oxygen of the cupric oxide, and reduces it to cuprous oxide; when it may be precipitated in the form of a granular powder of a brilliant red colour. After about two hours' moderate ebullition, the liquid is set aside to settle, decanted off the precipitate, which is washed and dried.

The suboxide properly employed by itself, furnishes a red which vies with the finest carmine, and by its means every tint may be obtained from red to orange, by adding a greater or smaller quantity of peroxide of iron.

The preparations of gold, and particularly the oxide and purple of Cassius, are likewise employed with advantage to colour enamel red, and this composition resists a powerful fire tolerably well. For some time back, solutions of gold, silver, and platinum have been used with success instead of their oxides; and in this way, a more intimate mixture may be procured, and, consequently, more homogeneous tints.

Black Enamel.—Black enamels are made with peroxide of manganese or protoxide of iron; to which more depth of colour is given with a little cobalt. Clay alone, melted with about a third of its weight of protoxide of iron, gives, according to Clouet, a fine black enamel.

Violet Enamel.—The peroxide of manganese in small quantity by itself furnishes, with saline or alkaline fluxes, an enamel of a very fine violet hue; and variations of shade are easily had, by modifying the proportions of the elements of the coloured frit. The great point is to maintain the manganese in a state of peroxidation, and, consequently, to beware of placing the enamel in contact with any substance attractive of oxygen.

Such are the principal coloured enamels hitherto obtained by means of metallic oxides; but it is to be wished that new trials be made with such oxides as have not yet been employed. From such researches some interesting results would unquestionably be derived.

Of painting on Enamel.—Enamelling is only done on gold and copper; for silver swells up, and causes blisters and holes in the coat of enamel. All enamel paintings are, in fact, done on either copper or gold.

If on gold, the goldsmith prepares the plate that is to be painted upon. The gold should be 22 carats fine: if purer, it would not be sufficiently stiff; if coarser, it would be subject to melt; and its alloy should be half white and half red, that is, half silver and half copper; whereby the enamel with which it is covered will be less disposed to turn green, than if the alloy were entirely copper.

The workman must reserve for the edge of the plate a small fillet, which he calls the *border.* This ledge serves to retain the enamel, and hinders it from falling off when applied and pressed on with a spatula. When the plate is not to be counter-enamelled.

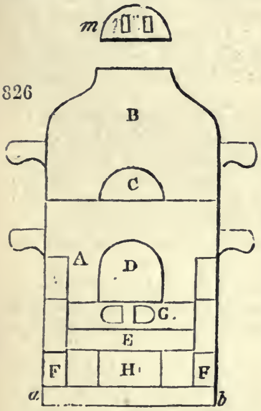
it should be charged with less enamel, as, when exposed to heat, the enamel draws up the gold to itself, and makes the piece convex. When the enamel is not to cover the whole plate, it becomes necessary to prepare a lodgment for it. With this view, all the outlines of the figure are traced on the plate with a black-lead pencil, after which recourse is had to the graver.

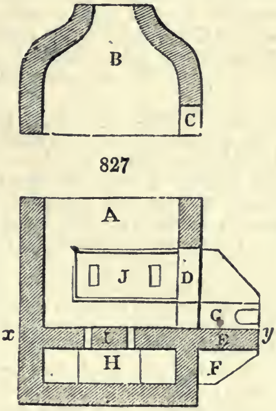
The whole space enclosed by the outlines must be hollowed out in *bas-relief*, of a depth equal to the height of the fillet, had the plate been entirely enamelled. This sinking of the surface must be done with a flat graver as equally as possible; for if there be an eminence, the enamel would be weaker at that point, and the green would appear. Some artists hatch the bottom of the hollow with close lines, which cross each other in all directions; and others make lines or scratches with the edges of a file broken off square. The hatchings or scratches lay hold of the enamel which might otherwise separate from the plate. After this operation, the plate is cleansed by boiling it in an alkaline lye, and it is washed first with a little weak vinegar, and then with clear water.

The plate thus prepared is to be covered with a coat of white enamel, which is done by bruising a piece of enamel in an agate or porcelain mortar to a coarse powder, like sand, washing it well with water, and applying it in the hollow part in its moist state. The plate may meanwhile be held in an ordinary forceps. The enamel powder is spread with a spatula. For condensing the enamel powder, the edges of the plate are struck upon with a spatula.

Whenever the piece is dry, it is placed on a slip of sheet iron perforated with several small holes (see *fig.* 825), which is laid on hot cinders, and left there until it ceases to steam. It must be kept hot till it goes to the fire; for were it allowed to cool, it would become necessary to heat it again very gradually at the mouth of the furnace of fusion, to prevent the enamel from decrepitating and flying off.

826





827

825

828

830

Before describing the manner of exposing the piece to the fire, we must explain the construction of the furnace. It is square, and is shown in front elevation in *fig.* 826. It consists of two pieces, the lower part A, or the body of the furnace, and the upper part B, or the capital, which is laid on the lower part, as is shown in *fig.* 827, where these two parts are separately represented. The furnace is made of good fire-clay, moderately baked, and resembles very closely the assay or cupellation furnace. Its inside dimensions are 9 inches in width, 13 inches in height in the body, and 9 in the capital. Its general thickness is 2 inches.

The capital has an aperture or door, C, *fig.* 826, which is closed by a fire-brick stopper *m*, when the fire is to be made active. By this door fuel is supplied.

The body of the furnace has likewise a door D, which reaches down to the projecting shelf E, called the bib (*mentonnière*), whose prominence is seen at E, *fig.* 826. This shelf is supported and secured by the two brackets, F, F; the whole being of earthenware. The height of the door D, is abridged by a peculiar fire-brick G, which not only covers the whole projection of the shelf E, but enters within the opening of the door D, filling its breadth, and advancing into the same plane with the inner surface of the furnace. This plate is called the hearth; its purpose will appear presently; it may be taken out and replaced at pleasure, by laying hold of the handle in its front.

Below the shelf E, a square hole, H, is seen, which serves for admitting air, and for extracting the ashes. Similar holes are left upon each side of the surface.

On a level with the shelf, in the interior of the furnace, a thin fire-tile I rests, perforated with numerous small holes. This is the grate represented in a ground view in *fig.* 825. *Figs.* 828, 829, 830, represent, under different aspects, the muffle: *Fig.* 828 shows the elevation of its further end; *fig.* 829 its sides; and *fig.* 830 its front part. At J, *fig.* 827, the muffle is seen in its place in the furnace, resting on two bars of iron, or, still better, on ledges of fire-clay, supported on brackets attached to the lateral sides of the furnace. The muffle is made of earthenware, and as thin as possible. The fuel consists of dry beech wood, or oaken branches, about an inch in diameter, cut to the length of nine inches, in order to be laid in horizontal strata within the furnace, one row only being placed above the muffle. When the muffle has attained to a white red heat, the sheet-iron tray, bearing its enamel plate, is to be introduced with a pair of pincers into the front of the muffle, and gradually advanced towards its further end. The mouth of the muffle is to be then closed with two pieces of charcoal only, between which the artist may see the progress of the operation. Whenever the enamel begins to flow, the tray must be turned round on its base to insure equality of temperature; and as soon as the whole surface is melted, the tray must be withdrawn with its plate, but slowly, lest the vitreous matter be cracked by sudden refrigeration.

The enamel plate, when cold, is to be washed in very dilute nitric acid, and afterwards in cold water, and a second coat of granular enamel paste is to be applied, with the requisite precautions. This being passed through the fire, is to be treated in the same way a third time, when the process will be found complete. Should any chinks happen to the enamel coat, they must be widened with a graver, and the space being filled with ground enamel, is to be repaired in the muffle. The plate, covered with a pure white enamel, requires always to be polished and smoothed with sandstone and water, particularly if the article have a plane surface; it is then finally glazed at the fire.

The painting operation now follows. The artist prepares his enamel colours by pounding them in an agate mortar, with a pestle of agate, and grinding them on an agate slab, with oil of lavender, rendered viscid by exposure to the sun in a shallow vessel, loosely covered with gauze or glass. The grinding of two drachms of enamel pigment into an impalpable powder will occupy a labourer a whole day. The painter should have alongside of him a stove in which a moderate fire is kept up, for drying his work whenever the figures are finished, It is then passed through the muffle.

The following was the process adopted by Henry Bone, R.A., and his son, Henry Pierce Bone, who produced the largest enamels ever painted; and beyond the time expended in producing them and consequent expense there appears no practical limit to the size of enamel paintings.

Preparing the plate.—For small plates (up to two inches long) *pure* gold is the best material. Silver (quite pure) is also used, but is apt to get a disagreeable yellow colour at the edges by repeated firings. For larger sizes, copper is used. The copper should be annealed until quite free from spring, and then cleaned with dilute sulphuric acid (one part acid, four water), and shaped in a wooden mould, afterwards used in making the plate so as to produce a convex surface, varying according to the size of the plate, taking care that the shaping does not reproduce the spring in the copper, in which case the process must be repeated. If the place is not raised in the centre, in the course of repeated firings the corners will rise irregularly, producing undulations over the plate, perfect flatness being next to impossible for large pictures. The copper is then laid face downwards on the convex wooden mould used for shaping, and enamel, ground fine with water, is spread over it with a small bone spoon; when covered, a fine cloth doubled is pressed gently on it to absorb the water, and then it is smoothed with a steel spatula. This forms the back of the plate, and when fired this part is finished. The copper is now reversed on a convex board the exact counterpart of the other, and covered with white enamel ground fine in the same way as above. The plate is now ready for firing, and after it has been fired and cooled, the surface must be ground smooth with a flat piece of flint or other hard substance, with silver sand and water. It must next be covered with a softer and more transparent kind of enamel called flux, ground and spread on in the same way as the first enamel, but this time only on the face of the plate. This is fired as before, and when cool the surface must be again ground smooth, and when glazed in the furnace the plate is finished. For the first coat a white solid enamel is used to prevent the green colour from the oxidised copper showing through; the second coat is a softer enamel, to enable the colours used to melt with less heat.

Firing.—The plate is placed on a planche of firestone, or well-baked Stourbridge clay, supported on a bed of whiting, thoroughly dried in the furnace, the exact shape of the plate as originally made, which must be used in all subsequent firings. After the whiting is formed in the shape of the plate it should be notched with a flat knife diagonally across, as in the accompanying diagram, (*fig.* 831). The use of this is to produce an effect of diagonal bracing while the plate cools, and experience has shown that it tends considerably to keep the plate in its original shape. When the plate is small (up to three inches in length) it may be annealed for passing into the hot muffle as follows:—The planche bearing the plate may be placed on another planche heated in the muffle and placed in the front of the muffle for a few minutes, until the steam of the plate or the oil of the picture shall have evaporated; it may then be put in the mouth of the muffle, and gradually inserted to the hottest part. After firing it should be placed on another hot planche, and allowed to cool gradually. Large pictures require a different arrangement of the furnace. Over the muffle there should be a fixed iron annealing box, with an iron shelf and door. The bottom should be of cast iron about one inch thick. This should be so arranged that when the muffle attains a white heat the bottom of the annealing box should be of a brightish red at the back, and a dull blood-red in front. Large pictures should be placed on the bottom of the box before the furnace is lit, and the larger the size of the picture the slower should the furnace be brought to its full heat, so as to allow five or six hours for the largest size, and two or three for smaller plates. When fired the picture should be returned to the shelf of the annealing box, and left there till quite cold, for which purpose large plates require at least twelve hours. The colours used are mostly the same as those prepared for jewellers and glass painters.

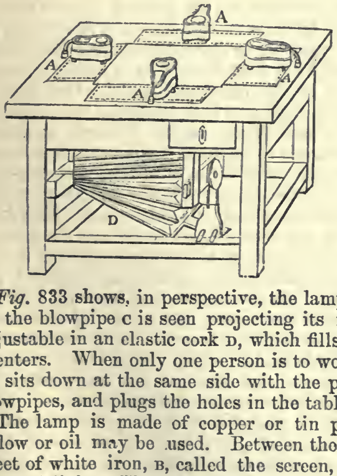
b Bed of whiting.

Enamelling at the Lamp.—The art of the lamp enameller is one of the most agreeable and amusing that we know. There is hardly a subject in enamel which may not be executed by the lamp-flame in very little time, and more or less perfectly, according to the dexterity of the artist, and his acquaintance with the principles of modelling.

In working at the lamp, tubes and rods of glass and enamel must be provided, of all sizes and colours.

The enamelling table is represented in *fig.* 832, round which several workmen, with their lamps, may be placed, while the large double bellows D below is set a-blowing by a treadle moved with the foot. The flame of the lamp, when thus impelled by a powerful jet of air, acquires surprising intensity. The bent nozzles or tubes A, A, A, A, are made of glass, and are drawn to points modified to the purpose of the enameller.

832



833

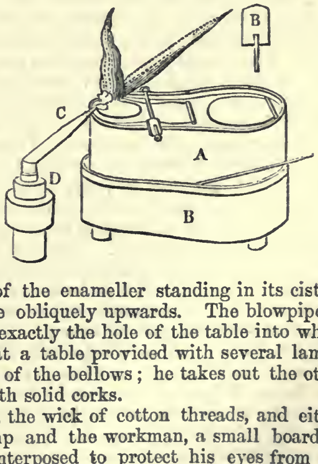


Fig. 833 shows, in perspective, the lamp A of the enameller standing in its cistern B; the blowpipe C is seen projecting its flame obliquely upwards. The blowpipe is adjustable in an elastic cork D, which fills up exactly the hole of the table into which it enters. When only one person is to work at a table provided with several lamps, he sits down at the same side with the pedal of the bellows; he takes out the other blowpipes, and plugs the holes in the table with solid corks.

The lamp is made of copper or tin plate, the wick of cotton threads, and either tallow or oil may be used. Between the lamp and the workman, a small board or sheet of white iron, B, called the screen, is interposed to protect his eyes from the glare of light. The screen is fastened to the table by a wooden stem, and it throws its shadow on his face.

The enamelling workshop ought to admit little or no daylight, otherwise the artist, not perceiving the flame distinctly, would be apt to commit mistakes.

It is impossible to describe all the manipulations of this ingenious art, over which taste and dexterity so entirely preside. But we may give an example. Suppose the enameller wishes to make a swan. He takes a tube of white enamel, seals one of its ends hermetically at his lamp, and while the matter is sufficiently hot, he blows on it a minikin flask, resembling the body of the bird: he draws out and gracefully bends the neck; he shapes the head, the beak, and the tail; then with slender enamel rods of a proper colour, he makes the eyes; he next opens up the beak with pointed scissors; he forms the wings and the legs; finally attaching the toes, the bird stands complete.

The enameller also makes artificial eyes for human beings, imitating so perfectly the colours of the sound eye of any individual as to render it difficult to discover that he has a blind and a seeing one.

It is difficult to make large articles at the blowpipe; those which surpass 5 or 6 inches become nearly unmanageable by the most expert workman.

Enamelling of Cast Iron and other Hollow Ware for Saucepans, &c. In December 1799, a patent was obtained for this process by Dr. Samuel Sandy Hickling. His Specification is subdivided into two parts:—

The coating or lining of iron vessels, &c., by fusion with a vitrifiable mixture, composed of 6 parts of calcined flints, 2 parts of *composition* or Cornish stone, 9 parts of litharge, 6 parts of borax, 1 part of argillaceous earth, 1 part of nitre, 6 parts of calx of tin, and 1 part of purified potash. Or, 2nd,

8 parts of calcined flints, 8 red lead, 6 borax, 5 calx of tin, and 1 of nitre. Or, 3rd,

12 of potter's composition, 8 borax, 10 white lead, 2 nitre, 1 white marble calcined, 1 argillaceous earth, 2 purified potash, and 5 of calx of tin. Or, 4th,

4 parts calcined flint, 1 potter's composition, 2 nitre, 8 borax, 1 white marble calcined, ½ argillaceous earth, and 2 calx of tin.

Whichever of the above compositions is taken, must be finely powdered, mixed, and fused; and the vitreous mass is to be ground when cold, sifted, and levigated with water. It is then made into a pap with water or gum-water. This pap is smeared or brushed over the interior of the vessel, dried and fused with a proper heat in a muffle.

Calcined bones are also proposed as an ingredient of the flux.

The fusibility of the vitreous compounds is to vary according to the heat to be applied to the vessel, by using various proportions of the siliceous and fluxing materials. Colours may be given, and also gilding.

The second part or process in his Specification describes certain alloys of iron and nickel, which he casts into vessels, and lines or coats them with copper precipitated from its saline solutions. It also describes a mode of giving the precipitated copper an enamel surface by acting upon it with bone-ashes and zinc with the aid of heat.

A factory of such enamelled hollow wares was carried on for some time, but it was given up for want of due encouragement.

A patent was granted to Thomas and Charles Clarke, on the 25th of May 1839, for a method of enamelling or coating the internal surfaces of iron pots and saucepans, in such a way as shall prevent the enamel from cracking or splitting off from the effects of fire. This Specification prescribes the vessel to be first cleaned by exposing it to the action of dilute sulphuric acid (sensibly sour to the taste) for three or four hours, then boiling the vessel in pure water for a short time, and next applying the composition. This consists of 100 lbs. of calcined ground flints; 50 lbs. of borax, calcined, and finely ground with the above. That mixture is to be fused and gradually cooled.

40 lbs. weight of the above product is to be taken with 5 lbs. weight of potter's clay; to be ground together in water until the mixture forms a pasty consistent mass, which will leave or form a coat on the inner surface of the vessel about one-sixth of an inch thick. When this coat is set, by placing the vessel in a warm room, the second composition is to be applied. This consists of 125 lbs. of white glass (without lead), 25 lbs. of borax, 20 lbs. of soda (crystals), all pulverised together and vitrified by fusion, then ground, cooled in water, and dried. To 45 lbs. of that mixture, 1 lb. of soda is to be added, the whole mixed together in hot water, and when dry pounded; then sifted finely and evenly over the internal surface of the vessel previously covered with the first coating or composition whilst this is still moist. This is the glazing. The vessel thus prepared is to be put into a stove, and dried at the temperature of 212° Fahr. It is then heated in a kiln or muffle like that used for glazing china. The kiln being brought to its full heat, the vessel is placed first at its mouth to heat it gradually, and then put into the interior for fusion of the glaze. In practice it has been found advantageous also to dust the glaze powder over the fused glaze, and apply a second fluxing heat in the oven. The enamel, by this double application, becomes much smoother and sounder.

Messrs. Kenrick, of West Bromwich, produced in their factory some excellent specimens of enamelled saucepans of cast iron. Dr. Ure exposed the finely-enamelled saucepans of Messrs. Kenrick to very severe trials, having fused even chloride of calcium in them, and found them to stand the fire very perfectly without chipping or cracking. Such a manufacture is one of the greatest improvements recently introduced into domestic economy; such vessels being remarkably clean, salubrious, and adapted to the most delicate culinary operations of boiling, stewing, making of jellies, preserves, &c. They are also admirably fitted for preparing pharmaceutical decoctions, and ordinary extracts.

The enamel of these saucepans is quite free from lead. In several of the saucepans which were at first sent into the market, the enamel was found on analysis to contain a notable proportion of oxide of lead. In consequence of the quantity of borax and soda in the glaze, this oxide was so readily acted upon by acids that sugar of lead was formed by digesting vinegar in them with a gentle heat.

A suitable oven or muffle for lining or coating metals with enamel may have the following dimensions:—

The outside, 8 feet square, with 14-inch walls; the interior muffle, 4 feet square at bottom, rising 6 inches at the sides, and then arched over; the crown may be 18 inches high from the floor; the muffle should be built of fire-brick, 2½ inches thick. Another arch is turned over the first one, which second arch is 7 inches wider at the bottom, and 4 inches higher at the top. A 9-inch wall under the bottom of the muffle at its centre divides the fire-place into two, of 16 inches width each, and 3 feet 3 inches long. The flame of the fire plays between the two arches and up through a 3-inch flue in front, and issues from the top of the arch through three holes about 4 inches square. These open into a flue, 10 x 9 inches, which runs into the chimney.

The materials for the enamel body (ground flint, potter's clay, and borax) are first mixed together, and then put into a reverberatory furnace, 6 feet 7 inches long, by 3 feet 4 inches wide, and 12 inches high. The flame from an 18-inch fire-place passes over the hearth. The materials are spread over the floor of the oven, about 6 inches thick, and ignited or fritted for 4 or 5 hours, until they begin to heave and work like yeast, when another coating is put on the top, also six inches thick, and fired again, and so on the whole day. If it be fired too much, it becomes hard and too refractory to work in the muffles. The glaze is worked in an oven similar to the above. It may be composed of about one-half borax and one-half of Cornish stone (partially-decomposed granite) in a yellowish powder procured from the potteries. This is fritted for 10 hours, and then fused into a glass which is ground up for the glaze.

The Patent Enamel Company use coloured enamel very extensively, and by the use of stencil plates produce cheaply very good designs in enamel upon articles of iron. Their manufacture by this process of street plates, and signs in enamel are of much interest. The following are recipes for enamels in general use:—

Grey Mixture Enamel.

	lbs.	oz.
Sand	10	0
Red lead	33	0
Boracic acid	20	0
Cullett	114	0
Bicarbonate of soda	16	0
Nitre	1	2
Manganese	0	8½
	194	10½

Another is—

	lbs.	oz.
Flint	36	0
Boracic acid	24	0
Bicarbonate of soda	24	0
Nitre	18	0
	102	0

White Mixture Enamel.

	lbs.	oz.
Cullett	11	0
Boracic acid	7	0
Bicarbonate of soda	0	4
Phosphate of lime	3	8
Oxide of antimony	0	2
	21	14

ENAMELLED LEATHER. Leather glazed upon one surface, the so-called enamelling composition being in all respects analogous to the ordinary varnishes. Instead of enamelling the grain surface, as is usually done, Mr. Nossiter removes that surface by splitting or buffing, and then produces what is called 'a finish' upon the surface thus formed, by means of a roller, or glass instrument. The flesh side of the skin may be thus prepared for enamelling; and it is less liable to crack, and the enamel to become cloudy on it than on the grain side. See LEATHER.

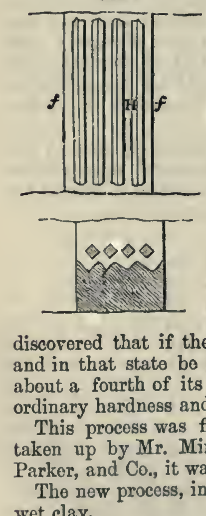
ENARGITE. An arsenio-sulphide of copper, occurring in the form of a grey or iron-black mineral with metallic lustre. It is found in certain mines in Mexico, Peru, and Chili.

ENCAUSTIC PAINTING. A mode of painting with heated or burnt wax, which was practised by the ancients. The wax, when melted, was mixed with as much colour, finely powdered, as it could imbibe, and then the mass was spread on the wall with a hot spatula. When it became cold, the designer cut the lines with a cold pointed tool, and other colours were applied and melted into the former. Many modifications of the process have been employed. Amongst the moderns, the term has been improperly given to some cements, which have nothing of an encaustic character about them.

ENCAUSTIC TILES are tiles in which any design has been produced by fusing in other colours than such as form the colour of the ground. Encaustic tiles are of all ages, and we find them representing every variety of subject.

The manufacture of encaustic tiles has been carried to great perfection in our own times. It will be well to consider this manufacture in connection with *Tesseræ*, there being, indeed, no difference in the first production of tiles or tesseræ, except that the latter are at first moulded with the spaces which are to be filled in with the coloured clays to form the patterns impressed upon them.

834



The Roman tesseræ, of which many very fine examples have been discovered in this country, were often formed of natural stones (sometimes coloured artificially), but generally of baked clay. The beauty of many of these has led to the production of modern imitations, which have been gradually improved, until, in the final result, they far exceed any work of the Romans.

About half a century since, Mr. C. Wyatt obtained a patent for a mode of imitating tesselated pavements, by inlaying stone with coloured cements. Terra-cotta, inlaid with coloured cements, has also been employed, but with no very marked success.

Mr. Blashfield produced imitations of those pavements, by colouring cements with the metallic oxides: these stood exceedingly well when under cover, but they did not endure the winter frosts, &c. Bitumen, coloured with metallic oxides, was also employed by Mr. Blashfield. In 1839 Mr. Singer, of Vauxhall, introduced a mode of forming tesseræ from thin layers of clay. These were cut into the required forms, dried and baked. In 1840 Mr. Prosser, of Birmingham, discovered that if the material of porcelain (china clay) be reduced to a dry powder, and in that state be compressed between steel dies, the powder is condensed into about a fourth of its bulk, and is converted into a compact solid substance of extraordinary hardness and density.

This process was first applied to the manufacture of buttons, but was eventually taken up by Mr. Minton, and, in conjunction with Mr. Blashfield, Messrs. Wyatt, Parker, and Co., it was carried to a high degree of perfection for making tesseræ.

The new process, invented by Mr. Prosser, avoided the difficulty altogether of using wet clay.

This change in the order of the potter's operations, although very simple in idea (and a sufficiently obvious result of reflection on the difficulties attending the usual course of procedure), has nevertheless required a long series of careful experiments to find out the means of rendering it available in practice.

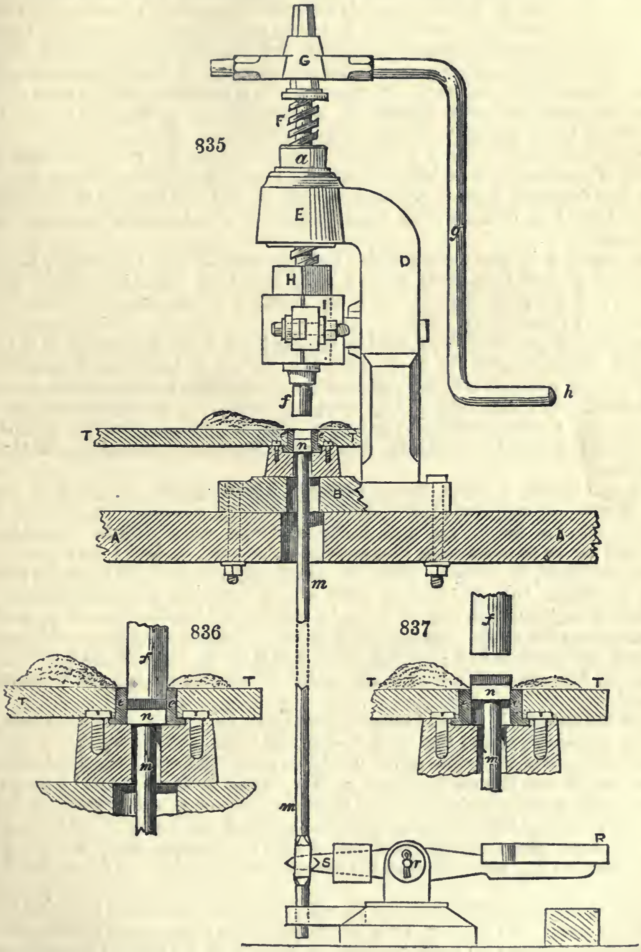
The power which the hand of the potter has exercised over his clay has been proverbial from time immemorial, but it is limited to clay in its moist or plastic state; and clay in its powdered state is an untractable material, requiring very exact and powerful machinery to be substituted for the hand of the potter; in order, by great pressure, to obtain the requisite cohesion of the particles of clay.

In the new process, the clay, or earthy material, after being prepared in the usual manner, and brought to the plastic state, as above described (except that no kneading or tempering is requisite), is formed into lumps, which are dried until the water is evaporated from the clay.

The lumps of dried clay are then broken into pieces, small enough to be ground by a suitable mill into a state of powder, which is afterwards sifted, in order to separate all coarse grains and obtain a fine powder, which it is desirable should consist of particles of uniform size as nearly as can be obtained. The powder, so prepared, is the state in which the clay is ready for being moulded into the form of the intended article by the new process.

The machine and mould used for moulding articles of a small size, in powdered clay, are represented in the annexed drawings, wherein *fig.* 835 is a lateral elevation of the whole machine.

A A is the wooden bench or table whereon the whole is fixed, that bench being sustained on legs standing on the floor. B D E is the frame, formed in one piece of cast



835

836

837

iron; the base, B, standing on the bench, and being fixed thereto by screw bolts; the upright standard, D, rising from the base, and sustaining at its upper end the boss, E, wherein the nut or box, *a*, is fixed for the reception of the vertical screw, F. The screw, F, works through the box, *a*, and has a handle, G, *g*, *h*, applied on the upper end of the screw; the handle is bended downwards at *g*, to bring the actual handle, *h*, to a suitable height for the person who works that machine to grasp the handle, *h*, in his right hand, and, by pulling the handle, *h*, towards him, the screw, F, is turned round in its box, *a*, and descends. The lower end of the screw, F, is connected with a square vertical slider, H, which is fitted into a socket, I, fixed to the upright part, D, of the frame, and the slider, H, is thereby confined to move up or down, with an exactly vertical motion, when it is actuated by the screw, without deviation from the vertical.

Thus far the machine is an ordinary screw press, such as is commonly used for cutting and compressing metals for various purposes. The tools with which the press is furnished for the purpose of this new process consist of a hollow mould, *e e*, formed of steel, the exterior cavity of the mould being the exact size of the article which is to be moulded. The mould, *e e*, is firmly fixed on the base, B, of the frame, so as to be exactly beneath the lower end of the piston *a*, or plug, *f*, which is fastened to the lower end of the square slider, H, and the plug, *f*, is adapted to descend into the hollow of the mould, *e e*, when the slider, H, is forced downwards by action of the screw, F, the plug *f* being very exactly fitted to the interior of the mould, *e e*.

The bottom of the mould, *e e*, is a moveable piece, *n*, which is exactly fitted into the interior of the mould, but which lies at rest in the bottom of the mould, *e e*, during the operation of moulding the article therein; but afterwards the moveable bottom, *n*, can be raised up by pressing one foot upon one end, R, of a pedal lever, R S, the fulcrum of which is a centre pin, *r*, supported in a standard resting upon the floor, and the end, S, of the lever operates on an upright rod, *m*, which is attached at its upper end to the moveable bottom, *n*, of the mould, *e e*.

A small horizontal table, T T, is fixed round the mould, *e e*, and on that table a quantity of powdered clay is laid in a lump in readiness for filling the mould.

The two detached figures, marked *figs.* 836 and 837, are sections of the mould *e e*, and the plug, *f*, on a larger scale than *fig.* 835, in order to exhibit their action more completely.

The operation is extremely simple: the operator, holding the handle, *h*, with his right hand, puts it back from him, so as to turn back the screw, F, and raise the slider, H, and the plug, *f*, quite out of the mould, *e e*, and clear above the orifice of the mould, as shown in *fig.* 835.

Then, with a spatula of bone, held in the left hand, a small quantity of the powder is moved laterally from the heap, along the surface of the table, T, T, towards the mould *e e*, and gathered into the hollow of the mould with a quiet motion, so as to fill that hollow very completely, and by scraping the spatula evenly across over the top of the mould, *e e*, the superfluous powder will be removed, leaving the hollow cavity of the mould exactly filled with the powder in a loose state, and neither more nor less than filled.

Then the handle, *h*, being drawn forwards with a gentle movement of the right hand, it turns the screw, F, so as to bring the slider, H, and the plug, *f*, which thereby descends into the mould, *e e*, upon the loose powder wherewith the mould has been filled, and begins to press down that powder, which must be done with a gentle motion without any jerk, in order to allow the air that is contained in the loose powder to make its escape; but the pressure, after having been commenced gradually, is continued and augmented to a great force, by pulling the handle strongly at the last, so as to compress the earthy material down upon the bottom, *n*, of the mould, into about one-third the space it had occupied when it was in the state of loose powder. The section, *fig.* 836, shows this state of the mould, *e e*, and the plug, *f*, and the compressed material.

Then the handle, *h*, is put backwards again, so as to turn back the screw, F, and raise up the slider, H, and the plug, *f*, until the latter is drawn up out of the mould, *e e*, and clear above the orifice of the mould, as in *fig.* 835, and immediately afterwards by pressure of one foot on the pedal, R, of the pedal lever, R, S, and by action of the upright rod, *m*, the moveable bottom, *n*, of the mould is raised upwards in the mould *e e*, so as to elevate the compressed material which is resting upon the bottom, *n*, and carry the same upwards, quite out of the mould *e e*, and above the orifice of the mould, as is shown in *fig.* 837, and then the compressed material can be removed by the finger and thumb.

The compressed material which is so withdrawn is a solid body, retaining the exact shape and size of the interior cavity of the mould, and possessing sufficient coherence to enable it to endure as much handling as is requisite for putting a number of them into an earthenware case or pan, called a sagger, in which they are to be enclosed, according to the usual practice of potters, in preparation for putting them into the potter's kiln for firing; the sagger protects the articles from discoloration by smoke, and from partial action of the flame, which, if a number of small articles were exposed thereto without being so enclosed, might operate more strongly upon some than upon others of those articles; but by means of the saggers the heat is caused to operate with cleanness, uniformity, and certainty upon a number of small articles at once.

After the firing is over, the articles being removed from the saggers, are in the state of what is termed biscuit, and are ready for use, unless they are required to be glazed, in which case they may be dipped into a semi-liquid composition of siliceous and other matters, ground in water to the consistency of cream, and the surface of the articles which are so dipped becomes covered with a thin coating of the glazed composition; then the articles are again put into saggers, and subjected to a second operation of firing in another kiln, the heat whereof vitrifies the composition and gives a glassy surface to the articles, all which is the usual course of making glazed earthenware or porcelain; but for articles formed by the new process, a suitable glazing composition is more usually applied within the saggers, into which the articles are put for the first firing, and the glazing is performed at the same time with the first burning, without any other burning being required. Or, in other cases, the composition of the earthy materials which are chosen for the articles may be such that they will become partially vitrified by the heat to which they are exposed in the kiln, and thereby external glazing is rendered unnecessary.

The great contraction which must take place in drying articles which have been moulded from clay in the moist state is altogether prevented, and consequently all uncertainty in the extent of that contraction is avoided. Tiles, tesseræ, and other articles are now made by this machine; and very beautiful pavements are constructed, excelling the finest works of the Romans in form, in colour, and in all the mechanical conditions.

It will be evident that any pattern can be impressed upon the clay by having a mould with the pattern in relief upon it. In some cases the coloured clay is placed in the depressed portions of the tile before firing at all; in others, it is subjected to the first firing before the coloured clay is introduced. In either case, the second or coloured clay, for the production of the kind of tile called encaustic, is spread in the state of a cream, so as to fill the pattern, every trace being carefully removed from the other part. See TILES.

ENCHASING. The art of ornamenting gold and silver metal work with designs punched out from behind, or engraved on the surface. It is also applied to enclosing gems in the metal for ornamentation.

ENCRINITAL or **ENTROCHAL MARBLE.** Marble containing the fossil remains of Encrinites, or 'stone-lilies.' Much of the encrinital marble used for ornamental purposes comes from the Mountain Limestone of Derbyshire.

ENDELLIONITE. An old name for Bournonite, in allusion to its occurrence at Endellion, in Cornwall.

ENDIRONS or **ANDIRONS.** Iron racks used in ancient houses when the fires were of wood, and on the hearth, to support the ends of the logs of wood.

ENDIVE. An esculent plant, the *Cichorium Endivium*, belonging to the natural order of the *Compositæ*.

ENDOGENOUS. See EXOGENOUS.

ENDOSMOSE. See EXOSMOSE.

ENGLISH VARNISH. Drying oil prepared with litharge is made to dissolve gum mastic until it assumes the appearance of a jelly. This is English Varnish, and is used by artists for glazing, flowing freely under the brush.

ENGRAVING, a word derived from ἐν, *in*, and γράφω, to *grave* or *write*, is the art of executing designs or devices upon metal, stones, and other hard substances. In the common acceptation of the word in the present day, it means the execution of such works on plates of copper or steel, for the purpose of obtaining from them impressions in ink or some other coloured fluid. Engraving, in the widest sense of the term, is the oldest of the fine arts; at least, the Scriptures mention it before any reference is made either to painting or sculpture. In the Book of Exodus, ch. xxviii. v. 29, we read that 'Aaron shall bear the names of the children of Israel in the breast-plate of judgment upon his heart;' and again, in the same chapter, Moses is commanded to 'make a plate of pure gold, and grave upon it, like the engravings of a signet, Holiness to the Lord.' Further on, in the 35th chapter of the same book, Moses speaks of Bezaleel, the son of Uri, as a man 'filled with the spirit of God, in wisdom, in understanding, and in knowledge, and in all manner of workmanship; and to devise curious works, to work in gold, and in silver, and in brass, and in the cutting of stones,' &c. Of him and of Aholiab it is said,—'Them hath he filled with wisdom of heart, to work all manner of work, of the engraver,' &c. &c. These extracts will suffice to show the antiquity of the art of incising, or cutting hard substances; whether or not it had its origin at a period anterior to the time of Moses there is no record; but it is not improbable that the Israelites acquired some knowledge of the art from the Egyptians during their lengthened captivity: an assumption strengthened by the fact, that numerous specimens of hieroglyphic engraving, on metal plates and on stone, have been discovered in Egypt and brought to this country; their dates, however, have not, in all cases, been ascertained with certainty.

It is unnecessary to trace back, among the nations of antiquity, all that might be written respecting the state of this art in its various applications; but, as an example of its adoption for a purpose altogether practical, a passage from Herodotus may be adduced. This historian, referring to a period about 500 years before the Christian era, says:—'Aristagoras exhibited to the king of Sparta a tablet, or plate, of brass, on which was inscribed every part of the habitable world, the seas, and the rivers;' or, in other words, Aristagoras, who was a native of Cuma, had in his possession a metallic map. Moreover, as it is intended to limit this notice to the art of engraving on steel or copper for printing purposes, we pass over those branches or departments of the art that relate to die-sinking, seal-engraving, and engraving on coins, the latter a common process with the Ancient Britons and Saxons, who also, according to the opinion of many modern antiquaries, used to ornament their weapons of war with designs cut by the graving tool.

The transition from all previous methods of engraving, to that which in some degree assimilates to what is now practised as the result of the discovery of printing, has been thus described by the late Mr. Landseer, who quotes an earlier writer, Mr. Strutt:—'Soon after the Conquest (though, from other information, I think it must have been at the least 250 years from that memorable era) a new species of engraving, entirely different from the mingled work of the engraver, goldsmith, and chaser, which had preceded it, was introduced into, or invented in, England, of which there is scarcely an old country church of any consequence, but affords some curious specimens, and England more than any other nation in Europe. The brass plates on our old sepulchral monuments are executed entirely with the graver, the shadows being expressed by lines or strokes, strengthened in proportion to the required depth of shade, and occasionally crossed with other lines a second and, in some instances, a third time, precisely in the same manner as a copper-plate is engraven that is intended for producing impressions. These engraved effigies are commonly found on those horizontal tombstones which form part of the pavement within the churches; and the feet of the congregation, which kept the lights bright by friction, filled the incisions with dust, and thus darkened the shades: very neat or exquisite workmanship is not therefore expected; yet some of them bear no small evidence of the abilities of the monks, or other workmen, by whom they were performed.' Impressions, technically called 'rubbings,' are taken from these monumental brasses by antiquaries, for the purpose of illustrating works in archæology. The process is simple enough: a sheet, or sheets, as may be required, of white paper, sufficiently large to cover the brass tablet, are laid upon it; these are then rubbed over with a lump of 'shoemaker's heel-ball,' a composition of wax and lamp-black, which leaves on the paper an impression of the raised portions of the metal.

The fifteenth century, which must always be considered as the dawn of universal light and knowledge, gave to the world the art of printing, and from this invention, arose a new era in the art of engraving. The earliest method of printing, both books and illustrations, was, as is described under the article ENGRAVING ON WOOD, from engraved blocks or tablets. It seems singular that, though engraving on various metals had been practised long before that on wood, no attempt had ever been made to obtain impressions from the plates; like many other important discoveries, this is said to have been the result of accident. Vasari, the historian of Italian art, says that, in the year 1460, Maso, or Thomaso Finiguerra, a Florentine goldsmith, chanced to let fall a small engraved plate, on which, as was customary with engravers, he had rubbed a little charcoal and oil, that he might better see the state of his work, into some melted sulphur, and observing that the exact impression of his engraving was left on the sulphur, he repeated the experiment, by passing a roller gently over it. It was successful, and Finiguerra imparted his discovery to Baldini, also a goldsmith of Florence, by whom it was communicated to others. But the most probable origin of the art of printing from metallic plates, is that which is attributed to the early Italian workers in *niello*, or inlaid modelling work, an art used for ornamenting table utensils, swords, armour, &c.: this art consisted in cutting or engraving the required design on silver, and filling up the incisions with a black composition, said to be made of silver and lead, which, from its dark colour, was called by the ancients *nigellum*, abbreviated by the Italians into *niello*; this mixture, when run into the engraved lines, produced a regular effect of *chiar-oscuro* in the entire work. From these engraved plates or objects, the artists in *niello*, who were the goldsmiths and silversmiths of that period, were accustomed to take impressions, by smoking the metal, and then, after cleaning the smooth surface with oil, impressing upon it a piece of damp paper. From such an origin, or from some other very similar to it, undoubtedly, came the art of chalcography, or plate-printing, and it is equally certain, that the art of engraving with the *burin*, or as it is now called, 'line engraving,' arose in the workshops of the gold- and silversmiths.

The practice of making paper from rags, without which the former art would have proved comparatively useless, had been adopted generally throughout Europe towards the end of the fourteenth century, whereby the chief obstacle to printing was removed.

Not very long after the discovery of plate-printing, the engravers, separating themselves from the manufacturing goldsmiths and chasers, formed themselves into a distinct body, opened schools for pupils, and took up their rightful position among the artists of the time.

Italy and Germany have each contended for the honour of being the first discoverers of the art of printing from engraved plates; but the best authorities give to the former country the priority of claim, though the Germans, to whom the printing press was earliest known, soon surpassed their rivals, both in that art and in engraving: but they have not always maintained the superiority.

The principal Italian engravers, contemporary with, or immediately following Finiguerra, were Baldini, Botticelli, and Andrew Mantegna; in Germany, the names of Martin Schön, who began his career about the year 1460, and engraved his own compositions, Israel van Mecheln, Leydenwurf, and Wolgemuth, stand prominently forward; but it was not till the commencement of the sixteenth century, that engraving occupied a high position among the arts of either country. Singularly enough, Italy, Germany, and Holland produced each an engraver, whose works to this day are held in the highest estimation: while Marc Antonio Raimondi (born at Bologna, in 1488), and Albert Dürer (born at Nuremberg, in 1471), were respectively practising the art in Italy and Germany, Lucas van Leyden (born at Leyden, in 1494) disputed in the Low Countries the palm with these distinguished competitors. As these artists have ever been considered the patriarchs of engraving, a few words respecting the merits of each may not inappropriately be introduced here.

Travelling to Venice for improvement, Marc Antonio saw there some prints, by Albert Dürer, of the Life of the Virgin; these he copied with tolerable fidelity; he soon, however, quitted Venice, and went to Rome, where he made the acquaintance of Raffaelle, a large number of whose works he engraved. 'The purity of his outlines,' says Bryan, 'the beautiful character and expression of his heads, and the correct drawings of the extremities, establish his merits as a perfect master of design.' His works frequently exhibit a deficiency in reflex light and harmony of *chiar-oscuro*, and he appears to have been ignorant of the principles of rendering local colour, or tints, in the abstract; neither did he attempt, or else was unable, to express the various textures of substances: these are, however, minor defects by comparison, and may easily be excused when the state of art generally at that period is taken into account. 'Raffaelle,' says Landseer, 'was Mark Antonio's object; and the blandishments, the splendour, and the variety which would have been indispensably necessary to the translation of Correggio or Titian, were not called for here.'

Albert Dürer, the head of the German school of engraving, laboured under disadvantages with which the artists of Italy had not to contend: the latter had frequently, if not constantly, the graceful forms and flowing outlines of antique sculpture made familiar to them: and hence their works exhibit, even from the earliest time, much greater elegance of manner, and refinement in execution, than those of Germany. The engravings by Dürer, whom Landseer supposes to be the first who corroded his plates with *aqua-fortis*, partake largely of the stiff, dry, and Gothic manner, peculiar to the country and the period, and which to this day is more or less discernible in German art. If Dürer had been so fortunate as to have had the pictures of Raffaelle to engrave, he would doubtless have left the world prints of a very different character from those we now see: we should have had more grace of expression, and freedom of lines, but less originality in the style of execution, and probably, less vigour. Dürer engraved only his own designs, and his faults or defects were those of his time: but notwithstanding his Gothic bondage, nothing that has ever appeared in more recent periods surpasses, in executive excellence, his 'St. Jerome seated in a Room;' here all the objects are rendered with a fidelity that only the camera could emulate. That very remarkable and mysterious composition known as 'The Death's Head,' is also a masterly example of execution: the helmet, with all its pomp of heraldic appendage, and the actual and reflex lights on its polished surface, are characteristically, though minutely, expressed: the skull is accurately drawn, and its bony substance unmistakably described. The head of the Satyr, with its beard and wild redundance of snaky tangled hair, has considerable and well-managed breadth of light and shade: the drapery of the female, quaint as it is in style, is not, as we see it in Dürer's other works, hard, stiff, and formal, but relaxes into freedom and simplicity, and has quite a silky texture; in fact, it approaches very nearly to what we now call 'picturesque composition of forms, and light and shade.' Dürer's etching appears to have been bitten in, or corroded with the acid, at once. He seems either not to have known, or did not care to practise, the process now adopted, of 'stopping out,' for the purpose of producing gradation of shade. The admirable wood engravings by this artist are referred to in their proper place.

The works of Van Leyden, the Dutchman, are even more Gothic in taste and style than those of Dürer, with whom he is said to have been intimately acquainted: they exhibit the same amount or degree of stiff, angular drapery; as much, perhaps even more, inattention to grace and dignity of form, without his fertile imagination, his occasional vigour, and his truthful observation of individual nature. His execution is neat and clearly defined, but his plates are deficient in firmness and harmonious effect, and his lines are without variation in substance; those that represent near objects, and those that express objects at a distance, are equally fine and delicate; hence the monotony apparent in his prints. They are almost entirely sacred or legendary subjects, from his own designs; among the finest are 'The Temptation of St. Anthony,' engraved in 1509, when he was only thirteen years of age, 'The Crucifixion,' and the 'Adoration of the Magi.

It would be beyond the province of this notice to record the progress of the art, through the continental schools, till it took root in England; yet a short history of its introduction and growth on our soil may not be considered out of place.

Until the middle of the last century, neither painting nor engraving had attained any eminence in this country; the latter art, especially, was practised chiefly by foreigners, as Hollar, Simon, Vaillant, Blooteling, &c.; previously to whom we had, of our own countrymen, Faithorne, an admirable engraver of portraits, Payne, White, and one or two others of inferior merit; but, with the exception of Faithorne, none whose works are now held in much esteem. The encouragement afforded by George III., almost as soon as he ascended the throne, to the fine arts generally, and the establishment of the Royal Academy, which offered to artists a position in the country they had never before held, gave an impulse to every section or branch of art professors. Hogarth's name had, however, become widely known many years before: his numerous plates, all of them from his own designs, are to this day much sought after, not so much, perhaps, for any especial excellence as examples of fine engravings, as for the talent and genius which the subjects display. 'Hogarth composed comedies as much as Molière,' was the remark of Walpole: he died just as art was beginning to be recognised and patronised in England. Francis Vivares, a Frenchman by birth, but long settled in England, where he studied the art under Chatelain, carried landscape-engraving to a high point of excellence; some of his prints after pictures by Claude and Gaspar Poussin exhibit remarkable freedom in the foliage of the trees, and truth in the texture of the various objects introduced in the landscape. Woollett, born at Maidstone, in Kent, who died in 1785, and Sir Robert Strange, a native of one of the Orkney Islands, who died in 1792, advanced the art still further; indeed, it is a question whether engraving has ever found more able exponents than these two distinguished men: the latter engraved several portraits, which have rarely been surpassed at any period in the history of art. The works of both these engravers are characterised by bold and vigorous execution, produced by the combined use of the etching-needle and the graver. Cotemporary with these, or their immediate successors, were Browne, who sometimes worked with Woollett, Bartolozzi, Hall, Rooker, Green, Ryland, Watts, Sharp, McArdell, Smith, Earlom, &c.; all aided, by their proficiency, to uphold the honour of the art; while John Landseer, Raimbach, Engleheart, Pye, and John Burnet, may be regarded as the chief connecting links between the past generation and the present.

Engraving on metal plates may be classed under the following heads:—*Etching*, *line*, *mezzotinto*, *chalk*, *stipple*, and *aquatint*. Before describing the processes of working these respective kinds, a notice of the instruments used by the engraver is necessary. These, with some modifications, are employed in all the styles.

The *etching-point*, or *needle*, is a stout piece of steel-wire inserted into a handle; two or three, varying in thickness, are requisite, and they should be frequently and carefully sharpened. This is best done by turning the needle round in the fingers while rubbing it on a hone, and afterwards on a leather strop prepared with putty powder, or on an ordinary razor-strop, to take off any roughness, and to make it perfectly round.

The *dry-point* is a similar instrument, used for delicate lines: it must be sharpened on the hone till a fine conical point is obtained.

The *graver*, or *burin*, is the principal instrument employed in engraving: several are required, differing from each other in form, from the extreme *lozenge* shape to the *square*; the former being used for cutting fine lines, the latter for broad: the graver fits into a handle about five inches and a half long, and it should be well tempered before using, an operation requiring great care. The angle at the meeting of the two lower sides is called the *belly*, and the breadth of the end, the *face*. To sharpen the former, lay one of the flat sides of the graver on the oilstone, keeping the right arm tolerably close to the side, and rub it firmly; next rub the other in the same way: the face is sharpened by holding it firmly in the hand, with the belly upwards, in a slanting direction; rub the end rather gently on the stone, at an angle of about forty-five degrees, taking care to carry it evenly along until it acquires a very sharp point: this being done, hold the engraver a little more upright to square the point, which a very few rubbings will effect. The graver for *line* work must be slightly turned up, to enable the engraver to run it along the plate; otherwise, the first indentation he makes on the metal would cause his instrument to become fixed: the graver for *stipple* should be slightly turned down, to make dots only.

The *scraper*, which should have three fluted sides, is used for taking off the *burr* left by the action of the needles on the metal.

The *burnisher* is employed to soften lines that have been *bitten in*, or engraved too dark, and to polish the plate, or get rid of any scratches it may accidentally have received.

The *dabber* used to lay the *etching-ground* evenly, is made by enclosing a small quantity of fine cotton wool very tightly in a piece of silk, the threads of which should be, as much as possible, of uniform thickness.

There are a few other materials which an engraver should have at hand, but they are not of sufficient importance to be mentioned here; we may, however, point out what is technically called a *bridge*, which is nothing more than a thin board for the hand to rest on; it should be smoothly planed, and of a length and breadth in proportion to the size of the plate; at each end a small piece of wood should be fastened to raise it above the plate when covered with wax. A *blind*, made of tissue-paper stretched upon a frame, ought to be placed between the plate and the light, to enable the engraver to see his work on the metal with greater facility and clearness.

In describing the processes of engraving the various styles enumerated above, little more than a general outline of each method can be given, yet sufficient, it may be presumed, to show the nature of the operation: to narrate all the details that might be included on the subject would supply matter enough for a small volume.

Etching may be classed under two heads: that which is made the initiatory process in line-engraving, and that which is known as *painter's-etching*: the latter was practised to some extent by very many of the old painters, particularly those of the Dutch school; and it has also come into fashion with many of the artists of our own day, but more for amusement, however, than for any other purpose; in both cases the method of proceeding is alike. Etching is the result of a chemical process resulting in corrosion of the metal on which the design has been laid down, or transferred, in the following manner. The plate must first be covered with a substance already spoken of as *etching-ground*, which may be purchased of most of the principal artists' colourmen, but many engravers make their own: the annexed receipt has been handed to us by Mr. C. W. Sharpe, who has engraved some very large steel-plates, as that which he always uses:—

	Parts
Black pitch	1
White wax	1
Burgundy pitch	¼
Asphaltum	1
Gum mastic	1

Melt the first three ingredients over a slow fire in a pipkin, then add the other two, finely powdered, stirring the whole together all the time; when well mixed, pour it into warm water, and make it up, while warm, into balls; if too soft, a little less wax should be used. Care must be taken not to let the mixture burn during the process of making.

The etching-ground resists the action of the *aqua-fortis*. It should be tied up in a piece of strong silk, and applied thus, which is called *laying the ground*:—Take the plate firmly in a small hand vice; hold it, with the polished face upwards, over a charcoal fire, that it may not get smoked, till it is well, but not too much, heated: rub the etching-ground, in the silk, over the plate till it is evenly covered; the wax, melting with the heat, oozes through the silk. To effect a more equal distribution of the *ground*, take the *dabber* and dab the plate gently all over, till it appears of an uniform colour; continue the dabbing till the plate begins to cool, but not longer. The ground is then blackened by being held over the smoke of a candle, or two or three tied together,—wax is far preferable to tallow; keep the plate in motion, so that every part be made equally dark, and also to avoid injury, by burning, to the composition; when cold the plate is ready to receive the design. To transfer this, a very correct outline of the subject is made with a black-lead pencil on a piece of thin hard paper: fasten the tracing, or drawing, at the top edge, with its face downwards, on to the etching-ground, with a piece of banking-wax, described hereafter, and by passing it through a printing-press—such as is used by plate printers, to whom it should be taken—the drawing is transferred to the ground. The *bridge* being laid over the plate, the process of etching may now be commenced; the points, or needles, which are used to complete the design, remove the ground from the metal wherever they pass, and expose the latter to the action of the acid during the process of what is termed *biting-in*. The needles with the most tapering points should be used for the skies and distances, changing them for others for the foreground, which generally requires broader and deeper lines. Any error that has been made may be remedied by covering the part evenly with the etching-ground mollified by spirits of turpentine, using a camel's-hair pencil for the purpose; and, when dry, the lines may be re-etched through it.

The next operation is that of *biting-in*, performed thus:—A wall or border of *banking-wax* is put round the edge of the plate: this wax, called sometimes *bordering-wax*, is made by melting over a slow fire, in a glazed pot, two parts of Burgundy pitch, and one of bees'-wax, to which is added when melted, a gill of sweet oil; when cold it is quite hard, but by immersion in warm water it becomes soft and ductile, and must be applied in this state: it will adhere to the metal by being firmly pressed down with the hand: the object in thus banking up the plate is to prevent the escape of the acid which is to be applied; but a spout or gutter must be left at one corner to pour off the liquid when necessary. Mr. Fielding,—to whose work on the art of engraving we are indebted for some of the practical hints here adduced, availing ourselves, however, of the improvements introduced into modern practice,—recommends the following mixture as the best:—'Procure some strong nitric acid, and then mix, in a wide-mouthed bottle, one part of the acid, with five parts of water, adding to it a small quantity of sal-ammoniac, in the proportion of the size of a hazel-nut to one pint of acid, when mixed for biting. The advantage of using the sal-ammoniac is, that it has the peculiar property of causing the aqua-fortis to bite more directly downwards, and less laterally, by which means lines laid very closely together are less liable to run into each other, nor does the *ground* so readily break up.' When the mixture is cool—for the acid becomes warm when first mixed with water—pour it on the plate, and let it continue there till the more delicate lines are presumed to be corroded to a sufficient depth; this will probably be in about a quarter of an hour; sweep off the bubbles as they appear on the plate, with a camel's-hair pencil, or a feather; then pour off the acid through the gutter at the corner, wash the plate with warm water, and leave it to dry. Next, cover those parts which are sufficiently bitten in with Brunswick black, applying it with a camel's-hair pencil, and leave it to dry; again put on the acid, and let it remain twenty minutes or half an hour, to give the next degree of depth required; and repeat this process of *stopping out* and *biting in*, until the requisite depths are all attained: three *bitings* are generally enough for a *painter's etching*. The work is now complete, unless the graver is to be used upon it, and the banking-wax may be removed, by slightly warming the margin of the plate; and, finally, wash the latter with a soft rag dipped in spirits of turpentine, and rubbing it with olive-oil. If, when the plate is cleaned, the engraver finds that the acid has acted as he wishes, he has secured what is technically termed 'a good bite.'

Steel plates require another method of *biting-in*, on account of their extreme hardness, and liability to rust; the mode just described is applicable only to copper, the metal generally used by painters for their etchings. For steel plates mix together

	Parts
Pyroligneous acid	1
Nitric acid	1
Water	3

This mixture should not be allowed to remain on above a minute; let it be washed off at once, and never use the same water twice; the plate must be set up on its edge, and dried as quickly as possible to avoid rust: the acid may be strengthened where a stronger tint is required.

Re-biting, a process frequently adopted to increase the depth of tint where it is required, or to repair any portion of a plate that has been worn by printing or accidentally injured, is thus performed. The plate must be thoroughly cleaned, all traces of grease removed, by washing it with spirits of turpentine and potass, and polished with whiting; it is then, when warmed over a charcoal fire or with lighted paper, ready for receiving the *ground*; this is laid by using a dabber charged with etching-ground, and carefully dabbing the surface; by this means the surface of the plate only is covered, and the lines already engraved are left clear; any part of the plate that it may not be necessary to *re-bite*, must be stopped out with Brunswick black, and then the acid may be poured over the whole, as in the first process.

Etching on soft ground is a style of engraving formerly much practised in imitation of chalk or pencil drawings; since the introduction of lithography, however, it has been entirely abandoned. The *soft ground* is made by adding one part of hog's lard to three parts of common, or hard, etching-ground, unless the weather be very warm, when a smaller quantity of lard will suffice; it should be laid on and smoked in the manner already described. Mr. Fielding gives the following method for working on it. 'Draw the outline of your subject faintly on a piece of smooth thin writing-paper, which must be at least an inch larger every way than the plate; then damp it, and spread it cautiously on the ground, and turning the edges over, paste down to the back of the plate; in a few hours the paper will be dry, and stretched quite smooth. Resting your hand on the bridge, take an H or HB pencil, and draw your subject on the paper exactly as you wish it to be, pressing strongly for the darker touches, and more lightly for the delicate parts, and, accordingly as you find the ground more or less soft, which depends on the heat of the weather or the room you work in, use a softer or harder pencil, remembering always that the softer the ground the softer the pencil' (should be). 'When the drawing is finished, lift up the paper carefully from the plate, and wherever you have touched with the pencil, the ground will stick to the paper, leaving the copper more or less exposed. A *wall* is then put round the margin, the plate bit in, and if too feeble, re-bit in the same way as a common etching, using *hard etching-ground* for the re-bite.'

Line-engraving unquestionably occupies the highest place in the category of the art; and, taking it as a whole, it is the most suitable for representing the various objects that constitute a picture. The soft, pulpy, and luminous character of flesh; the rigid, hard, and metallic character of armour; the graceful folds and undulations of draperies, the twittering, unsteady, and luxuriant foliage of trees, with the bright yet deep-toned colour of skies, have by this mode, when practised by the best engravers, been more successfully rendered than by any other. The process of line-engraving is, first, to etch the plate in the manner already described, and afterwards to finish it with the graver and dry point. An *engraver's etching* differs from a *painter's etching* in that every part of the work has an unfinished appearance, though many engravers, especially of landscapes, carry their etchings so far as to make them very effective: engravers of historical and other figure subjects, generally, do little more than etch the outlines, and the broad shadowed masses, or colours, of the draperies; the flesh being entirely worked in with the *burin*, or graver: no definite rules can be laid down as to the extent to which the etching should be advanced ere the work of the tool commences, as scarcely two engravers adopt the same plan precisely: much must always depend on the nature of the subject. Neither would it be possible to point out in what particular way the graver should be used in the representation of any particular object: this can only be learned in the studio of the master, or by studying the works of the best engravers: as a rule it may be simply stated, that in making the incision, or line, the graver is pushed forward in the direction required, and should be held by the handle, at an angle very slightly inclined to the plane of the steel or copper plate: the action of the graver is to cut the metal clean out.

Some years ago an instrument, called a *ruling machine*, was invented by Mr. Wilson Lowry, and has been brought into use for laying in flat tints in skies, buildings, and objects requiring straight, or slightly curved lines: considerable time is saved to the artist by its use, and more even tints are produced than the most skilful hand-work generally is able to effect; but to counterbalance these advantages, freedom is frequently sacrificed, and in printing a large number of impressions, the machine-work, unless very skilfully ruled in, is apt to wear, or to become clogged with ink, sooner than that which is graved.

Mezzotinto engraving is generally supposed to owe its origin to Colonel Ludwig von Siegen, an officer in the service of the Landgrave of Hesse; there is extant a portrait by him, in this style, of Amelia, princess of Hesse, dated 1643. Von Siegen is said to have communicated his invention to Prince Rupert, to whom many writers have assigned the credit of originating it: there are several plates executed by the Prince still in existence. It differs from every other style of engraving, both in execution and in the appearance of the impression which the plate yields: a mezzotint engraving resembles a drawing done in washes of colour, by means of a camel's-hair pencil, rather than a work executed with any sharp-pointed instrument; but a pure mezzotint engraving is rarely produced in the present day, even for portraits: the advantages derived from combining line and stipple, of which we shall speak presently, with it, to express the different kinds of texture in objects, have been rendered so obvious as almost to make them necessary: this combination is termed the *mixed* *style.* The distinguishing excellences of mezzotint are the rich depth of its shadows, an exquisite softness, and the harmonious blending of light and shade: on the other hand, its great defect is the extreme coldness of the high lights, especially where they occur in broad masses.

The instruments used for this kind of work are, *burnishers, scrapers, shading tools, roulettes*, and a *cradle*, or *rocking tool.* The burnisher and scraper differ in form from those already described: the roulette is used to darken any part which may have been scraped away too much; it ought to be of different sizes: the cradle is of the same form as the shading tool, and is used for the purpose of laying grounds.

The operation of engraving in mezzotint is precisely the opposite of that adopted in all other styles: the processes in the latter are from *light* to *dark*, in the former from *dark* to *light*, and are thus effected. A plate of steel or copper is indented all over its face by the *cradle*, an instrument which somewhat resembles a chisel with a *toothed* or serrated edge, by which a *burr* is raised on every part in such quantities that if filled in with ink, and printed, the impression would exhibit a uniform mass of deep black: this operation is called *laying the ground;* it is performed by rocking the cradle to and fro, and the directions, or *ways*, as the engravers call them, are determined by a plan, or scale, that enables the engraver to pass over the plate in almost any number of directions without repeating any one of them. When an outline of the subject has been first etched in the ordinary way before the ground is laid, the engraver proceeds to scrape away, and then burnish the highest lights, after which the next lightest parts are similarly treated, and the process is repeated after this manner till the work is finished; the deepest shades are produced from the ground that is left untouched. There is, however, no style of engraving for the execution of which it is so difficult to lay down any definite rules, for almost every engraver has his own method of working.

Chalk or *stipple* engraving, for the terms are synonymous, is extremely simple. The plate has first to be covered with the etching ground, and the subject transferred to it in the ordinary way: the outline is then laid in by means of small dots made with the stipple graver; all the darker parts are afterwards etched in dots larger and laid closer together. The work is then bitten in with the acid; and the ground being taken off, the stipple graver must again be taken up to complete the operation; the light parts and the dark are respectively produced by small and large dots laid in more or less closely together. Stipple is well adapted for, and is often used in, the representation of flesh, when all the other parts of the subject are executed in line: hence it is very frequently employed in portraiture, and in engravings from sculpture. *Chalk engraving* is simply the imitation of drawings in chalk, and is executed like stipple, only that the dots are made with less regularity, and less uniformity of size; in the present day, the two terms are generally considered as expressing the same kind of work.

Aquatint engraving, which represents a drawing in Indian-ink or bistre even more than does mezzotint, has been almost entirely superseded by lithography, and still more recently by chromo-lithography; and there seems little probability that it will ever come into fashion again. This being the case, and as any detailed description of the mode of working would, to be of any service, occupy a very considerable space, it will, doubtless, be deemed sufficient to give only a brief outline of its character and of the mode of operation; this we abbreviate from the notice of Mr. Fielding, formerly one of our most able engravers in aquatint. The process consists in pouring over a highly-polished copper-plate a liquid composed of resinous gum, dissolved in spirits of wine, which latter, evaporating, leaves the resin spread all over the plate in minute grains that resist the action of the aqua-fortis, which, however, corrodes the bare surface of the copper that is left between them: this granulated surface is called a *ground.* The ground having been obtained, the margin of the plate should be varnished over, or stopped out, and, when dry, the subject to be aquatinted must be transferred to the plate, either by tracing or drawing with a soft blacklead pencil, which may be used on the ground with nearly the same facility as paper; if the former method be adopted the tracing must be carefully fastened down to the copper by bits of wax along the upper edge. A piece of thin paper, covered on one side with lampblack and sweet oil, is placed between the tracing and the ground, with the coloured side downwards, and every line of the subject must be passed over with the tracing point, using a moderate pressure. The tracing being finished and the paper removed, a wall of prepared wax, about three quarters of an inch high, must be put round the plate, with a large spout at one corner, to allow of the acid running off.

The plate is now ready for use; and the completion of the design is commenced by stopping out the highest lights on the edges of clouds, water, &c., with a mixture of oxide of bismuth and turpentine varnish, diluting it with spirits of turpentine till of a proper consistence to work freely. Next pour on the acid, composed of one part of strong nitric acid and five parts of water; let it remain, according to its strength, from half a minute to a minute, then let it run off, wash the plate two or three times with clean water, and dry it carefully with a linen cloth. This process of stopping-out and biting-in is continued till the work is complete; each time the aqua-fortis is applied a fresh tint is produced, and as each part successively becomes dark enough it is stopped out; in this manner a plate is often finished with one ground bitten in ten or twelve times. We would recommend those who may desire to become thoroughly acquainted with this very interesting yet difficult mode of engraving to consult Fielding's 'Art of Engraving.'

A few remarks explanatory of the method of printing steel or copper plates seem to be inseparable from the subject. The press used for the purpose consists of two cylinders or rollers of wood, supported in a strong wooden frame, and moveable at their axes. One of these rollers is placed just above, and the other immediately below, the plane or table upon which the plate to be printed is laid. The upper roller is turned round by means of cogged wheels fixed to its axis. The plate being inked by a printer's inking-roller, an operation requiring great care, the paper which is intended to receive the impression is placed upon it, and covered with two or three folds of soft woollen stuff like blanketing. These are moved along the table to the spot where the two rollers meet; and the upper one being turned by the handle fixed to the fly-wheel, the plate passes through it, conveying the impression as it moves; the print is then taken off the plate, which has to undergo the same process of inking for the next and every succeeding impression. The *proofs* of an engraved plate are always taken by the most skilful workmen in a printing establishment; in the principal houses there are generally employed from two to six men, according to the amount of business transacted, whose duty it is to print proof impressions only; they are called *provers.* A careful, steady workman is not able to print more than from 180 to 200 good ordinary impressions from a plate, the subject of which occupies about seven inches by ten inches, even in what is considered a long day's work, that is, about fourteen hours; the *prover*, from the extreme care required in inking the plate, and from the extra time occupied in wiping it, and preparing the Indian-paper, will do from thirty to forty, according as the subject of the plate is light or heavy. This difference in the cost of production, taking also into account that the *proofs* are worked off before the plate has become worn, even in the least degree, and that very few proofs, compared with the ordinary prints, are generally struck off, is the reason why they are sold at a price so much greater than the latter.

Notwithstanding the vast multiplication of engravings within the last few years, it is generally admitted, by those best acquainted with the present state of the art, that it is not in a healthy condition. The highest class of pictorial subjects—history, and the highest style of engraving—line, have given place to subjects of less exalted character, and to a mixed style of work, which, however effective for its especial purpose, is not pure art. The pictures by the late Sir E. Landseer have gained for engravings of such subjects a popularity that has driven almost everything else out of the field, and have created a taste in the public which is scarcely a matter of national congratulation. We have engravers in the country capable of executing works equal to whatever has been produced elsewhere at any time, but their talents are not called into requisition in such a way as to exhibit the art of engraving in its highest qualities. Publishers are not willing to risk their capital on works which the public cannot appreciate, and hence their windows are filled with prints, the subjects of which, however pleasing and popular, are not of a kind to elevate the taste; while the conditions under which engravers generally are compelled to work, offer but little inducement for the exercise of the powers at their command. Engraving on copper is in the present day but rarely attempted; formerly nothing else was thought of; now the demand for engraving is so great that copper, even aided by the electrotype, is insufficient to meet its requirements. In consequence of the comparatively small number of impressions which it yields, a copper-plate will seldom produce more than 500 or 600 good prints; we have known a steel, with occasionally retouching, produce more than 30,000, when well engraved, and carefully printed; very much depends on the printer, both with regard to the excellence of the impression and the durability of the plate. The public demand is for prints both large and cheap, and to obtain this result, the engraver is too often obliged to sacrifice those qualities of his art which under other circumstances his work would exhibit. Such is the state of engraving with us now. There are few, even of the best artists we have, who by their utmost efforts can earn an income equal to that of a tradesman in a small but respectable way of business. This is an evil to be deplored, for it assists to deteriorate the art by forcing the engraver to labour hard for a maintenance, instead of placing him in a position that would enable him to exalt the art and his own reputation at the same time.

A process of depositing steel upon an engraved copper-plate was some time ago brought over to this country from France. M. Joubert, a French engraver long settled in England, introduced it here; he has informed us that a copper-plate thus covered may be made to yield almost any number of impressions, for as the steel coating becomes worn it can be entirely taken off, and a new deposit laid on without injury to the engraving, and this may be done several times. M. Joubert has repeated the experiment with the most satisfactory results. He thus describes his process in a communication made to the Society of Arts, and printed in their Journal:—

'If the two wires of a galvanic battery be plunged separately into a solution of iron, having ammonia for its basis, the wire of the positive pole is immediately acted upon, while that of the negative pole receives a deposit of the metal of the solution—this is the principle of the process which we have named "acierage."

'The operation takes place in this way: By placing at the positive pole a plate or sheet of iron, and immersing it in a proper iron solution, the metal will be dissolved under the action of the battery, and will form an hydrochlorate of iron, which, being combined with the hydrochlorate of ammonia of the solution, will become a bichloride of ammonia and iron; on a copper-plate being placed at the opposite pole and likewise immersed, if the solution be properly saturated, a deposit of iron, bright and perfectly smooth, is thrown upon the copper-plate, from this principle:—

'Water being composed of hydrogen and oxygen:

'Sal-ammoniac being composed of—

'1st. Hydrochloric acid, containing chlorine and hydrogen;

'2nd. Ammonia, containing hydrogen, nitrogen, and oxygen:

'The water is decomposed under the galvanic action, and the oxygen fixes itself on the iron plate, forming an oxide of iron; the hydrochloric acid of the solution acting upon this oxide becomes a hydrochlorate of iron, whilst the hydrogen precipitates itself upon the plate of the negative pole, and, unable to combine with it, comes up to the surface of the solution in bubbles.

'My invention has for its object certain means of preparing printing surfaces, whether for intaglio or surface printing, so as to give them the property of yielding a considerably greater number of impressions than they are capable of doing in their ordinary or natural state. And the invention consists in covering the printing surfaces, whether intaglio or relief, and whether of copper or other soft metal, with a very thin and uniform coating of iron, by means of electro-metallurgical processes. And the invention is applicable whether the device to be printed from be produced by engraving by hand, or by machinery, or by chemical means, and whether the surface printed from be the original, or an electrotype surface produced therefrom. I would remark, that I am aware that it has been before proposed to coat type and stereotypes with a coating of copper, to enable their surfaces to print a larger number of impressions than they otherwise would do; I therefore lay no claim to the general application of a coating of harder metal on to the surface of a softer one, but my claim to invention is confined to the application of a coating of iron by means of electricity on to copper and other metallic printing surfaces.

'In carrying out the invention I prefer to use that modification of Grove's battery known as Bunsen's, and I do so because it is desirable to have what is called an intensity arrangement. The trough I use for containing the solution of iron in which the engraved printing surface is to be immersed, in order to be coated, is lined with gutta-percha, and it is 45 inches long, 22 inches wide, and 32 inches deep. In proceeding to prepare for work, the trough, whether of the size above mentioned or otherwise, is filled with water in combination with hydrochlorate of ammonia (sal-ammoniac) in the proportion of 1,000 lbs. by weight of water to 100 lbs. of hydrochlorate of ammonia. A plate of sheet iron, nearly as long and as deep as the trough, is attached to the positive pole of the battery and immersed in the solution. Another plate of sheet iron, about half the size of the other, is attached to the negative pole of the battery, and immersed in the solution, and when the solution has arrived at the proper condition, which will require several days, the plate of iron attached to the negative pole is removed, and the printing surface to be coated is attached to such pole, and then immersed in the bath till the required coating of iron is obtained thereto. If, on immersing the copper-plate in the solution, it be not immediately coated with a bright coating of iron all over, the bath is not in a proper condition, and the copper-plate is to be removed and the iron plate attached and returned into the solution. The time occupied in obtaining a proper coating of iron to a printing surface varies from a variety of causes, but a workman after some experience and by careful attention will readily know when to remove the plate from the solution; and it is desirable to state that a copper-plate should not be allowed to remain in the bath and attached to the negative pole of the battery after the bright coating of iron begins to show a blackish appearance at the edges. Immediately on taking a copper-plate from the bath great care is to be observed in washing off the solution from all parts, and this I believe may be most conveniently done by causing jets of water forcibly to strike against all parts of the surface. The plate is then dried and washed with spirits of turpentine, when it is ready for being printed from in the ordinary manner.

'If an engraved copper-plate be prepared by this process, instead of a comparatively limited number of impressions being obtained and the plate wearing out gradually, a very large number can be printed off without any sign of wear in the plate, the iron coating protecting it effectually; the operation of coating can be repeated as many times as required, so that almost an unlimited number of impressions can be obtained from one plate, and that a copper one.

'This process will be found extremely valuable with regard to electrotype plates, and also for photogalvanic plates, since they can be so protected as to acquire the durability of steel, and more so, for a steel plate will require repairing from time to time, these will not, but simply recoating them whenever it is found necessary; by these means one electro copper-plate has yielded more than 12,000 impressions, and was found quite unimpaired when examined minutely.'—J. D.

For a more complete description of the process of precipitating iron by the electrotype process, as now practised, see ELECTRO-METALLURGY.

ENGRAVING ON WOOD. The art of wood-engraving is so intimately connected with that of book-printing, that it is impossible to dissever the one from the other, inasmuch as the earliest books were printed from large woodcuts, the entire page, text, and illustrations being engraved in one solid block. Hence the term 'block-books' given to these ancient works. The impression from these engraved pages is generally taken in a thin ink, sometimes of a brown hue, which occasionally spreads or blots on the lines or letters; and the printing is generally supposed to have been effected by friction on the back of the damped paper laid on the inked lines; the sheets so printed were afterwards pasted back to back, and thus formed consecutive pages of the volume. Such books originated from the large woodcuts of a devotional class, which, in the early part of the 15th century, were spread by the clergy among the common people, perhaps to counteract the evil produced by the use of playing cards, which were also printed in large sheets of cuts, and severed afterwards; but on this point typographical antiquaries are not agreed, as dates and other evidence are wanting to enable us to fix either time or place to these early productions. The earliest woodcut bearing a date is that belonging to Earl Spencer, and representing St. Christopher carrying the Saviour across an arm of the sea; it has two lines of text beneath it, and the date 1423 thus expressed: 'millesimo cccc° xx° tercio.'[1] The British Museum is possessed of some very early single-leaf woodcuts: one representing Christ brought before Pilate, is executed in bold coarse outline, the figures are very large, and retain the characteristic features of the drawings seen in manuscripts of the 14th century. Another undated cut is one of those fanciful inventions which the scholastic men of that early day delighted in constructing; it is termed *Turris Sapiencie*, every stone of which is inscribed with the name of some moral virtue, the foundation buttresses being prudence, fortitude, justice, and temperance; the windows which give it internal light being discretion, religion, devotion, and contemplation. Another representing the Seven Ages of Man is supposed to be a work of the middle of the 15th century. It was found pasted inside the covers of an old book, a practice which has preserved many specimens of old engraving which would else have been lost. On the opposite cover is a fragment of another large cut, representing the Virgin with St. Joachim and St. Anne. The St. Christopher above named was discovered in the cover of a volume in the conventual library at Buxheim, in Suabia. All these old woodcuts, as well as the block-books, are generally daubed with flat tints of coarse colour, supposed to have been done with stencil-plates, such as the card painters used on some occasions; but evidently rudely executed by hand in others. They are all precisely of the kind to attract the uneducated eye; and to this day similar coarse prints are used by the clergy to aid the devotions of the peasants of the Germanic nations.

The most celebrated of the block-books is that termed the 'Biblia Pauperum.' Each page is divided by architectural compartments into three subjects, from the Old and New Testament, selected to form 'parallel passages' of sacred writ; above and below are other compartments with heads of the Prophets, and in the intervening spaces, or upon scrolls, are explanatory inscriptions. The page measures 10 inches by 7½, and is one of the most elaborate works of its class; but it exhibits very small claims to attention as a specimen of art, certainly less than the 'Cantica Canticorum,' each

---

[1] Much interest was excited some few years ago by the discovery of a cut in the library at Brussels apparently bearing an earlier date; but strict investigation has since proved that one of the C's in the date has been omitted; this makes just one hundred years difference in its age. But the date thus altered is quite in accordance with the general character of the design and execution of the cut, which, on the contrary, do not at all agree with the earlier date originally assigned to it.

page of which is divided horizontally into two pictures, with slight descriptive lines on scrolls; or the 'Apocalypsis Sancti Johannes,' which is similarly arranged, and in both of which we occasionally find much power of drawing and ability of grouping. The dates of these books can only be conjecturally given, but they are probably contemporary with the St. Christopher, or but a few years later. Judging from general characteristics, the 'Apocalypse' seems to be the earliest. The figures are executed entirely in outline, with no attempt at shadows, which appear sparingly on the St. Christopher, and are very freely introduced in the 'Canticles,' and still more abundantly in the 'Biblia Pauperum.' These effects are always produced by a series of short lines laid parallel to each other, nor is any attempt made to enrich the meagre character of the work by crossing the lines, as in more modern engraving. The debate, which has excited so many historians as to the place where printing first had birth, has included many doubts concerning the country where these old block-books were fabricated; but from the armorial bearings which appear on the shields of some figures in the 'Canticles,' Germany seems to be the country where that series was designed;[1] probably Flanders or Holland may claim the 'Biblia Pauperum,' which does not bear equal traces of refinement in art. The 'Speculum Humanæ Salvationis' has been claimed for Laurence Coster of Haarlem. This book was a combination of block-book and moveable type, having long cuts across the top of each page, divided by columns into two subjects, with moveable types beneath. It is not unusual to meet with woodcut pages of type alone at this period; and books with such pages, or with the addition of woodcuts, were produced by the old engravers after the invention of moveable types; but, as metal-cast letters speedily usurped the place of the wooden ones, the wood engravers seem to have soon confined themselves to the pictorial branch of the art.

The love of pictured illustrations of narrative history gave a permanence to the art of wood-engraving; and the works printed in Italy, as well as those introduced into England by Caxton, were adorned with cuts. They are, however, of the rudest kind, with broad heavy lines, and were most probably produced from coarse pen drawings made on the surface of the wood, and mechanically cut by the engraver. Toward the close of the fifteenth century 'cross-hatching' (as lines of shadow crossing each other are technically termed) is first seen, and in the 'Nuremburg Chronicle,' 1493, they are freely used. The designers and engravers of these cuts, perceiving the effect, which may be so readily obtained in wood-engraving, by leaving the wood untouched with the graver for solid masses of shadow, have availed themselves of it, and given stronger effect to their cuts thereby. Michael Wohlgemuth and William Pleydenwurff were the designers employed; the former artist was the master of Albert Dürer, who ultimately raised wood-engraving to the highest point of excellence.

Dürer's first great work was a series of sixteen large cuts illustrative of the Apocalypse. They were published in 1498, and attracted great attention from the vigour and strange originality of their design, and the artistic character of their treatment. In 1511 another series of cuts was published at Nuremberg by Dürer, illustrative of the Apocryphal Life of the Virgin. They evidence the great improvement which the artist had made during the interval, and are certainly the finest woodcuts which had ever been executed up to that period; but they are eclipsed by the series of eleven large cuts published soon after, representing scenes in the Passion of Christ; and which may be fairly considered triumphs of the art of wood-engraving, unsurpassed in design and execution by any successors. The art had now become appreciated wherever it was known, and a host of wood engravers found employ in Nuremberg, cutting the designs of Dürer, Hans Burgmair, Hans Schaufelein, and other artists; who found no lack of patronage in the old imperial city, for the Emperor Maximilian I., extensively employed them in various works illustrative of his real or fancied exploits.[2]

So important was this royal patronage, that the engravers set no bounds to the size of the works they attempted, and hit upon the plan of joining one block of wood to another, until in the engraving representing the triumphal arch in honour of this emperor, a woodcut was completed in this way, measuring ten feet by nine. The size is, however, not its only claim to attention, for it is throughout designed and engraved with the utmost care and beauty.

In all these cuts of the great masters of the art of wood-engraving, we only find the name of the designer recorded; thus, Dürer, and others of his era, whose names

---

[1] Among them are the double-headed eagle of Austria, the black eagle of Germany, the three crowns of Cologne, the cross-keys of Ratisbon, the arms of Wurtemberg, Nymphenburg, and Alsace.

[2] Such were the adventures of the Knight Theurdank, under which form the emperor was figured; 'The Wise King,' an equally flattering picture of his early education and actions; and the magnificent series of cuts, known as the 'Triumphs of Maximilian.'

occur on cuts, were the designers and draughtsmen on the wood; but the engraver was considered in the light of a mechanician, and, except in a very few instances, his name was not displayed. To fully understand this, it is necessary here to explain the whole process of wood-engraving at this time. A block of wood being prepared from a perpendicular cutting of pear-tree, upon the surface was made a drawing, in which every line was delineated with pencil or reed-pen, exactly as the cut was ultimately to appear; the intervening spaces of plain wood between every line were then cut away; and in this manual dexterity consisted the whole merit of the engraver. The abundance of cross-hatching so constantly found in old woodcuts, is explained by the fact of this being the easiest and best mode for the draughtsman to employ in getting his effects of light and shade; the extreme labour it involves to the engraver not being considered; but when it is understood that each minute space has to be cut down from each angle of the lines, and the centre entirely cleared out, some idea may be formed of the labour required, when thousands of such squares occur on some of Dürer's large cuts, independent of other work. The backs of some of these old blocks, particularly those in the 'Triumphs of Maximilian,' are marked with the names of the engravers, and there is proof that women practised the art; but it is not at all likely that the artists who designed, and drew upon the wood these designs, went through the merely mechanical labour of engraving them.

The great impetus thus given to wood-engraving,[1] kept it prominently before the world during the whole of the sixteenth century, when the presses of the Continent continually brought forth a series of volumes remarkable for the beauty of the cuts by which they were illustrated. This practice of the book trade gave rise to a series of artists known as 'the little masters' of the German school, from the small size of their works; among whom the principal who connected themselves with engraving on wood were Virgil Solis, Henry Aldegraver, the two Behaims, Lucas Cranach, Urse Graff, Albert Altdorffer, Jost Ammon, and Solomon Bernard.

In Italy, Ugo da Carpi practised with success, from the year 1518, the art of engraving on wood imitations of tinted drawings: an art which originated with the Germans, but which he much enlarged and improved. It consisted in a series of blocks cut to imitate patches of colour, and made to print over each other in gradations of tint, until the chiar-oscuro of a drawing was secured; then the coarser and bolder lines defining the whole design were printed over all, and a capital imitation effected of the bold cartoons, consisting of vivid outline and broad washes of tint, used as first sketches for their pictures and frescoes by the artists of that era.

A perfect rage for book illustration seems to have beset the printers soon after the death of Dürer. The most prolific artists who supplied their wants were Jost Ammon and Solomon Bernard: the former executed a multitude of designs on every imaginable subject; the latter, equally prolific, devoted himself chiefly to the illustration of sacred or classic literature. The greatest publishers of such books were Sigismond Feyeraband, of Frankfort-on-the-Maine; Jean de Tournes, and Trechsel, of Lyons; and Plantyn, of Antwerp. From their presses issued a series of small volumes, which can only come under the generic title of 'picture books;' for they were got up for the sake of exhibiting the favourite art of wood-engraving, and only contain a few descriptive lines of type beneath each cut. The cuts executed by Ammon are all remarkable for correctness of drawing and vigorous effect; those of Bernard are less scholastically correct, but contain more evidence of grace and fancy. The designs of these artists abound in books published between 1550 and 1580; but the most admirable series were executed in a little volume, published at Lyons, in 1538, without the name of draughtsman or engraver, the 'Simulachres de la Mort,' known among bibliographers as the 'Lyon's Dance of Death,' a collection of cuts which, for minute beauty and perfection of design and execution, are completely unrivalled, and have not been equalled by any modern copyist.[2] This was the Augustan age of book illustration, which flourished in popular favour until the close of the sixteenth century, when a minute *tameness*, in contradistinction to the *vigour* of the earlier engravers, began to appear, and reached its culmination in such cuts as were given in Nicolay's 'Travels in Turkey' (Antwerp, 1576).

---

[1] Dürer's engravings were so exceedingly popular, that they found their way all over Europe. Raphael admired them in Rome, and was induced to perpetuate his own designs by employing Marc Antonio Raimondi to engrave them on metal under his own superintendence. So originated the modern print trade. Dürer's designs were so much in request, that Lucas van Leyden imitated them on copper, for sale to such persons as could not perceive the great difference between the vigorous originals and his tame and disagreeable copies. Dürer was ultimately obliged to apply for legal restrictions against these piracies.

[2] The designs have been popularly ascribed to Holbein, and, apparently, with reason. An artist named Hans Lutzelburgher, of Basle, has been conjectured to have been the engraver, from the initials H. L. on one of them. By this time it had become usual to append the initials of engravers to woodcuts, as well as those of the designers.

Titian is said to have furnished designs for various woodcuts, particularly the series of Costumes published at Venice in 1590; and a very large coarse cut of the Destruction of Pharaoh and his Host, more than four feet long, is said to have been one among many of uncommon size executed from his designs; they were printed on separate blocks, and then pasted together in the manner of wall-papers. One representing the Sacrifice of Abraham is remarkable for the variously-tinted inks in which it is printed to exhibit gradations of distance.

Wood-engraving in the early part of the seventeenth century had sunk from its high estate. The last great artist who had employed himself in connection with the art was Hans Holbein; and we do not find a great name again conjoined with it until the middle of that century, when Rubens employed Jeghers, of Antwerp, to engrave some of his drawings on wood. The generality of woodcuts in books of this era rival in coarseness the older block-books; the wood-engravers seem to have sunk into mechanics, unassisted by good artists to furnish them with drawings. The art had become vulgarised, its profession a trade, and the demand and supply scarcely better than the requirements of the ballad-printer desired. They were ancillary to the commonest uses of the press, and all art speedily vanished from the cuts manufactured probably at a very cheap rate for temporary use. Of this kind are the cuts sprinkled through the English books of the time of James and Charles I. It is possible that the printers were supplied with them from Germany and Flanders. It was customary to use woodcuts repeatedly, particularly if merely ornamental; in this way initial letters were reproduced as the stock in trade of the printing-office;[1] and even scenes of adventure, adopted unscrupulously for other events, to which there was the slightest general resemblance.[2] The names of these 'wood-cutters' have not descended to our time; their works are widely scattered over general literature, and it is not until the middle of the century that we meet with any instance of an attempt to arrest the downward progress of the art. Then, as we have previously noted, Rubens, probably anxious to rival Dürer, engaged Christopher Jegher, of Antwerp, to execute, under his own superintendence and at his expense, a series of large drawings made by himself upon the wood. They differ from the style of the earlier masters, and frequently have a confused blotted look in the lines, which produce deep shadows; they possess, however, all that boldness and vigour of treatment for which the great Flemish painter was so deservedly celebrated; but the engraving is coarse and mechanical. Rubens appears to have felt this, and sometimes a tinted block is added over all, with high lights cut upon it, to give softness and brightness to the whole: an idea he may have adopted from the engravers of Italy who succeeded Ugo da Carpi (among whom may be honourably mentioned Andreas Andreani, of Mantua, born 1540, died 1620), or from the designs of Lalleman engraved by Businck, which were nearly contemporaneous in France.

Though 'fallen from its high estate,' the art never sank into complete decay, either in England or upon the Continent; there were always a few who followed the profession, and aided the printer with such cuts and diagrams as he might require. The family of the Jeghers practised in Antwerp until the end of the century: a clever series of woodcuts illustrative of the Service of the Mass was published at Ghent, and executed by Kraaft in 1732. In France, the family of Le Sueur were employed through three generations by booksellers; the last, Nicholas, died in 1764; while Papillon, the author of a *Traité de la Gravure en Bois*, had practised the art from the commencement of the century until 1770, and had been patronised so extensively by the booksellers of France and Holland that he counts his cuts by the thousand. In England, E. Kirkhall executed cuts for books, and from 1722 to 1724 a series of 12 block-prints, in imitation of Ugo da Carpi's work already alluded to; in this latter style he produced a greater pupil in J. Jackson, who very successfully copied some of the great works of Titian, Paul Veronese, and others, during the years 1738 to 1741; at this time he resided in Venice, after a short sojourn in Paris, where he was occasionally employed as a wood engraver. Many cuts scattered through English books about the same period bear the initials of F. H. for Francis Hoffman, whose name is engraved in full on a tail-piece, representing Cupids surrounding a lighted altar, to be

---

[1] In the old printing office of Plantyn, at Antwerp, is still preserved a large quantity of woodcuts, originally engraved for the books he issued at the end of the 16th century, particularly the emblems of Alciati and Sambuco.

[2] The number of impressions a woodcut will yield has never yet been established. The elasticity of wood gives it a great advantage over metal in press-printing; and while copper and steel wear out, wood shows little sign of wear: many thousands of impressions may be taken by a moderately careful printer without injuring a woodcut. As an instance with what impunity a bad printer may use a coarse woodcut, may be mentioned the fact, that the ballad printers of the middle of the last century occasionally used cuts that had been engraved in the reign of Charles I., and had headed popular ballads for more than 100 years.

seen in the first edition of 'Gulliver's Travels,' 1726, vol. ii. p. 47. An engraver named Lister executed some cuts of a much better character than usual about 1760, particularly those in the 'Oxford Sausage;' and in Sir John Hawkins's 'History of Music' are some of the largest and most ambitious cuts at that time attempted anywhere. They were engraved by T. Hodgson. Three other persons named respectively, W. Pennock, S. Watts, and H. Cole, occasionally devoted themselves to wood-engraving, which seems to have been practised by such copper-plate engravers as occupied themselves with 'general work' for the printing trade or the public, and who varied their labours by occasionally engraving shop-bills or door-plates.

There is one great change in the cuts produced during this period, the result of a different style of drawing made for the wood engravers, and which discarded cross-hatching and its consequent tedious labour, for a tinted or washed drawing which could be cut into a series of lines by the tool, expressing the varied tints more simply and readily. The art of 'lowering' or scraping down to a lower level various parts of a cut that should appear light, and so assist the press in its labours, was also practised, and the harder wood of the box-tree used. Such was the state of the art when a Northumbrian peasant boy was destined to appear, again draw universal attention to the neglected profession, and found the modern school of wood engraving.

Thomas Bewick was the son of parents engaged in a colliery, who lived at Cherryburn twelve miles west of Newcastle-on-Tyne; he was born in 1753 and passed his early years helping his father's labour. His leisure hours were earnestly devoted to the small amount of knowledge a village school could impart; but as a strong love for nature, and for its imitation, soon developed itself in the boy, his father determined to apprentice him to an engraver of Newcastle, Mr. R. Beilby, whose work was of that 'general' kind undertaken in a busy country town. There he occasionally engraved initials on tea-spoons or names on door-plates, until, in the second year of his apprenticeship, his master received an application from Dr. Hutton for woodcut diagrams, such as were then executed in London, to illustrate his treatise on Mensuration. Beilby knew that young Bewick had been making some attempts in this style, and he encouraged him to persevere; he did so, and Hutton's book was published in 1770 with Bewick's cuts. The young engraver had many difficulties to contend against, and he had even to construct his own tools; among the rest, a double-pointed graver to enable him to cut both sides of a line at once, and so ensure its equal thickness throughout. In 1775, he executed a cut and sent it to the Society of Arts, in London, who awarded him a medal; and in the following year he visited London, and was employed by Hodgson, whom we have already noted as the engraver of the cuts in Hawkins's 'History of Music;' as well as by H. Cole. There need be little doubt that this visit to the London wood engravers was useful to Bewick, for he must have become by that means acquainted with the usual mode of practising the art, the proper kinds of tools used, and the various things which make the mechanical part of the profession; but he had fortunately formed a style of his own, so very original, and based so firmly on the study of nature, that wood-engraving in his hands became an art presenting many novel and attractive features never visible before. The wood engravers from the days of Dürer, or from the first invention of the art, depended slavishly on the drawings made upon the wood, and did little more than cut away the interstices; but Bewick cut out of the wood a vast deal of that which no draughtsman could so draw; for with the aid of a slightly-tinted drawing, he would cut the foliage of trees, the plumage of birds, the texture of animals, or small figures and birds, by the graving tool alone. His dextrous hand was guided by a perfect knowledge of nature, and every line he cut expressed drawing; in this was his great distinction over all other wood engravers; he cut his pictures out of the wood, the others cut the wood out of the pictures.

Bewick disliked London, and speedily returned to his native place. His first work was an illustrated edition of Gay's 'Fables,' published in 1779 by T. Saint, a printer of Newcastle, much engaged in the publication of children's books, and such as the travelling chapmen carried in their packs for the edification of the villagers. These cuts bear the earliest traces of that accurate delineation of nature, and minute truthfulness of expression, which ultimately gave his works universal renown. The wild plants and grasses, however minute they are cut, can always be distinguished by the naturalist; the proper foliage of every tree is truthfully cut by his graver; the birds and insects, however minute, are perfect in drawing; and the general effect of his woodcuts artistically powerful. As he fully felt the value of leaving the wood itself to express solid shadow, he had not the timidity which imagines labour to be necessary to success. The little cut of the Fox and Bramble in this volume is a good illustration of Bewick's mode. Every leaf of the bramble is cut out, white upon black, with the most truthful power of drawing; the spines on the stem of the bramble are visible to the eye; the fern beside it is similarly expressed by cutting the form of its foliage with the most perfect freedom upon the solid block of wood. Each bush has its distinctive leaf. The dogs in the distance are similarly cut out by the graver on a tinted ground; and the few lines which cover the body of the fox entangled in the bramble, express its texture with a spirit which no mere cutting of a drawing placed on wood by a professional draughtsman could ever give. Bewick's cuts are sometimes termed *coarse*, but no elaboration of labour will elevate the costliest woodcut above these works, for which Bewick obtained but nine shillings each; unless drawing can be expressed by the engraver as perfectly as Bewick could express it.

Assisted by his brother John, the Newcastle engraver issued a series of works devoted to natural history; the best being the 'History of British Birds.' Here Bewick's knowledge of nature and power of expression by means of his graver shone forth conspicuously. His books became equally celebrated for the humorous tail-pieces he occasionally introduced redolent of whim and original genius. He laboured stedfastly at his art to a good old age. His brother John left Newcastle to reside in London, where he was much employed, but a pulmonary complaint killed him at the early age of thirty-five. He died in 1795. Thomas Bewick lived to the advanced age of seventy-five. He died in 1828, having worked upon a large woodcut only a few days before his death.

The pupils educated by Bewick were few. The best were Charlton Nesbit, Luke Clennell, William Harvey, and John Jackson. Nesbit settled in London, and was extensively employed during a long life. Clennell after a while, devoted himself to painting. Harvey turned his attention to drawing on wood, and his designs for book illustration may be numbered by the thousand; his best are in Lane's edition of the 'Arabian Nights' Entertainments.' Jackson was greatly employed by the publisher of the latter work, Mr. Charles Knight, particularly on the best cuts in the once-famed 'Penny Magazine.'

At the early part of the present century, Mr. Robert Branston founded a London school of wood-engravers, of which he was the head. His style was peculiar, unlike Bewick's, though like him he was self-taught. His cuts have more refinement, but less knowledge of nature; his best pupil was John Thompson, who combines in his best cuts the refined knowledge of light and shade with much of Bewick's power of expressing drawing. Samuel Williams was one of the few modern engravers who made his own drawings upon the wood, and he produced very brilliant effects by frequently leaving the wood in solid masses of black. Drawings for wood engravers were at this time chiefly supplied by artists who devoted themselves to that particular branch of the art; and knew how to design their compositions so that they should best display the peculiarities of wood-engraved effects. Thurston, Craig, and Harvey were the principal artists so engaged.

A large number of wood engravers, the pupils of the Newcastle and London *ateliers*, helped to supply the booksellers at home and abroad for a considerable number of years. It was the custom, some thirty years ago, for the foreign booksellers, particularly in Paris, to send the blocks across the Channel to English engravers to execute; this led ultimately to several settling on the Continent, particularly in France and Germany. The French publishers always sent the wood-block with the drawing carefully executed on its surface by a native artist. These drawings were always elaborately executed in pencil, greatly resembling etchings; little was consequently left for the engraver to do, but follow the lines and cut away the spaces; patience hence became the chief virtue of the wood engraver; and it was ultimately found that its exercise produced so certain an effect, that apprentices knowing nothing of art might aid in thus working out good engravings; and the old style of tinted drawing on wood was discarded for this 'fac-simile' work; the best draughtsmen among the French and German artists having willingly furnished these drawings, English artists of a higher grade were induced to draw on wood, but they occasionally failed from not clearly understanding the peculiar effects their work should produce, and the characteristics of the art. Generally speaking, wood engravers prefer cutting from the drawings of professional draughtsmen on wood; who generally execute their work with such elaborate precision, that the engraver has nothing more to do than follow their lines; this, however, has made mere mechanism of much modern wood-engraving; and many expensive cuts exhibiting pencilling in crossed and re-crossed lines, occupying wearisome labour, and costing many ill-bestowed sovereigns, can only be classed with such 'art' as is devoted to engraving the Lord's Prayer in the compass of a silver penny; and merely produces the same general effect that Bewick would have obtained in a few bold lines.

The great difference between ancient and modern wood-engraving consists in this very boldness, and the practice of the art was essentially different in the sixteenth and eighteenth centuries. The old wood engravers cut on large blocks of soft wood, such as pear-tree, the way of the grain; the moderns, on small blocks of the hardest wood they can obtain—the turkey box, and across the grain. For printing paper-hangings, oil-cloths, and the like, wood-blocks cut on the old system, i.e. on the *side-grain* of the wood, is still employed. The old engravers cut the work downwards with small knives or gouges; the moderns use gravers of various widths to cut out the spaces between fine lines, and broader chisels or gouges to clear away the broad spaces of white. Wood-engraving is the exact opposite to copper-plate engraving in the mode by which the lines of engraving are produced. The copper-plate engraver produces his lines by cutting *into* the metal at once, the wood engraver produces his line by a double operation, by slicing away the wood on each side of it; for though it is recorded that Bewick invented a double cutting fork-shaped graver to cut away both sides of a line at once, no such tool has ever since been used in the profession.

In order to make the whole process of wood-engraving clear to the reader, we will now simply describe the production of a woodcut from the time it leaves the timber-merchant, until it is fit for the hands of the printer. The log of box is cut into transverse slices, ⅞ths of an inch in depth, in order that the face of the cut may be on a level with the surface of the printer's type, and receive the same amount of pressure; the block is then allowed to remain some time to dry, and the longer it is allowed to do so the better, as it prevents accidents by warping and splitting, which sometimes happen after the cut is executed, if the wood is too green. The slice is ultimately trimmed into a square block, and if the cut be large, it is made in various pieces strongly clamped and screwed together; and this enables engravers to get large cuts done in an incredibly short space of time, by putting the various pieces into different engravers' hands, and then screwing the whole together. The upper surface of the wood is carefully prepared so that no inequalities may appear upon it, and it is then consigned to the draughtsman to receive the drawing. He covers the surface with a light coat of flake white mixed with weak gum-water, and the thinner this coat the better for the engraver. The French draughtsmen use an abundance of flake white, but this is liable to make the drawing rub out under the engraver's hands, or deceive him as to the depth of the line he is cutting in the wood. The old drawings of the era of Dürer seem to have been carefully drawn with pen and ink on the wood; but the modern drawing being very finely drawn with the pencil or silver point is obliterated easily, and there is no mode of 'setting' or securing it. To obviate this danger the wood-engraver covers the block with paper, and tears out a small piece the size of a shilling to work through, occasionally removing the paper to study the general effect; in damp and wintry weather he sometimes wears a shade over the mouth to hinder the breath from settling on the block. It is now his business to produce in relief the whole of the drawing; with a great variety of tools he cuts away the spaces, however minute, between each of the pencil lines: and should there be tints washed on the drawing to represent sky and water, he cuts such parts of the block into a series of close lines, which will, as near as he can judge, print the same gradation of tint. Should he find he has not done so completely, he can re-enter each line with a broader tool, cutting away a small shaving, thus reducing their width and consequently their colour. Should he make some fatal error that cannot be otherwise rectified, he can cut out the part in the wood, and wedge a plug of fresh wood in the place, when that part of the block can be re-engraved. An error of this sort in a woodcut is a very troublesome thing; in copper engraving it is scarcely any trouble; a blow with a hammer on the back will obliterate the error on the face, and produce a new surface; but in wood the surface is cut entirely away, except where the lines occur, and it is necessary to cut it deep enough not to touch the paper as it is squeezed through the press upon the lines in printing. To aid the general effect of a cut, it is sometimes usual to lower the surface of the block before the engraving is executed in such parts as should appear light and delicate; they thus receive a mere touch of the paper in the press, the darker parts receiving the whole pressure and coming out with double brilliancy. When careful printing is bestowed on cuts they are first carefully brought to the height of the type, by *underlaying*, as it is termed, with paper of the required thickness; an impression is then taken with the tympan of the press, and the dark parts of the engraving *overlayed* with paper carefully cut out; another impression is then taken, and the same process is to be continued of *laying* on and cutting out for the light parts until a satisfactory impression be produced, corresponding with the engraver's proof, which the pressman should always keep under his observation.

Wood-engraving is a most useful adjunct to the author, and must always command a large amount of attention. In this country the art has been carried to the highest degree of perfection. In works like the present, the author is greatly aided by a diagram, which can more clearly explain his meaning than a page of letter-press;

and it can be set up and printed with the type, a mode which no other style of art can rival in simplicity and cheapness. The taste for elaborately-executed wood-engravings may again decrease, as we find it did for nearly two centuries; but it was never a lost art, and never will be, owing to the practical advantages we speak of, unless it be superseded by some simpler mode of doing the same thing hitherto undiscovered. The number of persons who practise wood-engraving in London alone is very large, and when we consider the quantity done in the great cities of the Continent, and the large amount of book illustration in constant demand, the creative power of one single genius—Thomas Bewick—shines forth in greater vigour than ever.—F.W.F.

When a large number of impressions are to be taken from a wood-block, a cast in metal is taken from it, in the manner described under STEREOTYPE. In some cases electrotype copies are taken in copper, and the comparatively thin sheet of copper produced is mounted upon a wood-block of the proper thickness.

Photography has been employed most serviceably by the wood engraver. Drawings are reduced by the aid of the camera to any required size, and the impression received directly upon the wood which is to be cut. Most of the wood-engravings which illustrate this volume have been produced by the use of the photographic process. See PHOTOGRAPHY.

Engraving on brass plates has been used as a cheap mode of superseding wood-engraving for works of a cheap character.

ENGRAVING ON GLASS. This work does not deal with mere matters of manipulation, therefore the process of engraving on glass, by means of the glass-cutter's wheel, and with tools, finds some notice under GLASS only. One process of engraving on glass is carried out by covering the glass with an etching wax, carefully cutting out the pattern, then covering the glass with powdered fluor-spar, and pouring sulphuric acid upon it. Or, by preparing fluoric acid in a metal bottle, and projecting the vapour as formed directly upon the exposed part of the glass. Attention has of late been drawn to a process of engraving glass by the sand-jet, an American invention.

Mr. Tilghman's attention seems first to have been directed towards cutting stone or hard metal by a jet of sand impelled by escaping steam under high pressure. His early experiments were with very high pressure; but, as he progressed in the knowledge of results obtainable with various velocities, a great use for this process seemed to develop itself in sand driven by moderate air-blasts, and applied to grinding or depolishing glass for ornamental purposes.

For grinding glass a common rotatory fan is used, 30 inches in diameter, making about 1,500 revolutions per minute, which gives a blast of air of the pressure of about 4 inches of water, through a vertical tube, 2 feet high by 60 inches long, and 1 inch wide.

Into the top of this tube the sand is fed, and falling into the air-current and acquiring velocity from it, is dashed down against the sheets of glass, which are slowly moved across, about 1 inch below the end of the tube. About 10 or 15 seconds' exposure to the sand-blast is sufficient to completely grind or depolish the surface of ordinary glass, so that sheets of it carried on endless belts may be passed under this 1 inch wide sand-shower at the rate of 5 inches forward movement per minute. In the machine in use for this purpose the spent sand is reconveyed to the upper hopper by elevators, and the dust made by the sand-blast (which might otherwise be a source of annoyance to the workman) is drawn back into the fan, and thence passes with the wind into the blast ton, and again mingles with the shower of sand upon the glass.

By covering parts of the glass surface by a stencil or pattern of any tough or elastic material, such as paper, lace, caoutchouc, or oil paint, designs of any kind may be engraved.

There is a kind of coloured glass made by having a thin stratum of coloured glass melted or 'flashed' on one side of an ordinary sheet of clear glass. If a stencil of sufficient toughness is placed on the coloured side, and exposed to the sand-blast, the pattern can be cut through the coloured stratum in from about 4 to 20 minutes, according to its thickness.

The theoretical velocity of a current of air of the pressure of 4 inches of water, Mr. Tilghman calculates, is (neglecting friction), about 135 feet per second; the actual velocity of the sand is doubtless much less.

If a current of air of less velocity is used, say about 1 inch of water, very delicate materials, such as the green leaves of the fern, will resist a stream of fine sand long enough to allow their outlines to be engraved on glass. By graduating the time of exposure with sufficient nicety, so as to allow the thin parts of the leaves to be partly cut through by the sand, while the thicker central ribs and their branches will resist, the effect of a shaded engraving may be produced.

The grinding of such a hard substance as glass by an agent which is resisted by such a fragile material as a green leaf, seems at first rather singular. The probable explanation is, that each grain of sand which strikes with its sharp angle on the glass pulverises an infinitesimal portion, which is blown away as dust, while the grains which strike the leaf rebound from its soft elastic surface.

The film of bichromatised gelatin, used as a photographic negative, may be sufficiently thick to allow a picture to be engraved on glass by fine sand, driven by a gentle blast of air.

For cutting stone, the inventor uses steam as the impelling jet; the higher the pressure the greater is the velocity imparted to the sand, and the more rapid its cutting effect.

In using steam of about 100 lbs. pressure, the sand is introduced by a central iron tube, about $\frac{3}{16}$ths-inch bore, while the steam is made to issue from an annular passage surrounding the sand tube.

A certain amount of suction of air is thus produced, which draws the sand through the sand-tube into the steam-jet, and both are then driven together through a tube, about 6 inches long, in which the steam imparts its velocity to the sand, and finally strike on the stone, which is held about an inch distant from the end of the tube.

At the part struck a red light is visible, as if the stone was red-hot, though really it is below 212° Fahr. The light is probably caused by the breaking-up of the crystals of the sand and stone.

The cutting effect is greatest when free escape is allowed for the spent sand and steam. In making a hole of diameter but slightly greater than that of the steam jet, the rebounding steam and sand greatly interfere with, and lessen the efficiency of the jet.

Under favourable conditions, using steam which he estimated as equal to about $1\frac{1}{2}$ horse-power, at a pressure of about 125 lbs., the cutting effect per minute was about $1\frac{1}{2}$ cubic inch of granite, or 3 cubic inches of marble, or 10 cubic inches of soft brown sandstone.

By means of flexible or jointed connecting tubes, the blast-pipe is made moveable in any direction; grooves and mouldings of almost any shape can thus be made, or by means of stencil plates, letters or ornaments can be cut either in relief or in intaglio, with great rapidity in the hardest stone.

At a high velocity, quartz sand will cut substances much harder than itself, as before stated. With a steam jet of 300 lbs. pressure, a hole $1\frac{1}{2}$ inch in diameter was cut through a piece of corundum $1\frac{1}{2}$ inch thick in 25 minutes.

A hole 1 inch long and $\frac{1}{4}$ inch wide was cut through a hard steel file $\frac{1}{4}$ inch thick, in 10 minutes, with a jet of 100 lbs. steam.

A stream of small lead shot driven by 50 lbs. steam, wore a small hole in a piece of hard quartz; the shot were found to be only very slightly flattened by the blow, showing their velocity to have been moderate.

Among the curious examples of glass cut by this sand-blast was shown a piece of ordinary window-glass, which, having been partially protected by a covering of wire gauze, had been cut entirely through, thus producing a glass sieve, with openings about $\frac{1}{12}$th of an inch, the intervening glass meshes being only $\frac{1}{16}$th of an inch wide. This seems to have been produced more as a curiosity than for any practical purpose. Should such a sheet of perforated glass be required, it is questionable if it could be produced from a solid sheet by any other method.

A microscopic examination of the sheet glass depolished by this process shows a succession of pits formed by the blows of the impinging grains of sand, and looks more uniform than do surfaces ground by the rubbing process.

One curious fact connected with the use of this process is that when a surface to be cut in intaglio or otherwise is partially protected by templates of metal, these templates curl up under the blows of the sand, so that paper patterns are really more durable than patterns cut from brass. Sheet steel, cut into shapes and then hardened, will also curl up under the blows of the fine particles of sand, unless protected by sheets of yielding material. Fine lace will protect glass during the depolishing process, and leave its designs in polished lines on a ground surface. This account is derived from the 'Journal of the Franklin Institute.' See Glass.

ENGRAVING ON STONE; SEAL OR GEM ENGRAVING. Some very delicate and beautiful results are obtained by engraving upon lithographic stones. The art, is not, however, of sufficient importance to occupy our already crowded space. Seal or gem engraving is an art of great antiquity. We may here simply allude to the apparatus in general use by the workman, and which consists of a lathe turned by a treddle, and moving a small horizontal steel cylinder, into which the tools are inserted, allowing them to revolve against the gem, which is held by the hand of the workman close to each point, cutting the surface by the aid of diamond-powder made into a paste with olive-oil. The tools are very simple, and adapted to produce the kind of abrasion wished for by the artist. When thus engraved the surface is polished with box-wood tools and rotten-stone. The ancient gems are remarkable for a higher and finer polish than is possessed by the generality of modern works, as well as for a more vigorous and sculpturesque effect.

The arts of incising a design upon a precious stone, and of sculpturing it in relief, originated with the nations of antiquity, and were practised by them with great success. Carnelian was their favourite stone for general use, but they also worked on onyx, chalcedony, jasper, and blood-stone. They frequently used the various tints of the stone to heighten the effect of their work, and produce *relief*. The ancients have preserved the names of many of the early Greek gem engravers who have never been surpassed for ability. One of their most celebrated works is the sardonyx of three strata, which formed part of the cabinet of gems of the Empress Josephine, and which represents the busts of Ptolemy Philadelphus (B.C. 285 to 258) and his queen Arsinœ. Its shape is an obtuse oval, measuring 6¼ inches by 5. Another with the same heads is preserved in the Imperial Cabinet at Vienna, measuring 4½ inches each way. But the largest and most important of these antique works is the apotheosis of Augustus, preserved in the Royal Cabinet of France, which measures 8 inches by 9, and represents more than twenty figures of men and deities, a wonderful monument of patient labour and artistic power. So fond were the ancients of these costly and beautiful works, that the Emperor Heliogabalus is recorded to have covered his shoes with engraved gems. They were also used to adorn coffers and other luxurious articles of furniture, as well as drinking vessels, patera, &c.—*Fairholt.*

ENLEVAGE. The discolouring or discharging style in calico-printing.

ENSTATITE. A name now applied to those varieties of bronzite which contain little or no iron. Enstatite is the chief constituent of the French rock called *Lherzolite*, and it has been also found in certain meteorites. The name, derived from ἐνστάτης (*enstates*), 'an opponent,' refers to the refractory behaviour of the mineral before the blowpipe.

ENTOZOA. Those animals which live *within* the bodies of other animals.

ENTRESOL. A floor between other floors; a low set of apartments placed above the first floor. The Quadrant, Regent Street, has a good example of the entresol. In Italy the term *Mezzanino*, or 'little middle floor,' is used to indicate the same arrangement.

ENVELOPES. The manufacture of envelopes has so largely increased, that the old method of folding them by means of a *bone folding stick*, although a good workman could thus produce 3,000 a day, was not capable of meeting the demand; hence the attention of several was turned to the construction of machines for folding them. Amongst the most successful are the following:—

Envelope folding.—In the envelope-folding machine of Messrs. De La Rue & Co., each piece of paper, previously cut by a fly-press into the proper form for making an envelope (and having the emblematical stamp or wafer upon it), is laid by the attendant on a square or rectangular metal frame or box, formed with a short projecting piece at each corner, to serve as guides to the paper, and furnished with a moveable bottom which rests on helical springs. A presser at the end of a curved compound arm, which moves in a vertical plane, then descends, and presses the paper down into the box,—the bottom thereof yielding to the pressure; and thereby the four ends or flaps of the piece of paper are caused to fly up; the presser may be said to consist of a rectangular metal frame, the ends of which are attached to the outer part of the curved arm, and the sides thereof to the inner portion of the arm; so that the ends and sides of the presser can move independently of each other. The ends of the presser then rise, leaving the two sides of it still holding down the paper; two little lappet pieces next fold over the two side flaps of the envelope; and immediately a horizontal arm advances, carrying a V-shaped piece charged with adhesive matter or cement (from a saturated endless band), and applies the same to the two flaps. A third lappet presses down the third flap of the envelope upon the two cemented flaps, and thereby causes it to adhere thereto; and then a pressing piece, of the same size as the finished envelope, folds over the last flap and presses the whole flat. The final operation is to remove the envelope, and this is effected by a pair of metal fingers, with India-rubber ends, which descend upon the envelope, and, moving sideways, draw the envelope off the bottom of the box (the pressing piece having moved away and the bottom of the box risen to the level of the platform of the machine) on to a slowly-moving endless band, which gradually carries the finished envelopes away. A fresh piece of paper is laid upon the box or frame, and the above operations are repeated. This machine makes at the rate of 2,700 envelopes per hour.

Another machine for the same object was invented by Mr. A. Remond, of Birmingham, and is that employed by Messrs. Dickinson & Co. The distinguishing feature of this arrangement is the employment of atmospheric pressure to feed in the paper which is to form the envelope, and to deflect the flaps of the envelope into inclined positions, to facilitate the action of a plunger, which descends to complete the folding. The pieces of paper, cut to the proper form, are laid on a platform, which is furnished with a pin at each corner, to enter the notches in the pieces of paper, and retain them in their proper position, and such platform is caused alternately to rise and bring the upper piece of paper in contact with the instrument that feeds the folding part of the machine, and then to descend until a fresh piece is to be removed. The feeding instrument consists of a hollow horizontal arm, with two holes in the under side, and having a reciprocating movement. When it moves over the upper piece of paper on the platform, a partial vacuum is produced within it, by a suitable exhausting apparatus, and the paper is thereby caused to adhere to it at the holes in its under surface by the pressure of the atmosphere. The instrument carries the paper over a rectangular recess or box; and then, the vacuum within it being destroyed, it deposits the paper between four pins, fixed at the angles of the box, and returns for another piece of paper. As the paper lies on the top of the box, the flap which will be undermost in the finished envelope is pressed by a small bar or presser on to the upper edge of two angular feeders, communicating with a reservoir of cement or adhesive matter, and thereby becomes coated with cement; and at the same time, the outermost or seal flap may be stamped with any required device, by dies, on the other side of the machine. A rectangular frame or plunger now descends and carries the paper down into the box; the plunger rises, leaving the flaps of the envelope upright; streams of air, issuing from a slot in each side of the box, then cause the flaps to incline inwards: and the folding is completed by the plunger again descending; the interior and under surface of such plunger being formed with projecting parts, suitable for causing the several flaps to hold in proper superposition. The bottom of the box (which is hinged) opens, and discharges the envelope down a shoot to a table below; the feeding instrument then brings forward another piece of paper; and a repetition of the above movements takes place.

EPHESITE. A micaceous mineral accompanying the emery of Gummach-Dagh, near Ephesus. It has been described by Dr. J. L. Smith.

EPIDERMIS. The outer covering or scarf-skin. The fibrous horny coating of some shells which sometimes are used in the arts.

EPIDOTE. A complex mineral silicate, usually containing alumina, peroxide of iron, lime, magnesia, and protoxide of iron. It crystallises in the oblique or monoclinic system, often in long well-shaped glassy crystals. The colour is generally some shade of green, often of a characteristic pistachio green, but sometimes passing into black.

Epidote is not uncommon in granite, and other crystalline rocks; whilst it forms the main constituent of a rock known as *Epidosite* or *Epidote-rock*. The first crystals occur in limestone, in trappean rocks, and in deposits of iron ore. The name (ἐπίδοσις, *epidosis*, increase) was originally proposed by Haüy on crystallographic considerations, but has since been much extended, and the species now includes a large number of varieties, the more important of which will be noticed under their respective names.

EPIZOA. Those animals which live parasitic *upon* other animals. See Entozoa.

EPSOMITE. Native Epsom salts, or sulphate of magnesia.

EPSOM SALTS. A sulphate of magnesia, consisting of magnesia 16·26, sulphuric acid 32·52, water 51·22. It derives its name from a mineral spring containing the salt at Epsom. It is largely manufactured by the evaporation of sea-water, after crystallisation of the common salt; or by precipitating the magnesia from sea-water by means of lime, and then dissolving this precipitate in sulphuric acid. It may also be prepared from carbonate of magnesia, or from magnesian limestone (dolomite). See Magnesia, Sulphate of.

EQUISETACEÆ. (*Equus*, a horse, *seta*, a hair.) A group of plants commonly called 'horse-tails.' The species of equisetum grow very abundantly in ditches, lakes, and rivers, in this and other parts of the world. The stems are striated, hollow, articulated, usually branched, having no true leaves, but in their place green-jointed branches arranged in whorls at the articulations of the stem. In South America they grow to a large size. The stems usually contain a great deal of silica in their composition, and the *Equisetum hyemale*, or Dutch rush, finds its use in the arts on this account. See Dutch Rush.

EQUISETUM. A genus of Equisetaceæ.

EQUIVALENTS, CHEMICAL. By this term is understood the proportions in which substances combine with each other to form definite compounds. These proportions are referred to the common standard, hydrogen, which is taken as unity. The limits of this work preclude the possibility of entering into the history of the steps by which the doctrine of equivalents was gradually developed; but it is proper that we should indicate some of the methods by which the equivalents of elements and compounds are ascertained and demonstrated to be correct. But before proceeding, it is necessary to define the term 'equivalent.' This is not easy to do, because the theoretical ideas of all chemists are not the same. Suppose, for example, the constitution of water were to be taken as the starting point. On submitting it to the action of the pile, it is immediately observed that the ratio of the two gases evolved is as 1 to 2. One chemist will at once assume that water is a simple binary compound of one equivalent of each of its constituents. But this involves the assumption that the gaseous volume of the equivalent of hydrogen is twice that of oxygen. The other chemist assuming that one volume of a gas represents an equivalent, considers water to be a ternary compound, having the formula H^2O. It is plain that the atom of hydrogen will have only half the value on the second hypothesis that it will on the first, or, what comes to the same thing, the atom of oxygen will be twice as great. If, with some chemists, we consider the volumes of the gases to represent atoms or equivalents, then, water consisting of two volumes of hydrogen and one volume of oxygen, and as by weight water contains 8 parts of oxygen to 1 part of hydrogen, it is plain that 8 parts of oxygen by weight will represent 1 equivalent, and 1 part by weight of hydrogen will represent 2 equivalents. Consequently 1 equivalent of hydrogen will weigh ·5. But to avoid fractional numbers it will (on these assumptions) be more convenient to write the equivalent of hydrogen = 1, and oxygen 16. In this country it has, until recently, been usual to consider the atom of hydrogen as occupying twice the space in the gaseous state of that of oxygen. The atomic weights being, therefore, oxygen 8 and hydrogen 1.

We have said that it is by no means easy to define an equivalent. The difficulty arises not merely from the different aspects under which theoretical chemists regard the elements and their compounds, but also from the practical difficulties attending the determination of the true constitution of some substances. Thus the equivalent of bismuth is assumed by some to be 71 and by others 213; the oxide in the one case becomes BiO, in the other BiO^3; the first equivalent being only one-third as great as the second. But, it is to be observed, the variations in the theoretical views of chemists are of no consequence, so long as we clearly comprehend the nature of those variations. The *relative* values or proportions are the same in all cases. It is, in fact, somewhat the same as if one class regarded the avoirdupois pound as made up of 16 ounces, each ounce weighing 437·5 grains, and the other considered it as consisting of 8 ounces, each ounce containing 875·0 grains.

In order to clearly understand the nature of the equivalents as received in this country, it is necessary to remember that there are three relations of volume amongst gases, namely, one, two, and four volumes. The first relation applies solely to elementary gases. The two others apply to elements and compounds. [It is true that the vapour-densities of pentachloride of phosphorus, chloride of ammonium, and, perhaps, one or two other substances, appear to differ from this rule, but it is probable that, like sulphur, the vapour densities require to be determined under special conditions of temperature or pressure.] In the table of equivalents the density of the vapours of those substances which are capable of assuming the gaseous states are so placed that the number obtained by experiment may be compared with that deduced from theoretical considerations. In the following table the vapour-volumes or combining measures of some of the more important elements are given. We shall see presently the practical value of the information contained in it:—

Element	Combining Measure	Element	Combining Measure
Hydrogen	two volumes	Oxygen	one volume
Chlorine	do.	Sulphur	do.
Bromine	do.	Selenium	do.
Iodine	do.	Phosphorus	do.
Fluorine (*hypothetical*)	do.	Arsenic	do.
Nitrogen	do.	Carbon	do.

It must be remembered that all volatile compounds possess four-volume formulæ, except a few, which in this country are always written as if possessing a condensation to two volumes; such are carbonic acid, carbonic oxide, sulphurous acid, &c. With the above information it will be easy for any person to calculate the density of any vapour or gas by the aid of the following directions:—

To obtain the density of any vapour or gas having a condensation to four volumes, such as most organic or inorganic compounds.—Multiply half the density of hydrogen by the atomic weight of the vapour or gas. Example:—Find the density of the vapour of hydrobromic acid. The atomic weight of hydrobromic acid is 81. The density of hydrogen is 0·0692, half of which is 0·0346. Then 0·0346 × 81 = 2·8026. Experiment gave 2·73.

To obtain the density of any vapour or gas having a condensation to two volumes.—Multiply the density of hydrogen by the atomic weight of the gas or vapour. Example:—Find the density of chlorine gas. The atomic weight of chlorine being 35·5, and the density of hydrogen 0·0692, we have by the rule, 0·0692 × 35·5 = 2·4566. The density by experiment is 2·44.

To obtain the density of any vapour or gas having a condensation to one volume.—Multiply twice the density of hydrogen by the atomic weight of the gas or vapour. Example:—Find the density of the vapour of oxygen. The atomic weight of oxygen being 8, and twice the density of hydrogen being 0·1384, we have 0·1384 × 8 = 1·1072. Experiment has yielded 1·1056.

The above methods of calculating the densities of vapours and gases are those always employed by the writer of this article, and will be found incomparably shorter and more convenient than any other.

It is perfectly plain that, by a simple inversion of the above rules, it is equally easy from the known density of a gas or vapour to calculate its atomic weight. Nevertheless, for the sake of those who are unaccustomed to calculations of this kind, we append the following rules:—

To calculate the atomic weight of any gas or vapour having a condensation to four volumes.—Divide the density of the gas by half the density of hydrogen. Example: —Find the atomic weight of hydrobromic acid gas, the density of which is 2·8026; $\frac{2{\cdot}8026}{0{\cdot}0346} = 81{\cdot}000$.

To calculate the atomic weight of any gas or vapour having a condensation to two volumes.—Divide the density of the gas by the density of hydrogen.

To calculate the atomic weight of any gas or vapour having a condensation to one volume.—Divide the density of the gas by twice the density of hydrogen.

It is plain, then, that if we are in possession of the atomic weight and vapour-volume of any substance, it is easy to determine the density of its vapour or gas. Also, that having the density of the vapour and the vapour-volume, it is easy to calculate the atomic weight. If we consider for an instant what is meant by the term 'density of a vapour or gas,' it will appear equally easy to find, from the density of the gas, the weight of 100 cubic inches at the standard temperature and pressure. By the density of a gas is meant the number expressing how much it is heavier or lighter, bulk for bulk, than air. If, therefore, we multiply the density of a gas by the weight of 100 cubic inches of air, at the standard temperature and pressure (= 30·00 grains), we immediately find the number required. Example:—The density of hydrogen is 0·0692 and 0·0692 × 30 = 2·0760, or the weight of 100 cubic inches of hydrogen, at a temperature of 60° Fahr., and 30 inches of the barometer.

From what has been said, it is evident that no difficulty exists in determining the equivalents of bodies which can be obtained in a gaseous state. Where the equivalent of a fixed body is to be ascertained, or where it is desired to proceed in a different manner, the method employed must depend upon the nature of the substance. We shall consider three of the most simple and general cases, namely, an acid, an alkali, and a neutral body.

1. *Mode of determining the equivalent of an acid.*—For this purpose it is necessary to analyse a salt, the constitution of which is known. If the base or metallic oxide in the salt is one of which the atomic weight is well established, it is very easy to determine the combining proportion of the acid. We say, as the percentage of oxide is to the percentage of acid, so is the atomic weight of the oxide to the atomic weight of the acid. Example:—Butyrate of silver has the following composition:—

Oxide of silver	59·487
Butyric acid	40·513
	100·000

We therefore say:—

$$\underbrace{59{\cdot}487}_{\text{Percentage of oxide of silver.}} : \underbrace{40{\cdot}513}_{\text{Percentage of acid.}} :: \underbrace{116}_{\text{Equivalent of oxide of silver.}} : \underbrace{79{\cdot}000}_{\text{Equivalent of the acid.}}$$

It must be remembered that the atomic weight so obtained is that of the anhydrous acid, so that one equivalent of water must be added to find the atomic weight of the acid in its ordinary condition. If the equivalent desired be that of a hydrogen acid, the method of proceeding must be slightly modified, but the details need not be given, as they are self-evident.

2. *Mode of determining the equivalent of an alkali.*—Several methods present themselves, each possessing certain advantages. Most alkalis, organic and inorganic, form salts well adapted for enabling their atomic weight to be ascertained by analysis. We shall select as an example ammonia, and the salt employed to settle the atomic weight will be the sulphate, which contains—

Oxide of ammonium	39·40
Sulphuric acid	60·60
	100·00

In the same way that an oxide of known composition is the datum employed to determine the equivalent of an acid, so, on the other hand, an acid, the formula of which is well established, serves to enable the formula of an alkali to be deduced. We therefore say:—

$$\underbrace{60\cdot60}_{\text{Percentage of acid.}} \quad : \quad \underbrace{39\cdot40}_{\text{Percentage of alkali.}} \quad :: \quad \underbrace{40\cdot00}_{\text{Equivalent of the acid.}} \quad : \quad \underbrace{26\cdot00}_{\text{Equivalent of the alkali.}}$$

Most alkalis, especially those derived from the organic kingdom, form well-defined and easily crystallisable compounds with some of the metallic chlorides, especially those of gold, platinum, and palladium. These salts are well adapted for enabling atomic weights to be fixed.

3. *Mode of determining the equivalent of a neutral substance.*—Neutral bodies are formed upon so many models or types that no general method can be given for the required purpose. If volatile at moderate temperatures, the density of the vapour can be ascertained, and this is generally sufficient. Salts have their equivalents found by determining the percentage composition, and proceeding as in Examples 1 and 2. The equivalent of a metal is found by forming a compound with some substance, the atomic weight of which is well known, such as oxygen or sulphur. The compound is then carefully analysed. Example:—It has been found that 100 parts of oxide of copper contain—

Copper	80·00
Oxygen	20·00
	100·00

We therefore say:—

$$\underbrace{20\cdot00}_{\text{Percentage of oxygen.}} \quad : \quad \underbrace{80\cdot00}_{\text{Percentage of copper.}} \quad :: \quad \underbrace{8\cdot00}_{\text{Equivalent of oxygen.}} \quad : \quad \underbrace{32\cdot00}_{\text{Equivalent of copper.}}$$

A precisely analogous mode of proceeding may be adopted with chlorides, iodides, &c.—C. G. W.

It is important to clearly separate the idea of *chemical equivalence* from that of *atomic weight.* Two elements can be strictly called equivalent to each other only when one is capable of being substituted for the other in chemical combination. Thus 35·5 parts of chlorine (its atomic weight) are strictly equivalent to 1 part of hydrogen; but 16 parts of oxygen (its modern atomic weight) are equivalent to 2 parts of hydrogen; 14 parts of nitrogen usually to 3 of hydrogen; 12 of carbon to 4 of hydrogen; and so on. Hence the idea of chemical equivalence is by no means the same as that of atomic weight; the atom of one element not being necessarily equivalent to another in its combining power. For the modern doctrine of equivalence, see Watts's 'Dictionary of Chemistry,' and in this work, the articles Atomicity and Atomic Weights.

ERASINE. See Abietene.

ERBIUM. The metallic radicle of Erbia, one of the earths associated with yttria. It was discovered by Mossander in 1842. Salts of erbia give characteristic absorption-spectra exhibiting dark bands. See Watts's 'Dictionary of Chemistry.'

EREMACAUSIS,—*slow combustion.* This term has been applied to that constant combination of oxygen with carbon and hydrogen, to form carbonic acid and water, which is unceasingly going on in nature, as in the decay of timber or the 'heating' of hay or grain put together in a moist state. Perfect dryness, and a temperature below freezing, stop this eremacausis, or slow combustion.

ERGOT OF RYE. Diseased grains of rye ('spurred rye') which become elongated and curved in shape, and of a jet-black colour, by the attack of a fungus called *Cordyceps purpurea.* In this state the rye is highly poisonous. The ergot of rye has been employed in medicine.

ERINITE. A hydrous arsenate of copper.

ERMINE. The Ermine, *Mustela Erminea,* is one of the weasel tribe. This little animal is most destructive, destroying a considerable quantity of game. It is upwards of 9½ inches long, exclusive of the tail which measures 3½ inches more. In the winter the fur becomes quite white, except the tip of the tail which always remains black. In the summer it is of a fine chestnut colour, and the fur is then known by the furriers as Roselet. It is a native of northern countries. It is especially abundant in Russia, Siberia, Kamtschatka, Lapland, and Norway. It is found occasionally in Scotland. See Fur.

ERRATIC BLOCKS. Rounded and weather-worn fragments of the harder rocks, which are found very widely scattered, at great distances from the places whence they were originally derived. They are generally supposed to have been removed by the transporting power of icebergs and fields of ice.

ERUBESCITE. A name for purple copper-ore, or 'horse-flesh ore.' See Copper.

ERYTHRIC ACID. The colorific principle of Angola and Madagascar Orchilla weeds. By macerating the lichen in milk of lime, Stenhouse obtained 12 per cent. of crude erythric acid. It yields red compounds with ammonia, and also in its reaction with hypochlorite of lime. See Lichen; Orchilla.

ERYTHRINE or **ERYTHRITE.** A hydrous arsenate of copper, known also as cobalt-bloom. See Cobalt.

ERYTHROXYLON COCA. The coca. This shrub is a native of Peru, and is cultivated extensively in the Andes. The dried leaves, mixed with finely-powdered chalk, are chewed by the Peruvians. This peculiar stimulant brings on a condition of apathy. It prevents hunger and retards sleep, so that the natives who work in the mines will sometimes, under its influence, labour from twenty to thirty hours at a stretch. The continued use of coca is more injurious than that of opium or tobacco. See Coca.

ESCARPMENT. A word which has long been in use in geological works; and by the earlier writers it was employed to denote any hill that had a sharp slope or scarp, but of late years it has acquired a more restricted meaning, and it is now applied only to hills of one particular kind. 'It may be defined,' says Mr. Whitaker 'as the boundary ridge of a formation or bed, that is to say, the ridge along which a formation or bed is cut off, and beyond which it does not extend, except in the form of outliers; it follows the line of the strike.'—*Geology of the London Basin.*

ESCHALOT (*Échalote,* Fr.), commonly Shallot. A small kind of onion. *Allium ascalonicum.*

ESCULIN. A substance found in the inner white bark of the horse-chestnut tree, remarkable for its fluorescent power. See Fluorescence.

ESPARTO, or *Spanish Grass,* as its name denotes, is imported from Spain, where it is indigenous in certain mountains and uncultivated districts on the Mediterranean coast. It is also produced on the north coast of Africa, where it is called by the Arabs *alfe, alfa,* or *alva.* It appears to have been used by the Romans for cordage, and called by them *Spartium.*

This plant, classed as a sedge by botanists (and by them denominated *Lygeum Spartum* and *Stipa tenacissima*), grows in tufts and bunches similar to the rushes in this country; it varies from 2 to 4 feet in height, and consists of a long flat lanceolated leaf or blade, which, as the sap descends and the plant ripens, takes a cylindrical form. It is pulled up from the roots, exposed to the sun, and, when dry, laid in small bundles, and these again, for facility of carriage, into larger ones, which are transported in carts, or more generally on donkeys' backs (both Spain and Africa, in the uncultivated and wild districts of the country where the plant exists, being, comparatively speaking, without roads) to the port of shipment.

The plant being now imported to the extent of 30,000 to 40,000 tons yearly, was selling at the commencement of the year 1862 at 5*l.* per ton; but owing to the reduction in the price of rags, and to the general stagnation of trade caused by the American war, this price has been latterly reduced.

Numerous patents have (as might naturally be expected) been taken out for the treatment of this plant; those by Mr. Routledge would appear, from the increasing employment of this material, to be the most useful, effectual, and economical. Mr. Routledge represents, indeed, that the cost of production either in the condition of half stuff or paper, is below that of rags to produce a similar quality of paper, and the power required for reducing much less. Judging from the specimens of paper exhibited by Mr. Routledge in 1862, manufactured by him at his mills at Eynsham, in Oxfordshire, exclusively from esparto, as well as from the other specimens of paper manufactured at various other mills employing his process, in which esparto is used as a blend with the ordinary rag material, the results are very satisfactory, demonstrating that a new material has at length been brought into use meeting this long-desired requirement, both as regards quality and economy.

One satisfactory feature in Mr. Routledge's process is the fact that no material alteration in existing machinery or appliances is required; no higher pressure boiling in expensive vessels is necessitated; the silica, always more or less combined with a coating of raw fibres, is got rid of, and the gummo-resinous matter neutralised, permitting the fibres to be eliminated and drawn out by the ordinary pulping engine, as now practised with rags. The assurance of a successful result appears to be dependent on the proper adjustments of the proportions of the chemicals employed; this secured, and the process is extremely simple, the issue appears to be reliable, and, what is of no little importance, invariable and constant.

The fibres produced from esparto are specifically lighter than those from any other paper-making material in use; their mechanical structure, moreover, admits of minute subdivision, without destroying the feathery or mossy arrangement which facilitates the intimate felting or blending of the ultimate fibres on the endless wire of the Fourdrinier machine; then, esparto paper, in consequence of this peculiarity, feels thicker in the hand, and takes a finer surface than that made from cotton rags, and, in proportion to the blend or admixture with other rag or paper-making material, imparts these advantageous characteristics. It is to be remarked, however, that its introduction generally into the trade being only, comparatively speaking, of recent date, it has not yet arrived at full development, its employment being hitherto limited to common and ordinary printing papers and cartridges, and in the unbleached state to brown and cap papers.

Our Imports for the last five years have been as follow:—

Places	1868		1869		1870		1871		1872	
	Tons	Value	Tons	Value	Tons	Value	Tons	Value	Tons	Value
From		£		£		£		£		£

ESSENCE D'ORIENT, the name of a pearly-looking matter procured from the blay or bleak, a fish of the genus *Cyprinus*. This substance, which is found principally at the base of the scales, is used in the manufacture of artificial pearls. A large quantity of the scales being scraped into water in a tub, is there rubbed between the hands to separate the shining stuff, which subsides on repose. The first water being decanted, more is added with agitation till the essence is thoroughly washed from all impurities, when the whole is thrown upon a sieve; the substance passes through, but the scales are retained. The water being decanted off, the essence is procured in a viscid state, of a bluish-white colour, and a pearly aspect. The intestines of the same fish are also covered with this beautiful glistening matter. Several other fish yield it, but in smaller proportion. When well prepared, it presents exactly the appearance and reflections of the real pearl, or the finest mother-of-pearl; properties which are probably owing to the interposition of some portions of this same substance between the laminæ of these shelly concretions. Its chemical nature has not been investigated; it putrefies readily when kept moist, an accident which may however be counteracted by water of ammonia. See Pearls.

ESSENCE OF SPRUCE is prepared by boiling the young tops of the *Abies nigra*, or black spruce, in water, and concentrating the decoction by evaporation in a water-bath. With a duty of 10*l.* per cent. ad valorem—imposed August 20, 1852—we received:

in 1871, from all countries to the value of 10*l.* only; and
„ 1872, „ „ „ 21*l.* „

ESSENCES. See Perfumery.

ESSENTIAL OILS. See Oils, Fixed and Essential, and Otto.

ESSONITE. A lime-alumina garnet, of brownish-red colour, known also as *cinnamon-stone*. It comes chiefly from Ceylon, and is cut as a gem-stone, being indeed sometimes mistaken for the hyacinth or jacynth.

ETCHING ON GLASS. See Glass, and Engraving on Glass.

ETCHING VARNISH. (*Aetzgrund-Deckfirniss*, Ger.) Though the practice of the elegant art of etching does not come within the scope of our Dictionary, the preparation of the varnishes, and of the biting menstrua which it employs, legitimately belongs to it.

The varnish of Mr. Lawrence, an English artist resident in Paris, is made as follows: Take of virgin wax and asphaltum, each two ounces, of black pitch and burgundy-pitch, each half an ounce. Melt the wax and pitch in a new earthenware glazed pot, and add to them, by degrees, the asphaltum, finely powdered. Let the whole boil till such time as that, taking a drop upon a plate, it will break when it is cold, on bending it double two or three times betwixt the fingers. The varnish, being then enough boiled, must be taken off the fire, and after it cools a little, must be poured into warm water, that it may work the more easily with the hands, so as to be formed into balls, which must be kneaded, and put into a piece of taffety for use.

Care must be taken, first, that the fire be not too violent, for fear of burning the ingredients, a slight simmering being sufficient; secondly, that whilst the asphaltum is being put in, and even after it is mixed with the ingredients, they should be stirred continually with the spatula; and, thirdly, that the water into which this composition is thrown should be nearly of the same degree of warmth with it, in order to prevent a kind of cracking that happens when the water is too cold.

Preparation of the hard varnish used by Callot, commonly called the Florence Varnish.—Take four ounces of fat oil very clear, and made of good linseed oil, like that used by painters; heat it in a clean pot of glazed earthenware, and afterwards put to it four ounces of mastic well powdered, and stir the mixture briskly till the whole be well melted, then pass the mass through a piece of fine linen into a glass bottle with a long neck, that can be stopped very securely; and keep it for the use that will be explained below.

Method of applying the soft varnish to the plate, and of blackening it.—The plate being well polished and burnished, as also cleansed from all greasiness by chalk or Spanish white, fix a hand-vice on the edge of the plate where no mark is intended to be, to serve as a handle for managing it when warm; then put it upon a chafing-dish, in which there is a moderate fire, and cover the whole plate equally with a thin coat of the varnish; and whilst the plate is warm, and the varnish upon it in a fluid state, beat every part of the varnish gently with a small ball or dauber made of cotton tied up in taffety, which operation smooths and distributes the varnish equally over the plate.

When the plate is thus uniformly and thinly covered with the varnish, it must be blackened by a piece of flambeau, or of a large candle which affords a copious smoke; sometimes two or even four such candles are used together for the sake of despatch, that the varnish may not grow cold, which if it does during the operation, the plate must be heated again, that it may be in a melted state when that operation is performed; but great care must be taken not to burn it, which, when it happens, may be easily perceived by the varnish appearing burnt and losing its gloss.

The menstruum used and recommended by Turrell, an eminent London artist, for etching upon steel, was prepared as follows:—

Take Pyroligneous acid	4 parts by measure,
Alcohol	1 part, mix, and add
Nitric acid	1 part.

This mixed liquor is to be applied from 1 to 15 minutes, according to the depth desired. The nitric acid was employed of the strength of 1·28—the double aqua-fortis of the shops.

The *eau forte* or menstruum for copper, used by Callot, as also by Piranesi, with a slight modification, is prepared with 8 parts of strong French vinegar,

4	parts of	verdigris,
4	,,	sea salt,
4	,,	sal-ammoniac,
1	,,	alum,
16	,,	water.

The solid substances are to be well ground, dissolved in the vinegar, and diluted with the water; the mixture is now to be boiled for a moment, and then set aside to cool. This method is applied to the washed, dried, and varnished plate, after it has suffered the ordinary action of aqua-fortis, in order to deepen and finish the delicate touches. It is at present called the *eau forte à passer*.

ETHENE. See Olefiant Gas.

ETHER, $C^8H^{10}O^2$ ($\mathbf{C^4H^{10}O}$). *Syn. Sulphuric ether, Oxide of ethyl, Ethylic* or *Vinic ether*, &c. &c. By this term is known the very volatile fluid produced by the action on alcohol of substances having a powerful affinity for water, such as sulphuric acid.

Preparation on small scale.—A capacious retort with a moderate-sized tubulature is connected with an efficient condensing arrangement. Through the tubulature passes a tube connected with a vessel full of spirit, sp. gr. 0·83. The tube must have a stopcock to regulate the flow. A mixture being made of five parts of alcohol of the density given above, and nine parts of oil of vitriol, it is to be introduced into the retort, and a lamp-flame is to be so adjusted as to keep the whole gently boiling. As soon as the ether begins to come over, the stopcock connected with the spirit reservoir is to be turned sufficiently to keep the fluid in the retort at its original level.

Preparation on large scale.—The apparatus is to be arranged on the same principle, but, for fear of fracture, may be constructed of cast iron, lined with sheet lead in the part containing the mixture. The chief disadvantage of this arrangement is its opacity, whereby it becomes impossible to see the contents of the retort, and therefore not so easy to keep the liquid at its original level. In this case the quantity distilling over must be noted and the flow of spirit into the retort regulated accordingly. The most convenient mode of proceeding is to have a large stone bottle with a tubulature at the side near the bottom (like a water filter) to hold the spirit. A tube passes from the bottle to the retort. It has at the end, near the retort or still, a bend downwards leading into the tubulature. If a glass still be used, it must for safety be placed in a sand-bath. The distillate obtained, either on the large or small scale, is never pure ether, but contains sulphurous and acetic acids, besides water and alcohol. To remove these, the distillate is introduced, along with a little cream of lime, into a large separating globe, such as that mentioned under BROMINE. The whole is to be well agitated, and the lime-solution then run off by means of the stopcock. The purified ether still contains alcohol and water, to remove which it should be rectified in a water-bath. The fluid will then constitute the ether of commerce. If the second distillation be pushed too far the ether will, if evaporated on the hand, leave an unpleasant after-smell, characteristic of impure ether. If wished exceedingly pure, it must be shaken up in the separating globe, with pure water. This will dissolve the alcohol, and leave the ether, contaminated only by a little water, which may be removed by digestion with quicklime and redistillation at a very low temperature on a hot water-bath.

Pure ether is a colourless mobile liquid, sp. gr. 0·71. It boils at 95° F. The density of its vapour is 2·56 (calculated). Gay-Lussac found it 2·586.

The word 'ether,' like that of alcohol, aldehyde, &c., is now used as a generic term to express a body derived from an alcohol by the elimination of water. Many chemists write the formula C^4H^5O, and call it oxide of ethyl in the same manner as they regard alcohol as the hydrated oxide of the same radical. But there is no just reason for departing from the law we have laid down with reference to the formulæ of organic compounds. We shall therefore write ether $C^8H^{10}O^2$ ($\mathbf{C^4H^{10}O}$). This view has many advantages. We regard, with Gerhardt and Williamson, ether and alcohol as derived from the type water. Alcohol is two atoms of water in which one equivalent of hydrogen is replaced by ethyl; ether is two atoms of water in which both atoms of hydrogen are replaced by that radical. But there are a large class of compound ethers procurable by a variety of processes. These ethers were long regarded as salts in which oxide of ethyl acted the part of a base. Thus, when butyrate of soda was distilled with alcohol and sulphuric acid, the resulting product was regarded as butyrate of oxide of ethyl. The compound ethers are regarded as two atoms of water in which one equivalent of hydrogen is replaced by the radical of an alcohol, and the other by the radical of an acid. In addition to those, there are others more closely resembling the simple ethers. They are founded also on the water type, both atoms of hydrogen being replaced by alcohol radicals, but by different individuals. They are called mixed ethers. The following formulæ show the chemical constitution of all these varieties placed for comparison in juxtaposition with their type:—

$$\underbrace{\left.\begin{matrix}H\\H\end{matrix}\right\}O^2}_{\text{Water (2 eqs.)}} \qquad \underbrace{\left.\begin{matrix}C^4H^5\\C^4H^5\end{matrix}\right\}O^2}_{\text{Common ether.}} \qquad \underbrace{\left.\begin{matrix}C^4H^5\\C^2H^3\end{matrix}\right\}O^2}_{\text{Methylo-ethylic ether.}} \qquad \underbrace{\left.\begin{matrix}C^4H^5\\C^8H^7O^2\end{matrix}\right\}O^2}_{\text{Butyric ether.}}$$

$$\left.\begin{matrix}\mathbf{H}\\\mathbf{H}\end{matrix}\right\}\mathbf{O} \qquad \left.\begin{matrix}\mathbf{C^2H^5}\\\mathbf{C^2H^5}\end{matrix}\right\}\mathbf{O} \qquad \left.\begin{matrix}\mathbf{C^2H^5}\\\mathbf{C\,H^3}\end{matrix}\right\}\mathbf{O} \qquad \left.\begin{matrix}\mathbf{C^2H^5}\\\mathbf{C^4H^7O}\end{matrix}\right\}\mathbf{O}$$

In the above formulæ the first represents the type water. The second common ether, the two equivalents of ethyl replacing the two of hydrogen. In the third, we have a mixed ether, one of the equivalents of hydrogen being replaced by ethyl and the other by methyl. The fourth illustration is that of a compound ether: one of the hydrogens is there replaced by ethyl, and the other by the oxidised radical of butyric acid.

Ether is largely used in medicine and chemistry. In small doses it acts as a powerful stimulant. Inhaled in quantity it is an anæsthetic. It is a most invaluable solvent in organic chemistry for resinous, fatty, and numerous other bodies.—C. G. W. See Watts's 'Dictionary of Chemistry.'

ETHER, ACETIC, is used to flavour silent corn spirits in making imitation brandy; it requires therefore some additional notice beyond the other ethers. It may be prepared by mixing 20 parts of acetate of lead, 10 parts of alcohol, and 11½ of concentrated sulphuric acid; or 16 of the anhydrous acetate, 5 of the acid, and 4½ of absolute alcohol; distilling the mixture in a glass retort into a very cold receiver, agitating with weak potash-lye the liquor which comes over, decanting the supernatant ether, and rectifying it by re-distillation over magnesia and ground charcoal.

Acetic ether is a colourless liquid of a fragrant smell and pungent taste, of specific gravity 0·866 at 45° F., boiling at 166° F., burning with a yellowish flame, and disengaging fumes of acetic acid. It is soluble in 8 parts of water.

Acetic ether may be economically made with 3 parts of acetate of potash, 3 of very strong alcohol, and 2 of the strongest sulphuric acid, distilled together. The first product must be re-distilled along with one-fifth of its weight of sulphuric acid; as much ether will be obtained as there was alcohol employed.

ETHER, SULPHURIC, NITRIC, CHLORIC, &c. The stronger mineral acids etherify the alcohols directly, and the names of the resulting ethers are derived from the acid employed. (See Watts's 'Dictionary of Chemistry.') A duty of 1*l*. 5*s*. per gallon was fixed on sulphuric ether on the 25th September 1862. We imported in 1871, 4,001 gals., of the value of 1,874*l*.; and in 1872, 2,246 gals., of the value of 1,791*l*.

ETHIOPIAN PEPPER. The fruit of the *Xylopia* (*Uvaria*) *aromatica*, which is much used as pepper in Africa. This is one of the *Anonaceæ* or Custard Apple family. The wood of one species, *Anona palustris*, is so soft that it is used instead of corks to stopper bottles with. The lancewood is obtained from another species, *Duguetia quitarensis*.

ETHIOPS was the name given by the alchemists to certain black metallic preparations. *Martial ethiops* was the black oxide of iron; *mineral ethiops*, the black sulphuret of mercury; and *ethiops per se*, the black oxide of mercury.

ETHYL. The radical of ordinary alcohol and ether. See Watts's 'Dictionary of Chemistry.'

ETHYLAMINE, C^4H^7N ($\mathbf{C^2H^7N}$). An exceedingly volatile base, discovered by Wurtz. It is produced in a great number of reactions. Several alkaloïds existing in the animal and vegetable kingdoms afford ethylamine on distillation with potash. Its density at 476° is 0·964. It boils at 66° Fahr. It is regarded as ammonia in which an equivalent of hydrogen is replaced by ethyl.—C.G.W.

ETHYLENE. Olefiant gas; bicarburetted hydrogen gas. See OLEFIANT GAS.

ETIOLATION. Deprived of colour by being kept in the dark. Celery, sea-kale, and other plants are purposely *blanched* or etiolated by excluding the light, this exclusion preventing the formation of *chlorophyll*, the green colouring matter of leaves.

EUCALYN. An unfermentable sugar separated during the fermentation of melitose, which is a sugar obtained from certain species of Tasmanian *Eucalyptus*.

EUCALYPTUS. The gum-tree of the New Hollanders. Mr. Backhouse says: 'We often find large cavities between the annual concentric circles of the trunk filled with a most beautiful red or rich vermilion-coloured liquid gum, which flows out as soon as the saw has afforded it an opening.' Several varieties of the Eucalyptus yield essential oils by distillation, which may be used for scenting soap, &c. There was a large collection shown at the Exhibition in 1862, in the Australian section. The gum yielded by the *Eucalyptus resinifera* is considered by druggists as not in the least inferior to the kind which the *Pterocarpus* or red saunders wood of India produces. This species yields, on incision, an astringent substance known as 'Botany-Bay Kino,' which contains a principle called *Eucalyptine*. A saccharine substance, known as 'Australian manna,' is derived from another species, *E. mannifera*. Many of the Australian Eucalypti are called 'Stringy-bark trees,' in consequence of the fibrous layers in their bark. The bark of several species has been used in tanning and in paper-making. Some of the Eucalypti are so rich in oil that it is said one of the towns on the Australian gold-fields was for a time lighted by gas extracted from eucalyptus leaves. The ashes of the wood are peculiarly rich in potash. Much attention has been lately called to the extraordinary influence of *E. globulus* in improving the climatic condition of marshy districts, whence it has been called the 'fever-destroying tree.' This species, known as the Blue-gum tree, is a native of Tasmania, but has been successfully cultivated in Southern Europe, Algeria, Natal, the West Indies, &c. It is said that at the Cape the cultivation of this tree has completely changed the unhealthy character of parts of the colony. The bark and leaves of this species are reputed to possess febrifugal properties.

EUCHROITE. A hydrous arsenate of copper, occurring in green crystals, of the rhombic system, at Libethen in Hungary.

EUCLASE. A silicate of alumina and beryllia, allied to the emerald. It crystallises usually in small colourless crystals belonging to the oblique system, and exhibiting highly perfect cleavage. The stone is sufficiently hard to be cut and polished, but is of no value to the jeweller in consequence of its extreme brittleness; indeed, this fragility suggested the name to Haüy (εὐ, *eu*, perfect; κλάω, *klao*, to cleave). The euclase is found in Brazil and in the Ural Mountains.

EUDIOMETER is the name of any apparatus subservient to the chemical examination of the atmospheric air. It means a *measure of purity*, but it is employed merely to determine the proportion of oxygen which it may contain. The explosive eudiometer—in which about two measures of hydrogen are introduced into a graduated glass tube containing five measures of atmospheric air, and an electric spark is passed across the mixture—is the best of all eudiometers; and of these, the siphon form proposed by Dr. Ure, in a paper published by the Royal Society of Edinburgh, in 1819, is the most convenient.

EUGENIA. A genus of plants of the order *Myrtaceæ*, called after Prince Eugène of Savoy. *Eugenia Pimenta* is the Allspice Tree. This tree is cultivated largely in the West Indies in regular walks, known as 'Pimento walks.' The Pimento is the dried unripe berries of the Pimenta. When the fruit has attained its full size, but is yet green, it is gathered and sun-dried. It is afterwards put in bags of one hundredweight each for the European market; some planters kiln-dry it. Pimento is imported almost entirely from Jamaica, hence it is sometimes called Jamaica pepper. See ALLSPICE; PIMENTO.

EUKAIRITE. An ore of silver found at the Skrikerum copper-mine in Sweden. According to Berzelius, it consists of selenium, 26·; silver, 38·93; copper 23·05; earthy matter, 8·90; carbonic acid, &c., 3·12.

EULYTINE. A silicate of bismuth, found in small tetrahedral crystals, with other bismuth ores, at Schneeberg, and at Bräunsdorf in Saxony.

EUPHORBIACEÆ. The Spurge family. Most of the plants of this order abound in a milky acrid juice in which the peculiar principle of the plant resides. It contains a great number of plants which are either useful or dangerous to man. The *Jatropha* yields the manihot or cassava. The *Ricinus* is the castor-oil tree; the *Croton*, *Cascarilla*, and *Box*, and the caoutchouc varieties, are included in this vast family of plants, which are found in all parts of the globe, and said to number 2,800 species.

EUPHORBIUM, commonly called from Euphorbius, is an acrid resin obtained from *Euphorbia officinarum* (Linn.), and imported from Western Africa. It is used only medicinally.

EUPHOTIDE. A rock composed mainly of saussurite and smaragdite, or some other variety of diallage. It has been cut and polished as an ornamental stone.

EUPIONE. A fluid first discovered by Reichenbach in wood-tar. All the properties of eupione agree with the indifferent hydrocarbons found in Boghead naphtha. Eupione is so indifferent to the action of acids, that it may be repeatedly treated with concentrated oil of vitriol, or fuming nitric acid, without any action taking place. Its density varies with the boiling point, from 0·633 to 0·740. It is said to be contained among the products of the distillation of rape-oil. There is no doubt that these hydrocarbons will, eventually, be of great value in the arts.—C.G.W. See NAPHTHA, BOGHEAD.

EURITE. A name applied to some felstones in consequence of their easy fusibility compared with hornstones, which they often greatly resemble in general characters.

EURYANGIUM SUMBUL. The Sumbul plant, a native of Bucharia. See SUMBUL.

EVANSITE. A hydrous phosphate of alumina from Hungary, named by Mr. D. Forbes after the late Mr. Brooke Evans, of Birmingham,

EVAPORATION (Eng. and Fr.; *Abdampfen*; *Abdünsten*, Ger.) is the process by which any substance is converted into, and carried off, in vapour. Though ice, camphor, and many other solids evaporate readily in dry air, we shall consider, at present, merely the vaporisation of water by heat artificially applied.

The vapour of water is an elastic fluid, whose tension and density depend upon the temperature of the water with which it is in contact. Thus the vapour rising from water heated to 165° F. possesses an elastic force capable of supporting a column of mercury 10·8 feet high; and its density is such that 80 cubic feet of the vapour contain one pound weight of water; whereas 32½ cubic feet of steam of the density corresponding to a temperature of 212° and a pressure of 30 inches of mercury, weigh one pound. When the temperature of the water is given, the elasticity and specific gravity of the vapour emitted by it may be found.

Since the vapour rises from the water only in virtue of the elasticity due to its gaseous nature, it is obvious that no more can be produced, unless what is already incumbent upon the liquid have its tension abated, or be withdrawn by some means. Suppose the temperature of the water to be midway between freezing and boiling, viz. 122° F., as also that of the air in contact with it to be the same, but replete with moisture, so that its interstitial spaces are filled with vapour of corresponding elasticity and specific gravity with that given off by the water, it is certain that no fresh formation of vapour can take place in these circumstances. But the moment a portion of vapour is allowed to escape, or is drawn off by condensation to another vessel, an equivalent portion of vapour will be immediately exhaled from the water.

The pressure of the air and of other vapours upon the surface of water in an open vessel, does not prevent evaporation of the liquid; it merely retards its progress. Experience shows that the space filled with an elastic fluid, as air or other gaseous body, is capable of receiving as much aqueous vapour as if it were vacuous, only the repletion of that space with the vapour proceeds more slowly in the former predicament than in the latter, but in both cases it arrives eventually at the same pitch. Dr. Dalton very ingeniously proved that the particles of aeriform bodies present no permanent obstacle to the introduction of a gaseous atmosphere of another kind among them, but merely obstruct its diffusion momentarily, as if by a species of friction. Hence, exhalation at atmospheric temperatures is promoted by the mechanical diffusion of the vapours through the air with ventilating fans or chimney draughts; though, under brisk ebullition, the force of the steam readily overcomes that mechanical obstruction.

The quantities of water evaporated under different temperatures in like times, are proportional to the elasticities of the steam corresponding to these temperatures. A vessel of boiling water exposing a square foot of surface to the fire, evaporates about 725 grains in the minute; the elasticity of the vapour is equivalent to 30 inches of mercury. To find the quantity that would be evaporated from the same surface per minute at a heat of 88° F.:—At this temperature the steam incumbent upon water is capable of supporting 1·21 inch of mercury; whence the rule of proportion is 30 : 1·28 :: 725 : 30·93; showing that about 31 grains of water would be evaporated in the minute. If the air contains already some aqueous vapour, as it commonly does, then the quantity of evaporation will be proportional to the difference between the elastic force of that vapour, and what rises from the water.

Suppose the air to be in the hygrometric state denoted by 0·38 of an inch of mercury, then the above formula will become 30 : 1·28 − 0·38 :: 725 : 21·41; showing that not more than 21½ grains would be evaporated per minute under these circumstances.

The elastic tension of the atmospheric vapour is readily ascertained by the old experiment of Le Roi, which consists in filling a glass cylinder (a narrow tumbler for example) with cold spring water, and noting its temperature at the instant it becomes so warm that dew ceases to be deposited upon it. This temperature is that which corresponds to the elastic tension of the atmospheric vapour.

Whenever the elasticity of the vapour, corresponding to the temperature of the water, is greater than the atmospheric pressure, the evaporation will take place not only from its surface, but from every point in its interior; the liquid particles throughout the mass assuming the gaseous form, as rapidly as they are actuated by the heat which subverts the hydrostatic equilibrium among them, to constitute the phenomena of ebullition. This turbulent vaporisation takes place at any temperature, even down to the freezing point, provided the pneumatic pressure be removed from the liquid by the air-pump, or any other means. Ebullition always accelerates evaporation, as it serves to carry off the aqueous particles not simply from the surface, but from the whole body of the water.

The vapours exhaled from a liquid at any temperature contain more heat than the fluid from which they spring; and they cease to form whenever the supply of heat into the liquid is stopped. Any volume of water requires for its conversion into vapour about *five times* as much heat as is sufficient to heat it from the freezing to the boiling temperature. The heat, in the former case, seems to be absorbed, being inappreciable by the thermometer; for steam is no hotter than the boiling water from which it rises. It has been therefore called by Dr. Black, *latent heat*; in contradistinction to that perceived by the touch and measured by the thermometer, which is called *sensible heat*. The quantity of heat absorbed by one volume of water in its conversion into steam, is about 1,000° F.; it would be inadequate to heat 1,000 volumes of water, one degree of the same scale. Were the vessel charged with water so heated, opened, it would be instantaneously emptied by vaporisation, since the whole caloric, equivalent to its constitution as steam, is present. When, upon the other hand, steam is condensed by contact with cold substances, so much heat is set free as is capable of heating about five times its weight of water from 32° to 212° F.

Equal weights of vapour of any temperature contain equal quantities of heat; for example, the vapour exhaled from one pound of water, at 77° F., absorbs during its formation, and will give out in its condensation, as much heat as the steam produced by one pound of water at 212° F. The first portion of vapour with a tension = 30 inches, occupies a space of 27·31 cubic feet; the second, with a tension of 0·92 inch, occupies a space of 890 cubic feet.[1] Suppose that these 890 volumes were to be compressed into 27·31 in a cylinder capable of confining the heat, the temperature of the vapour would rise from 77° to 212°, in virtue of the condensation, as air becomes so hot by compression in a syringe, as to ignite *amadou*. The latent heat of steam at 212° F. is $1180° - 180 = 1000$; that of vapour, at 77°, is $1183 - 45 = 1135$; so that, in fact, the lower the temperature at which the vapour is exhaled, the greater is its latent heat, as Joseph Black and James Watt long ago proved by experiments upon distillation and the steam-engine.

From the preceding researches it follows, that evaporation may be effected upon two different plans:—

1. Under the ordinary pressure of the atmosphere; and that either,

(A) By external application of heat to boilers, with (*a*) an open fire; (*b*) steam; (*c*) hot liquid *media*.

(B) By evaporation with air; (*a*) at the ordinary temperature of the atmosphere; (*b*) by currents of warm air.

2. Under progressively lower degrees of pressure than the atmospheric, down to evaporation in as perfect a vacuum as can be made.

It is generally affirmed, that a thick metallic boiler obstructs the passage of the heat through it so much more than a thin one as to make a considerable difference in their relative powers of evaporating liquids. Dr. Ure states that he made a series of experiments upon this subject. Two cylindrical copper pans, of equal dimensions, were provided; but the metal of the one was twelve times thicker than that of the other. Each being charged with an equal volume of water, and placed either upon the same hot plate of iron, or immersed, to a certain depth, in a hot solution of muriate of lime, he found that the ebullition was greatly more vigorous in the thick than in the thin vessel, which he ascribed to the conducting substance up the sides, above the contact of the source of heat, being 12 times greater in the former case than in the latter.

If the bottom of a pan, and the portions of the sides, immersed in a hot fluid medium, solution of caustic potash or muriate of lime, for example, be corrugated, so as to contain a double expanse of metallic surface, that pan will evaporate exactly double the quantity of water, in a given time, which a like pan, with smooth bottom and sides, will do immersed equally deep in the same bath. If the corrugations contain three times the quantity of metallic surface, the evaporation will be threefold in the above circumstances. But if the pan, with the same corrugated bottom and sides, be set over a fire, or in an oblong flue, so that the current of flame may sweep along the corrugations, it will evaporate no more water from its interior than a smooth pan of like shape and dimensions placed alongside in the same flue, or over the same fire. This curious fact Dr. Ure states he has verified upon models constructed with many modifications. Among others, he caused a cylindrical pan, 10 inches diameter, and 6 inches deep, to be made of tin-plate, with a vertical plate soldered across its diameter; dividing it into two equal semi-cylindrical compartments. One of these was smooth at the bottom, the other corrugated; the former afforded as rapid an evaporation over the naked fire as the latter, but it was far outstripped by its neighbour when plunged into the heated liquid medium.

If a shallow pan of extensive surface be heated over a subjacent fire, by a liquid medium, or a series a steam-pipes upon its bottom, it will give off less vapour in the same time when it is left open, than when partially covered. In the former case, the cool incumbent air precipitates by condensation a portion of the steam, and also opposes considerable mechanical resistance to the diffusion of the vaporous particles. In the latter case, as the steam issues with concentrated force and velocity from the contracted orifice, the air must offer less proportional resistance, upon the known hydrostatic principle of the pressure being as the areas of the respective bases of the communicating vessels.

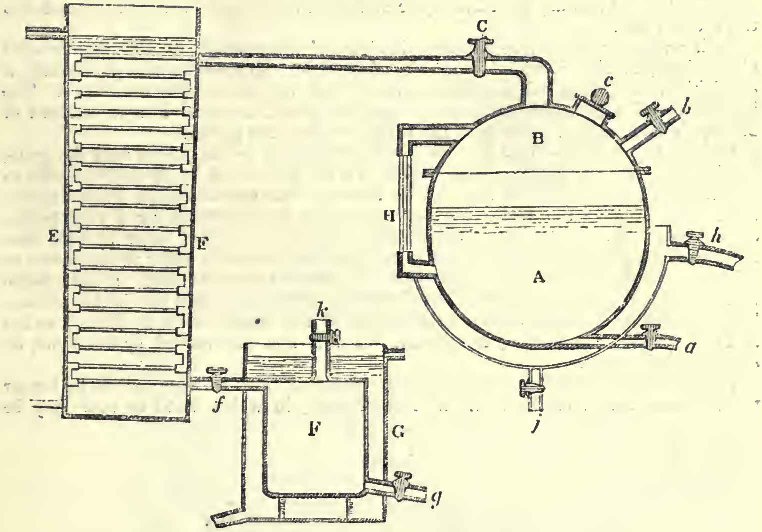
In evaporating by surfaces heated with ordinary steam, it must be borne in mind

---

[1] One pound avoirdupois of water contains 27·72 cubic inches; one cubic inch of water forms 1696 cubic inches of steam at 212° F.: therefore one pound of water will form 27·31 cubic feet of such steam; and 0·93 : 30 :: 27·31 : 890 cubic feet.

that a surface of 10 square feet will evaporate fully one pound of water per minute, or 725 × 10 = 7250 gr., the same as over a naked fire; consequently the condensing surface must be equally extensive. Suppose that the vessel is to receive of water 2,500 lbs. which corresponds to a boiler 5 feet long, 4 broad, and 2 deep, being 40 cubic feet by measure, and let there be laid over the bottom of this vessel 8 connected tubes, each 4 inches in diameter and 5 feet long, possessing therefore a surface of 4·8 feet square. If charged with steam, they will cause the evaporation of half a pound of water per minute. The boiler to supply the steam for this purpose must expose a surface of 4·8 square feet to the fire. It has been proved experimentally that 10 square feet surface of thin copper can condense 3 lbs. of steam per minute, with a difference of temperature of 90 degrees Fahr. In the above example, 10 square feet evaporate 1 lb. of water per minute; the temperature of the evaporating fluid being 212° F., consequently $3 : 1 :: 90 : \frac{90}{3}$. During this evaporation the difference of the temperature is therefore = 30°. Consequently the heat of the steam placed in connection with the interior of the boiler, to produce the calculated evaporation, should be, $212 + 30 = 242°$, corresponding to an elastic force of 53·6 inches of mercury. Were the temperature of the steam only 224, the same boiler in the same time would produce a diminished quantity of steam, in the proportion of 12 to 30; or to produce the same quantity the boiler or tubular surface should be enlarged in the proportion of 30 to 12. In general, however, steam boilers employed for this mode of evaporation are of such capacity as to give an unfailing supply of steam.

838



We shall now illustrate, by some peculiar forms of apparatus, different systems of evaporation. *Fig.* 838 explains the principles of evaporating *in vacuo*. A B represents a pan or kettle charged with the liquor to be evaporated. The somewhat wide orifice *c*, secured with a screw-plug, serves to admit the hand for the purpose of cleaning it thoroughly out when the operation is finished; *h* is the pipe of communication with the steam boiler; *b* is a tube prolonged and then bent down with its end plunged into the liquor to be evaporated, contained in the charging back (not shown in the figure). H is a glass tube communicating with the vacuum pan at the top and bottom, to show by the height of the column the quantity of liquid within. The eduction evaporating pipe C is provided with a stop-cock to cut off the communication when required. *i* is a tube for the discharge of the air and the water from the steam-case or jacket; the refrigerator E is best formed of thin copper tubes about 1 inch in diameter, arranged zigzag or spirally like the worm of a still in a cylinder. The small air-tight condenser F, connected with the efflux-pipe *f* of the refrigerator, is furnished below with a discharge-cock *g*, and surrounded by a cooling case, for the collection of the water condensed by the refrigerator. In its upper part there is a tube *k*, also furnished with a cock, which communicates with the steam boiler, and through which the pan A B is heated.

The operation of this apparatus is as follows: after opening the cocks C, *f*, *g*, and before admitting the cold water into the condenser E, the cock of the pipe *k* is opened, in order that by injecting steam it may expel the included air; after which the cocks *k* and *g* are to be shut. The water must now be introduced into the condenser, and the cock *b* opened, whereon the liquid to be evaporated rises from the charging back, through the tube *b*, and replenishes the vacuum pan to the proper height, as shown by the register glass tube H. Whenever the desired evaporation or concentration is effected, the cock C must be closed, the pipe *k* opened, so as to fill the pan with steam, and then the efflux cock *a* is opened to discharge the residuary liquor. By shutting the cocks *a* and *k*, and opening the cock *b*, the pan will charge itself afresh with liquor, and the operation will be begun anew, after *b* has been shut and C opened.

The contents of the close water cistern F, may be drawn off during each operation. For this purpose, the cock *f* must first be shut, the cold water is to be then run out of the condenser G, and *k* and *g* are to be opened. The steam entering by *k* makes the water flow, but whenever the steam itself issues from the cock *g*, this orifice must be immediately shut, the cock *f* opened, and the cold water again introduced, whereupon the condensed water that had meanwhile collected in the under part of the refrigerator flows off into the condenser vessel F. Since some air always enters with the liquor sucked into the pan, it must be removed at the time of drawing off the water from the two condensers, by driving steam through the apparatus. This necessity will be less urgent if the liquor be made to boil before being introduced into the vacuum pan.

Such an apparatus may be modified in size and arrangement to suit the peculiar object in view, when it will be perfectly adapted for the concentration of extracts of every kind, as well as saline solutions containing vegetable acids or alkalis. The interior vessel A B should be made of tinned or plated copper. For an account of Howard's vacuum pan, made upon the same principle, see SUGAR.

When a boiler is set over a fire, its bottom should not be placed too near the grate, lest it refrigerate the flame, and prevent that vivid combustion of the fuel essential to the maximum production of heat by its means. The evil influence of leaving too little room between the grate and the copper may be illustrated by a very simple experiment. If a small copper or porcelain capsule containing water be held over the flame of a candle a little way above its apex, the flame will suffer no abatement of brightness or size, but will continue to keep the water briskly boiling. If the capsule be now lowered into the middle of the flame, this will immediately lose its brightness, becoming dull and smoky, covering the bottom of the capsule with soot; and, owing to the imperfect combustion, though the water is now surrounded by the flame, its ebullition will cease.

Fig. 839 is a section of two evaporating coppers *en suite*, so mounted as to favour the full combustion of the fuel. A is the hearth, in which wood or coal may be burned. For coal, the grate should be set higher and be somewhat smaller. *a* is the door for feeding the fire; *d*, an arch of fire-bricks over the hearth; *c*, a grate through which the ashes fall into the pit beneath, capable of being closed in front to any extent by a sliding door *b*. B and C are two coppers encased in brickwork; *f* the flue. At the end of the hearth near *m*, where the fire plays first upon the copper, the sole is made somewhat lower and wider, to promote the spreading of the flame under the vessel. The second copper C, receives the benefit of the waste heat; it may be placed upon a higher level, so as to discharge its concentrated liquor by a stop-cock or siphon into the first.

839

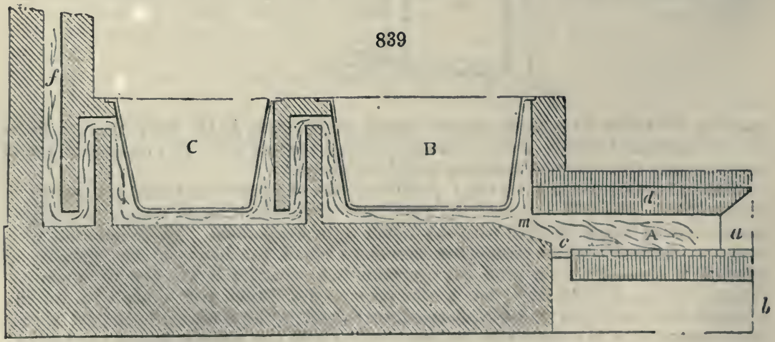


Fig. 840 represents a pan for evaporating liquids, which are apt, during concentration, to let fall crystals or other sediment.

These would be injured either by the fire playing upon the bottom of the pan, or, by adhesion to it, they would allow the metal to get red hot, and in that state run every risk of being burnt or rent on the sudden intrusion of a little liquor through the incrustation. When large coppers have their bottoms planted in loam, so that the flame circulates in flues round their sides, they are said to be *cold-set.*

A is a pear-shaped pan, charged with the liquid to be evaporated; it is furnished with a dome cover, in which there is an opening with a flange *f*, for attaching a tube, to conduct the steam wherever it may be required. *a* is the fire-place; *b*, the ash-pit. The conical part terminates below in the tube *g*, furnished with a stop-cock at its nozzle *h*. Through the tube *c d c′*, furnished above and below with the stop-cocks *c* and *c′*, the liquid is run from the charging back or reservoir. During the operation, the upper cock *c* is kept partially open, to replace the fluid as it evaporates; but the under cock *c′* is shut. The flame from the fireplace plays round the kettle in the space *e*, and the smoke escapes downwards through the flue *i* into the chimney. The lower cylindrical part *g* remains thus comparatively cool, and collects the crystalline or other solid matter. After some time, the under stop-cock *c′*, upon the supply-pipe, is to be opened to admit some of the cold liquor into the cylindrical neck. That cock being again shut, the sediment settled, and the large stop-cock (a horizontal side valve would be preferable) *h* opened, the crystals are suffered to descend into the subjacent receiver; after which the stop-cock *h* is shut, and the operation is continued. A construction upon this principle is well adapted for heating dyeing coppers, in which the sediment should not be disturbed, or exposed to the action of the fire. The fireplace should be built as for the brewing copper.

840

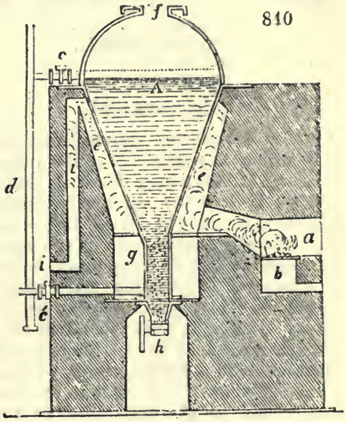

Fig. 841 represents an oblong evaporating pan, in which the flame, after beating along its bottom, turns up at its further end, plays back along its surface, and passes off into the chimney. A is a rectangular vessel, from 10 to 15 feet long, 4 to 6 feet broad, and 1 or 1½ foot deep. The fire-bricks, upon which the pan rests, are so arranged as to distribute the flame equally along its bottom.

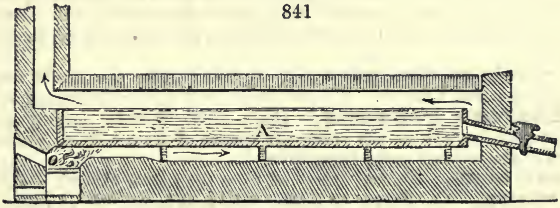
841



Leidenfrost in 1756 ('*Annales de Chimie*') observed some remarkable facts connected with evaporation, which have since received some striking illustration from the experiments of M. Boutigny.

When water is thrown on a plate heated considerably above the boiling point of water, the liquid assumes a spheroidal form, and this condition has hence received the name of the *spheroidal state.* This water rolls about like melted crystal without any signs of ebullition, and it is dissipated but very slowly. The explanation usually given is as follows:—'The cause of the phenomena appears to be this: water exhibits an attraction for the surface of almost all solids, and wets them; fluid mercury exhibits the opposite property, or repulsion for most surfaces. The attraction of water for surfaces brings it into the closest contact with them, and greatly promotes the communication of heat by a heated vessel to the water contained in it. But heat appears to develope a repulsive power in bodies, and it is probable that, above a peculiar temperature, the heated metal no longer possesses this attraction for water. The water not being attracted to the surface of the hot metal, and induced to spread over it, is not rapidly heated, and therefore boils off slowly.'—*Graham.*

The explanation given by this excellent authority has been selected as representing fairly the prevailing view. It is not, however, satisfactory. The water is said to be at a sensible distance from the hot plate, and a layer of aqueous vapour of very high temperature is known to surround the water, and yet the *spheroidal* water does not acquire the boiling temperature. Here is evidence of some peculiar, and as yet unexplained condition, belonging, either to heat of a certain kind or degree, or to the molecules of the body under its influence.

Boutigny observed that water may pass into the *spheroidal state* when projected upon metal above the temperatures of 142°. Ether and alcohol pass into the *spheroidal state* between the temperatures 142° F. and 273° F. A thermometer being plunged in liquids while in the *spheroidal state*, indicated the following temperatures:—

Water	205·7° F.
Absolute alcohol	167·9
Ether	93·6
Hydrochloric ether	50·9
Sulphurous acid	13·1

All these being some degrees below the boiling temperature of those fluids.

Boutigny has shown that the vapour escaping from water in the *spheroidal state*, although it has a very elevated temperature, does not possess the usual elasticity of steam; it does not exert an expansive power. But if the vessel from which the vapour is forming is allowed to cool, to a certain point, a degree of elasticity equal to the elevated temperature of the vapour is suddenly exerted. This is supposed by Boutigny to explain many steam-boiler explosions.

Whenever evaporation takes place, it should be remembered, it produces cold—that is, it lowers the temperature of the body from which the evaporation is taking place. Leslie, by the evaporation of ether *in vacuo*, froze mercury. Thilorier solidified carbonic acid by the intense cold produced by its own evaporation. Boutigny froze water in a red-hot vessel, by the evaporation of sulphurous acid from the heated vessel in which the water is in the *spheroidal state*. Faraday froze mercury in a red-hot crucible by the evaporation of a mixture of solid carbonic acid and ether. But the lowest temperature yet reached has been in the experiments of Natterer, of Vienna, who obtained as low a temperature as − 220° F. by mixing liquid nitrous oxide with bisulphide of carbon, and evaporating this mixture *in vacuo*. Carré's freezing-machine depends for its action on the rapid evaporation of a solution of ammonia.

The *spheroidal condition* of fluids does not appear to be dependent entirely on heat. By dropping alcohol or ether on the surface of the same fluids, such *spheroidal drops* may be obtained; and water splashed upon water often assumes the same condition. Mr. Tomlinson has some curious experiments upon the formation of these varieties of spheroids.

Further remarks on these points will be found under the heads respectively of COAL; FREEZING; and VAPOUR. See also HEAT, in Watts's 'Dictionary of Chemistry.'

EVERLASTING FLOWERS. These dried flowers, largely used by the French as *Immortelles*, are for the most part species of *Gnaphalium*, *Helichrysum*, and other plants of the natural order *Compositæ*.

EVERNIC ACID. An acid extracted from the lichen *Evernia prunastri*.

EXANTHINE. The Purree or Indian yellow of India. See INDIAN YELLOW.

EXOGENS. A botanical term, applied to plants which grow by addition to the outer parts of the stem. Most British trees are Exogens. The correlative term *Endogens* is applied to plants which, like palms, appear to grow by addition to the inner parts of the stem. The stem varies in structure in four principal ways: it is either formed by successive additions to the outside of the wood, when it is called *exogenous*, or by successive additions to its centre, when it is called *endogenous*, or by the union of the bases of leaves, and the extension of the point of the axis, which is called *acrogenous*, or by simple elongation or dilatation where no leaves or buds exist, as among *Thallogens*.—*Lindley*.

EXOSMOSE and ENDOSMOSE. As some manufacturing processes involve the phenomena expressed by these two words, it appears necessary briefly to explain them.

When two liquids are separated by a porous sheet of animal membrane, unglazed earthenware, porous stone, or clay, these liquids gradually diffuse themselves; and supposing salt and water to be on one side of the division, and water only on the other, the saline solution passes in one direction, while the water, though with less intensity, passes in another.

Instead of the two words introduced by Dutrochet, Professor Graham proposed the use of the single term Osmose (from *ὠσμός*, impulsion).

It was supposed that there was, at the same time, an impulsive force acting from without and another acting from within; that there was indeed a current *flowing in*, and another *flowing out.* It appears, however, to be proved that the *osmose* between water and saline solutions, consists not in the passage of two liquid currents, but in the passage of particles of the salt in one direction, and of pure water in the other. Professor Graham observed that common salt diffuses into water through a thin membrane of ox-bladder deprived of its outer muscular coating, at the same rate as when no membrane is interposed. This force plays an important part in the functions of life, and it will be found to explain many of the phenomena associated with Dyeing, Tanning, &c. See OSMOSE FORCE.

EXPANSION (Eng. and Fr.; *Ausdehnung*, Ger.) is the increase of bulk experienced by all bodies when heated, unless a change in molecular arrangement takes place, as in the case of clays in the potter's kiln.

Table I. exhibits the linear expansion of several solids by an increase of temperature from 32° to 212° F.; Table II. exhibits the expansion in bulk of certain liquids.

TABLE I.—*Linear Dilatation of Solids by Heat.*

Dimensions which a bar takes at 212° whose length at 32° is 1·000000.

If the density of water at 39° be called 1·00000,
at 212° it becomes . . . . . . 0·9548,
and its volume has increased to . . 1·04734;
at 77° it becomes . . . . . . 0·9973587,
and its volume has increased to only . 1·00265,
which, though one-fourth of the whole range of temperature, is only $\frac{1}{18}$ of the total expansion. Water at 60° F. has a specific gravity of . 0·9991253,
and has increased in volume from 39° to . 1·00008,
which is only about $\frac{1}{58}$ of the total expansion to 212°, with $\frac{1}{6\cdot4}$ of the total range of temperature.

All gases expand the same quantity by the same increase of temperature, which from 32° to 212° F. $=\frac{180}{480}=\frac{3}{8}$ of its initial volume, or 100 volumes become 1·375. For each degree of F. the expansion is $\frac{1}{480}$.

When dry air is saturated with moisture, its bulk increases, and its specific gravity diminishes, because aqueous vapour is less dense than air, at like temperatures.

The following Table gives the multipliers to be employed for converting one volume of moist gas at the several temperatures, into a volume of dry gas:—

Temperature	Multiplier	Temperature	Multiplier
53° F.	0·9870	64°	0·9799
54	0·9864	65	0·9793
55	0·9858	66	0·9786
56	0·9852	67	0·9779
57	0·9846	68	0·9772
58	0·9839	69	0·9765
59	0·9833	70	0·9758
60	0·9827	71	0·9751
61	0·9920	72	0·9743
62	0·9813	73	0·9735
63	0·9806		

Lavoisier and Laplace arrived, after an extensive series of experiments, at the two important conclusions following:—

1st. All solid bodies whatever, being gradually heated from the temperature of melting ice to that of boiling water, and then gradually cooled from the temperature of boiling water to that of melting ice, will be found to have exactly the same dimensions at the same temperature during the process of heating and cooling; the gradual diminution of bulk in cooling corresponding exactly with the gradual increase of bulk in heating.

2nd. Glass and metallic bodies gradually heated from the temperature of melting ice to that of boiling water, undergo degrees of expansion proportional to those of mercury at the same temperature; that is to say, between the limits just mentioned, the expansion of the solid corresponding to two degrees of the thermometer, is twice the expansion which corresponds to one degree, the expansion which corresponds to three degrees is three times the expansion which corresponds to one degree, and so on; the quantity of expansion being multiplied in the same proportion as the number of degrees through which the thermometer has risen is multiplied. See HEAT, Watts's 'Dictionary of Chemistry.'

Experiments by Fresnel, Forbes, Powell, Trevelyan, and Tyndall have a tendency to prove that heat occasions a repulsion between the particles of matter at small distances. If a heated poker is laid slantingly on a block of lead at the ordinary temperature, it will commence to vibrate, first slowly, and will increase with such rapidity as to produce a musical note, which continues for some time, usually changing to an octave at the termination. These results would appear to prove a movement amongst the particles constituting the bar.

Some remarkable examples of expansion are furnished by the influence of sunshine on the Britannia Tubular Bridge.

The most interesting effect is that produced by the sun shining on one side of the tube, or on the top, while the opposite side and bottom remain shaded and comparatively cool; the heated portions of the tube expand, and thereby warp or bend the tube towards the heated side, the motion being sometimes as much as 2½ inches vertically and 2½ inches laterally.

While the tubes were supported on the temporary piers on the beach, these motions were easily observed. An arm carrying a pencil was fixed on the south side of the tube, at the centre, and a board was fixed on a post independent of the tube, and at right angles to it; the pencil was pressed against the board by a spring, and the rise and fall, and the lateral motions of the tube, were consequently traced on the board. In this way a very interesting diagram was taken daily. The lowest part of each figure is the starting point, or normal position of the tube, to which the pencil always accurately returns during the night. As soon as the sun rises in the morning it starts towards the right hand, rising obliquely, the top and one side of the tube being warmed, and the bottom and opposite side remaining unaffected. It continues thus till one o'clock, when the sun, having ceased to shine on the southern side, begins to warm the northern side, the top still retaining its high temperature; the tube thus acquires a nearly horizontal motion towards the left hand, the slight descent in the line indicating the diminishing effects of the sun on the top as it gradually sinks. The greatest deflection to the left hand is not attained until sunset, after which the tube rapidly descends in a uniformly-curved line to its resting point. In the summer time this point is hardly attained before the rising sun compels it to commence its journey anew. When the sun is frequently obscured by passing clouds, very curious diagrams are obtained. During the absence of the sun the tube begins to cool rapidly, and to return to its normal position; every passing cloud is thus beautifully recorded.

The middle of the centre arch of Southwark Iron Bridge rises one inch in the height of summer. When great lengths of iron pipe are laid down for the conveyance of steam or hot water, sliding joints are necessary to prevent destruction either of the apparatus or of the building in which it is placed.

The practical applications made of the expansion and contraction of metals by heat are many. The tire of a wheel is put on hot, and by its contraction on cooling, firmly binds the other parts of the wheel together; boiler-plates are riveted with red-hot rivets; collars of metal are driven on while hot, and the like.

Mollard drew together the walls of a building that had bulged, by screwing up bars of iron tight to the walls while they were hot, and a similar process was adopted in the Cathedral of Armagh.

Playfair and Joule ('Chemical Society's Memoirs') have made a valuable series of researches on the expansion of bodies by heat, principally salts; these have not, however, any sufficient practical bearing to occupy our space.

EXPLOSIVE AGENTS. The peculiar characters of such explosive compounds as GUNPOWDER, GUN-COTTON, DYNAMITE, NITRO-GLYCERINE, and the like, will be found under those articles respectively. In this place it is intended to describe in a general way some explosive compounds which are less known, and which have not as yet been employed successfully.

Chlorate-of-Potash Compounds.—The peculiar powers of chlorate of potash, and its violent oxidising properties have led to many experiments. This salt has been mixed with the prussiates of potash, with sugar and with starch, and sometimes with the addition of sulphur. These gunpowder substitutes have been known as *white gunpowder*, *German gunpowder*, &c. Ingenious attempts have been made to reduce the dangerous nature of the chlorate-of-potash mixtures by combining them with inert materials. One kind consists of mixtures of the salt with organic substances containing, in addition to carbon, a considerable proportion of hydrogen, such as powdered nut-galls, tannin, and resins. Horsley's powder was somewhat of this character, with the addition of some nitro-glycerine. That of Messrs. Hochstäder, which was introduced in 1860, and subsequently modified by M. Reichen, was somewhat similar. Strips of blotting-paper were soaked in a pasty mass consisting essentially of a mixture of chlorate of potash, saltpetre, charcoal (and small quantities of other readily oxidisable substances), together with a little gum or other binding material dissolved in water. The paper becomes coated with the explosive mixture, and at the same time impregnated with the oxidising salts, of which it absorbs a part of the solution; the strips are rolled up tightly while wet, and when dry they become hard and compact cylindrical masses, which are violently explosive when confined, but resist detonation when submitted to percussion or friction. One of these *white gunpowders* was recommended for its safety; the chlorate of potash and the other ingredient being kept separately until required for use.

Tutonite is a blasting agent of this class. It has the peculiarity of being made up in the form of hard pellets or disks, instead of being in a granulated form or in powder.

Safety Powder was a blasting agent devised by Mr. Kellow, and manufactured at the works at South Down, opposite to Devonport. It consisted of spent tan and sawdust, saturated with saltpetre or nitrate of soda, and a little chlorate of potash; the compound being subsequently crudely mixed with sulphur. (The manufacture was abandoned, the works having been destroyed by fire.)

Pyrolithe is the name of a blasting powder very nearly resembling that of Mr. Kellow's.

Poudre Barytique or *Saxifragine* is of a similar character. It is the invention of a Belgian officer, Captain Wynants, and consists of a mixture of charcoal and nitrate of baryta, with a small proportion of saltpetre. The baryta-powder is comparatively very slow burning; and its special characters are such that its application could not but remain limited to ordinary mining and quarrying uses.

Picric Acid or *Carbazotic Acid.*—Among the numerous products obtained by the action of nitric acid upon materials of organic origin, one of the earliest discovered possessing explosive properties is the product known as picric acid, which is furnished in that way by indigo, &c. Picric acid was discovered in 1788, and prepared in small quantities. It is now readily manufactured from the coal-tar product known as carbolic acid, and is now an article of commerce as a cheap and brilliant yellow dye. See Picric Acid. This, when mixed with saltpetre or chlorate of potash, particularly with the latter, furnishes products which in violence of action more nearly resemble gun-cotton and nitro-glycerine preparations than does any other readily explosive agent. Both mixtures are susceptible of detonation by friction, and especially that containing chlorate of potash, which is indeed inapplicable to practical purposes on account of its dangerous nature.

M. Designolle has produced safer mixtures of picrate of potash for artillery, small arms, and for blasting purposes. One of these consisting of picrate of potash, saltpetre, chlorate of potash, and charcoal gave satisfactory results. Mr. Abel informs us that the picrate of ammonia incorporated with saltpetre furnishes one of the safest explosive mixtures of a violent character yet produced.

Colonia Powder is a modified gunpowder saturated with nitro-glycerine.

Dualine is Schultze's sawdust powder impregnated with nitro-glycerine.

Glyoxiline consists of a mixture of gun-cotton pulp and saltpetre converted into porous pellets, which are saturated with nitro-glycerine, and afterwards coated with varnish to protect it from damp.

Lithofracteur.—Lieutenant Trauzl, in his 'Explosive-Nitrilverbindungen,' describes this preparation as simply a dynamite, in which an imperfect kind of gunpowder has been substituted for a proportion of the siliceous earth; and he gives the following as the approximate percentage composition of the material: nitro-glycerine 52, siliceous earth and sand 30, powdered coal 12, nitrate of soda 4, and sulphur 2. It has not been found in practice equal to dynamite.

Fulminates of Mercury and Silver.—These violent explosive agents are used only in the preparation of percussion caps, and have not been applied to any other useful purpose.

Iodide of Nitrogen and *Chloride of Nitrogen* will be described under their respective heads.

The following remarks on the 'Development of Force from Explosive Agents' are abstracted from Mr. Abel's paper read before the Institution of Civil Engineers in 1873.

'The character of explosion and the mechanical force developed, within given periods, by the metamorphoses of explosive mixtures, such as gunpowder, is subject to modifications, and even the most violent explosive compounds known (the mercury and silver fulminates, and the chloride and iodide of nitrogen) behave in different ways under the operation of heat or other disturbing influences, according to the circumstances which attend the metamorphosis of the explosive agent (*e.g.* the position of the source of heat with reference to the mass of the substance to be exploded, or to the extent of initial resistance opposed to the escape of the products of explosion). Thus chloride of nitrogen, when covered with a film of water, explodes with great violence when brought into contact with a decomposing agent; but if the covering of water is entirely removed, and the usual means are resorted to for causing the instantaneous decomposition of the liquid, its transformation into gases takes place with little or no explosive violence. Again, if a heap of fulminate of mercury be ignited at any portion of the exposed surface or immediately beneath it, the substance inflames into a dull explosion, and but little mechanical work is performed; but if the heap be ignited in the centre, or near the base, the explosion is very violent, and considerable shattering effect is produced. In these instances the covering of the water, on the one hand, and the external portions of the heap of fulminate on the other, perform the functions of the tamping in a blast-hole, or the walls of a shell, in determining accumulation of pressure and consequent development of violent explosion at the point of first ignition, which is then instantaneously transmitted through the mass. Applying this result to practical purposes, it is found that by igniting a charge of powder at or near the base in an ordinary blast-hole, considerable destructive force can be developed without the use of any tamping, as the upper portion of the charge acts itself as tamping to the part first ignited, and develops its violent explosion. The destructive action is, of course, still further increased, if tamping be employed under the above conditions.

'Nitro-glycerine and analogous explosive compounds which bear some relation to the chloride of nitrogen in their power of sudden explosion, require the fulfilment of special conditions for the development of their explosive force. Thus, the explosion of nitro-glycerine by the simple application of heat can only be accomplished if the source of heat be applied in such a way that chemical decomposition is established in some portion of the mass, and is formed by the continual application of heat to that part.

'The development of the violent explosive action of nitro-glycerine, freely exposed to air, through the agency of a detonation, was for some time regarded as a peculiarity of that substance; it has, however, been demonstrated that gun-cotton and other explosive compounds and mixtures do not necessarily require confinement for the full development of their explosive force, but that this result is attainable (and very readily in some instances, especially in the case of gun-cotton), by means similar to those applied in the case of nitro-glycerine.

'The manner in which a detonation operates in determining the violent explosion of gun-cotton, nitro-glycerine, &c., has been made the subject of careful investigation. It has been demonstrated experimentally, that the result cannot be ascribed to the direct operation of the heat developed by the chemical changes of the charge of detonating material used as the exploding agent. An experimental comparison of the mechanical force exerted by different explosive compounds, and by the same compound employed in different ways, has shown that the remarkable power possessed by the explosion of small quantities of certain bodies (the mercury and silver fulminates) to accomplish the detonation of gun-cotton, while comparatively large quantities of other highly explosive agents are incapable of producing that result, is generally accounted for satisfactorily by the difference in the amount of force suddenly brought to bear in the different instances upon some portion of the mass operated upon. Most generally, therefore, the degree of facility with which the detonation of a substance will develop similar change in a neighbouring explosive substance may be regarded as proportionate to the amount of force developed within the shortest period of time by that detonation, the latter being, in fact, analogous in its operation to that of a blow from a hammer, or of the impact of a projectile.

'Several remarkable results of an exceptional character have, however, been obtained, which indicate that the development of explosive force under the circumstances referred to is not always simply ascribable to the sudden operation of mechanical force. These were especially observed in the course of a comparison of the conditions essential to the detonation of gun-cotton and of nitro-glycerine by means of particular explosive agents (chloride of nitrogen, &c.), as well as in an examination into the effects produced upon each other by the detonation of these two substances. In illustration, it may be instructive to give two examples. The detonation of compressed gun-cotton is accomplished by the explosion of 5 grains of confined fulminate of mercury, placed in contact with the mass, but it requires ten times that quantity of the violent explosive agent, chloride of nitrogen, also confined, to produce the same result. Again, the mechanical force exerted by the explosion of nitro-glycerine is fully equal to that developed by the fulminate of mercury, yet a quantity of nitro-glycerine about seventy times greater than the minimum of the fulminate required to detonate compressed gun-cotton, fails, when exploded in contact with the latter, to produce any other result than the complete mechanical disintegration of the mass.

'Instances of the apparently simultaneous explosion of numerous distinct and even somewhat widely-separated masses of explosive substances (such as simultaneous explosions in several distinct buildings at powder-mills) do not unfrequently occur, in which the generation of a disruptive impulse by the first or initiative explosion, which is communicated with extreme rapidity to contiguous masses of the same nature, appears much more likely to be the operating cause than that such simultaneous explosions should be brought about by the direct action of heat and mechanical force.

'It need scarcely be stated that the detonation of a large quantity of an explosive body is accomplished by the initiative detonation of a very small portion of the mass; this is the case even if the material is arranged in the form of a train of considerable length, the detonating fuze being applied at one extremity. Rows of gun-cotton disks, from 3 feet to 5 feet in length, with intervals of 0·5 inch and 1 inch between the individual masses, have been detonated in this way. There is, however, a limit to the distance to which a detonation will be transmitted along a row of spaced disks, the limit being determined by the particular weight of the masses employed; if it be exceeded, those masses which are at the further extremity will be inflamed and scattered, instead of being detonated. A few preliminary experiments have been made with the view of determining, by means of Noble's chronoscope, the rapidity with which detonation progresses along a row of gun-cotton disks. This will, no doubt, vary with the sizes of the masses. In an experiment with disks weighing 2 ounces each, placed in a row without intervals, it was found that the detonation extended to 3 feet in about one five-thousandth part of a second.'

EXPRESSED OILS. See OILS.

EXTRACT OF LEAD. A common name for the solution of acetate of lead, also called Goulard's Lotion.

EXTRACTS. (*Extraits*, Fr.; *Extracten*, Ger.) The older apothecaries used this term to designate the product of the evaporation of any vegetable juice, or infusion, or decoction; whether the latter two were made with water, alcohol, or ether; whence arose the distinction of aqueous, alcoholic, and etherous extracts.

Fourcroy made many researches upon these preparations, and supposed that they had all a common basis, which he called the *extractive* principle. But Chevreul and other chemists have since proved that this pretended principle is a heterogeneous and very variable compound. By the term *extract* therefore is now meant merely the whole of the soluble matters obtained from vegetables, reduced by careful evaporation to either a pasty or solid consistence. The watery extracts, which are those most commonly made, are as various as the vegetables which yield them; some containing chiefly sugar or gum in great abundance, and are therefore innocent or inert; while others contain very energetic impregnations. The conduct of the evaporating heat is the capital point in the preparation of extracts. They should be always prepared, if possible, from the juice of the fresh plant, by subjecting its leaves or other succulent part, to the action of a powerful screw, or hydraulic press; and the evaporation should be effected by the warmth of a water-bath, heated not beyond 100° or 120° Fahr. Steam heat is now applied advantageously in some cases, where it is not likely to decompose any of the principles of the plant. But by far the best process for making extracts is *in vacuo*, upon the principles explained in the article EVAPORATION. It is much easier to fit up a proper apparatus of this kind than most practical men imagine. The vacuum may either be made through the agency of steam, as there pointed out, or by means of an air-pump. One powerful air-pump may form and maintain a good vacuum under several receivers, placed upon the flat ground flanges of so many basins, each provided with a stop-cock at its side for exhaustion. The airless basin containing the juice being set on the shelf of a water-bath, and exposed to a proper temperature, will furnish in a short time a large quantity of medicinal extract, possessing the properties of the plant unimpaired.

For exceedingly delicate purposes, the concentration may be performed in the cold, by placing saucers filled with the expressed juice over a basin containing sulphuric acid, putting a glass receiver over them, and exhausting its air.

The use of the air-pump for evaporating such chemical substances as are readily injured by heat, has been very common since Professor Leslie's discovery of the efficacy of the combined influence of rarefied air and an absorbing surface of sulphuric acid in evaporating water at low temperatures. It has been supposed that the virtues of narcotic plants in particular might be better obtained and preserved by evaporation *in vacuo* than otherwise, as the decomposing agency of heat and atmospheric oxygen would be thereby excluded. There is no doubt that extracts thus made from the expressed juices of fresh vegetables possess, for some time at least, the green aspect and odour of the plants in far greater perfection than those usually made in the air, with the aid of artificial heat. Dr. Meurer has endeavoured to show that the colour and odour are of no use in determining the value of extracts of narcotics, that the albumen left unchanged in the extracts made *in vacuo*, tends to cause their spontaneous decomposition, and that the extracts made with the aid of alcohol, as is the practice in Germany, are more efficacious at first, and much less apt to be injured by keeping. M. Baldenius has detailed experiments to prove that the juices of recent plants mixed with alcohol, in the homœopathic fashion, are very liable to spontaneous decomposition. To the above expressed juice, the Germans add the alcoholic tincture of the residuary vegetable matter, and evaporating both together, prepare very powerful extracts.

Extracts of bark and other vegetable substances to be used in tanning or dyeing are made in the countries in which the plants grow. The operation is very roughly performed, and the imported extracts are usually very full of impurities.

In 1872 we imported of *Extracts unenumerated* as follows, the values only being given:—

	Value
From Belgium	£5,265
„ France	4,043
„ United States of America	6,853
„ British North America	4,400
„ Other Countries	1,253
	21,814

Of extracts of bark and other vegetable substances used for tanning or dyeing we exported in the same year to the value of 8,794*l*., of unenumerated extracts to the value of 3,089*l*., and of extract of malt to the value of 25*l*.

EXUVIÆ. Cast skins, shells, or coverings of animals which are shed or cast off, as the skins of serpents or caterpillars, the shells of lobsters, and the like. In geology, the shells and other similar remains of animals found in the rocks.

F

FACETTING. The process of cutting faces upon ornamental articles. Steel jewellery, such as beads, studs, buttons, the ornaments on the hilts of dress-swords and similar objects, are ground on horizontal laps with fine emery. Facets on gold and silver are cut and polished on revolving wheels, after the same general method as that pursued by the lapidary for cutting facets on stones.

FACTORY. In the sense in which this term is introduced here, it is contracted from 'manufactory;' meaning the place where workmen are employed in fabricating goods. To describe all the various factories would be to describe all the different manufactures, or at least, the arrangements of the machines by which the raw material is converted into marketable goods. The arrangements of a cotton factory fairly represent all the arrangements for other branches of textile manufactures. Under SILK, WOOL, &c., will be found particulars of the machines used and their general arrangements in these factories respectively. See COTTON FACTORY.

FÆCULA. See FECULA.

FAHLERZ, FAHLITE, or **FAHL-ORE.** A mineral known also as *Grey Copper ore*, and *Tetrahedrite*; the latter name referring to the common occurrence of this ore in tetrahedral crystals belonging to the cubic system. The chemical composition of fahlerz varies greatly in different specimens, but, speaking broadly, it may be said to be a double sulphide of copper and antimony; the antimony, however, may be replaced to a greater or less extent by the isomorphous elements—arsenic and bismuth, whilst the copper may be replaced in like manner by iron, zinc, silver, or mercury. We may thus recognise an antimonial series and an arsenical series, these being connected by an arsenio-antimonial and a bismutho-arsenico-antimonial series. Many varieties of fahlerz contain sufficient silver to render them important as silver ores, and these argentiferous varieties have been described under the names of *Polytelite* and *Freibergite*. The following analyses are selected with the view of showing some of the variations presented in the composition of different forms of fahlerz:—

	I	II	III	IV
Sulphur . . .	25·77	22·53	27·48	21·17
Antimony . . .	23·94	19·34	24·85	24·63

I. From Kapnik, in Transylvania; by H. Rose. II. From Kotterbach, near Iglo; by Vom Rath. III. From Foxdale silver-lead mine, Isle of Man; by David Forbes. IV. From the Habachtfund mine, Freiberg, Saxony; by H. Rose. See COPPER.

FAHLUNITE. An altered form of the mineral called *Iolite* or *Dichroite*.

FAÏENCE or **FAYENCE.** An old French term, nearly corresponding in meaning with our household word 'crockery.' It is now commonly applied by collectors to all the finer kinds of earthenware. Some authorities maintain that the word is derived from the town of Faenza, near Bologna. It is known that Majolica or Raffaelle ware was made at an early date at Faenza, and hence Majolica is sometimes distinguished as 'Faenza' ware. But this is a very different material from what is now commonly called Faïence. See MAJOLICA.

FAIKES or **FAKES.** A *miner's term* in Scotland for fissile sandy shales, or sandstone possessing a shale-like structure. Dark bituminous shales are called *blaes*, and the two varieties are thus distinguished.

FAINTS is the name of the impure spirit which comes over first and last in the distillation of whiskey; the former being called the *strong*, and the latter which is much more abundant, the *weak* faints. This crude spirit is much impregnated with fetid essential oil (fusel oil); it is therefore very unwholesome, and must be purified by rectification.

FAIRY-STONE. A name given in the south of England to the fossil sea-urchins found in the chalk. They are sometimes called 'fairy loaves.'

FALLING STONES. A name given to meteoric stones. See METEORIC STONES.

FALSE SILVER. A term applied by the ancients, in all probability, to zinc. Strabo, in a passage quoted in Watson's 'Chemical Essays,' speaks of false silver, with the addition of copper, making orichalcum, or brass.

FALSE TOPAZ. A light yellow pellucid variety of quartz crystal. It may be distinguished from yellow topaz, for which, when cut, it is frequently substituted, by its difference of crystalline form, the absence of cleavage, inferior hardness, and lower specific gravity. Found in the Brazils, &c.

FAMP is a siliceous bed, composed of very fine particles. This term is confined chiefly to the North of England. Famp possesses little cohesion, and when exposed to the action of the air it crumbles into a sandy kind of clay. Beds of 'famp' often separate the hard 'posts' of sandstone; they also contain more mica than the sandstone rocks among which they are interspersed. See POST.

FAN (*Eventail*, Fr.; *Fächer*, Ger.) is usually a semi-circular piece of silk or paper, pasted double, enclosing slender slips of wood, ivory, tortoise-shell, whalebone, &c., arranged like the tail of a peacock in a radiating form, and susceptible of being folded together and expanded at pleasure. This well-known hand ornament is used by ladies to cool their faces by agitating the air. Fans made of feathers, like the wing of a bird, have been employed from time immemorial by the natives of tropical countries.

Fan is also the name of the apparatus for winnowing corn, for urging the fires of furnaces, and for purposes of ventilation. For an account of the powerful blowing and ventilating fan machines, see IRON MANUFACTURE and VENTILATION OF MINES.

FANG, *a mining term.* A niche cut in the side of an adit or shaft to serve as an air-course. Sometimes the term *a fanging* is applied to a main of wood-pipes.

FAREWELL ROCK. The name given in South Wales to the Millstone Grit, because no coal is found worth working after this rock has been reached.

This rock is much used for the hearths of furnaces, its power of resisting the most intense heat being remarkable.

FARINA (*Farine*, Fr.; *Mehl*, Ger.) is the flour of any species of corn, or starchy root, such as potato, arrow-root, &c. See BREAD and STARCH.

FASSAITE. A variety of augite containing alumina, lime, magnesia, and iron. It occurs in the Fassathal, in Piedmont.

FATS (*Graisses*, Fr.; *Fette*, Ger.) occur in a great number of the animal tissues, being abundant under the skin in what is called the cellular membrane, round the kidneys, in the folds of the omentum, at the base of the heart, in the mediastinum, the mesenteric web, as well as upon the surface of the intestines, and among many of the muscles. Fats vary in consistence, colour, and smell, according to the animals from which they are obtained; thus, they are generally fluid in the cetaceous tribes, soft and rank-flavoured in the carnivorous, solid and nearly scentless in the ruminants, usually white and copious in well-fed young animals; yellowish and more scanty in the old. Their consistence varies also according to the organ of their production; being firmer under the skin and in the neighbourhood of the kidneys than among the moveable viscera. Fat forms about one-twentieth of the weight of a healthy animal. But as taken out by the butcher it is not pure; for being of a vesicular structure, it is always enclosed in membranes, mixed with blood, blood-vessels, lymphatics, &c. These foreign matters must first be separated in some measure mechanically, after the fat is minced small, and then more completely by melting it with hot water, passing it through a sieve, and letting the whole cool very slowly. By this means a cake of cleansed fat will be obtained.

Braconnot and Raspail have shown that solid animal fats are composed of very small microscopic, partly polygonal, partly reniform particles, which are connected together by very thin membranes. These may be ruptured by mechanical means, then separated by triturating the fresh fats with cold water, and passing the unctuous matter through a sieve. The particles float in the water, but eventually collect in a white granular crystalline appearance, like starch. Each of them consists of a vesicular integument, of the nature of stearine, and an interior fluid like elaine, which afterwards exudes. The granules float in the water, but subside in spirits of wine. When digested in strong alcohol, the liquid part dissolves, but the solid remains.

These particles differ in shape and size, as obtained from different animals; those of the calf, ox, sheep, are polygonal, and from $\frac{1}{50}$th to $\frac{1}{350}$th of an inch in diameter; those of the sow are kidney-shaped, and from $\frac{1}{50}$th to $\frac{1}{100}$th; those of man are polygonal, and from $\frac{1}{50}$th to $\frac{1}{600}$th; those of insects are spherical, and at most $\frac{1}{500}$th of an inch.

Fats all melt at a temperature much under 212° F. When strongly heated with contact of air, they diffuse white pungent fumes, then blacken, and take fire. When subjected to distillation they afford a changed fluid oil, carburetted hydrogen, and the other products of oily bodies. Exposed for a certain time to the atmosphere they become rancid, and generate the same fat acid as they do by saponification. In their fresh state they are all composed principally of stearine, margarine, and oleine, with a little colouring and odorous matter; and in some species, hircine, from the goat; phocenine, from the dolphin; and butyrine from butter. By subjecting them to a great degree of cold, and compressing them between the folds of blotting-paper, a residuum is obtained, consisting chiefly of stearine and margarine; the latter of which may be dissolved out by oil of turpentine.

Beef and Mutton Suet.—When fresh, this is an insipid, nearly inodorous fat, of a firm consistence, almost insoluble in alcohol, entirely so, if taken from the kidneys and mesenteric web of the ox, the sheep, the goat, and the stag. It varies in whiteness, consistence, and combustibility, with the species and health of the animals. They may all be purified in the manner above described. Strong sulphuric acid developes readily the acid fats by stirring it through melted suet. Alkalis, by saponification, give rise to one of the three acids, the stearic, margaric, or oleic. Beef suet consists of stearine, margarine, and oleine; mutton and goat suet contain a little hircine. The specific gravity of the tallow of which common candles are made is, by Ure's experiments, 0·936. The melting point of suet is from 98° to 104° F. The proportion of solid and fluid fat in it is somewhat variable, but the former is in much larger proportion. Mutton suet is soluble in 44 parts of boiling alcohol, of 0·820; beef suet in 44 parts. Marrow fat consists of 76 of stearine, and 24 of oleine; it melts at 115° F.

Hog's lard is soft, fusible at 81° F, convertible, by an alkaline solution, into a stearate, margarate, oleate, and glycerine. Its sp. grav. is 0·938, at 50° F. It consists of 62 of oleine, and 38 of stearine, in 100 parts.

Goose-fat consists of 68 oleine and 32 stearine.

Butter, in summer, consists of 60 of oleine and 40 of stearine; in winter, of 35 of oleine and 65 of stearine; the former substance being yellow and the other white. It differs, however, as produced from the milk of different cows, and also according to their pasture.

Chevreul investigated with great care the composition of fats. He has shown that they are mixtures of simple fats as oleine, stearine, and margarine. For his investigations, see those articles in Watts's 'Dictionary of Chemistry.'

The following statement is given on the authority of Braconnot:—

	Oleine	Stearine		Oleine	Stearine
Hog's lard . . .	62	38	Duck-fat . . .	72	28
Ox marrow . . .	24	76	Ox tallow . . .	25	75
Goose-fat . . .	68	32	Mutton suet. . .	26	74

The late Dr. Robert Dundas Thomson gave the following list of animal fats and their melting points:—

Badger-fat . . .	86°	Pheasant	109°
Beef tallow . . .	98½	Turkey.	113
Calf	136·8	Stearine (human) . . .	120
Camel	131	„ (sheep) . . .	109
Cochineal fat . . .	104	„ (oxen) . . .	111
Cow's butter . . .	79·7	„ (hog) . . .	109
Duck-fat	77	„ (duck) . . .	109
Dog	79¾	Cetine	120
Fox	129	Chlorestine	278
Hare.	117½	Cantharides fat . . .	93½
Hog's lard. . . .	80·5	Margarine (butter) . .	105
Horse grease . . .	140	Palmitine	115
Human fat . . .	77		

The purification and decoloration of fats have been the object of many patents. One of the best is to mix 2 per cent. of strong sulphuric acid with a quantity of water, in which the tallow is heated for some time with much stirring; to allow the materials to cool, to take off the supernatant fat, and to re-melt it with abundance of hot water. More tallow will thus be obtained, and that considerably whiter and harder than is usually procured by the melters.

Dr. Ure stated that he found that chlorine and chloride of lime did not improve, but rather deteriorated, the appearances of oils and other fatty bodies. According to Appert, minced suet subjected to the action of high-pressure steam in a digester, at 250° or 260° F., becomes so hard as to be sonorous when struck, whiter, and capable, when made into candles, of giving a superior light. A convenient mode of *rendering* minced tallow, or melting it, is to put it in a tub, and drive steam through it from numerous orifices in ramifying pipes placed near the bottom. Mr. Watts's plan of purifying fats, patented in March 1836, has been successful. He employs dilute sulphuric acid, to which he adds a little nitric acid, with a very small quantity of bichromate of potash to supply oxygen, and some oxalic acid These are mixed with the fat in the steaming tub. When the lumps of it are nearly dissolved, he takes for every ton of fat, one pound of strong nitric acid, diluted with one quart of water; to which he adds two ounces of alcohol, naphtha, sulphuric ether, or spirits of turpentine; and after introducing this mixture, he continues the boiling for half an hour. The fat is finally washed.

Others have proposed to use vegetable or animal charcoal first, especially for rancid oils, then to heat them with a solution of sulphate of copper and common salt, which is supposed to precipitate the fetid albuminous matter.

Mr. Prynne obtained a patent in March 1840, for purifying tallow for the candlemaker, by heating it along with a solution of carbonate of potash or soda for 8 hours, letting the whole cool, removing the tallow to another vessel, heating it by means of steam up to 206° F., along with dry carbonate of potash (pearlash): letting this mixture cool very slowly; and finally removing the tallow to a vessel inclosed in steam, so as to expel any subsidiary moisture.

A patent for a like purpose was obtained in June 1842, by Mr. H. H. Watson. He availed himself of the blanching power of oxygen, as evolved from permanganate of potash (chameleon mineral), in the act of its decomposition by acids, while in contact with the melted fat. He prescribed a leaden vessel (a well-joined wooden tub will also serve) for operating upon the melted tallow with one-twentieth of its weight of the manganate dissolved in water, and acidulated to the taste. The whole are to be well mixed, and gradually heated from 150° up to 212° F., and maintained at that temperature for an hour. On account of the tendency of the dissolved manganate to spontaneous decomposition, it should be added to the dilute acid, mixed with the fat previously melted at the lowest temperature consistent with its fluidity.

Mr. Wilson, of Vauxhall, has applied centrifugal action to the separation of the liquid from the more solid parts of fatty matters, employing in preference the *hydro-extractors* used by Seyrig and Co. for drying textile fabrics. Mr. Wilson applies a stout cotton twill in addition to the wire-grating; and in order to avoid the necessity of digging the concrete parts, and to prevent them from clogging the interstices for the discharge of the oily matter, he places the whole in a bag 8 inches in diameter, and of such length that when laid on the rotating machine against the grating the two ends will meet. The speed of the machine must be kept below that at which stearic acid or stearine would pass: which is known by the limpidity of the expressed fluid. To take advantage of the liquefying influence of heat, he keeps the temperature of his own room about 2° F. above that of the substances under treatment.

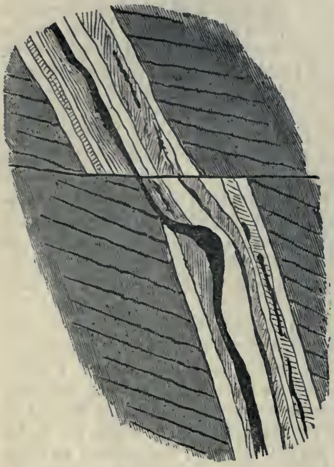
The chemistry of fat will be found in Watts's 'Dictionary of Chemistry.' For *Imports*, &c., see TALLOW.

See also GLYCERINE; MARGARINE; OLEINE; SOAP; STEARINE.

FAULTS (*Failles*, Fr.), in mining, are disturbances of the strata, the name being derived from the circumstance that these movements interrupt the miner's operations, and render it difficult to discover where the vein of ore or bed of coal has been '*thrown*' by the disturbance producing the fault. Any fissure in a rock accompanied by a displacement of any kind is called a 'fault.' By a movement of the earth a crack may be produced, but, if there has not been a movement, it is simply a fissure; while, if the rock on either side of the crack has been moved, it becomes a *fault*.

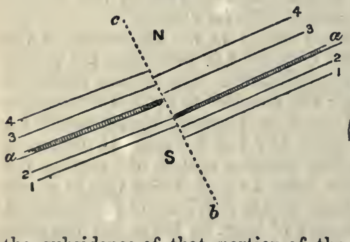
A mineral vein may be regarded as a fissure formed during the consolidation of the rocks in which it exists, or by some movement of the entire mass, producing these cracks at right angles to the line of greatest mechanical force; these have been eventually filled in with the mineral or metalliferous matter which we find in them. After this has taken place, there has sometimes been a movement of a portion of the ground, and the mineral vein, or lode, has been fractured. A simple illustration of this is the following, *fig.* 842, where we have the mineral vein dislocated, and subsequently to the dislocation there has been a formation of a string of spathose iron, following the bendings of a crack formed by the movement, which, in this case, has been less than the width of the lode. In the large majority of examples the 'heave' or 'throw' of the lode has been very considerable. It is usual to speak of a *fault* as if the fissure had actually moved the lode. It should be understood that an actual movement of great masses of the solid earth is implied, and consequently, the *lode* having been formed before the movement, it is moved with the rock in which it is enclosed. *Fig.* 844 is the plan of veins 1, 2, 3, 4, and an elvan course *a a*, which have been dislocated along the line *b*, *c*, and all the lodes and the elvan course moved. In this case the movement has probably taken place from the North towards the South. This disturbance will be continued to a great depth, and in *fig.* 843 is a section showing the dislocation of a lode into three parts. In this case the movement has probably been the subsidence of that portion of the ground containing the lode *b*, and the further subsidence of that portion containing the lode *a*; the condition of the surface being subsequently altered by denudation. The inclination of a lode is frequently changed by these movements, thus *fig.* 845 supposes *c d* to represent the original condition of the lode; by a convulsion, the portion *a b* has fallen away leaving a chasm between, and the 'dip' or inclination of the lode is therefore materially changed. The direction of the lode is frequently altered by these movements. Many lodes in Cornwall have a direction from the N. of E. to the S. of W. up to a fault, on the other side of which the direction is changed from the S. of E. to the N. of W. Where these disturbances are of frequent occurrence, the difficulties of mining are greatly increased.

842



843

844



845

The dislocations and obstructions found in coal-fields, which render the search for coal so difficult, and its mining so laborious and uncertain, are the following:—

1. *Dykes.* 2. *Slips.* 3. *Hitches.* 4. *Troubles.*

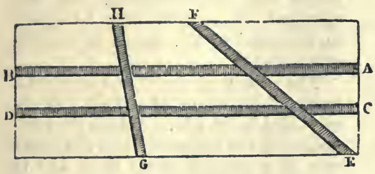
The first three infer dislocation of the strata; the fourth, changes in the bed of coal itself.

1. A *dyke* is a wall of extraneous matter, which divides all the beds in a coal-field.

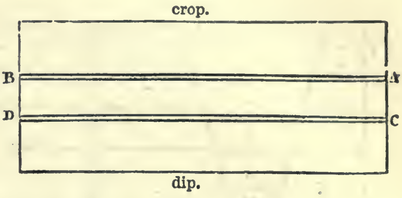
Dykes extend not only in one line of bearing through coal-fields for many miles, but run sometimes in different directions, and have often irregular bendings, but no sharp angular turns. When from a few feet to a few fathoms in thickness, they occur sometimes in numbers within a small area of a coal-basin, running in various directions, and even crossing each other. *Fig.* 846, represents a ground plan of a coal-field, intersected with greenstone dykes. A B and C D are two dykes standing parallel to each other; E F and G H are cross or oblique dykes, which divide both the coal-strata and the primary dykes A B and C D.

2. *Slips* run in straight lines through coal-measures, and at every angle of incidence to each other. *Fig.* 847 represents a ground plan of a coal-field, with two slips A B and C D, the line of bearing of the planes of the strata, which throw them down to the outcrop. This is the simplest form of a slip. *Fig.* 848, exhibits part of a coal-field intersected with slips, like a cracked sheet of ice. Here A B is a dyke; while the narrow lines show faults of every kind, producing dislocations varying in amount of slip from a few to a great many fathoms. The faults at the points *a, a, a* vanish; and the lines at C denote four small partial slips called *hitches*.

846

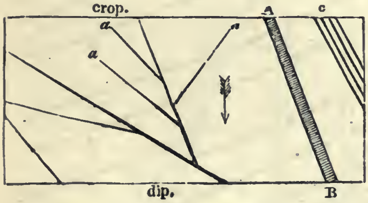


847

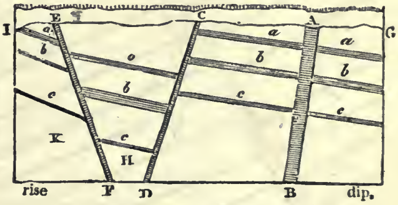


The effects of slips and faults—whether produced by dykes, or otherwise—on the coal-strata appear more prominently when viewed in a vertical section, than in a ground plan, where they seem to be merely walls, veins, or lines of demarcation. *Fig.* 849 is a vertical section of a coal-field, from dip to rise, showing three strata of coal *a, b, c.* A B represents a dyke at right angles to the plane of the coal-beds. This rectangular wall merely separates the coal-measures, without affecting their line of rise; but further to the rise, the oblique dyke C D interrupts the coals *a, b, c,* and not only disjoins them, but has produced a movement which has thrown them and their concomitant strata greatly lower down; but still, with this depression, the strata retain their parallelism and general slope. Nearer to the outcrop, another dyke, E F, interrupts the coals *a, b, c,* not merely breaking the continuity of the planes, but throwing them moderately up, so as to produce a steeper inclination, as shown in the figure. It sometimes happens that the coals in the compartment H, betwixt the dykes C and E, may lie nearly horizontal, and the effect of the dyke E, F, is then to throw out the coals altogether, leaving no vestige of them in the compartment K.

848

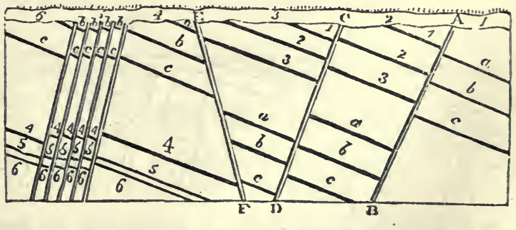


849



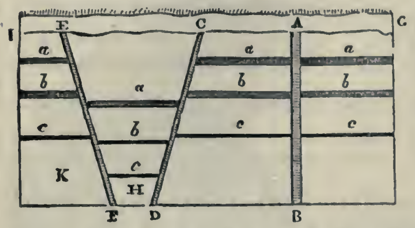
The effect of slips on the strata is also represented in the vertical section, *fig.* 850, where *a, b, c* are coals with their associated strata, A B is an intersecting slip, which throws all the coals of the first compartment much lower, as is observable in the second, No. 2; and from the amount of the slip, it brings in other coal-seams, marked 1, 2, 3, not in the compartment No. 1. C D, is a slip producing a similar result, but not of the same magnitude; E F represents a slip across the strata, reverse in direction to the former; the effect of which is to throw up the

850



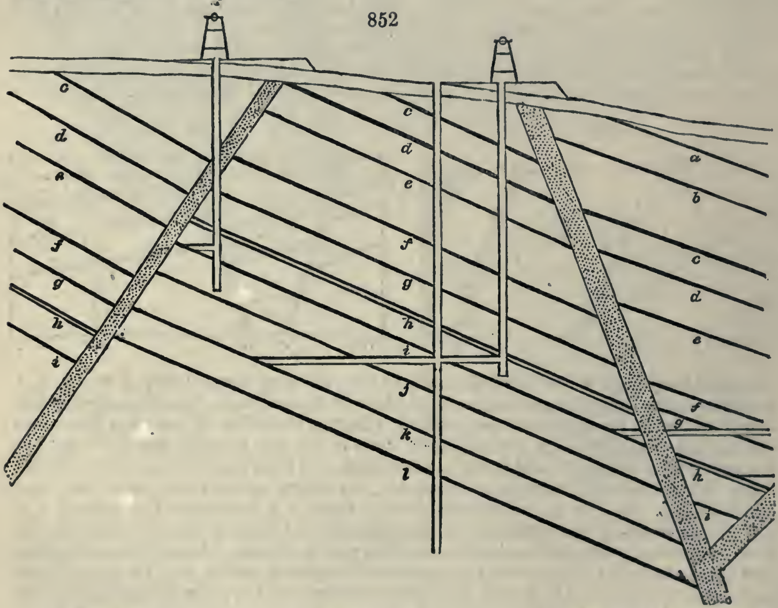
coals as shown in the area No. 4. Such a slip occasionally brings into play seams seated under those marked *a*, *b*, *c*, as seen at 4, 5, 6; and it may happen that the coal marked 4 lies in the prolongation of a well-known seam, as *c*, in the compartment No. 3, when the case becomes puzzling to the miner. In addition to the above varieties, a number of slips or hitches are often seen near one another, as in the area marked No. 5, where the individual displacements are inconsiderable, but the aggregate dislocation may be great, in reference to the seams of the 6th compartment.

851



The results of dykes and slips on a horizontal portion of a field are exemplified in *fig.* 851. Where the coal-measures are horizontal, and the faults run at a greater angle than 45° to the line of bearing, they are termed 'dip' and 'rise' faults, as A B, C D, E F. The following *fig.* 852, which is an accurate section of the Mostyn coal-field, Flintshire, will show the amount to which those disturbances are experienced. The letters mark with sufficient distinctness the beds on either side of the faults.

852



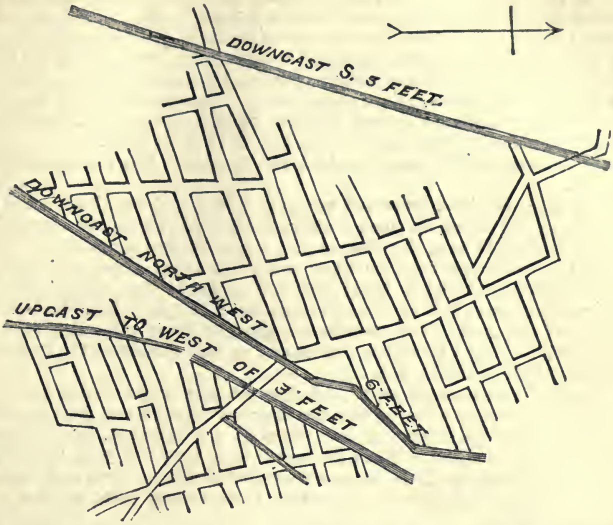
a. Worked out.
b. Ditto.
c. 5 yd. coal worked out.
d. 3 yd. ditto.
e. Inferior coal.
f. Ditto.
g. Yard coal worked out.
h. 4 ft. coal (tolerable).
i. Main coal, 6 ft. (very good).
j. 5 ft. coal.
k. Stone coal.
l. 3 ft. coal.

853

Fig. 853 gives a true section of a portion of the North Staffordshire Coal-field, showing the dislocations which have been produced, and the mechanical force exerted by the movements which have taken place.

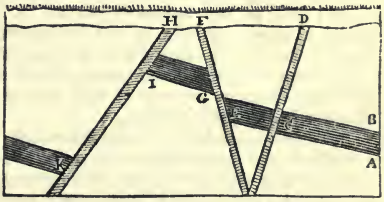
Fig. 854 shows a colliery in plan, and the amount of the movement produced by the dislocations.

854



Coal viewers or engineers regard the dislocations now described as being subject in one respect to a general law, which may be thus explained:—Let *fig.* 855 be a portion of a coal-measure; A being the pavement and B the roof of the coal-seam. If, in pursuing the stratum at C, a dyke D occurs, standing at right angles with the pavement they conclude that the dyke is merely a partition-wall between the beds by its own thickness, leaving the coal-seam undisturbed on either side; but if a dyke F forms, as at E, an obtuse angle with the pavement, they conclude that the dyke is not a simple partition between the strata, but has thrown up the several seams into the predicament shown at G. Finally, should a dyke H make at I an acute angle with the pavement, they conclude that the dyke has thrown down the coal-measures in the position of K.

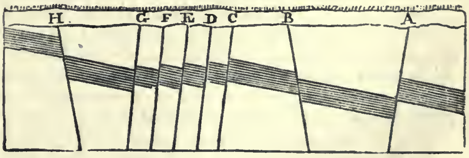
855



Dykes and faults are denominated upthrow or downthrow, according to the position they are met with in working the mine. Thus, in *fig.* 849, if the miner is advancing to the rise, the dyke A B obviously does not change the direction; but C D is a downthrow dyke of a certain number of fathoms towards the rise of the basin, and E F is an upthrow dyke likewise towards the rise. On the other hand, when the dykes are met with by the miner in working from the rise to the dip, the names of the above dykes would be reversed; for what is an upthrow in the first case becomes a downthrow in the second, relative to the mining operations.

3. *Hitches* are small and partial slips, where the dislocation does not exceed the thickness of the coal-seam; and they are often correctly enough called *steps* by the miner. *Fig.* 856 represents the operation of the *hitches* A, B, C, D, E, F, G, H, on the coal-measures. Though observed in one or two seams of a field, they may not appear in the rest, as is the case with dykes and faults.

856



Troubles are smaller, but often numerous faults, by which the beds of coal are disturbed, and as these greatly interfere with the progress of the miner, he regards them as *troubles*, and hence their name.

In the above description the language of the mine has been retained, but in the case of the dyke, as of the *fault-proper*, it is not that the dyke has lifted the coal-bed up or down, but during the convulsive movements of the earth, when those trap dykes were being forced from below, great movements were produced on either side of the fissures through which the molten matter ascended, and hence the alteration in the position of the beds, which were previously, perhaps, nearly in a horizontal plane. See Dyke.

FEATHERS. (*Plumes*, Fr.; *Federn*, Ger.) 'The most beautiful, the most complex, and the most highly elaborated of all the coverings of animals, due to the development of the epidermal system, is the plumage of birds.'—*Owen*.

A feather consists of the *quill*, the *shaft*, and the *vane*. The vane consists of *barbs* and *barbules*.

The *quill* is pierced by a lower and an upper orifice, and contains a series of light, dry, conical capsules, fitted one upon another, and united together by a central pedicle.

The *shaft* is slightly bent, the concave side is divided into two surfaces by a middle longitudinal line continued from the upper orifice of the quill, the convex side is smooth. Both sides are covered with a horny material similar to that of the quill, and they enclose a peculiar white, soft, elastic substance, called the *pith*. The *barbs* are attached to the sides of the shaft. The *barbules* are given off from either side of the barbs, and are sometimes similarly barbed themselves, as may be seen in the barbules of the long feathers of the peacock's tail.

The barbules are commonly short and close set, and curved in contrary directions, so that the two adjoining series of barbules interlock together and form the mechanism by which the barbs are compacted into the close and resisting vane of the quill, or 'feather,' properly so called. When the barbules are long and loose, they characterise that form of the feather which is properly called a 'plume,' and such are the most valuable products of the plumage of birds in a commercial point of view, as *e.g.* the plumes of the ostrich.

The Down.—The lower barbs in every kind of feather are usually loose, forming the down, which is increased in most birds by what is called the 'accessory plume.' This is usually a soft downy tuft, but varies in different species, and even in the feathers of different parts of the body of the same bird. The value of feathers for bed stuffing depends upon the proportion of loose soft down that enters into their composition; and as the 'accessory plume' in the body feathers of the swans, geese, and ducks, is almost as long as the feather from which it springs, hence arises the commercial value of the feathers of those aquatic birds.—*Owen*.

The first covering of the young bird is a down. In most birds a certain portion of the down feathers is retained with the true feathers, and this proportion is usually greatest in the aquatic birds.

It is most remarkable in the eider duck (*Anas mollissima*). 'The down of the eider combines, with its peculiar softness, fineness, and lightness, so great a degree of elasticity that the quantity of this beautiful material which might be compressed and concealed between the two hands of a man will serve to stuff the coverlet of a bed.'—*Owen*.

Feathers constitute the subject of the manufacture of the *Plumassier*, a name given to the artisan who prepares the feathers of certain birds as ornaments for ladies and for military men, and to him also who combines the feathers in various forms. We shall content ourselves with describing the method of preparing ostrich feathers, as most others are prepared in the same way.

Several qualities are distinguished in the feathers of the ostrich; those of the male, in particular, are whiter and more beautiful. Those upon the back and above the wings are preferred; next those of the wings, and lastly, of the tail. The down is merely the feathers of the other parts of the body, which vary in length from 4 to 14 inches. This down is black in the males, and grey in the females. The finest white feathers of the female have always their ends a little greyish, which lessens their lustre, and lowers their price. These feathers are imported from Algiers, Tunis, Alexandria, Madagascar, and Senegal; this being the order of their value.

The *scouring process* is thus performed:—4 ounces of white soap, cut small, are dissolved in 4 pounds of water, moderately hot, in a large basin; and the solution is made into a lather by beating with rods. Two bundles of the feathers, tied with packthread, are then introduced, and are rubbed well with the hands for five or six minutes. After this soaping, they are washed in clear water, as hot as the hand can bear.

The whitening or bleaching is performed by three successive operations.

1. They are immersed in hot water mixed with Spanish white, and well agitated in it; after which they are washed in three waters in succession.

2. The feathers are azured in cold water containing a little indigo tied up in a fine cloth. They should be passed quickly through this bath.

3. They are sulphured in the same way as straw hats are (see SULPHURING); they are then dried by hanging upon cords, when they must be well shaken from time to time to open the fibres.

The ribs are scraped with a bit of glass cut circularly, in order to render them very pliant. By drawing the edge of a blunt knife over the filaments they assume the curly form so much admired.

Those feathers which are of a dingy colour are dyed black. For 20 pounds of feathers, a strong decoction is made of 25 pounds of logwood in a proper quantity of water. After boiling it for 6 hours, the logwood is taken out, 3 pounds of copperas are thrown in, and, after continuing the ebullition for 15 or 20 minutes, the copper is taken from the fire. The feathers are then immersed by handfuls, thoroughly soaked, and worked about, and left in two or three days. They are next cleansed in a very weak alkaline lye, and soaped three several times. When they feel very soft to the touch, they must be rinsed in cold water, and afterwards dried. White feathers are very difficult to dye a fine black.

For dyeing other colours, the feathers should be previously well bleached by the action of the sun and the dew; the end of the tube being cut sharp like a toothpick, and the feathers being planted singly in the grass. After fifteen days' exposure, they are cleared with soap as above described.

Rose colour or *pink*, is given by safflower and lemon-juice.

Deep red, by a boiling-hot bath of brazil-wood, after aluming.

Crimson. The above deep-red feathers are passed through a bath of cudbear.

Prune de Monsieur. The deep-red is passed through an alkaline bath.

Blues of every shade, are dyed with the indigo vat.

Yellow, after aluming, with a bath of turmeric or weld.

Other tints may be obtained by a mixture of the above dyes.

Feathers supply us with a soft elastic down on which we can repose our wearied frames, and enjoy sweet slumbers. Such are called *bed* feathers.

Goose feathers are most esteemed. There is a prejudice that they are best when plucked from the living bird, which is done thrice a year, in spring, midsummer, and the beginning of harvest. The qualities sought for in bed feathers are softness, elasticity, lightness, and warmth. Their only preparation when cleanly gathered is a slight beating to clear away the loose matter, but for this purpose they must be first well dried either by the sun or stove; stoving or hot air being also necessary to remove any animal matter liable to putrefy.

The feathers of the eider duck, *Anas mollissima*, called eider-down, possess in a superior degree all the good qualities of goose-down. It is used only as a covering to beds, and never should be slept upon, as it thereby loses its elasticity.

Quills for writing.—These consist usually of the feathers plucked out of the wings of geese. Dutch quills have been highly esteemed, as the Dutch were the first who hit upon the art of preparing them well, by clearing them both inside and outside from a fatty humour with which they are naturally impregnated, and which prevents the ink from flowing freely along the pens made with them. The Dutch for a long time employed hot cinders or ashes to attain this end; and their secret was preserved very carefully, but it at length transpired, and the process was then improved. A bath of very fine sand must be kept constantly at a suitable temperature, which is about 140° F.; into this the quill-end of the feather must be plunged, and left in it a few instants. On taking the feathers out they must be strongly rubbed with a piece of flannel, after which they are found to be white and transparent. Both carbonate of potash in solution and dilute sulphuric acid have been tried to effect the same end, but without success. The yellow tint which gives quills the air of age, is produced by dipping them for a short time in dilute muriatic acid, and then making them perfectly dry. But this process must be preceded by the sand-bath operation.

Quills are dressed by the London dealers in two ways: by the one, they remain of their natural colour; by the other, they acquire a yellow tint. The former is called the Dutch method, and the principal workman is called a Dutcher. He sits before a small stove fire, into which he thrusts the barrel of the quill for about a second, then lays its root quickly below his blunt-edged knife, called a hook, and, pressing this firmly with the left hand, draws the quill briskly through with his right. The bed on which the quill is laid to receive this pressure is called the plate. A skilful workman can pass 2,000 quills through his hands in a day of ten hours. They are next cleansed by being scrubbed by a woman with a piece of rough dog-fish skin, and then tied up in bundles.

In the goose's wing, the five exterior feathers only are valuable for writing; the first is the hardest and roundest of all, but the shortest; the next two are the best of the five. The heaviest quills are generally the best.

Our recent *Imports* have been as follow:—

FEATHER ALUM or *Hair-Salt.* A hydrous sulphate of alumina, resulting from volcanic action, and from the decomposition of iron pyrites, especially in the coal-measure shales. See ALUM.

FEATHER ORE, *Plumosite,* or *Heteromorphite.* A sulphide of antimony and lead, allied to *Jamesonite.* Its composition is, sulphur 19·2, antimony 31·0, lead 49·8. It is sometimes found in capillary forms and like a cobweb, but it is also found massive.

FECULA (*Fécule,* Fr.; *Stärkmehl,* Ger.) sometimes signifies corn-flour, sometimes starch, from whatever source obtained; and it is also applied to chlorophyll, the green matter of plants. The term is applied to any pulverulent matter obtained from plants by simply breaking down the texture, washing with water, and subsidence.

FEEDER, *a mining term.* A small lateral lode falling into the main lode or mineral vein.

FELL. The hide of an animal.

FELL-MONGER. The business of the fell-monger is to separate the wool from the skin. The wool is sold to the wool-stapler, and the stripped skins sent to the leather-dressers or parchment-makers.

FELSITE or **FELSTONE.** A compact rock, composed mainly of felspar, with more or less quartz. It has been shown that most felsites contain the elements of granite in a compact instead of a crystalline form. See FELSPATHIC ROCKS.

FELSPAR or **FELDSPAR** (*Feldspath,* Fr. and Ger.) Under the name of *felspar,* the mineralogist associates a number of important rock-forming minerals, which, from the many characters they possess in common, were formerly confounded together, and are with difficulty distinguished from one another by mere inspection; but which, nevertheless, are sufficiently distinct, both in chemical composition, and in crystalline form, to admit of division into several well-defined species. The felspars are, in all cases, anhydrous double silicates, consisting of a silicate of alumina, combined with a silicate of a protoxide which may be either potash, soda, or lime; but as these oxides are capable of mutually replacing each other, it commonly happens that two or even more of them coexist in the same species. In all the members of the felspar-group, there exists the simple relation of one atom of the sesquioxide, alumina, to one of the protoxide base or bases; but the proportion of silica varies considerably in the different species. The amount of silica bears a definite relation to the geological character of the rock in which the felspar occurs, and to the minerals with which it is associated; the highly-silicated species, as orthoclase, albite, and oligoclase, occurring in granites, trachytes, and other so-called acid rocks; whilst the less silicated felspars, as labradorite, are confined to basalts, certain lavas, and other basic rocks.

Exposed to a high temperature, the felspars fuse, with greater or less difficulty, to a vitreous enamel possessing considerable hardness, a property which has led to their use in glazing porcelain. All the felspars are sufficiently hard to scratch glass, but are themselves scratched by quartz; and this hardness, combined with their crystalline form, often serves to distinguish them from other minerals. Their specific gravity varies from about 2·5 in orthoclase to upwards of 2·7 in labradorite; and by its constancy in the different species, becomes a useful characteristic. The lustre is commonly vitreous, passing into pearly on the more perfect cleavage planes; whilst certain of the rarer varieties enjoy peculiar opalescent and iridescent properties, of which the jeweller takes advantage, to a limited extent. With the exception of labradorite, all the felspars are either unacted, or imperfectly acted, on by acids.

According to the nature of their basic constituents, the felspars admit of classification into four groups, viz.:—

I. Potash-felspar (often containing soda); *orthoclase* or *common felspar*; and *sanidine*, or *glassy felspar*.

II. Soda-felspar (often containing potash); *albite*, and *oligoclase*, or *soda-spodumene*.

III. Soda-lime-felspar (often containing potash); *labradorite*, or *labrador-felspar*; and *andesine*.

IV. Lime-felspar; *anorthite*.

With regard to this arrangement it may be remarked that some of the species here enumerated appear to shade insensibly one into another, so that doubts have not unnaturally been entertained by certain mineralogists as to the real specific distinctions between such minerals. Of late years, Tschermak, an Austrian mineralogist, has specially applied himself to this question, and has arrived at the conclusion that there are only three really distinct species: namely, a potash-felspar (*orthoclase*), a soda-felspar (*albite*), and a lime-felspar (*anorthite*); all the other so-called species being merely mixtures in various proportions of these three extreme types. But as orthoclase crystallises in the monoclinic, or singly-oblique system, whilst albite and anorthite crystallise in the triclinic, or doubly-oblique system, it is difficult to conceive how orthoclase can be isomorphous with the other felspars. Hence Tschermak has been led to recognise two distinct kinds of mixed felspars; those that contain both potash and soda being regarded as mechanical mixtures of orthoclase and albite, like *perthite*, whilst those containing both soda and lime are true isomorphous mixtures of albite and anorthite. Although much theoretical interest attaches to these views, it will be convenient in this place to adhere to the old-established classification cited above.

I. ORTHOCLASE (*Orthose*, Fr.; *Orthoklas*, Ger.; *Ortosa*, Ital.) This is the most ordinary species, and that which in popular language is called simply 'felspar.' It occurs as a colourless, grey, or flesh-red mineral, crystallising in oblique rhombic prisms, and frequently presenting the peculiar forms called twin-crystals. The crystals always exhibit two well-marked directions of cleavage at right angles to each other, whence the name of the species (ὀρθὸς, straight; κλάω, to cleave). Orthoclase is a potash-felspar, of which the following is an analysis from the Baveno granite: silica, 65·72; alumina, 18·57; potash, 14·02; soda, 1·25; lime, 0·34; magnesia, 0·10; = 100 (*Abich*). This mineral is an important constituent of granite, gneiss, syenite, pegmatite, felstone, and trachyte: of granite it ordinarily composes from 40 to 45 per cent. The species orthoclase has been subdivided into a great number of varieties, frequently founded on very insufficient grounds. The purest and most transparent varieties are distinguished as *adularia;* and when exhibiting a faint bluish opalescence are used in jewellery under the name of *Moon-Stone.* Other opalescent varieties are the *microcline*, from the zircon-syenite of Norway; and the *Murchisonite* from Dawlish, and from Heavitree, near Exeter—a mineral named after the late Sir R. Murchison. A bright green orthoclase, coloured by a trace of oxide of copper, occurs near Lake Ilmen, in Siberia, and is employed for ornamental purposes under the name of *Amazon-stone*, from having been first found in the River Amazon. *Erythrite* is a flesh-coloured felspar, from Kilpatrick, containing 3 per cent. of magnesia; whilst the felspar called *hyalophane* is notable for containing a large percentage of baryta. *Loxoclase* and *Chesterlite*, are American varieties of orthoclase; whilst *Valencianite* is the name given to a Mexican adularia.

Sanidine, or *glassy felspar*, is a transparent potash-soda-felspar, regarded often as a distinct species. It occurs in tabular, vitreous crystals, embedded in trachyte and other volcanic rocks; and much resembles the artificial felspar obtained in certain metallurgical operations. The well-known glassy felspar from the Drachenfels consists of silica, 66·6; alumina, 18·5; potash, 8·0; soda, 4·0; lime, 1·0; peroxide of iron, 0·6; = 98·7 (*Berthier*). *Rhyacolite* is a name proposed by Rose for a Vesuvian variety of glassy felspar, which appears, however, to be only a mixture of felspar and nepheline. The transparent felspars occurring in the lavas of Vesuvius are sometimes termed *ice-spar.*

II. Albite, or *Cleavelandite*—known also as *pericline* and *tetartine*—is a soda-felspar first described by G. Rose. It consists of silica, 68·75; alumina, 18·79; soda, 10·90; potash, 1·21; lime, 0·51; magnesia, 0·09; peroxide of iron, 0·54; = 100·79 (*Weiss*). Albite differs from orthoclase in the form of its crystals, which are much less symmetrical, and belong to an essentially distinct system (triclinic). It was at one time supposed to be a frequent constituent of granite, and syenite, but it is now known that much of the felspar formerly mistaken for albite is really oligoclase. *Peristerite* is a Canadian albite, remarkable for the beauty of its opalescence.

Perthite is a flesh-red potash-soda-felspar from Perth in Canada East, notable for being a mixed mineral made up of alternating bands of orthoclase and albite.

Oligoclase, or *soda-spodumene*, is composed of silica, 62·54; alumina, 22·49; soda, 7·84; potash, 4·54; lime, 2·18; magnesia, 0·41; = 100 (*Deville*). This is an analysis of the mineral from Teneriffe, where it occurs in trachyte; but it is found also in granite, syenite, serpentine, and basalt. The name *sun-stone*, occasionally applied to certain varieties of orthoclase, is properly restricted to a Norwegian oligoclase, presenting an aventurine appearance, which has been referred to the presence of minute crystals of either specular iron, or göthite.

III. Labradorite, or *Labrador felspar*, is a soda-lime-felspar, consisting of silica, 55·75; alumina, 26·50; lime, 11·0; soda, 4·0; peroxide of iron, 1·25; water, 0·50; = 99 (*Klaproth*). This beautiful mineral was first observed by the Moravian missionaries, on the shores of St. Paul's Isle, off the coast of Labrador, where it occurs associated with hypersthene, hornblende, and magnetic iron-ore. It forms a common constituent of most basalts and melaphyres, and occurs also in many recent lavas, as well as in certain meteoric stones.

From the beautiful chatoyant reflections which this mineral exhibits when polished, it is highly valued for purposes of ornament. The parts exhibiting the play of colours are disposed in irregular spots and patches, and the same spot, held in different positions, displays various tints. The cause of this play of colours has not been satisfactorily determined, but it is commonly supposed to proceed from minute internal fissures or cleavage-planes in the stone; whilst the aventurine-like appearance is due to certain microscopic embedded crystals, regarded variously as göthite, specular iron ore, or magnetic pyrites. See Labradorite.

Delesse has applied the name of *Vosgite* to a French labradorite. rendered hydrous by partial alteration.

Andesite is a felspar occurring in the trachyte of the Andes, in the Vosges and elsewhere. Its composition is silica, 60·26; alumina, 25·01; soda, 7·74; lime, 6·87; potash, 0·84; magnesia, 0·14; = 100·86 (*Rammelsberg*).

IV. Anorthite, a lime-felspar, composed of silica, 43·96; alumina, 35·30; lime, 18·98; soda, 0·47; magnesia, 0·45; potash, 0·39; peroxide of iron, 0·63; = 100·18 (*Abich*). It occurs in the ejected limestone-blocks on Monte Somma; and has been found also in the island of Procida, in the Bay of Naples; and in the syenite of Carlingford, in Ireland.

Amphodelite is a Scandinavian anorthite, whilst *Thiorsaurite* is an Icelandic variety. *Barsowite* and *Bytownite* are two closely allied minerals; the former from Siberia, and the latter from Canada. In the species called *Danburite*—a mineral frequently classed with the lime-felspars—a large proportion of the silica is replaced by the analogous compound, boric acid.

Although in many cases it is by no means easy to distinguish the several species of felspar one from another, yet a broad distinction may be readily drawn between those felspars which crystallize in the *monoclinic* (singly-oblique) and those which crystallize in the *triclinic* (doubly-oblique) system. The former present two cleavage planes at right angles to each other, and are hence called *orthoclastic*; whilst the latter have their directions of cleavage oblique to each other, and are therefore called *plagioclastic* felspars. The triclinic or plagioclastic species are characterised by fine striæ on the cleavage planes, indicating the junction of twin-crystals; transparent microscopic sections viewed under polarised light, exhibit coloured bands corresponding with these twin-lamellæ. The plagioclases comprise all species of felspar, except orthoclase and sanidine.

The principal economic value of the felspathic minerals depends on their application to porcelain manufacture, partly as a constituent of the paste itself, but chiefly as a glaze. From the decomposition of the felspar in certain granites, the well-known kaolin, or China clay, is commonly supposed to result. The felspathic minerals are also employed as manures, the alkalis present rendering them especially valuable. See CLAY; POTTERY; MANURES.

FELSPATHIC. Of or belonging to felspar.

FELSPATHIC ROCKS. (*Roches feldspathiques*, Fr.; *Feldspathgesteine*, Ger.) Rocks in which felspar forms an essential and frequently the principal constituent. *Felstone*, *felsite*, or *cornean*, is a rock consisting almost exclusively of a compact orthoclase, associated with a small amount of free silica, and much resembling in its general characters certain forms of quartz, whence it has unfortunately been termed *petrosilex*. From all varieties of quartz, it may however be readily distinguished by its fusibility, and hence it was called by Werner *fusible hornstone*. A felstone occurring with the magnetic iron-ore of Dannemora retains its Swedish name of *Hälleflinta;* and the *leelite* of Dr. Clarke appears to be a very similar rock. The name of *adinole* has been applied by Beudant to a rock closely related to felstone, but consisting of compact albite-felspar. When distinct felspar-crystals are developed in a compact base of felstone, the rock becomes a *felspar-porphyry;* and when these are accompanied by quartz it forms a *quartziferous-porphyry* or *elvanite*. Of these rocks, formed of mixtures of felspar and quartz, several varieties are recognised; such as *eurite*, *aplite*, *granulite*, and *leptynite*. *Pegmatite* is a very similar rock, often known as *graphic granite* from the peculiar disposition of the quartz-crystals in the felspar-base. Such a rock may be termed a *binary granite*, since it requires only the addition of some micaceous mineral to convert it into a true *granite*. The granitic rocks have been divided into numerous varieties founded either on peculiarities of texture, such as *gneiss*, which is commonly regarded as a schistose granite; or on variations in composition, arising generally from the presence of certain accessory minerals: thus, the *beresite* from Bersof in the Ural Mountains is a granite containing iron-pyrites. In certain granitic rocks, the mica is replaced by other minerals giving rise to several distinct varieties: in the Cornish *luxullianite*, for example, it is replaced by schorl, and in the so-called *protogine* of the Alps by talc; whilst in *syenite* its place is supplied by hornblende. In the *zircon-syenite* of Norway, zircon occurs as an accessory constituent; and to this rock the Siberian *miascite* is closely related. On the disappearance of the quartz in syenite, a rock is obtained consisting of felspar and hornblende, and commonly termed *greenstone;* of which rock *diorite*, *aphanite*, *timazite*, and *amphibolite*, may be mentioned as varieties. A singular concretionary greenstone from the Island of Corsica is known as *Napoleonite* or *orbicular diorite*, and sometimes very improperly as *Corsican granite*.

The rocks passing under the names of *basalt*, *dolerite*, *anamesite*, and *melaphyre*, all bear a greater or less resemblance to greenstone, but are distinguished by containing the more basic felspars, labradorite or oligoclase, associated always with augite, and often with various other minerals, such as olivine, magnetic iron-ore, &c. Many of these rocks are popularly united under the general name of *trap*.

Another series of felspathic rocks is formed by those volcanic products of which *trachyte* is the type. This rock consists almost exclusively of felspar, and often becomes porphyritic by the presence of crystals of sanidine. Among the varieties of trachyte may be noticed the *andesite* of the Andes, and the *domite* of the Puy-de-Dôme. *Rhyolite* is a highly-silicated trachytic rock. A compact fissile rock allied to trachyte is termed *phonolite* or *clinkstone*, in allusion to the ringing sound which it emits on being struck.

When trachytic rocks have been completely fused they pass into a vitrified condition, forming a variety of *obsidian* or *volcanic glass*. A capillary form of obsidian from the Sandwich Islands is known as *Pélé's hair*. When obsidian loses its vitreous texture it passes into *pitchstone;* and when presenting a concretionary structure it is termed *pearlstone*. *Pumice* is simply a cellular or fibrous form of felspathic lava.

Special descriptions of such felspathic rocks as are of any practical importance will be found under their respective headings.

FELT. (*Feutre*, Fr.; *Filz*, Ger.) A material formed by working into a sheet, wool or hair, upon the principle of their matting together.

FELTING (*Feutrage*, Fr.; *Filzen*, Ger.) is the process by which loose flocks of wool, and hairs of various animals, as the beaver, rabbit, hare, &c., are mutually interlaced into a compact textile fabric. The first step towards making felt is to mix, in the proper proportions, the different kinds of fibres intended to form the stuff; and then, by the vibratory strokes of the bowstring, to toss them up in the air, and to cause them to fall as irregularly as possible, upon the table, opened, spread, and scattered. The workman covers this layer of loose flocks with a piece of thick blanket stuff slightly moistened; he presses it with his hands, moving the hairs backwards and forwards in all directions. Thus the different fibres get interlaced, by their ends pursuing ever tortuous paths; their vermicular motion being always, however, root foremost. As the matting gets denser, the hand pressure should be increased, in order to overcome the increasing resistance to the decussation.

A first thin sheet of soft spongy felt being now formed, a second is condensed upon it in like manner, and then a third, till the requisite strength and thickness be obtained. These different pieces are successively brought together, disposed in a way suitable to the wished-for article, and united by continued dexterous pressure. The felt must be next subjected to the fulling mill. See Hat Manufacture, and Kamptulicon.

FENKS. The refuse of whale blubber. It is used as a manure, and has been employed in the manufacture of Prussian blue.

FENNEL. The *Anethum Fœniculum*, a plant yielding an aromatic oil. The leaves are used for making sauce; the seeds are carminative.

FENUGREEK. The *Trigonella Fœnum-Græcum*, an herb cultivated throughout Greece and the East as an article of food. The seeds, which alone are used, are eaten, both boiled and raw, mixed with honey. The *Trigonella cærulea* is a native of Switzerland and Bohemia. The flowers are of a delicate blue colour, and have an odour like that of Balsam of Peru. This odour increases by drying, and the Italian perfumers use it extensively. The Swiss use it to flavour some of their cheeses.

FER ACIEREUX. Steely iron produced by the Catalan process. See Iron.

FERMENT (Eng. and Fr.; *Hefe*, Ger.) is the substance which, when added in a small quantity to vegetable or animal fluids, tends to excite those intestine motions, or changes, which accompany fermentation. It seems to be the result of an alteration which vegetable albumen and gluten undergo with contact of air amidst a fermenting mass. The precipitates or lees which fall down, when fermentation is finished, consist of a mixture of the fermenting principle with the insoluble matters contained in the fermented liquor, some of which, like *hordeine*, existed in the worts, and others are probably generated at the time.

To prepare a pure ferment, or at least a compound rich in that principle, the precipitate separated during the fermentation of a clear infusion of malt, commonly called yeast or barm, is made use of. This pasty matter must be washed in cold distilled water, drained and squeezed between the folds of blotting-paper. By this treatment it becomes a pulverulent mass, composed of small transparent grains, yellowish grey when viewed in the compound microscope. It contains much water, and is therefore soft, like moist gluten and albumen. When dried it becomes, like these bodies, translucid, yellowish brown, horny, hard, and brittle. In the soft humid state it is insipid, inodorous, insoluble in water and alcohol. If in this state the *ferment* be left to itself, at a temperature of from 60° to 70° F., but not in too dry a situation, it putrefies with the same phenomena as vegetable gluten and albumen, and leaves, like them, a residuum resembling old cheese. See Fermentation and Yeast.

FERMENT OILS. Volatile oils produced by the fermentation of plants, and not originally contained in them. These were the *quintessences* of the alchemists. In most cases they are obtained by placing the leaves of the flowering plant in water, and allowing them to ferment; after which the liquid is distilled, and the ferment oil usually separated by means of ether. The following ferment oils are described in Watts's 'Dictionary of Chemistry':—

Ferment oil of *Chærophyllum sylvestre.* Wild Chervil. Common parsley.
,, *Chelidonium majus.* The larger celandine.
,, *Conium maculatum.* Common hemlock.
,, *Erythræa centuarium.* Little centuary.
,, *Echium vulgare.* Vipers' bugloss.
,, *Erica vulgaris.* Common heath.
,, *Marrubium vulgare.* White horehound.
,, *Achillea millefolium.* Common yarrow.
,, *Plantago.* The plantain.
,, *Quercus robur.* Oak.
,, *Salix pentandra.* The willow.
,, *Salvia pratensis.* Meadow sage.
,, *Trifolium fibrinum.* The clover.
,, *Tussilago farfara.* Colt's foot.
,, *Vitis vinifera.* The vine.
,, *Urtica urens.* The nettle.
,, *Diseased apples.*

FERMENTATION. (*Fermentation*, Fr.; *Gährung*, Ger.) A change which takes place, under the influences of air and moisture at a certain temperature, in the constituent particles of either vegetable or animal substances. This change is indicated by a sensible internal motion—the development of heat—the evolution of gaseous products. Fermentation may be divided into several kinds, as—

Saccharine,
Acetic,
Alcoholic or Vinous,
Putrefactive,
Butyric,
Glyceric,
Lactic,
Mucous.

Of the latter examples but a brief notice is required. *Mucous fermentation* is established when the juice of the beetroot or carrot is kept at a temperature of 100° for some time, when a tumultuous decomposition takes place. All the sugar disappears, and the liquor is found to contain a large quantity of gum, and of mannite with lactic acid.

Lactic Fermentation.—If a solution of one part of sugar in five parts of water be made to ferment, by the addition of a small quantity of cheese or animal membrane, at a temperature of 90° or 100°, lactic acid is formed, which may be separated by adding a little chalk, the lactate of lime depositing in crystalline grains. In lactic fermentation *mannite* invariably is produced as a secondary product, the formation of which is not explained. It has been suggested that the formation of mannite is connected with the production of succinic acid, which Schmidt, in a letter to Liebig, stated that he had found in fermenting liquids containing sugar. He suggested the following equation (Schmidt's formulæ are retained):—

$$\underbrace{C^8H^9O^8}_{\text{Mannite.}} + \underbrace{C^4H^3O^4}_{\text{Succinic acid.}} = \underbrace{C^{12}H^{12}O^{12}}_{\text{Grape sugar.}}$$

Glyceric Fermentation.—When glycerine is mixed with yeast, and kept in a warm place for some weeks, it is decomposed and converted into *metacetonic acid.* This fermentation resembles the last named. The glycerine, $C^6H^7O^5$, forming metacetonic acid, $C^6H^5O^4$, as sugar, $C^6H^6O^6$, does lactic acid, $C^6H^5O^5$, by loss of the elements of water.—*Kane.*

Butyric Fermentation.—If the lactic fermentation is allowed to proceed beyond the point indicated for the formation of lactate of lime, the precipitate in part redissolves with a very copious evolution of hydrogen gas and carbonic acid, and the liquor contains butyrate of lime. In this action two atoms of lactic acid, $C^{12}H^{10}O^{10}$, produce butyric acid, $C^8H^7O^3$, carbonic acid, and hydrogen gas.

Putrefactive Fermentation. See PUTREFACTION.

The three first-named kinds of fermentation demand a more especial attention from their importance as processes of manufacture. Under the heads respectively of ACETIC ACID, BEER, BREWING, DISTILLATION, MALT, and WINE, will be found everything connected with the practical part of the subject; we have therefore only now to deal with the chemical and physical phenomena which are involved in the remarkable changes which take place. When vegetable substances are in contact with air and moisture, they undergo a peculiar change (*decomposition*). Oxygen is absorbed and carbonic acid and water are given off, while there is a considerable development of heat. This may take place with greater or less rapidity, and thus *eremacausis*, fermentation, or combustion, may be the result; the spontaneous ignition of hay (as an example) being the final action of this absorption of oxygen.

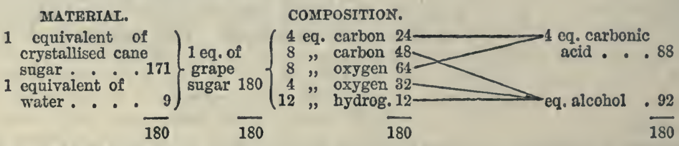
Saccharine Fermentation.—If starch, $C^{12}H^9O^9 + 2HO$, be moistened with an infusion of pale malt, it is rapidly converted into dextrine, $C^{12}H^{10}O^{10}$, and hence into grape sugar, $C^{12}H^{12}O^{12}$; this is especially called the saccharine fermentation, since sugar is the result.

Acetic and Alcoholic Fermentation.—If sugar is dissolved in water, it will remain perfectly unaltered if the air is excluded; but if exposed to the air, a gradual decomposition is brought about, and the solution becomes brown and sour. Oxygen has been absorbed, and *acetic acid* produced. If, however, the sugar is brought into contact with any organic body which is in this state of change, the particles of the sugar participate in the process, carbonic acid is evolved, and *alcohol* produced. There are some substances which are more active than others in producing this change. *Yeast* is the most remarkable; but blood, white-of-egg, glue, and flesh, if they have begun to putrefy, are capable of exciting fermentation; vegetable albumen and gluten being, however, more active. Vegetable albumen, gluten, and legumin differ from most vegetable bodies in the large quantity of nitrogen which they contain. These substances exist in all fruits; and hence, when fruit is crushed, the sugar of the juices in contact with the albumen or gluten being then exposed to the air, oxygen is rapidly absorbed, the nitrogenous body begins to putrefy, and the sugar passes into fermentative activity. The necessity for oxygen is at the commencement of the decomposition; when the putrefaction of the albumen or gluten has once begun, it extends throughout the mass without requiring any further action of the air. These may be regarded as natural ferments. Yeast is an artificial one. This body will be more particularly described. See Yeast.

To produce a vinous liquid, it is necessary that there shall be present sugar, or some body, as starch or gum, capable of conversion into sugar, a certain portion of water, and some ferment—for all practical purposes, *yeast*; and the temperature should be steadily maintained at about 80° Fahr. Both cane and grape sugar yield alcohol by fermentation; but Liebig considered that cane sugar, before it undergoes vinous fermentation, is converted into grape sugar by contact with the ferment, and that, consequently, it is grape sugar alone which yields alcohol and carbonic acid.

Grape sugar, as dried at 212°, contains exactly the elements of two atoms of alcohol and four of carbonic acid; as $2(C^4H^6O^2)$ and $4CO^2$ arise from $C^{12}H^{12}O^{12}$.

Cane sugar takes an atom of water to form grape sugar. It follows therefore that cane sugar should in fermenting yield more than its own weight of carbonic acid and alcohol; and it has been ascertained by experiment that 100 parts actually give 104, whilst by theory 105 should be produced, consisting of 51·3 of carbonic acid, and 53·7 of alcohol.—(*Kane.*) Dr. Pereira has given the following very intelligible arrangement to exhibit these changes:—



These facts will sufficiently prove that vinous or alcoholic fermentation is but a metamorphosis of sugar into alcohol and carbonic acid.

Such are the generally-received views. We find, however, some other views promulgated which it is important to notice.

The following remarks on the Fermentation of Worts, as coming from the hands of a practical brewer, are of considerable value:—

As to the theories respecting the causes of fermentation that have for some time past engaged the attention of the highest scientific talent of the present day, it would be premature, and, perhaps, somewhat to be deprecated, to attempt in an article of this kind to establish either the one theory or the other; it is sufficient to the purposes of the brewer's art to know the general principles that affect fermentation, more particularly the alcoholic fermentation of beer-wort, and a long-past experience has taught us that these can be reckoned up and controlled with all the precision attainable in ordinary chemical manipulations.

The ferment, under the names of Yeast, Barm, Store, or Must, when examined under a tolerably powerful microscope, in physical appearance seems to be composed of innumerable spherical forms, semi-opaque, and somewhat of a cream colour, varying according to the shade imparted to the malt in the process of drying. Perhaps the best way to conduct the examination is as follows:—Select a well-distended bubble of yeast, just touch it with a glass plate, immediately transfer it to the microscope and commence the examination, directing the light from the reflector underneath, so that it shall pass upward through the glass plate. The thin film of yeast adhering to it will then be in a very convenient form for careful examination; it will then at once be seen that the spherules are agglomerated together with just the same accident that would occur with ordinary soap-bubbles, no appearance of any regular organised arrangement being evinced. As the yeast dries, these individual spheres or spherules burst in like manner to the soap-bubble alluded to, and the substance of which it was composed falls on the spot to which it had become fixed; it would appear to have contained gas only, for neither internal structure nor even liquid is discoverable. Now take a drop of the beer-wort in a state of active fermentation, place it on the glass plate support of a microscope, and hold it up to the eye, allowing a sufficiently strong light to pass through it. If the microscope be now rolled round after the manner of an ordinary kaleidoscope, the spherules will be seen to roll about the fluid in exactly the same manner that shot would in the latter instrument; but of course allowance must be made for the difference in their specific gravities respectively, and the density of the medium enveloping each. If some of the bottom yeast be now examined in the like manner, it will appear to have amongst it quantities of these spherules in a ragged condition. In addition to the spherical forms just described, there may be seen extremely minute black specks, having somewhat the shape of a four-rayed rhomboidal star: it is difficult to determine what these may be; their opacity almost precludes the idea of their being of organic origin; perhaps they may be a particle of the lime-salts in an insoluble state, originally contained in the water from which the beer was brewed; many of them are attached to spherules of yeast, after the manner that an air-bubble is sometimes seen to suspend small particles of solid substances.

It often happens that, mixed with the yeast proper, there may be other ferments, and these, so far as science has lent us aid, it is desirable to describe. The lactic ferment is of the most common occurrence. M. W. Schultze is very definite in his description of it. He says: 'When completely developed, it presents an appearance of minute, translucent strips, in four divisions, slightly drawn together in the middle; in its early stages, it only presents a quantity of small specks moving around each other. It refracts light strongly, has a peculiar mild brilliancy, and the contents of the exterior membrane cannot be seen.' M. Pasteur says the diameter of this parasite is about one fifteen-thousandth of an inch, and that by its physical appearance it is most easily distinguished from yeast ferment.

The ordinary atmosphere contains an abundance of germs of ferment, and M. Schultze affirms that the motes floating in the air are, by the spores which they contain, capable of aiding the development of lactic fermentation in worts. M. Hoffman assures us of their presence upon grain and the stalks of grapes; and it is suspected that the dust adhering to grain, and even malt, may be a means of developing lactic fermentations; and, in the same way that yeast multiplies itself in sweet wort, the lactic ferment may also propagate itself, and, independently of the original lactic fermentation, produce what is commonly designated secondary fermentation. M. Schultze says that lactic fermentation requires a supply of nitrogen, and its presence, duration, and force depend on the quantity present of that element. The heating of wort from 140° to 149° appears to oppose the development of the cellules of lactic ferment; a little below 140° its production is slow and not abundant; between 120° and 70° it becomes rapid and energetic; the temperature most favourable to its production being between 95° and 113°. When lactic acid is present in a wort it appears to check a further production of it, but if the free acid be neutralised with soda a fresh formation commences at once. Whenever a wort has become sour, the lactic ferment is always to be found in it, more abundantly in proportion to the amount of spontaneous fermentation that has occurred; therefore spontaneous fermentation is judged to be of lactic origin, and, indeed, is lactic fermentation which has passed its ordinary limits. Experienced chemists also affirm that in the fermentation of beer with yeast, if the temperature is allowed to attain 89° alcohol ceases to be produced, but that the fermentation degenerates into the lactic condition, and lactic acid is the product of it.

Butyric Ferment.—There is another kind of ferment which it is very important to describe, and which, probably, is without exception the most troublesome and deadly of the brewer's enemies; this is the butyric ferment: it appears to originate principally from organic impurities in the water, but it is asserted also to be produced in the ordinary fermentation of beer, if such fermentation be allowed to attain a temperature above 84°; in all cases diarrhœa is produced when it is drunk whether in beer or water; in beer it may be suspected when there is odour of pine-apple, especially if the beer has the character of soon producing headache. Mr. Charles Heisch is of opinion that it is to be found in all water that has become contaminated with sewage, even to the smallest amount; the brewer will do well to make himself acquainted with Mr. Heisch's researches upon this particular subject. It may be briefly stated that the conclusions he appears to have arrived at are: First, that where this ferment is found in water, be the amount of it ever so small, that water must not be used for food purposes till the ferment is thoroughly eradicated from it, for they increase so rapidly under favourable circumstances, that they must ultimately prove injurious to health; Secondly, in any dilute solution of sugar they quickly betray their presence by a turbidity accompanied eventually by the butyric odour. He describes them as minute spherical cells, with, in most cases, a very bright nucleus. Their vitality is in no way destroyed even by half-an-hour's boiling; ordinary filtration, even through the finest Swedish filter-paper, does not remove them; filtering through a good bed of animal charcoal, frequently dried, appears to remove them effectually: the softer the water the more quickly they grow; in hard water they appear at first to form small clots, consisting of cells mixed with crystals of carbonate of lime. The addition of nitrates or ammoniacal salts to the water does not seem to accelerate their growth. By permitting the action of these germs on sugar to go on, at a temperature between 60° and 70°, they present uniformly the following appearances:—The cells generally group together in bunches like grapes, quite differently from the ordinary yeast globules; they next spread out into strings, with a wall surrounding and connecting the cells; the original cell-walls then seem to break, and leave apparently tubular threads branched together.

The following experiment with malt and some very hard water, shows a permanent hardness of 40° and an ordinary hardness of 59°, with so little as only ·010 of free ammonia and ·003 of albuminoidal ammonia, to the 100,000 grains of water. Half-a-pint of this water was placed in a clean glass beaker and covered; it was crystal bright, and remained so for at least three weeks, depositing only carbonate salts as the water evaporated. Ten corns of malt were then put into the water and the beaker replaced in the window, that it should be subjected to as much light as possible. The corns eventually sank, and about 48 hours afterwards the water had attained quite a milky turbidity, bubbles of gas were continually being evolved from the corns, and a distinct and very unpleasant odour arose from the fermentation that was evinced, and which most certainly had not any alcoholic odour about it. Upon examination with the microscope, the minute spherical forms in common with yeast were distinctly to be seen, and where there was room for locomotion many of them appeared to be disporting themselves, very much after the fashion of midges in the air, or the little water-beetle seen so commonly on the surface of a stream on a summer day; amongst them there were also the little specks of opaque substance, already noticed in the microscopical examination of ordinary fermentation with yeast. With only a cursory glance, the observer might easily have been led to suppose that these movements were accidental, but after attentive observation it became quite evident that it was organised work with a definite purpose, which appeared to be to form strings of about five globules, not always straight, and, when these strings were completed, they remained at rest.

Now with these facts before us, let us try to mark out a safe line of conduct for the guidance of the brewer; and the first step is, undoubtedly, to obtain the alcoholic ferment in a state of great purity, and to maintain it in full health and vital energy. Experience proves that these latter qualifications are best secured by allowing the yeast to have contact only with a cold and still atmosphere; and the more intense the cold in contact with it, the more satisfactory will be the result of its application to the purpose of fermentation, as the most intense cold does not even impair the energy of the ferment. Careful selection and cultivation are the principal means to adopt to preserve or obtain yeast in a state of purity; and if it be kept from air currents, there is less danger of infection from the mischievous germs that are always present in the common atmosphere. If grape-juice be introduced into a number of phials, with long, upright, straight necks at the top, thereby giving to the atmosphere free admission to the liquid contained, in process of time spontaneous fermentation generally sets in; but if the necks be bent short round, and turned downwards, fermentation seldom sets in. This is obviously from the increased difficulty the circulating atmosphere has in depositing the germs of lacteous ferment upon the fluid. The knowledge of these facts is valuable, for it shows to us a simple mechanical arrangement by which we may successfully resist the inoculation of our fresh yeast and sound beer-worts from the atmosphere. The means may be thus described:—First, the yeast-safe must be provided with a means of refrigeration, that the progress of fermentation shall be completely arrested; secondly, the circulation of the atmosphere that has actual contact with the yeast must be obstructed as much as possible. Antiseptics must not be resorted to, for whatever will destroy the vitality of either lacteous or butyric ferment, will also have the like effect upon yeast ferment. Neither should it be attempted to decrease acid tendency by the use of neutralising agents, for the door is thus opened for the advancement of the acetic change; and this is why, in the manufacture of lactic acid, that, as the fermentation advances or proceeds, and lactic acid is produced, it is found necessary to continually make to it additions of carbonate of lime, that the existing acid may be taken up; for, if this is not done, the lactic product ceases to be formed before the fermentation is completed.

By the aid of scientific investigations prosecuted to the present time, we are enabled to arrange the different kinds of fermentation and their products. When a glucose solution comes in contact with yeast, about 95 per cent. of it is changed into alcohol and carbonic acid gas, the remaining portion into glycerine, succinic acid, and other compounds; if in the progress of the fermentation, the heat be allowed to rise considerably, some of the alcohol present becomes oxidised, and acetic acid is the result; the germs of lacteous ferment also increase rapidly (being already present in the solution), for it is practically impossible to prepare a saccharine wort that shall be entirely free from them; any breath of air that passes over it, the vessel that contains it, or any substance whatever that touches the liquid, may be the medium of their introduction and incorporation with it; and, being there, it is only a question of circumstance and time, when they will assert their presence, lactic acid and mannite being the products of the fermentation induced by them. If this lactic fermentation be allowed to spend itself, the ferment appears to degenerate into the butyric form, and butyric acid is the product, carbonic anhydride and hydrogen being evolved.

Respecting the temperatures adjudged to be the best for favouring alcoholic fermentation, this is a subject to which we must give the most patient reasoning; for, although brewing is an art known and practised throughout the world from time immemorial, it is a curious circumstance, that in no part of the manipulation is there so much diversity of opinion as upon this one point—temperature; but it is not to be wondered at, when we take into consideration that it is upon the particularly nice attainment of a peculiar flavour, that one beer is appreciated by some, and a totally different one by others; so we see that the 'right flavour' varies with the palate of the consumer, and that for its attainment we have to rely almost entirely upon the due proportion of the various products of fermentation. This no doubt explains to some extent the cause of the different temperatures that are in favour with different brewers. But there is another circumstance that it will be well to consider. It is, perhaps, much to be regretted that the chemists who have given us the results of their researches have not considered it necessary to state the bulk of the material upon which they operated in the prosecution of their experiments, for undoubtedly this circumstance has an important effect upon the temperature indicated; the rate at which the heat is generated, is transmitted by the vessel containing the fermenting wash, and is absorbed or carried off by the surrounding medium, must have its effect upon the thermometer's indications, and upon the resulting products of the fermentation. In conducting a mash, we know that for the complete transformation of the starch in a small mash, a considerably higher mashing-temperature is required than is necessary for a large mash; and by the same rule, fermentations must be conducted in small vessels with a higher temperature than is required for larger vessels. But in proportion as the yeast is subjected to the higher temperatures, or prolonged exposure, so it degenerates both in vitality and character; therefore it is best to maintain a uniformly low temperature, and give the required impetus by an allowance of a larger quantity of yeast. It would have been of considerable advantage to us as brewers, if those gentlemen to whom we are so much indebted had stated the particular kinds of ferment that appeared to be mostly developed by the influence of the temperature and time attendant on the fermentations which were the subject of their researches; but their investigations have, however, proved to us thus much:—

1. That alcoholic fermentation with ordinary brewer's yeast may be conducted with a temperature so low even as 40° Fahr.

2. That alcohol in the presence of gluten or yeast at temperatures above 52° is liable to become acetic.

3. That at temperatures above 61° the germs of lacteous ferment begin to show vitality.

4. That at temperatures above 84° alcoholic fermentation ceases, and lactic fermentation degenerates into the butyric formation.

In apportioning the quantity of yeast to a brewing, the gravity of the wort must be a first consideration.

In practice we find that with different gravities it does not answer to apportion yeast by the rule of proportion, taking gravity for the data of calculation, for the higher gravities require a higher percentage to be allowed them than the lower gravities; this arises from two causes:

1st. It is self-evident that, as soon as fermentation commences, the amount of alcohol manufactured in a certain bulk of wort of a high gravity must bear a greater proportion to that bulk than would the alcohol produced from the same bulk of wort at a low gravity; and it is found that the presence of alcohol in a wort has the power of arresting the progress of fermentation, the more effectually as the quantity present bears a higher proportion to the bulk. Of course, therefore, this is more easily accomplished in worts of high gravities; and, in order to carry on the attenuation in such worts, an extra quantity of yeast must be allowed to meet this emergency.

For this reason it is sometimes found necessary to supplement the first addition of yeast to a brewing by another portion to be added when the fermentation appears sluggish, before the full amount of attenuation is reached; and it is a good plan at this time to freshen up the vitality of the ferment by a slight addition of *malt meal* well whisked up with it.

2nd. If worts of different gravities be examined thirty-six hours after the setting-on has occurred, it will be found that each pound of yeast added will have done the work of attenuation at a greater rate in the lighter gravities than will be the case with the heavier worts. This undoubtedly arises in a great measure from the presence in the lighter worts of the larger proportion of albuminous constituents, and this condition adds considerably to the energy of the fermentation. The increased percentage of the albuminoids occurring in worts of light gravities, arises simply from the fact that for them the exhaustion of the malt is usually carried as far as possible; the stronger worts consequently consisting of the more soluble saccharine constituents.

From the foregoing remarks it will be seen that there is great difficulty in the way of an attempt to give a reliable rule for apportioning the quantity of yeast to a brewing, for there are many points to consider. These it will be well to recapitulate:—

1. The temperature at which it is intended to conduct the fermentation; the lower this is the more yeast must be used.

2. The specific gravity of the ale to be fermented; the higher this is, the greater must be the percentage of the yeast apportioned.

3. The extent to which the exhaustion of the malt has been carried; the more so that this has been permitted, the less yeast must be used and the more slowly must the fermentation be conducted.

The extent to which granulation of the malt has occurred in the process of crushing; the more it has been pressed, the less yeast must be used, and the more slowly must the fermentation be conducted.

The character of the water used in the process of brewing, undoubtedly has its effect, though it is but seldom taken into account; the harder the water is, the more yeast by a considerable proportion must be allowed. This latter consideration leads us on to a subject, the importance of which cannot be over-estimated, however some may assume to deride it; but it does not require any elaborate reasoning to show that quality in the water is an advantage almost equal to quality in the malt and hops. It cannot be denied that the practical dyer must be master of the constituents contained in the water he uses in his processes, before he can hope for unvarying success; neither can we disregard the well-known effect of drinking water in its hard state; and recent researches bear testimony to how small a quantity of organic impurity in any water makes it extremely prejudicial as an article of food. These facts speak for themselves, and point to the necessity there is that every brewer should have the means of readily ascertaining the quality of the water he brews with. Amongst the most successful of the trade this necessity is acknowledged and met as well as possible by a frequent analysis of the waters supplied to the brewery; but the ordinary brewer has very seldom the time, the means, or the requisite ability to make a complete analysis of the water; but he may make an approximate analysis with rapidity and great advantage, much oftener than is customary. Let him study the use of permanganate of potash in the volumetric analysis for organic matter described in Mr. Sutton's 'Volumetric Analysis.' The ordinary and permanent hardness can also be easily tested, as also the presence of ammonia-compounds, and these are perhaps the facts which require watching in the waters supplied to breweries.

In conducting a healthy alcoholic fermentation, the following general rules should be observed:—The wort should be purified as much as possible from gross constituents and acetic tendency, first by using in its manufacture a water the lime-salts of which will aid in their precipitation. (Of the beneficial influence of the hard waters favoured by the brewer, Dr. Hassall suggests a theory which appears very satisfactory. He says: 'During ebullition, the excess of carbonic acid in the water, by which the carbonates of lime and magnesia are retained in solution, is expelled, and those salts are precipitated. Again, the alkaline phosphates present in malt have the power of converting the sulphate of lime into phosphate, which is thrown down; an alkaline sulphate, which is soluble, being synchronously formed. The greater part of the phosphate of lime produced, is re-dissolved in the acid generated during fermentation; consequently, the water, from being hard, thus becomes soft, and in this state is well suited for extracting the active properties of the malt and hops.') Secondly. The wort should be cleared by every means that care and mechanical ingenuity can provide.

The yeast for setting-on should be selected with every care, freed as much as possible from the gross flocks accruing in preceding manipulations, from tannic and gallic acids (the product of the hop), from atmospheric contaminations, and from acetic and butyric germs. It should be as virgin as possible, and the lower the temperature at which it was produced the better it will be. When about to be applied, the wort with which it is to be mixed should be of such a temperature as to induce immediately an active fermentation; this temperature must of course vary according to the gravity and bulk of the wort, say for bulks of about 25 barrels of a gravity of 22 lbs. per barrel; the temperature for stone squares may be from 67° to 70°, and for wood rounds from 64° to 67°. Let the yeast be added as soon as the wort begins to run into the fermenting utensil, and decrease the temperature by the subsequent running down, and the whole should be most thoroughly roused many times during the process of filling.

As to temperature, avoid extremes, and especially dangerously high ones; rather employing an extra quantity of yeast than a high temperature; and the less heating that is attempted, in the progress of the fermentation, by the means of attemperaters, the better. The fermentation should be expedited by all safe means available, for either heat or protracted working diminish the alcoholic excellence and tend to impair the flavour, in proportion as they have been permitted to affect the process.

When the desired amount of attenuation is obtained, no time should be lost in freeing the alcoholised product from degeneracy by contact with the yeast, and preserving by refrigeration as much as possible of the alcohol and carbonic acid gas that have been generated. To this end it is best to draw off the alcoholised product as quietly as possible into a clean settling back provided with a means of refrigeration, and when it has become sufficiently bright, rack and store at once; great experience and judgment are a necessity in determining this last point, and no amount of theory can supply the lack of them. Peculiarities of water, modes of mashing and fermentation, character of the barley season and malting, state of the weather, gravity of the wort, and peculiarities of the market for which the beer is brewed, are all points which have to be carefully attended to, or the previous management and care will result only in bitter disappointment. On the care with which the settling and racking have been conducted depend the flavour, brilliancy, and briskness of the product. Finings of any sort are of very little avail, and if their effects were more generally known, they would be but very seldom used; for, chemically, they must be injurious both to the beer and the consumer, and practically they prove so both to the cask and its contents. If they meet with either acids or alkalis, acetic and lactic tendencies are generated in the alcoholic solution with which they are mixed, and by their decay butyric decomposition is generated. If they are rendered insoluble, they become indigestible, and this latter result is found to be the effect of bisulphate of lime. All finings, be they soluble or insoluble, flatten the beers when mixed by the amount of agitation they require to make them take effect; thereby much of the carbonic acid gas (which is the product that gives to beers that brilliancy, sparkle, and pungency so grateful to the consumer's palate) is liberated and lost, and this also diminishes the keeping ability of the beer.

Liebig calls *putrefactive fermentation* every process of decomposition which, caused by external influences in any part of an organic compound, proceeds through the entire mass without the further co-operation of the original cause. *Fermentation*, according to Liebig's definition, is the decomposition exhibited in the presence of putrefying substances or ferments, by compounds nitrogenous or non-nitrogenous, which alone are not capable of putrefaction. He distinguishes, in both putrefaction and fermentation, processes in which the oxygen of the atmosphere continually co-operates, from such as are accomplished without further access of atmospheric air.

Liebig opposes the view which considers putrefaction and fermentation as the result of vital processes, the development of vegetable formations or of microscopic animals. He adduces that no trace of vegetable formations are perceptible in milk which is left for some time in vessels carefully tied over with blotting-paper, not even after fermentation has regularly set in, a large quantity of lactic acid having been formed. He further remarks of fermentative processes, that alcoholic fermentation having been observed too exclusively, the phenomena have been generalised, while the explanation of this process ought to be derived rather from the study of fermentative phenomena of a more general character.

Blondeau propounds the view that every kind of fermentation is caused by the development of fungi. Blondeau states that alcoholic fermentation is due to a fungus which he designates *Torula cerevisiæ;* whilst another, *Penicillium glaucum*, gives rise to lactic fermentation. The latter fermentation follows the former in a mixture of 30 grm. of sugar, 10 grm. of yeast, and 200 c. c. of water, which has undergone alcoholic fermentation at a temperature of about 20°, being terminated in about two days. Beer yeast, when left in contact with water in a dark and moist place, contains, according to Blondeau, germs both of *Torula cerevisiæ*, and of *Penicillium glaucum;* the former can be separated by a filter, and will induce alcoholic fermentations in sugar-water, whilst the latter are extremely minute, and pass through the filter; the filtrate, mixed with sugar-water, gives rise to lactic fermentation. Acetic fermentation is due to the development of *Torula aceti;* sugar is converted into acetic acid without evolution of gas, if 500 grm. dissolved in a litre of water be mixed with 200 grm. of casein, and confined in contact for a month at a temperature of about 20°. The conversion of nitrogenous substances into fat—for instance, of casein, in the manufacture of Roquefort cheese; of fibrin under similar circumstances, which Blondeau designated by the term fatty fermentation (*fermentation adipeuse*)—is caused by *Penicillium glaucum* or *Torula viridis;* and the former fungus is stated to act likewise in butyric and in urea fermentation (conversion of the urea into a carbonate of ammonia).

Opposed to this view Schubert has published an investigation upon yeast. In order to prove that the action of yeast is due merely to its porosity, he founds his investigation upon some experiments of Brendecke (particularly in reference to the statement that fermentation taking place in a solution of sugar in contact with porous bodies is due to an impurity of sugar); according to which various porous bodies, such as charcoal, paper, flowers of sulphur, &c., to which some bitartrate of ammonia is added, are capable of inducing fermentation in a solution of raw sugar. His observations are also based upon some experiments of his own, which seem to indicate that porous bodies, even without the addition of a salt, are capable of exciting fermentation in a solution of (pure?) cane-sugar. Whatever may be the means whereby alcoholic fermentation is induced, he states it to be indispensable that the body in question should be exposed for some time to the influence of air, and that oxygen and carbonic acid are absorbed by the ferment. Both oxygen and carbonic acid, being electro-negative substances, stand in opposition to the electro-positive alcohol, and therefore predispose its formation, but only when they are highly condensed by the powerful surface-attraction of the yeast, or of any porous body. The electrical tension, he states, may be increased by many salts, provided that the latter do not at the same time chemically affect either the sugar or the ferment.

C. Schmidt has communicated the results of his experiments to the '*Annal. Chem. Pharm.*' After stating numerous experiments, he continues: 'Nor are fungi the *primum movens* of saccharine fermentation; the clear filtrate obtained by throwing almonds crushed in water upon a moist filter, soon induces fermentation in a solution of urea and of grape-sugar; in the latter case, no trace of ferment-cells can be discovered under the microscope, not even after fermentation is fully developed. If the solution, still containing sugar, is allowed to stand eight days or a fortnight after fermentation has ceased, an exuberant development of cellular aggregations is observed, but no putrefaction ensues; the fungi, well washed and introduced into a fresh solution of grape-sugar, continue to grow luxuriantly, inducing, however, if at all, but very weak fermentation, which rapidly ceases; hence the growth of fungi during fermentative processes is but a secondary phenomenon. The increase of the residuary ferment, which occurs after yeast has been in contact with sugar, arises from a development of ferment cellulose, which probably takes place at the expense of the sugar. If muscle, gelatine, yeast, &c., in a very advanced state of putrid decomposition be introduced into a solution of 1 sugar in 4 water, all phenomena of putrefaction disappear; after a few hours, active fermentation sets in, ferment-cells being formed, and the liquid contains alcohol, but no mannite. The inactivity of crushed yeast is due, not to the destruction of the fungi, but to the chemical changes which are induced in yeast during the considerable time necessary for complete comminution. The crushed cells, introduced into sugar-water, give rise to the production of lactic acid, without evolution of gas.' Schmidt is of opinion that fermentation is a process analogous to the formation of ether. He believes that one of the constituents of yeast, together with the elements of grape-sugar, gives rise to the formation of one or several compounds, which are decomposed *in statu nascenti* (like sulpho-vinic acid), splitting into alcohol and carbonic acid.

We believe that the preceding paragraphs fairly represent the views which have been promulgated upon the phenomena of change, which are in many respects analogous to those of combustion and of vitality, presented in the fermentative processes. Much has been done, but there are still some points which demand the careful attention of the chemist.

In a practical point of view, the question which arises from the alteration in the specific gravity of the fluid by fermentation is a very important one, a knowledge of the original gravity of beer being required to fix the drawback allowed upon beer when exported, according to the terms of 10 Vict. c. 5. By this act a drawback is granted of 5*s.* per barrel of thirty-six gallons upon beer exported, of which 'the worts used *before fermentation* were not of less specific gravity than 1·054, and not greater specific gravity than 1·081,' and a drawback of 7*s.* 6*d.* per barrel upon beer of which 'the worts used *before fermentation* were not of less specific gravity than 1·081.' The brewer observes the original gravity of his worts by means of some form of the hydrometer, and preserves a record of his observation. The revenue officer has only the beer, from which he has to infer the original gravity. From the great uncertainty which appeared to attend this question, Professors Graham, Hofmann, and Redwood were employed by the Board of Inland Revenue to discover how the original gravity of the beer might be ascertained most accurately from the properties of the beer itself. When worts are fermented, the sugar passes into alcohol, and they lose in density, and assume as beer a different specific gravity.

The gravity of the wort is called the *original gravity*—that of the beer, *beer-gravity.* The report of Graham, Hofmann, and Redwood, upon 'original gravities,' may be supposed to be in the hands of every brewer; but as some of the points examined materially explain many of the phenomena of vinous fermentation, we have transferred a few paragraphs to our pages:—

'As the alcohol of the beer is derived from the decomposition of saccharine matter only, and represents approximately double its weight of starch-sugar, a speculative original gravity might be obtained by simply increasing the extract-gravity of the beer by that of the quantity of starch-sugar known to be decomposed in the fermentation. The inquiry would then reduce itself to the best means of ascertaining the two experimental data, namely, the extract-gravity and the proportion of alcohol in the beer, particularly of the latter. It would be required to decide whether the alcohol should be determined from the gravity of the spirits distilled from the beer; by the increased gravity of the beer when its alcohol is evaporated off; by the boiling-point of the beer, which is lower the larger the proportion of alcohol present; or by the refracting power of the beer upon light—various methods recommended for the valuation of the spirits in beer.

'Original gravities so deduced, however, are found to be useless, being in error and always under the truth, to an extent which has not hitherto been at all accounted for. The theory of brewing, upon a close examination of the process, proves to be less simple than is implied in the preceding assumption; and other changes appear to occur in worts, simultaneously with the formation of alcohol, which would require to be allowed for before original gravities could be rightly estimated. It was found necessary to study the gravity, in solution of each by itself, of the principal chemical substances which are found in fermented liquids. These individual gravities defined the possible range of variation in original gravity, and they brought out clearly for the first time the nature of the agencies which chiefly affect the result.

'The use of cane-sugar is now permitted in breweries, and the solution of sugar may be studied first as the wort of simplest composition. The tables of the specific gravity of sugar solutions, constructed by Mr. Bate, have been verified, and are considered entirely trustworthy. The numbers in the first and third columns of Table I., which follow, are however, from new observations. It is to be remarked that these numbers have all reference to weights, and not to measures. A solution of cane-sugar, which contains 25 grains of sugar in 1000 grains of the fluid, has a specific gravity of 1010·1, referred to the gravity of pure water taken as 1000; a solution of 50 grains of cane-sugar in 1000 grains of the fluid, a specific gravity of 1020·2, and so on. The proportion of carbon contained in the sugar is expressed in the second column; the numbers being obtained from the calculation that 171 parts by weight of cane-sugar ($C^{12}H^{11}O^{11}$) consist of 72 parts of carbon, 11 parts of hydrogen, and 88 parts of oxygen; or of 72 parts of carbon combined with 99 parts of the elements of water. It is useful to keep thus in view the proportion of carbon in sugar solutions, as that element is not involved in several of the changes which precede or accompany the principal change which sugar undergoes during fermentation, and which changes only affect the proportion of the oxygen and hydrogen, or elements of water, combined with the carbon. The proportion of oxygen and hydrogen in the altered sugar increases or diminishes during the changes referred to; but the carbon remains constant, and affords, therefore, a fixed term in the comparison of different solutions.

TABLE I.—*Specific gravity of solutions of Cane-sugar in water.*

Cane-sugar, in 1000 parts by weight	Carbon in 1000 parts by weight	Specific Gravity
25	10·53	1010·1
50	21·05	1020·2
75	31·58	1030·2
100	42·10	1040·6
125	52·63	1051
150	63·16	1061·8
175	73·68	1072·9
200	84·21	1083·8
225	94·73	1095·2
250	105·26	1106·7

'When yeast is added to the solution of cane-sugar in water, or to any other saccharine solution, and fermentation commenced, the specific gravity is observed to fall, owing to the escape of carbonic acid gas, and the formation of alcohol, which is specifically lighter than water; 171 grains of sugar, together with 9 grains of water, being converted into 92 grains of alcohol and 88 grains of carbonic acid ($C^{12}H^{11}O^{11}+HO=2C^{4}H^{6}O^{2}+4CO^{2}$). But if the process of fermentation be closely watched, the fall of gravity in cane-sugar will be found to be preceded by a decided increase of gravity. Solutions were observed to rise from 1055 to 1058, or 3 degrees of gravity, within an hour after the addition of the yeast, the last being in the usual proportion for fermentation. When the yeast was mixed in minute quantity only, such as $\frac{1}{300}$ of the weight of the sugar, the gravity of the sugar solution rose gradually in four days from 1055 to 1057·91, or also nearly 3 degrees; with no appearance, at the same time, of fermentation or of any other change in the solution. This remarkable increase of density is owing to an alteration which takes place in the constitution of the cane-sugar, which combines with the elements of water and becomes starch-sugar: a change which had been already proved by H. Rose and by Dubrunfaut to precede the vinous fermentation of cane-sugar. The same conversion of cane-sugar into starch-sugar, with increase of specific gravity, may be shown by means of acids as well as of yeast. A solution of 1000 parts of cane-sugar in water, having the specific gravity 1054·64, became with one part of crystallised oxalic acid added to it 1051·7; and, being afterwards heated for twenty-three hours to a temperature not exceeding 128° Fahr., it was found (when cooled) to have attained a gravity of 1057·63—an increase again of nearly 3 degrees of gravity.'

The difference between the gravities of solutions of cane-sugar and starch-sugar are of great practical value, but these must be studied in the original; the result, however, being 'that the original gravity of a fermented liquid or beer must be different, according as it was derived from a wort of cane-sugar or of starch-sugar.'

The gravity of malt wort was determined to be intermediate between that of pure cane-sugar and starch-sugar, and solutions containing an equal quantity of carbon exhibited the following gravities:—

Cane-sugar – 1072·9 Pale malt – 1074·2 Starch-sugar – 1076·0

Two other substances were found to influence the original gravity of the wort: dextrin, or the gum of starch, and caramel. Tables are given of the specific gravities of these, from which the following results have been deduced:—

Starch-sugar	1076
Dextrin	1066·9
Caramel	1062·3

Caramel is stated to interfere more than dextrin in giving lightness or apparent attenuation to fermented worts, without a corresponding production of alcohol.

'Another constituent of malt wort, which should not be omitted, is the soluble azotised or albuminous principle derived from the grain. The nitrogen was determined in a strong wort of pale malt with hops, of the specific gravity 1088, and containing about 21 per cent. of solid matter. It amounted to 0·217 per cent. of the wort, and may be considered as representing 3·43 per cent. of albumen. In the same wort, after being fully fermented, the nitrogen was found to amount to 0·134 per cent., equivalent to 2·11 per cent. of albumen. The loss observed of nitrogen and albumen may be considered as principally due to the production and growth of yeast, which is an insoluble matter, at the cost of the soluble albuminous matter. Solutions of egg-albumen in water, containing 3·43 and 2·11 per cent. respectively of that substance, were found to have the specific gravities of 1004·2 and 1003·1. Hence a loss of density has occurred during fermentation of 1·1 degree on a wort of 1088 original gravity, which can be referred to a change in the proportion of albuminous matter. It will be observed that the possible influence of this substance and of the greater or less production of yeast during fermentation, upon the gravity of beer, are restricted within narrow limits.'

The reporters proceed:—

'The process required for the determination of the original gravity of beer must be easy of execution, and occupy little time. It is not proposed, in the examination of a sample, to separate by chemical analysis the several constituents which have been enumerated. In fact, we are practically limited to two experimental observations on the beer, in addition to the determination of its specific gravity.

'One of these is the observation of the amount of solid or extractive matter still remaining after fermentation, which is always more considerable in beer than in the completely-fermented wash of spirits. A known measure of the beer might be evaporated to dryness, and the solid residue weighed; but this would be a troublesome operation, and could not indeed be executed with great accuracy. The same object may be attained with even a more serviceable expression for the result, by measuring exactly a certain quantity of the beer, such as four fluid ounces, and boiling it down to somewhat less than half its bulk in an open vessel, such as a glass flask, so as to drive off the whole alcohol. The liquid when cool is made up to four fluid ounces, or the original measure of the beer, and the specific gravity of this liquid is observed. It has already been referred to as to the extract-gravity of the beer, and represents a portion of the original gravity. Of a beer of which the history was known, the original gravity of the malt wort was 1121, or 121°; the specific gravity of the beer itself before evaporation, 1043; and the extract-gravity of the beer 1056·7, or 56·7°.

'The second observation which can be made with sufficient facility upon the beer, is the determination of the quantity of alcohol contained in it. This information may be obtained most directly by submitting a known measure of the beer to distillation, continuing the ebullition till all the alcohol is brought over, and taking care to condense the latter without loss. It is found in practice that four ounce-measures of the beer form a convenient quantity for the purpose. This quantity is accurately measured in a small glass flask, holding 1750 grains of water when filled up to a mark in the neck. The mouth of the small retort containing the beer is adapted to one end of a glass tube-condenser, the other end being bent and drawn out for the purpose of delivering the condensed liquid into the small flask previously used for measuring the beer. The spirituous distillate should then be made up with pure water to the original bulk of the beer, and the specific gravity of the last liquid be observed by the weighing bottle, or by a delicate hydrometer, at the temperature of 60° Fahr. The lower the gravity the larger will be the proportion of alcohol, the exact amount of which may be learned by reference to the proper tables of the gravity of spirits. The spirit-gravity of the beer already referred to proved to be 985·25; or it was 14·05° of gravity less than 1000, or water. The "spirit-indication" of the beer was therefore 14·05°; and the extract-gravity of the same beer 56·7°.

'The spirit-indication and extract-gravity of any beer being given, do we possess data sufficient to enable us to determine with certainty the original gravity? It has already been made evident that these data do not supply all the factors necessary for reaching the required number by calculation.

'The formation of the extractive matter, which chiefly disturbs the original gravity, increases with the progress of the fermentation; that is, with the proportion of alcohol in the fermenting liquor. But we cannot predicate from the theory any relation which the formation of one of these substances should bear to the formation of the other, and are unable, therefore, to say beforehand that because so much sugar has been converted into alcohol in the fermentation, therefore so much sugar has also been converted into the extractive substance. That a uniform, or nearly uniform relation, however, is preserved in the formation of the spirits and extractive substance in beer brewing, appears to be established by the observations which follow. Such an uniformity in the results of the vinous fermentation is an essential condition for the success of any method whatever of determining original gravities, at least within the range of circumstances which affect beer brewing. Otherwise two fermented liquids of this class, which agree in giving both the same spirit-indication and the same extractive gravity, may have had different original gravities, and the solution of our problem becomes impossible.'

The following table, one of several of equal value, gives the results of a particular

TABLE II.—*Fermentation of Sugar-Wort of original gravity* 1055·3.

I Number of Observation	II Period of Fermentation		III Degrees of Spirit-Indication	IV Degrees of Extract-Gravity	V Degrees of Extract-Gravity *lost*
	Days	Hours			
1	0	0	0	55·30	0
2	0	6	1·59	52·12	3·18
3	0	12	2·57	47·82	7·48

5	0	23	4·33	40·13	15·17
6	1	5	5·31	35·50	19·80
7	1	12	6·26	31·39	23·91
8	1	19	7·12	27·63	27·67
9	2	11	8·59	20·26	35·04
10	3	11	9·87	13·40	41·90
11	5	12	10·97	7·60	47·70
12	6	12	11·27	4·15	51·15

fermentation of cane-sugar. 'Fifteen and a half pounds of refined sugar were dissolved in 10 gallons of water, making $10\frac{7}{8}$ gallons of solution, of which the specific gravity was 1055·3 at 60°; and after adding three fluid pounds of fresh porter yeast, the specific gravity was 1055·95. The original gravity may be taken as 1055·3 (55·3°).

'Columns III. and V. respectively exhibit the spirit which has been produced, and the solid matter which has disappeared; the first in the form of the gravity of the spirit, expressed by the number of degrees it is lighter than water, or under 1000, and the second by the fall in gravity of the solution of the solid matter remaining below the original gravity 1055·3. This last value will be spoken of as "degrees of gravity lost;" it is always obtained by subtracting the extract-gravity (column IV.) from the known original gravity. To discover whether the progress of fermentation has the regularity ascribed to it, it was necessary to observe whether the same relation always holds between the columns of "degrees of spirit-indication" and "degrees of gravity lost." It was useful, with this view, to find what degrees lost corresponded to whole numbers of degrees of spirit-indication. This can be done safely from the preceding table, by interpolation, where the numbers observed follow each other so closely. The corresponding degrees of spirit-indication and of gravity lost, as they appear in this experiment upon the fermentation of sugar, are as follow:—

TABLE III.—*Fermentation of Sugar-Wort of original gravity* 1055·3.

Degrees of Spirit-Indication	Degrees of Extract-Gravity lost	Degrees of Spirit-Indication	Degrees of Extract-Gravity lost
1	1·71	7	27·01
2	4·74	8	31·87
3	9·26	9	37·12
4	13·48	10	42·55
5	18·30	11	47·88
6	22·54		

'In two other fermentations of cane-sugar, the degrees of gravity lost, found to correspond to the degrees of spirit-indication, never differed from the numbers of the preceding experiment, or from one another, more than 0·9° of gravity lost. This is a sufficiently close approximation.

'The following table is of much importance:—

TABLE IV.—STARCH-SUGAR.

Degrees of Spirit-Indication, with corresponding degrees of gravity lost.

Besides the degrees of gravity lost corresponding to whole degrees of spirit-indication, the degrees of gravity lost corresponding to tenths of a degree of spirit-indication are added from calculation.

Degrees of Spirit-Indication	·0	·1	·2	·3	·4	·5	·6	·7	·8	·9
0	...	·2	·3	·5	·7	·9	1·0	1·2	1·4	1·6

2	5·0	5·4	5·8	6·2	6·6	7·0	7·5	8·0	8·5	9·0
3	9·5	9·9	10·3	10·7	11·2	11·6	12·0	12·4	12·8	13·3
4	13·8	14·2	14·6	15·0	15·5	15·9	16·3	16·7	17·2	17·7
5	18·3	18·7	19·1	19·5	19·9	20·3	20·8	21·2	21·7	22·2
6	22·7	23·1	23·5	23·9	24·4	24·7	25·2	25·6	26·1	26·6
7	27·1	27·6	28·1	28·6	29·1	29·6	30·0	30·5	31·0	31·5
8	32·0	32·5	33·0	33·5	34·0	34·5	35·0	35·5	36·0	36·6
9	37·2	37·7	38·2	38·7	39·2	39·7	40·3	40·8	41·3	41·8
10	42·4	42·9	43·4	44·0	44·5	45·0	45·6	46·1	46·6	47·2
11	47·7									

'It is seen from this table that for 5° of spirit-indication, the corresponding degrees of gravity lost are 18·3°. For 5·9° of spirit-indication, the corresponding degrees of gravity lost are 22·2°.

'This table is capable of a valuable application, for the sake of which it was constructed. By means of it, the unknown original gravity of a fermented liquid or beer from cane-sugar may be discovered, provided the spirit-indication and extract-gravity of the beer are observed. Opposite to the spirit-indication of the beer in the table, we find the corresponding degrees of gravity lost, which last, added to the extract-gravity of the beer, gives its original gravity.

'Suppose the sugar beer exhibited an extract-gravity of 7·9° (1007·9), and spirit-indication of 11°. The latter marks, according to the table, 47·7° of gravity lost, which added to the observed extract-gravity, 7·9°, gives 55·6° of original gravity for the beer (1055·6).'

Similar tables are constructed for starch-sugar, and for various worts with and without hops.

After explaining many points connected with the problem, as it presented itself under varied conditions as it respected the original worts, the Report proceeds:—

'The object is still to obtain the spirit-indication of the beer. The specific gravity of the beer is first observed by means of the hydrometer or weighing bottle. The extract-gravity of the beer is next observed as in the former method; but the beer for this purpose may be boiled in an open glass flask till the spirits are gone, as the new process does not require the spirits to be collected. The spiritless liquid remaining is then made up to the original volume of the beer as before. By losing its spirits, the beer of course always increases in gravity, and the more so the richer in alcohol the beer has been. The difference between the two gravities is the new spirit-indication, and is obtained by subtracting the beer-gravity from the extract-gravity, which last is always the higher number.

'The data in a particular beer were as follow:—

Extract-gravity	1044·7
Beer-gravity	1035·1
Spirit-indication	9·6°

'Now the same beer gave by distillation, or the former method, a spirit-indication of 9·9°. The new spirit-indication by evaporation is, therefore, less by 0·3° than the old indication by distillation. The means were obtained of comparing the two indications given by the same fermented wort or beer in several hundred cases, by adopting the practice of boiling the beer in a retort, instead of an open flask or basin, and collecting the alcohol at the same time. The evaporation uniformly indicated a quantity of spirits in the beer nearly the same as was obtained by distillation, but always sensibly less, as in the preceding instance. These experiments being made upon fermented liquids of known original gravity, the relation could always be observed between the new spirit-indication and the degrees of specific gravity lost by the beer. Tables of the degrees of spirit-indication, with their corresponding degrees of gravity lost, were thus constructed, exactly in the same manner as the tables which precede; and these new tables may be applied in the same way to ascertain the original gravity of any specimen of beer. Having found the degrees of spirit-indication of the beer by evaporation, the corresponding degrees of gravity lost are taken from the table; and adding these degrees to the extract-gravity of the beer, also observed, the original gravity is found. Thus the spirit-indication (by the evaporation method) of the beer lately referred to, was 9·6°, which mark 43° of gravity lost in the new tables. Adding these to 1044·7, the extract-gravity of the same beer, 1087·7 is obtained as the original gravity of the beer.'

The results of the extensive series of experiments made, were, that the problem could be solved in the two extreme conditions in which they have only to deal with the pure sugars entirely converted into alcohol.

'The real difficulty is with the intermediate condition, which is also the most frequent one, where the solid matter of the beer is partly starch-sugar and partly extractive; for no accurate chemical means are known of separating these substances, and so determining the quantity of each in the mixture.

'But a remedy presented itself. The fermentation of the beer was completed by the addition of yeast, and the constituents of the beer were thus reduced to alcohol and extractive only, from which the original gravity, as is seen, can be calculated.

'For this purpose, a small but known measure of the beer, such as four fluid ounces, was carefully deprived of spirits by distillation, in a glass retort. To the fluid, when cooled, a charge of fresh yeast, amounting to 150 grains, was added, and the mixture kept at 80° for a period of sixteen hours. Care was taken to connect the retort, from the commencement, with a tube condenser, so that the alcoholic vapour which exhaled from the wash during fermentation should not be lost. When the fermentation had entirely ceased, heat was applied to the retort to distil off the alcohol, which was collected in a cooled receiver. About three-fifths of the liquid were distilled over for this purpose; and the volume of the distillate was then made up with water to the original volume of the beer. The specific gravity of the last

15	72·0									

spirituous liquid was now taken by the weighing bottle. To obtain a correction for the small quantity of alcohol unavoidably introduced by the yeast, a parallel experiment was made with that substance. The same weight of yeast was mixed with water, and distilled in another similar retort. The volume of this second distillate was also made up by water to the beer volume; its specific gravity observed, and deducted from that of the preceding spirituous liquid. This alcohol was added to that obtained in the first distillation of the beer, and the weight of starch-sugar corresponding to the whole amount of alcohol was calculated. This was the first result.

'For the solid matter of the beer: the spiritless liquid remaining in the retort was made up with water to the beer volume, and the specific gravity observed. A correction was also required here for the yeast, which is obtained by making up the water and yeast distilled in the second retort, to the original volume of the beer, and deducting the gravity of this fluid from the other. The quantity of starch-sugar corresponding to this corrected gravity of the extractive matter was now furnished by the table. This was the second result.

'The two quantities of starch-sugar thus obtained were added together. The specific gravity of the solution of the whole amount of starch-sugar, as found in the table, represented the original gravity of the beer.

'This method must give an original gravity slightly higher than the truth, owing to the circumstance that the dextrin, albumen, and salts, which are found among the solid matters dissolved in beer, are treated as having the low gravity of extractive matter, and accordingly amplified by about one-sixth, like that substance, in allowing for them ultimately as starch-sugar. The error from this source, however, is inconsiderable. It is to be further observed, that the error from imperfect manipulation, of which there is most risk in the process, is leaving a little sugar in the extractive matter from incomplete fermentation. This accident also increases the original gravity deduced. The process has given results which are remarkably uniform, and is valuable in the scientific investigation of the subject, although not of that ready and easy execution which is necessary for ordinary practice, and which recommends the former method.'

The following is a statement by M. L. Pasteur of a new process for making beer so as to render it unchangeable:—

'Every one knows that beer is very liable to change; during the summer it will deteriorate in a month or six weeks.

'The wort used in the preparation of beer is very difficult to preserve. At a high temperature the wort of beer, in the course of a few hours, especially in stormy weather, will go through a great many different alterations. The alterations in the wort of beer have such an influence in the making of this drink, that it becomes absolutely necessary for the brewer to use the greatest precautions to guard against its disastrous effects. A low temperature is essential to the preservation of the wort of beer, and sometimes ice is employed. What, then, are these alterations which rule over the process of fermentation, and why should not means for combating them be found, more simple and more economical than those already in use? I have devised a new process of cooling and of fermentation, and the following are some of the results of my work:—

'1. The changes in beer are due to the development and the multiplication of microscopical organisms which I will call *sick fermentation*.

'2. The germs of this fermentation are carried by the air, and by the utensils in use, &c.

'3. Whenever the beer does not contain these living germs, which are the cause of its deterioration, it becomes unchangeable, at whatever temperature it is made.

'4. I can show that by the employment of certain processes in brewing, all the malt, all the yeast, and all the beer receive the germs of diseases proper to these substances.

'Let us take a beer that has been made according to the usual process employed in England, France, or Germany. Let us expose it in closed bottles at a temperature of from 15° to 25° C. It constantly happens that this beer in the course of a few weeks will be unfit for use. Its preservation is only possible, in some exceptional cases, by the addition of a quantity of hops superior to those generally used. At the time that the change is taking place, the microscopical organisms will make their appearance and multiply. What gives birth to these organisms?

'My studies have proved that the most changeable organic liquids, such as blood, the juice of the grape, &c., can be preserved indefinitely, without any change whatever, when exposed to the ordinary air, but air deprived of those particles of dust which it always carries about, and which are deposited on the surface of all the objects of nature. The contradiction that this proposition has raised will soon be overcome by a simple experiment which I have often shown before the Academy, and which consists in shutting up the liquids in vessels, having an opening placed at the end of a winding-tube, but so far removed from the liquid contained in the vessels that the particles of dust held in suspension in the air cannot come in contact with the liquid.

'That settled, let us prepare a series of vessels where the wort of beer may be perfectly preserved for weeks, months, or years; then, by a very simple process, which is the employment of a second tube like that of which I have spoken, let us introduce separately in each of these a drop from all the beers of commerce. As the clearest beer always contains some globules of yeast in suspension, the alcoholic fermentation will be established, and the wort of beer contained in each of them will in a few days undergo some transformation. Or, if the experiment be carried on in a stove at summer heat, and allowed to remain some weeks, the globules of ordinary alcoholic yeast will soon be associated, in numbers more or less considerable, with the *sick fermentation* of which I have before spoken. The germs of this fermentation exist in all the beers of commerce. This interpretation of facts is confirmed by the following results:—

'If a beer deprived of all the germs of disease is prepared, and wort that has not undergone any change is then added, a beer is obtained, in all cases, that will be perfectly healthy and free from any living organisms excepting those which constitute the globules of the alcoholic yeast. This experiment proves the correlation that exists between the changes in beer and microscopical organisms.

'From my studies on wine I have deduced that wine is not a liquid that changes of itself; the same thing is true of beer. The causes of the changes come from without. The only modifications that are spontaneous are the changes of a chemical order, sometimes from contact with oxygen, or from the effects of growing old, and a reaction taking place between the constituent elements.

'These changes in the nature of a liquid have nothing to do with disease. When any change takes place in beer, such as becoming *thin*, *putrid*, *sour*, strange organisms are developed in it, and these organisms would not be there unless the germs had existed originally in the liquid mass. Beer might be carried into the hottest countries if these germs of disease did not exist in it.

'Nothing can better demonstrate that the changes in the wort of beer are due to microscopical organisms, than the fact that if this wort has been previously boiled, or any other means used to destroy the germs of vitality, no change whatever takes place when the wort is brought into contact with the air.

'Concerning the yeast of beer, the facts do not present themselves with such simplicity as when dealing with the wort or the beer. The latter are dead substances; the yeast, on the contrary, is living. Very skilful botanists, amongst whom are M. Turpin, M. Hoffmann, and M. Trécul, have arrived at the conclusion from their own observations, that the yeast of beer gives birth to different mildews, amongst others the *Penicillium glaucum*.

'It is well known that the yeast of beer is liable to great changes, and these changes are always accompanied by the development of microscopical organisms. From whence do these organic productions come? Are they a modification of the cellules of the yeast in the conditions of the new life, or do the organisms find their origin in the dust from the objects with which the yeast has been in contact?

'I prepared some yeast deprived of all germs foreign to its own nature, and I can therefore give an account of the changes it underwent when brought in contact with the pure air. In this condition the yeast appeared perfectly inert, like a mineral substance, giving rise to no fermentation whatever; it did not even give birth to the *Mycoderma vini*, which is so like the yeast in its structure, its form, and mode of development.

'If one understands the preceding principles, it is easy to see that beer, which is no longer exposed to changes, may be made at any temperature.

'We must consider, first, that the beer is forced to come to a state of ebullition when it is still in the form of extract of malt with hops; during this process all the germs of disease are destroyed. The hot wort is enclosed in a vat, and then cooled either by contact with the air or by a current of water. The germs can be easily kept out during the process of cooling, by allowing carbonic acid gas to enter one of the tubes, while the other tube allows the excess of gas to escape. It must then be put to the operation of fermentation, as much as possible sheltered from the common air, and using a yeast that is perfectly pure. Where is this pure yeast to be found?

'I have observed that even in the best breweries the yeasts are always impure, because this impurity is due to the processes now in use. The employment of impure yeast renders the making of beer in closed vessels impossible, and even exaggerates the defects of the present process, if closed vessels are employed.

'The physiological difference between yeast and the *sick fermentation* is worthy of attention. While the yeast of beer lives and multiplies in contact with the air more rapidly than in the presence of carbonic acid gas, the germs of disease, on the contrary, are cramped in their life by the presence of oxygen gas. The result is, when the operations are carried on, sheltered from the air, the accessory fermentations develop with facility, while the alcoholic fermentation is slackened, because the yeast of beer cannot spread in contact with the oxygen—a new source of activity. All the attempts to make beer in closed vessels have failed up to the present time. But these effects arise from the impurity of the yeast commonly used by brewers. For if the yeast does not contain germs foreign to its nature, they can neither appear spontaneously nor by a transformation in the yeast. Such are the principal motives for the employment of a pure yeast, especially in my process. Several methods can be employed for the production of pure yeast, but it would take too long to explain the means I have adopted; it will suffice to say that the difference of the action of the oxygen of the air on the yeast and on the sick fermentation should be profited by.

'I put then into the wort pure yeast; the fermentation takes place, and being effected, sheltered from the air, or in the presence of limited quantities of pure air, it does not give alien fermentations, because the yeast of beer only was sown; and whatever is advanced on the subject of possible transformation of yeast into *Mycoderma aceti*, common mildews, &c., or *vice versâ*, is erroneous. Lastly, when the beer is finished, it can be treated in the ordinary manner, without any fear of the contact with the air producing any serious inconveniences, because the beer finished or on the point of being finished, does not offer favourable conditions for receiving the germs of disease; at least, those which do not want the oxygen of the air to live and multiply. As to the others, which are the *Mycoderma aceti* and the *Mycoderma vini*, simple precautions enable them to be easily avoided.

'Beer made under the conditions I have shown, and placed according to custom in casks recently tarred, or put in bottles, may be preserved for an indefinite time, even in a stove of from 20° to 25° C. Far from suffering any change by time, it appears rather to become softened by the effect of old age, in the same manner as wines which can be preserved without deteriorating. One can now understand the possibility of suppressing the use of ice during and after the fermentation, since the new process is applicable in all temperatures. The temperature of the cellars where the beer is preserved should be not lower than 10° to 12° C.; a temperature that can be obtained, even in summer, in temperate climates, by having the cellars a moderate depth.'

FERMENTATION PANARY. See Bread.

FERRIC ACID. (FeO^3.) This compound having been prescribed as a source of supplying oxygen to persons confined in diving-bells and in mines, by M. Payerne, claims notice in a practical work. M. Frémy is the discoverer of this acid, which he obtains in the state of ferrate of potash, by projecting 10 parts of dry nitre in powder upon 5 parts of iron filings, ignited in a crucible; when a reddish mass, containing much ferrate of potash, is formed. The preparation succeeds best when a large crucible, capable of holding about a pint of water, is heated so strongly that the bottom and a couple of inches above it, appear faintly, but distinctly red, in which state the heat is still adequate to effect due deflagration without decomposition. An intimate mixture of about 200 grains of *dried* nitre with about one-half its weight of the finest iron filings, is to be thrown at once upon the side of the crucible. The mixture will soon swell and deflagrate. The crucible being taken from the fire, and the ignited mass being cooled, is to be taken out with an iron spoon, pounded, and immediately put into a bottle, and excluded from the air, from which it would speedily attract moisture, and be decomposed. It is resolved by the action of water, especially with heat, into oxygen gas, peroxide, and nitrate of iron. This acid has not been obtained in a free state; it appears indeed to be scarcely capable of existing alone, decomposing, as soon as liberated, into oxygen and ferric oxide.—*Graham.*

Mr. J. D. Smith prepares the ferrate of potash by exposing to a full red heat a mixture of finely-powdered peroxide of iron with four times its weight of dry nitre. It has an amethyst hue, but so deep as to appear black, except at the edges. Oxygen is rapidly evolved by the action of sulphuric or nitric acid upon its solution. He considers the atom of iron to exist in this compound associated with 3 atoms of oxygen, or double the proportion of that in the red oxide. Hence 52 grains of pure ferric acid should give off 12 grains of oxygen, equal to about 35 cubic inches; but how much of the ferrate of potash may be requisite to produce a like quantity of oxygen cannot be stated, from the uncertainty of the operation by which it is produced.

FERRICALCITE. A term sometimes applied to those limestones which contain a large percentage of oxide of iron. The iron ore—'Red ore,' of the Churnet Valley, North Staffordshire—may be regarded as a striking example.

FERRIC SALTS. Salts of ferric oxide, or peroxide of iron. Thus the sulphate of sesquioxide of iron may be called ferric sulphate.

FERROCYANIDES. The compounds of the radical ferrocyanogen. The latter radical is bibasic; when, therefore, it combines with hydrogen to form ferrocyanic acid, it takes up two atoms. These two atoms of hydrogen can be replaced by metals as in ferrocyanide of potassium or prussiate of potash, as it is commonly called. See Prussiate of Potash. Ferrocyanogen consists of C^6N^3Fe, which may also be written Cy^3Fe, or, for brevity's sake, Cfy.

The modes of preparing the ferrocyanides differ, according as the resulting substance is soluble or insoluble in water. The soluble salts, such as those with alkalis, are prepared either by neutralising hydroferrocyanic acid with the proper metallic oxide, or by boiling prussian blue with the oxide, the metal of which it is intended to combine with the ferrocyangen. Other methods may also be adopted in special cases. The processes for preparing the ferrocyanides of the alkali-metals on the large scale will be described in the article Prussiate of Potash.

When the ferrocyanide is insoluble in water, it may be prepared by precipitating a salt of the metal with ferrocyanide of potassium. Thus, in the preparation of the reddish or purple ferrocyanide of copper,

$$2(CuO,SO^3) + K^2Cfy = Cu^2Cfy + 2(KO,SO^3).$$

The above equation written in full becomes:—

$$2(CuO,SO^3) + K^2C^6N^3Fe = Cu^2C^6N^3Fe + 2(KO,SO^3).$$

$$\mathbf{2(CuSO^4) + K^4C^6N^6Fe = 2(K^2SO^4) + Cu^2C^6N^6Fe.}$$

Ferrocyanide of potassium is much used as a test for various metals, in consequence of the characteristic colours of the precipitates formed with many of them. The principal ferrocyanides, with their colours and modes of preparation, will be found in the following list:—

Ferrocyanide of aluminium.—An instable compound formed by digesting hydrate of alumina with ferroprussic acid.

Ferrocyanides of antimony and arsenic.—Neither of these salts is known in a state of purity.

Ferrocyanide of barium.—This salt may be prepared by boiling prussian blue in slight excess with baryta-water, and evaporating to crystallisation.

Ferrocyanide of bismuth.—When a solution of ferrocyanide of potassium is added to a solution of a salt of bismuth, a yellow precipitate is obtained. It becomes of a greenish tint on keeping for some time.

Ferrocyanide of cadmium may be obtained as a white precipitate on adding a solution of ferrocyanide of potassium to a soluble salt of cadmium.

Ferrocyanide of calcium may be prepared in the same manner as that of barium, but, owing to the sparing solubility of lime in water, we must substitute cream of lime for baryta-water.

Ferrocyanide of cerium is a white salt only slightly soluble in water. Its properties are very imperfectly known.

Ferrocyanide of chromium.—The protochloride of chromium gives a yellow precipitate with ferrocyanide of potassium.

Ferrocyanide of cobalt.—Salts of cobalt give a pale blue precipitate with ferrocyanide of potassium. It appears to decompose on keeping, as its colour becomes altered.

Ferrocyanide of copper.—When ferrocyanide of potassium is added to a solution of subchloride of copper, a white precipitate appears, which, on exposure, becomes converted into a purplish red substance, apparently identical with the ordinary ferrocyanide of copper which falls down on the admixture of salts of the protoxide of copper with solutions of ferrocyanide of potassium.

Ferrocyanide of glucinum may be obtained, according to Berzelius, under the form of an amorphous varnish, by decomposing ferrocyanide of lead with a solution of subsulphate of glucina.

Ferrocyanide of hydrogen constitutes ferroprussic acid.

Ferrocyanide of iron, or *prussian blue.*—This salt exists in several conditions, according to the mode of preparation. The ordinary salt is formed by adding a solution of ferrocyanide of potassium to a solution of a persalt of iron.

Ferrocyanide of lead is procured as a white precipitate by adding a solution of ferrocyanide of potassium to a salt of lead.

Ferrocyanide of magnesium is probably best prepared by neutralising ferroprussic acid with magnesia or its carbonate. It forms a pale yellow salt.

Ferrocyanide of manganese may be obtained as a white precipitate, on adding ferrocyanide of potassium to a solution of pure protochloride or protosulphate of manganese.

Ferrocyanide of mercury.—This compound cannot be obtained in a state of purity by precipitation. It has not been sufficiently examined.

Ferrocyanides of molybdenum.—Molybdinous salts give, with ferrocyanide of potassium, a dark brown precipitate, soluble in excess of the precipitant.

Ferrocyanide of nickel is obtained under the form of a pale apple-green precipitate, on addition of prussiate of potash to a salt of nickel.

Ferrocyanide of silver.—Ferrocyanide of potassium gives a white precipitate with silver salts.

Ferrocyanide of sodium may be formed by the action of caustic soda on prussian blue.

Ferrocyanide of strontium can be procured precisely in the same manner as the corresponding barium salt.

Ferrocyanide of tantalum has probably never been obtained pure. Wollaston found that tantalic acid (dissolved in binoxalate of potash) gave a yellow precipitate with prussiate of potash.

Ferrocyanide of thorium.—A white precipitate is produced by the action of solution of prussiate of potash on salts of thorium.

Ferrocyanide of tin.—Pure salts of tin, whether of the per- or prot-oxide, give white precipitates with ferrocyanide of potassium.

Ferrocyanides of titanium.—Solutions of titanates give a golden brown precipitate when treated with solution of ferrocyanide of potassium.

Ferrocyanides of uranium.—The protochloride gives a pale, and the perchloride a dark reddish brown precipitate with ferrocyanide of potassium.

Ferrocyanide of vanadium.—Salts of vanadic oxide give pale yellow, and of vanadic acid rich green precipitates with prussiate of potash.

Ferrocyanide of zinc cannot be prepared by precipitation. It may be obtained in the form of a white powder by the action of oxide or carbonate of zinc on ferroprussic acid.—C.G.W. See Watts's 'Dictionary of Chemistry.'

FERROCYANOGEN, a compound radical, in which the metallic iron is an important constituent. See previous article, and Watts's 'Dictionary of Chemistry.'

FERROUS SALTS. Salts of ferrous oxide or protoxide of iron. Thus green vitriol may be called ferrous sulphate, instead of sulphate of protoxide of iron. In like manner ferrous chloride is synonymous with protochloride of iron.

FERRUGINOUS QUARTZ. A quartz stained by iron, an intermediate state between quartz and jasper. See JASPER.

FETT-STEIN, Ger. (*Fat Stone.*) A variety of Nepheline, one of the Scapolite family, so called from its resinous lustre.

FEVERFEW. The popular name of the *Pyrethrum Parthenium*, much used amongst the peasantry as a remedy for fevers. It contains some tannic acid, and has been employed in Germany in tanning and currying leather. The *Pyrethrum officinale* is the Pelletory of Spain. See PYRETHRUM.

FIBRES, or **FIBROUS BODIES.** From time to time numerous grasses, fibrous barks, and other substances of a similar character, have been introduced into commerce; a few of these only have been found available for manufacture. It is, however, deemed of interest to describe briefly some of these. Some of the more important vegetable fibres will be fully noticed under their respective heads. (See COIR; ESPARTO; FLAX; HEMP; PHORMIUM, &c.)

China Grass.—This fibre is obtained from *Urtica* (*Bœhmeria*) *nivea*, which grows abundantly in China, and in various parts of our Indian empire. The samples which have been imported are principally obtained from Canton and Hong-Kong. In 1849, Messrs. Wright and Co. obtained a patent for the preparation of this fibre. Their process consisted essentially of boiling the stems in an alkaline solution, after they had been previously steeped for 24 hours in cold water, and for 24 hours in water at 90° Fahr. The fibre is then thoroughly washed with pure water, and finally subjected to the action of a current of high-pressure steam till nearly dry.

Callooee Hemp or Rhea.—This fibre is usually confounded with China grass; but there is little doubt they are obtained from two different kinds of urtica; the China grass from the *Urtica nivea* of Willdenhow; the Callooee Hemp, *Kalmoi*, or *Rami*, of Sumatra, and the *Rhea*, from the *Urtica tenacissima* of Roxburgh. The plant producing the Callooee hemp was introduced from Bencoolen to Calcutta in 1803, where, under the care of Dr. Roxburgh, it was for many years cultivated in the Botanic Gardens. In 1814, a quantity of the Callooee hemp was imported into England, and properly tested; its practical value was thought so highly of, that the Society of Arts awarded a silver medal to Capt. James Cotton, of the East India Company, who introduced it. 'The chief obstacle which interfered, however, with its use, was the difficulty which was found to exist in the preparation of the fibre from the stems of the plants; none of the processes usually adopted with flax or hemp were found to be at all suitable to them; and the rude, wasteful, and imperfect means employed by the natives in preparing the fibre for the manufacture of twine, thread, and fishing nets, by the mere process of scraping, were wholly inapplicable on a large scale, and gave besides only a very inferior result. When macerated or retted in water, it was found that the fibre itself was more easily destroyed than the glutinous matter of the stem. During the last forty years, various attempts have been made to devise a good and cheap process for preparing this fibre, but hitherto without much success; and consequently, till quite recently, the cost of the fibre was such as to preclude its being brought into the market as a substitute for flax. But recent investigations have shown that the *Urtica tenacissima* and the *U. heterophylla* may be obtained in almost unlimited quantities in various parts of India; and a process which has been lately patented appears, to a very great extent, to have removed the practical difficulties which previously stood in the way of its employment by manufacturers; so that in a few years it is probable that the Callooee hemp will constitute an important addition to the fibrous materials employed in the arts.'—*Jurors' Report, Great Exhibition,* 1851.

Neilgherry Nettle (*Urtica heterophylla*).—This nettle appears to be remarkable beyond all others for its stinging properties. It is abundant in Mysore, flourishing in Alpine jungles. The Todawars prepare the fibre of this plant by boiling the stems in water, after which they readily separate it from the woody parts and then spin it into a coarse but very strong fibre. The Malays simply steep the stems in water for ten or twelve days, after which they are so much softened that the outer fibrous portion is easily peeled off.

Yercum Nar.—This is the native name of the fibres of the *Calotropis* (*Asclepias*) *gigantea*, a plant which grows wild, abundantly, in various parts of the Bengal and Madras Presidencies, and is used by the natives in the manufacture of cord called *Lamb-dore*, or *Tondee Coir*.

Aloe fibre, or *Nar*, the produce of the *Agave vivipara*, and other allied species. This is often called the *Silk grass fibre*.

Pine-apple fibre, sometimes called *Ananas flax*. This has been prepared in Java and at Travancore. Many fine specimens have been brought to this country.

Plantain fibre.—In the Government establishments of Ceylon this is extensively employed. Canvas and ropes are made of it. It is obtained from the *Musa textilis*. It is calculated that 8 cwt. per acre of this excellent fibre might be obtained.

Mahant bark.—Employed at St. Vincent's in the manufacture of fishing nets, common cord, and coarse lines for fishing.

New Orleans moss (*Tillandsia usneoides*), a substitute for horse-hair as a stuffing material for upholsterers. Sometimes the fibrous husk of the Indian corn is used for the same purpose, but it is more brittle than the moss.

Palm-tree fibre. These fibres are obtained from many varieties of the palm.

Grass fibre.—Many of the grasses are now being used in the manufacture of paper, and for other purposes.

The following tables by Dr. Roxburgh and Dr. Wright, afford much information as to the relative strengths of different kinds of fibrous substances. The first table gives experiments made by Dr. Roxburgh in 1804; some of the fibres were, however, probably imperfectly prepared:—

Common Name	Botanical Name	Breaking Weight
		lbs.
1. Hemp (English)	*Cannabis sativa*	105
2. Murga (Sanseviera)	*Alectris nervosa*	120
3. Aloe	*Agave Americana?*	110
4. Ejoo	*Saguerus Rumphii*	96
5. Donsha	*Æschynomone cannabina*	88
6. Coir	*Cocos nucifera*	87
7. Hemp (Indian)	*Cannabis sativa*	74
8. Woollet comal	*Abroma Augusta*	74
9. ———?	*Banhinia*	69
10. Sunn	*Crotolaria juncea*	68
11. Bunghi paat	*Corchorus olitorius*	68
12. Ghu nala paat	„ *capsularis*	67
13. ———?	*Hibiscus manihot*	61
14. Flax (Indian)	*Linum usitatissimum*	39

In 1808, Dr. Roxburgh made another series of experiments, of which the following table gives the result:—

Common Name	Botanical Name	Breaking Weight
		lbs.
1. Bowstring hemp	*Asclepias Sp.*	248
2. Callooee hemp	*Urtica tenacissima*	240
3. ———?	*Corchorus capsularis*	164
4. Sunn	*Crotolaria juncea*	160
5. Hemp (Indian)	*Cannabis sativa*	158
6. Donsha	*Æschynomone cannabina*	138
7. ———?	*Hibiscus strictus*	128
8. Musta paat	„ *cannabinus*	115
9. Bunghi paat	*Corchorus olitorius*	113
10. Plantain	*Musa*	79

Experiments were made some years ago by Dr. Wright on several well-known vegetable fibres when made into ropes. The following were the results:—

Common Name	Botanical Name	Breaking Weight
		lbs.
1. Yercum nar	*Calotropis gigantea*	552
2. Janapum	*Crotolaria juncea*	407
3. Cutthalay nar	*Agave Americana*	362
4. Cotton	*Gossypium herbaceum*	346
5. Maroot	*Sansevicra zeylanica*	316
6. Pooley mungu	*Hibiscus cannabinus*	290
7. Coir	*Cocos nucifera*	224

The defect of all these fibres is, as it regards their use in weaving, that they break the knot, and in all weaving processes the fibres require frequent joining.

FIBRE, VEGETABLE, called also LIGNINE (*Ligneux*, Fr.; *Pflanzenfaserstoff*, Ger.), is the most abundant and general ingredient of plants, existing in all their parts, the root, the leaves, the stem, the flowers, and the fruit; amounting in the compact wood to 97 or 98 per cent. It is obtained in a pure state by treating sawdust successively with hot alcohol, water, dilute muriatic acid, and weak potash-lye, which dissolve, first, the resinous; second, the extractive and saline matters; third, the carbonate and phosphate of lime; and, lastly, any residuary substances. Ligneous fibres, such as sawdust, powdered barks, straw, hemp, flax, linen, and cotton cloth, are convertible by the action of strong sulphuric acid into a gummy substance analogous to *dextrine*, and a sugar resembling that of the grape.

Much attention has of late years been directed to the conversion of vegetable fibre into paper. See PAPER.

'*Recognition of vegetable and animal fibres in spun and woven tissues.*—Kopp has lately examined the chemical behaviour of animal and vegetable fibres with a view to their detection in mixed fabrics. Cellulose (vegetable tissue of whatsoever origin) resists boiling aqueous solutions of an alkali, but is readily attacked by sulphuric, nitric, and hydrochloric acids. Cotton can be soaked without material injury in cold water containing 5 to 10 per cent. of acid; but, if heated, the cotton is disintegrated, and rapidly converted into gum and sugar. Fuming nitric acid and mixtures of concentrated sulphuric and nitric acids do not dissolve cellulose, but convert it into gun-cotton. Ammonia has no action on cotton and hemp at any temperature. The cuprate of ammonia, an ammoniacal solution of copper, sometimes spoken of as 'Schweitzer's test,' dissolves cotton, hemp, and flax. Vegetable fibre has but little affinity for artificial colours. If steeped in their solutions, it takes merely a stain, which is easily removed by soap. Cellulose is not easily destroyed by chlorine or the hypochlorites. If burnt, it yields no particular smell. Wool, on the other hand, resists acids, even when strong and hot, but is dissolved by alkalis. As it contains sulphur, sulphide of sodium is found on steeping it in soda, which gives a black precipitate with the acetate of lead. Nitric acid turns it yellow. The effect of chlorine and the hypochlorites is very similar. Schweitzer's test has no action in the cold, but dissolves it when hot. If burnt, it gives off the well-known smell of burnt horn. The affinity for artificial colours is very great, even without the aid of mordants. Silk, if burnt, smells like wool. It is attacked by strong and hot acids more readily than wool. Nitric acid turns it yellow. Dilute acids have little immediate action. Alkalis dissolve it; but, as no sulphur is present, there is no formation of a sulphide, and the acetate of lead does not yield a black precipitate. Dilute alkalis affect it, but without solution. Ammonia has no action. In Schweitzer's test it dissolves like cotton. Its affinity for colours is like that of wool. To detect cotton, hemp, flax, and jute in mixture with wool and silk, boil the sample in an aqueous solution of soda containing 10 per cent. of hydrate of soda. Wool and silk dissolve, while the vegetable fibres remain unacted upon. The whole is thrown upon a cotton filter, and the undissolved matter is then washed with hot water, and afterwards with water acidulated with 5 per cent. of hydrochloric acid, to which, if the residue is black or dark-coloured, a few drops of chlorine-water are added. Meantime, the original alkaline filtrate can be tested for wool with the acetate of lead. If a white precipitate is formed, which dissolves on stirring, silk alone is present. A black precipitate indicates wool. The nitro-peroxide of sodium gives a violet colour if wool be present. If the tissue is deeply coloured it may be cut up and steeped for fifteen to twenty minutes in a mixture of two measures of concentrated sulphuric and one of fuming nitric acid. Wool, silk, and colouring matters are destroyed, while the cellulose is converted into gun-cotton. White and pale mixed tissues may be tested by their affinity for colours. Cleanse and rinse thoroughly in water to remove starch and similar dressings; boil for ten minutes in water containing 2 per cent. carbonate of soda and a little soap; then rinse in hot water; steep five to ten minutes in water at 50° to 60° C., containing 2 per cent. sulphuric acid, and wash again. In the meantime prepare the colour-bath by dissolving a few decigrammes of magenta in 28 to 30 cubic centimeters of water; heat to boiling, and during ebullition add to it, drop by drop, caustic soda till a pale rose colour only remains in the liquid; take off the fire, and put in the sample; after some minutes take out to dry. Silk and wool are dyed while the vegetable fibres remain colourless. Wool may be detected in silk by the presence of sulphur: if it is immersed for a short time in plumbate of soda, the silk will be colourless and the wool black. Or a piece of the tissue, two centimeters square, may be boiled in 10 to 12 cubic centimeters of Schweitzer's test: in five to ten minutes the silk will be dissolved. If the silk is black add double the volume of Schweitzer's test, and soak ten to twelve minutes; after taking out the undissolved wool the liquid, quickly neutralised with nitric acid, gives no precipitate if silk is only present, but cellulose is precipitated.'

FIBRIN. Recent researches have shown that the substance known as *animal fibrin* is formed by the union of two distinct albuminous principles, termed, by A. Schmidt, the *fibroplastic* and *fibrinogenous substances.* Fibrin may be obtained in a pure state by agitating or beating new-drawn blood with a bundle of twigs, when it will attach itself to them in long reddish filaments, which may be deprived of colour by working them with the hands under a streamlet of cold water, and afterwards freed from any adhering grease by digestion in alcohol or ether.

Fibrin, thus obtained, is solid, white, flexible, slightly elastic, insipid, inodorous, denser than water, but containing $\frac{4}{5}$ths of its weight of it, and without action on litmus. When dried, it becomes semi-transparent, yellowish, stiff, and brittle: water restores its softness and flexibility. 100 parts of fibrin consist of 53·36 carbon, 19·68 oxygen, 7·02 hydrogen, and 19·31 nitrogen. As the basis of flesh, it is a very nutritious substance, and is essential to the sustenance of carnivorous animals.

Fibrin, Vegetable. A nitrogenous substance very similar to animal fibrin. It occurs in the gluten prepared from wheaten flour, and in most kinds of grain.

FIBROLITE. A silicate of alumina occurring in fibrous or columnar forms, associated with corundum, in the Carnatic. Many of the pre-historic stone celts found in Switzerland, France, and the Channel Islands, are said to be wrought in fibrolite.

FIBROUS RESIDUES. *New Process for separating the Animal from the Vegetable Ingredients.*—Mr. F. O. Ward was an exhibitor in 1862 of this process, which received the high approval ot the jury of Class II., to whose attention it was especially directed. Mr. Ward has been associated with Captain Wynants in carrying out this interesting and useful discovery. These gentlemen placed in the hands of Dr. Hofmann a concise description of their process, which we give in Mr. Ward's words:—

'There is a class of rags of intermediate character, neither wholly composed of vegetal matter, nor exclusively of animal origin. I allude to the residue of fabrics containing both these classes of materials interwoven.

'Such are the rags of so-called union fabrics, wool and cotton; of the silk and alpacas woven with a cotton warp; and of the numerous varieties of stuffs, merinos, &c., which are more and more extensively manufactured every year. Such also are the rags known technically as "seams;" being the clippings which fall from woollen rags under the scissors of the sorters, who prepare them for the machine by which they are torn into "rag-wool." These pieces are cut off and withheld from the tearing machine, precisely because they have a sewing thread running along them, or portions of cotton lining adherent, or other vegetal admixture. In rags of this class, each of the materials present interferes with the use, and diminishes the value, of the other. The paper-maker cannot advantageously work off the cotton because of the wool, which would sprinkle his sheets with coloured specks. The rag-wool manufacturer, on the other hand, cannot advantageously convert the wool to his purpose because of the cotton, which would show amidst the wool when dyed, as filaments of paler hue.

'To meet this difficulty two plans have been of late years proposed, viz., the disintegration of the cotton by means of dilute acid, in order to the separate recovery of the wool; and the dissolution of the wool by means of caustic alkali, in order to the separate recovery of the cotton.

'Both these plans, it will be observed, involve the sacrifice of one material for the recovery of the other; for its recovery in the case of the wool, much impaired in strength by acidulation: in the case of the cotton at a considerable expenditure of the alkaline solvent.

'The process now under review was devised in the year 1857, with special reference to this class of mixed rags; as also to the unsortable residuum which remains under the name of "land rags," after the sorting of a heap has been pushed as far as economically possible. The object kept in view was to turn to account not one only, but both the classes, animal and vegetable, of intermingled ingredients; and this result is accomplished by the new method without the aid of the acid or alkaline disintegrants heretofore employed; without, in fact, any chemical agency stronger or more costly than that of water, applied in the form of a high-pressure steam atmosphere. This process is so extremely simple that its nature, and the mode of practising it, can be explained in half a dozen sentences.

'The mixed rags, or other analogous mixed residue, are introduced into an ordinary autoclave digester, and there kept for about three hours (more or less) surrounded with an atmosphere of steam heated to a pressure of from three to five atmospheres. The exact pressure and temperature requisite vary with the materials under treatment; wool requiring a higher temperature than leather, for example, and silk than wool. The materials condense a proportion of the steam and absorb its heat. The joint action of the moisture and heat is to convert the animal matter into a friable substance, which, however, still retains its original form and aspect. Thus the wool of mixed rags retains after digestion the same fibrous appearance that it had before, though it crumbles to powder when handled. It will be understood that ordinary crushing and beating machinery readily reduces this brittle coal-like product to dust, and detaches it from the interwoven vegetable matter, which preserves its fibrosity unimpaired. The beater is provided with a sieve, which retains the vegetable fibre, but suffers the animal dust to fall through. Ultimately the vegetable fibre is projected from the machine as a paper-material ready for use; the animal dust, meanwhile, being propelled by an Archimedian screw, and raised by a Jacob's-ladder till it reaches the mouths of the sacks successively placed for its reception.

'In the details of this process, and in the fuel- and labour-saving arrangements for drying the rags and handling them in their passage through the several departments of the factory, there are peculiarities not bearing on the broad principles of the plan, though essential to its successful prosecution. Special precautions of this kind, as they are learned, point by point, by costly manufacturing experience, cannot, with propriety, be divulged; nor, indeed, would they interest any reader not specially charged with the conduct of the operation. I pass on, therefore, to a brief consideration of the products.

'The fibrous product, or paper-material, presents but few peculiarities for notice. It consists principally of cotton, but usually contains also a percentage of flax and hemp, which increase its tenacity and value. The fibre is, for the most part, set free in the form of long parallel threads, the warp of the fabrics treated; but it also presents many shreds of an ordinary rag—portions, doubtless, of the calico with which the stuffs were lined. As the cotton warps of union fabrics are usually dyed in fast colours, often black, and as they are apt to retain a small percentage of the altered wool-dust, they require to be boiled under somewhat higher pressure than ordinary coloured rags; with which, in other respects, they are pretty much on a par as paper-material. Until the right pressure for boiling them had been ascertained, it was found difficult to bleach them to perfect whiteness; and some early failures, thus occasioned, rendered the material unpopular among paper-makers. Nevertheless, when properly manipulated, this material produces excellent white paper, as the samples exhibited show.

'The animal product, being an entirely novel article, requires particular attention. It issues from the beating machine as a dark-coloured powder, intermingled with small lumps of the same substance, which lumps are sifted out and crushed. This powder, as practically produced, with the dust and grit of the rags in it, contains, on an average, nearly 12 per cent. of nitrogen; a proportion corresponding to 14·5 per cent. of ammonia. The nitrogen exists to a small extent as ready-formed ammonia held in combination with brown acids—ulmic and humic—developed during the process. The bulk of the nitrogen, however, is present, not in the form of ammonia, but as a constituent of the wool-product itself. This organic compound is partially soluble, and more so as more moisture is supplied to the rags during their digestion. As ordinarily produced, it is a manure of highly ammoniferous power, the whole of its nitrogen being liberated as ammonia, under the influences with which it meets in the soil. The rate of this development holds a happy medium between that of ordinary woollen rags, which are reckoned too "slow" a manure, and that of guano, which is often as much too "sudden." The farmer desires an equable as well as a copious development of ammoniacal plant-food, whereof abrupt and superabundant supplies are apt, as he expresses it, to "burn" the roots; which have, moreover, subsequently to endure privation of the very food thus worse than wasted.

'The new manure may, I think, be regarded as being for plants what moderately-cooked food is for animals; the artificial preparation being, in both cases, carried just far enough to leave Nature her appropriate share of the work. As, however, wool, leather, hair, silk, and the like, are not rich in phosphatic salts, an admixture of these, whether in the form of bone-ash, bone, or coprolitic superphosphate, Kouria Mouria guano, or the like, improves the manure; producing, in fact, a fertilising compost, which for general use leaves nothing to be desired. Of course, for soils specially deficient in any particular ingredient, and for crops requiring a more than average supply of some one element, special additions are made to the manure; which become thus turnip manure, cereal manure, bean manure, &c., as desired.

'Another property may also be mentioned here, as giving to this manure, in one particular, a considerable advantage over guano. It is that whereas guano is liable, while in store, to undergo spontaneous decomposition, whence arises the loss of much volatile alkali, the new wool-product, on the contrary, manifests no such tendency, but remains perfectly stable at all ordinary temperatures and in all states of the weather, an advantage which it doubtless owes to the high temperature at which it is made. This manure may, therefore, be warehoused for any length of time, and during any climatic vicissitudes to which it may be exposed either at home or in tropical regions.

'This product is distinguished in commerce as "Ulmate of Ammonia," a name which, though not perhaps strictly correct, serves to indicate two of its most notable constituents—acid and alkaline—in the combination which they really affect.

'Its analysis, by Professor Voelcker, of the Royal Agricultural College, Cirencester, is subjoined:—

Moisture	11·59
Organic matter[1]	73·89
Ammonia in state of ulmate	2·05
Oxides of iron and alumina and phosphoric acid	2·52
Carbonate of lime	2·22
Alkalis and magnesia	1·26
Insoluble siliceous matter	6·47
	100·00

'The relative proportion of the manurial and fibrous products resulting from the working of this process varies, of course, with the nature of the materials treated. Some mixed *dèbris* are rich in vegetal, others in animal, fibre. Average mixed rags, however, contain these ingredients in pretty equal proportions; and in all cases the sum of the weights of the two products, fibrous and pulverulent, equals the weight of the raw materials, so that the process involves no waste.

'The pecuniary profit of the operation is liable, of course, to vary from time to time with the cost price of the raw material, and labour employed, and the selling price of the products, as also with the varying activity of trade, and the intervals of commercial depression. On this point it may suffice to observe that a process founded on correct principles, and yielding, under skilful conduct, good chemical results, is generally found to succeed also, on the average, as a commercial enterprise, if it be soundly and vigorously administered. The new manufacture is carried on at large works, built expressly for the purpose, on the left bank of the Thames, at Grays, Essex, where machinery, adequate to treat about 12 tons of rags per diem, has been fitted up. A large paper-mill has also been erected on the opposite side of the river, at Dartford, to convert the fibrous product into paper. The ulmate is for the most part sold to manure manufacturers, who use it as the nitrogenous ingredient of their several fertilising composts. It is, therefore, employed by many farmers who are not aware of the fact.

'With reference to the origination of this process, the separability of animal from vegetal matters by the peculiar means indicated above, first occurred to the exhibitor, and was communicated by him to his friend Captain Wynants during the course of experiments carried on by them jointly for the attainment of a different end, viz. the total reduction to manure of certain forms of waste. The modified design thus originated was worked out by both conjointly; and it is the wish of the associates that any credit which an indulgent appreciation may connect with its success should be understood as attaching equally to both. Their highest ambition as to this process will be satisfied should the means employed therein be regarded as simple and cheap, yet efficacious to their appointed end; that end being the recovery, from

Corresponding to ammonia	12·43
Total quantity of nitrogen	11·93
Corresponding to ammonia	14·48

mixed fibrous residua, under somewhat difficult conditions, of unquestionably useful products.'

FICHTELITE. A resinous hydrocarbon occurring in fossil pine-wood from the Fichtelgebirge in Bavaria.

FICTILE MANUFACTURE. See Pottery, &c.

FICUS. The fig. The species of this genus are of considerable number, and all of them are inhabitants of warm countries. Most of the species yield a milky juice containing caoutchouc. The *Ficus elastica* is the India-rubber bearing tree; the *Ficus indica*, the banyan tree; the *Ficus religiosa*, the pippul tree or sacred fig of India; the *Ficus sycamoris*, an Egyptian tree, probably the sycamore of the Bible; and the *Ficus carica*, the common fig.

FID. A tapered wooden pin used by seamen in splicing large ropes. It is also the name of an iron support passed through a hole in the heel of a mast.

FIDDLE BLOCK. A block shaped like a fiddle. It has two sheaves, one over the other; the lower one smaller than the upper.

FIDDLE STRINGS. The catgut cords stretched across a violin; fastened at the ends and raised by the bridge. See Catgut.

FIDDLE WOOD. A West-Indian timber tree, the *Citharexylon melanocardium*, much used for mills, carriage-wheels, &c.

FIG-WORT. The fig-wort family (*Scrophulariaceæ*) form a natural order of dicotyledonous plants, the species belonging to which are herbs, abounding most in temperate climates, but also found both in tropical and arctic regions. The leaves are generally exstipulate, or the stipules are very small. The juice of these plants possesses very varied properties. In some it is watery. In others, as *Verbascum*, it is mucilaginous. In the *Veronicæ* it is bitter, as it is also in *Scrophularia* and some others. In the *Pediculariæ* and *Gratiolæ* it is astringent; and in *Digitalis* it is highly narcotic. The genus *Scrophularia* is the type, and contains numerous species, which are principally natives of temperate climates, more especially in the Mediterranean region.

The common fig-wort, *S. nodosa*, may be taken as the type: a common plant on ditch-sides, woods, and moist places. Its root is swollen and knotty, and it was supposed to resemble scrofulous tumours of the neck. As in former times it was pretty generally believed that Nature thus pointed out the proper remedies for different diseases, this plant was immediately supposed to possess great virtues in cases of scrofula, and was largely used for that purpose externally. Hence the name for the plant, which was afterwards adopted for that of the genus. At the present day it is said to be used on the Continent, in form of an infusion as a wash, in cases of itch. *S. canina*, a native of Italy, is used in like manner as a cure for the mange in dogs. The flowers of *S. nodosa* contain generally a quantity of honey, and are remarkably attractive in consequence to wasps and bees. 'Flores vesparum deliciæ,' says Linnæus.

FIGURE STONE. A stone used by the Chinese for carving small figures. Some of it is the mineral called *agalmatolite*, and some merely *steatite*, or soapstone.

FILBERTS. The nuts of a variety of the Hazel, or *Corylus Avellana*.

FILE (*Lime*, Fr.; *Feile*, Ger.) is a well-known steel instrument, having teeth upon the surface for cutting and abrading metal, ivory, wood, &c.

When the teeth of these instruments are formed by a straight sharp-edged chisel, extending across the surface, they are properly called files; but when by a sharp-pointed tool, in the form of a triangular pyramid, they are termed rasps. The former are used for all the metals, as well as ivory, bone, horn, and wood; the latter for wood and horn.

Files are divided into two varieties, from the form of their teeth. When the teeth are a series of sharp edges, raised by the flat chisel, appearing like parallel furrows, either at right angles to the length of the file, or in an oblique direction, they are termed *single cut*. But when these teeth are crossed by a second series of similar teeth, they are said to be *double cut*. The first are fitted for brass and copper, and are found to answer better when the teeth run in an oblique direction. The latter are suited for the harder metals, such as cast and wrought iron and steel. Such teeth present sharp angles to the substance, which penetrate it, while single-cut files would slip over the surface of these metals. The double cut file is less fit for filing brass and copper, because its teeth would be very liable to become clogged with the filings.

Files are also called by different names according to their various degrees of fineness. Those of extreme roughness are called rough; the next to this is the bastard cut; the third is the second cut; the fourth, the smooth; and the finest of all, the dead smooth. The very heavy square files used for heavy smith-work are sometimes a little coarser than the rough; they are known by the name of rubbers.

Files are also distinguished from their shape, as flat, half-round, three-square, four-square, and round. The first are sometimes of uniform breadth and thickness throughout, and sometimes tapering. The cross section is a parallelogram. The half-round is generally tapering, one side being flat, and the other rounded. The cross section is a segment of a circle varying a little for different purposes, but seldom equal to a semicircle. The three-square generally consists of three equal sides, being equilateral prisms, mostly tapering; those which are not tapering are used for sharpening the teeth of saws. The four-square has four equal sides, the section being a square. These files are generally thickest in the middle, as is the case with the smith's rubber. In the round file the section is a circle, and the file generally conical.

The heavier and coarser kinds of files are made from the inferior marks of blistered steel. Those made from the Russian iron, known by the name of old sable, called from its mark CCND, are excellent. The steel made from the best Swedish iron, called Hoop L or Dannemora, makes the finest Lancashire files for watch and clock makers.

The steel intended for files is more highly converted than for other purposes, to give them proper hardness. It should, however, be recollected, that if the hardness be not accompanied with a certain degree of tenacity, the teeth of the file break, and do but little service.

Small files are usually made of cast steel, which would be used for all other kinds, if it were not for its high price. It is much harder than the blistered steel, and from having been in the fluid state, is entirely free from those seams and loose parts which are common to blistered steel.

The smith's rubbers are generally forged in the common smith's forge, from the converted bars, which are, for convenience, made square in the iron before they come into this country. The files of lesser size are made from bars or rods, drawn down from the blistered bars, and the cast ingots, and known by the name of tilted steel.

The file-maker's forge consists of large bellows, with coke as fuel. The anvil-block, particularly at Sheffield, is one large mass of millstone grit. The anvil is of considerable size, set into and wedged fast into the stone; and has a projection at one end, with a hole to contain a sharp-edged tool for cutting the files from the rods. It also contains a deep groove for containing dies or bosses, for giving particular forms to the files.

The flat and square files are formed entirely by the hammer. One man holds the hot bar, and strikes with a small hammer. Another stands before the anvil with a two-handed hammer. The latter is generally very heavy, with a broad face for the large files. They both strike with such truth as to make the surface smooth and flat, without what is called hand-hammering. This arises from their great experience in the same kind of work. The expedition arising from the same cause is not less remarkable.

The half-round files are made in a boss fastened into the groove above mentioned. The steel, being drawn out, is laid upon the rounded recess, and hammered till it fills the die.

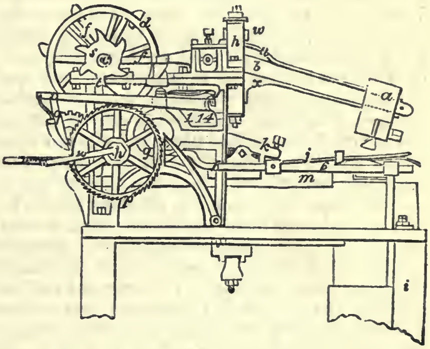
The three-sided files are formed similarly in a boss, the recess of which consists of two sides, with the angle downwards. The steel is first drawn out square, and then placed in a boss with an angle downwards, so that the hammer forms one side, and the boss two. The round files are formed by a swage similar to those used by common smiths, but a little conical.

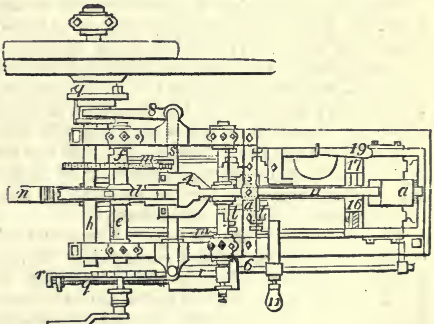
The file-cutter requires an anvil of a size greater or less, proportioned to the size of his files, with a face as even and flat as possible. The hammers weigh from one to five or six pounds. The chisels are a little broader than the file, sharpened to an angle of about 20 degrees. The length is just sufficient for them to be held fast between the finger and thumb, and so strong as not to bend with the strokes of the hammer, the intensity of which may be best conceived by the depth of the impression. The anvil is placed in the face of a strong wooden post, to which a wooden seat is attached, at a small distance below the level of the anvil's face. The file is first laid upon the bare anvil, one end projecting over the front, and the other over the back edge of the same. A leather strap now goes over each end of the file, and passes down upon each side of the block to the workman's feet, which, being put into the strap on each side, like a stirrup, holds the file firmly upon the anvil as it is cut. While the point of the file is cutting, the strap passes over one part of the file only, the point resting upon the anvil, and the tang upon a prop on the other side of the strap. When one side of the file is single cut, a fine file is run slightly over the teeth, to take away the roughness; when they are to be double cut, another set of teeth is cut, crossing the former nearly at right angles. The file is now finished upon one side, and it is evident that the cut side cannot be laid upon the bare anvil to cut the other. A flat piece of an alloy of lead and tin is interposed between the toothed surface and the anvil, while the other side is cut, which completely preserves the side already formed. Similar pieces of lead and tin, with angular and rounded grooves, are used for cutting triangular and half-round files.

Rasps are cut precisely in the same way, by using a triangular punch, instead of a flat chisel. The great art in cutting a rasp is to place every new tooth as much as possible opposite to a vacancy.

File-cutting machines have been from time to time invented. In 1778 M. de Montigny read a memoir before the Committee of Commerce, in which he mentioned the inventions for file-cutting in 1699 by Duverger, in 1725 by Fardouet, in 1740 by Thiout, in 1756 by Brachat and Gamain, and in 1778; since which, in 1800, Raoul invented a file-cutting machine; and in 1836 Ericsson introduced another. Sir John Robison, just before his death, invented a method for cutting curved files; and in 1843, Messrs. Johnson, Cammell, and Co. received the medal of the Scottish Society of Arts for perfecting Sir J. Robison's scheme. The accompanying woodcuts, which are representations of the file-cutting machine of Mr. W. Shilton of Birmingham, will show the general principle upon which those machines are constructed.

857





In order to render this invention better understood, two views of the apparatus for producing the crosscut or teeth of the files, are given.

Fig. 857 is an elevation of the upper part of the file-cutting machine, as seen on one side; *fig.* 858 is a plan or horizontal view, as the machine appears on the top.

a, is the head of the tilt hammer placed in the end of the lever *b*, which is mounted on an axle *c*, turning in proper bearings in the frame work of the machine; *d*, is the tilt wheel mounted on another axle *s*, also turning in bearings on the frame work of the machine, and having any required number of projections or tappets upon it for depressing the tail or shorter end of the hammer or tilt lever *b*.

The tilt wheel *d*, receives its rotatory motion from the toothed wheel *f*, mounted upon the same axle, and it takes into gear with a pinion *g*, upon the main shaft *h*, which is actuated by a band passed from any first mover to the rigger on its end, or in any other convenient manner. The bed upon which the blank piece of steel bears is marked *i*. This bed is firmly supported upon masonry placed upon proper sleepers: *j*, is one of the blank pieces of steel under operation, and is shown secured in the pair of jaws or holding clamps *k*, mounted on centre pins in the slide *l*, *fig.* 858, which slide is held down by a spring and slide beneath, and is moved backwards and forwards in the machine upon the (v) edges *m m*, of the frame, by means of the rack *n* and its pinion; the latter being mounted upon the axle of the ratchet wheel *p*, and which ratchet wheel is made to turn at intervals by means of the pall *q*, upon the end of the lever *r*, *fig.* 858. This lever is depressed, after every cut has been effected upon the blank by means of the teeth or tappets of the wheel *s*, coming in contact with the inclined plane *t*, upon the lever *r*. The tappet wheel *s*, is mounted upon the end of the axle *e*, of the tilt wheel, and consequently revolves with it, and by depressing the lever *r*, every time that a tooth passes the inclined plane *t*, the click *q*, is made to drive the ratchet wheel *p*, and thereby the advancing movement of the blank is effected after each blow of the tilt hammer.

There is a strong spring *u*, attached to the upper side of the tilt hammer, its end being confined under an adjustable inclined plane *v*, mounted in the frame *w*, which inclined plane can be raised or lowered by its adjusting screws as required, to produce more or less tension of the spring.

A similar spring is placed on the under side of the tilt hammer, to raise and sustain the cutter or tool clear of the bed after every blow, and, in conjunction with safety holders or catchers, to counteract any vibration or tendency the spring *u* may have to cause the hammer to reiterate the blow.

The end of the lower spring acts on an inclined plane, mounted in the frame *w*, which has an adjusting screw similar to *u*, to regulate the tension of the spring.

In case the under spring should raise, that is, return the hammer, with sufficient force or velocity to cause the top spring *u*, to reiterate the blow, the ends of the safety holders or catchers are made to move under and catch the tail of the lever *b*, immediately on its being raised by the under springs, which is effected by the following means:—The holders are mounted upon a plate or carriage 1, *fig.* 857, which turns upon a small pin or axle mounted in the ears of a cross bar; the upper ends of the holders are kept inclined towards the tail of the tilt hammer by means of a spring fixed to the cross bar, and which acts upon one end of the plate or carriage.

In order that the holders may be removed out of the way of the tail of the hammer *b*, when the tilt wheel is about to effect a blow, the tooth of the tilt wheel which last acted upon the hammer comes in contact with an inclined plane fixed on the plate or carriage 1, and, by depressing that end of the plate, causes the upper ends of the holders to be withdrawn from under the tail of the hammer *b*. The tilt wheel continuing to revolve, the next tooth advances, and depresses the tail of the hammer, but, before it leaves the tail of the hammer, the tooth last in operation will have quitted the inclined plane and allowed the spring to return the holders into their former position. After the tooth has escaped from the tail of *b*, the hammer will immediately descend and effect the blow or cut on the blank, and, as the tail of the hammer rises, it will come in contact with the inclined planes at the upper ends of the holders, and force them backwards; and, as soon as the tail of the hammer has passed the top of the holders, the spring will immediately force the holders forward under the tail of the hammer, and prevent the hammer rising again until the next tooth of the tilt wheel is about to depress the end of the hammer, when the same movements of the parts will be repeated, and the machine will continue in operation until a sufficient length of the blank of steel (progressively advanced under the hammer) has been operated upon, when it will be thrown out of gear by the following means:—

Upon the sliding bar 6, there is placed an adjustable stop, against which the foremost end of the slide *l l*, *fig.* 858, comes in contact as it is moved forward by the rack *n*, and its pinion. The sliding bar 6, is connected at its left end to the bent lever 8, the other end of this lever being formed into a forked arm, which embraces a clutch upon the main shaft, and, as the slide *l* continues to advance, it will come in contact with a stop; and when it has brought a sufficient length of the blank pieces of steel under the operation of the cutting tool, the slide *l*, in its progress, will have moved that stop and the bar 6 forward, and that bar, by means of the bent lever 8, will withdraw the clutch on the main shaft from locking into the boss of the fly-wheel, and consequently stop the further progress of the machine; the rigger and fly-wheel turning loosely upon the main shaft.

The cut file can now be removed from out of the clamps, and reversed to cut the other side, or another blank piece put in its place; and after throwing back the pall *q* of the ratchet wheel *p*, the slide *l*, and with it the fresh blank, may be moved back into the machine by turning the winch handle, on the axle of the ratchet wheel *p*, the reverse way, which will turn the pinion backwards, and draw back the rack *n*, without affecting any other parts of the machine; and on moving back the bar 6, by the handle 11, placed on the stop, the clutches will be thrown into gear again, and the machine proceed to cut the next blank.

When the blanks have been thus cut on one side, and are reversed in the machine to form the teeth upon the other side, there should be a piece of lead placed between the blank and the bed to protect the fresh-cut teeth.

It will be seen that the position of the stop upon the bar 6, will determine the length or extent of the blank piece of steel which shall be cut or operated upon; and in order that the progressive movement of the blanks under the cutting tool may be made to suit different degrees of fineness or coarseness of the teeth (that is, the distance between the cuts), there is an adjusting screw upon the lever *r*, the head of which screw stops against the under side of an ear projecting from the framework, and thereby determines the extent of the motion of the lever *r*, when depressed by the tappets of the wheel *s*, acting upon the inclined plane *t*, consequently determining the number of teeth the ratchet wheel *p* shall be moved round by the pall *q*; and hence the extent of motion communicated by the rack and pinion to the slide *l*, and the blank *j*, which regulates the distance that the teeth of the file are apart, and the lever *r* is forced upwards by a spring pressing against its under side.

It will be perceived that the velocity of the descent of the hammer, and consequently the force of the blow, may be regulated by raising or lowering the inclined plane *v* of the spring *u*; and in order to accommodate the bed upon which the blanks rest to the different inclinations they may be placed at, the part of the bed is formed of a semi-globular piece of hardened steel, which fits loosely into a similar concavity in the bed *r*, and is therefore capable of adjusting itself, so that the blanks shall be properly presented to the cutting tool, and receive the blow or cut in an equal and even manner; or the piece of steel may be of a conical shape, and fit loosely in a similar shaped concavity.

There are guides 16, placed on the top of the bed *i*, for the purpose of keeping the blanks in their proper position towards the cutting tool, and these can be regulated to suit blanks of any width, by turning the right and left handed screw 17. There is also another adjustable stop on the jaws or clamps *k* which serves as a guide when placing the blanks within the jaws: and 19 is a handle or lever for raising the clamps when required, which has a weight suspended from it for the purpose of keeping down the blanks with sufficient pressure upon the bed.

The cutting tool in the face of the hammer can be placed at any required angle or inclination with the blank, it being secured in the head of the hammer by clamps and screws. In cutting fine files a screw is employed in preference to the rack and pinion, for advancing the slide *l*, and the blank piece of steel in the machine.

Hardening the Files.—This is the last and most important part of file-making. Whatever may be the quality of the steel, or however excellent the workmanship, if it is not well hardened all the labour is lost.

Three things are strictly to be observed in hardening: first, to prepare the file on the surface, so as to prevent it from being oxidised by the atmosphere when the file is red-hot, which effect would not only take off the sharpness of the tooth, but render the whole surface so rough that the file would, in a little time, become clogged with the substance it had to work. Secondly, the heat ought to be very uniformly red throughout, and the water in which it is quenched, fresh and cold, for the purpose of giving it the proper degree of hardness. Lastly, the manner of immersion is of great importance, to prevent the files from warping, which in long thin files is very difficult.

The first object is accomplished by laying a substance upon the file, which, when it fuses, forms, as it were, a varnish upon the surface, defending the metal from the action of the oxygen of the air. Formerly the process consisted in first coating the surface of the file with ale grounds, and then covering it over with pulverised common salt (chloride of sodium). After this coating became dry, the files were heated red-hot, and hardened; after this, the surface was lightly brushed over with the dust of cokes, when it appears white and metallic, as if it had not been heated. This process has been improved, at least so far as relates to the economy of the salt, which from the quantity used, and the increased thickness, had become a serious object. Those who used the improved method are now consuming about one-fourth the quantity of salt used in the old method. The process consists in dissolving the salt in water to saturation, which is about three pounds to the gallon, and stiffening it with ale-grounds, or with the cheapest kind of flour, such as that of beans, to about the consistence of thick cream. The files required to be dipped only into this substance, and immediately heated and hardened. The grounds or the flour are of no other use than to give the mass consistence, and by that means to allow a larger quantity of salt to be laid upon the surface. In this method, the salt forms immediately a firm coating. As soon as the water is evaporated, the whole of it becomes fused upon the file. In the old method the dry salt was so loosely attached to the file, that the greatest part of it was rubbed off into the fire, and was sublimed up the chimney, without producing any effect.

The carbonaceous matter of the ale-grounds is supposed to have some effect in giving hardness to the file, by combining with the steel, and rendering it more highly carbonated. It will be found, however, upon experiment, that vegetable carbon does not combine with iron, with sufficient facility to produce any effect, in the short space of time a file is heating for the purpose of hardening. Some file makers are in the habit of using the coal of burnt leather, which doubtless produces some effect; but the carbon is generally so ill prepared for the purpose, and the time of its operation so short, as to render the result inconsiderable. Animal carbon, when properly prepared and mixed with the above hardening composition, is capable of giving hardness to the surface even of an iron file.

This carbonaceous matter may be readily obtained from any of the soft parts of animals, or from blood. For this purpose, however, the refuse of shoemakers and curriers is the most convenient. After the volatile parts have been distilled over, from an iron still, a bright shining coal is left behind, which, when reduced to powder, is fit to mix with the salt. Let about equal parts, by bulk, of this powder, and chloride of sodium be ground together, and brought to the consistence of cream by the addition of water. Or mix the powdered carbon with a saturated solution of the salt, till it becomes of the above consistence. Files which are intended to be very hard, should be covered with this composition, previous to hardening. All files intended to file iron or steel, particularly saw files, should be hardened with the aid of this mixture, in preference to that with the flour or grounds. Indeed, it is probable, that the carbonaceous powder might be used by itself, in point of economy, since the ammonia or hartshorn, obtained by distillation, would be of such value as to render the coal of no expense. By means of this method the files made of iron, which in itself is unsusceptible of hardening, acquire a superficial hardness sufficient for any file whatever. Such files may, at the same time, be bent into any form; and, in consequence, are particularly useful for sculptors and die-sinkers.

The next point to be considered is the best method of heating the file for hardening. For this purpose a fire, similar to the common smith's fire, is generally employed. The file is held in a pair of tongs by the tang, and introduced into the fire, consisting of very small cokes, pushing it more or less into the fire for the purpose of heating it regularly. It must frequently be withdrawn with a view of observing that it is not too hot in any part. When it is uniformly heated, from the tang to the point, of a cherry-red colour, it is fit to quench in the water. At present an oven, formed of fire-bricks, is used for the larger files, into which the blast of the bellows is directed, being open at one end, for the purpose of introducing the files and the fuel. Near to the top of the oven are placed two cross-bars on which a few files are placed, to be partially heating. In the hardening of heavy files, this contrivance affords a considerable saving, in point of time, while it permits them also to be more uniformly and thoroughly heated.

After the file is properly heated for the purpose of hardening, in order to produce the greatest possible hardness, it should be cooled as soon as possible. The most common method of effecting this is by quenching it in the coldest water. Some file-makers have been in the habit of putting different substances in the water, with a view to increase its hardening property. The addition of sulphuric acid to the water was long held a great secret in the hardening of saw-files. After all, however, it will be found that clear spring water, free from animal and vegetable matter, and as cold as possible, is the best calculated for hardening files of every description.

In quenching the files in water, some caution must be observed. All files, except the half-round, should be immersed perpendicularly, as quickly as possible, so that the upper part shall not cool. This management prevents the file from warping. The half-round file must be quenched in the same steady manner; but, at the same time that it is kept perpendicular to the surface of the water, it must be moved a little horizontally, in the direction of the round side, otherwise it will become crooked backwards.

After the files are hardened, they are brushed over with water and powdered cokes, when the surface becomes perfectly clean and metallic. They ought also to be washed well in two or three clean waters for the purpose of carrying off all the salt, which, if allowed to remain, would be liable to rust the file. They should moreover be dipped into lime-water, and rapidly dried before the fire, after being oiled with olive oil, containing a little oil of turpentine, while still warm. They are then finished.

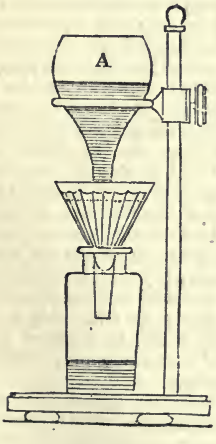
FILIGREE (*Filigrane*, Fr.; *Filigran*, or *Feine Drahtgeflecht*, Ger.) is, as the last term justly expresses it, intertwisted fine wire, used for ornamenting gold and silver trinkets. The wire is seldom drawn round, but generally flat or angular; and soldered by gold or silver solder with borax and the blowpipe. The Italian word, *filigrana*, is compounded of *filum* and *granum*, or granular net-work; because the Italians, who first introduced this style of work, placed small beads upon it.

FILTRATION (Eng. and Fr.; *Filtriren*, Ger.) is a process purely mechanical, for separating a liquid from the undissolved particles floating in it, which liquid may be either the useful part, as in vegetable infusions, or of no use, as the washings of mineral precipitates. The filtering substance may consist of any porous matter in a solid, foliated, or pulverulent form; as porous earthenware, unsized paper, cloth of many kinds, or sand. The white blotting-paper sold by the stationers answers extremely well for filters in chemical experiments, provided it be previously washed with dilute muriatic acid, to remove some lime and iron that are generally present in it. Filter papers are first cut square, and then folded twice diagonally into the shape of a cornet, having the angular parts rounded off. Or the piece of paper, being cut into a circle, may be folded fan-like from the centre, with the folds placed exteriorly, and turned out sharp by the pressure of the finger and thumb, to keep intervals between the paper and the funnel into which it is fitted, to favour the percolation. The diameter of the funnel should be about three-fourths of its height, measured from the neck to the edge. If it be more divergent, the slope will be too small for the ready efflux of the fluid. A filter covered with the sediment is most conveniently washed by spouting water upon it with a little syringe. A small camel's-hair paint-brush is much employed for collecting and turning over the contents in their soft state. Agitation or vibration is of singular efficacy in quickening percolation, as it displaces the particles of the moistened powders, and opens up the pores which had become closed. Instead of a funnel, a cylindrical vessel may be employed, having its perforated bottom covered with a disc of filtering paper folded up at the edges, and made tight there by a wire ring. Linen or calico is used for weak alkaline liquors; and flannels, twilled woollen cloth, or felt-stuff for weak acid ones. These filter bags are often made conical like a fool's cap, and have their mouths supported by a wooden or metallic hoop. Cotton wool put loose into the neck of a funnel answers well for filtering oils upon the small scale. In the large way, oil is filtered in conical woollen bags, or in a cask with many conical tubes in its bottom, filled with tow or cotton wool. Stronger acid and alkaline liquors must be filtered through a layer of pounded glass, quartz, clean sand, or bruised charcoal. The *alcarrhazas* are vessels of porous biscuit stone-ware made in Spain, which are convenient for filtering water, as also is the porous filtering stone of Teneriffe, largely imported into England at one time, but now superseded in a great measure by the artificial filters patented under many forms, consisting essentially of strata of gravel, sand, and charcoal-powder.

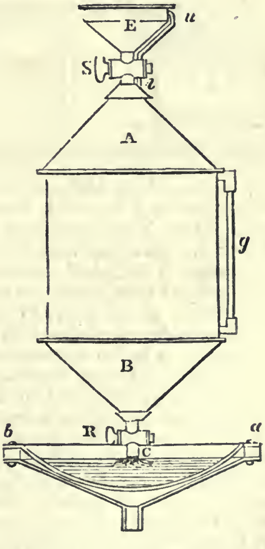
It is convenient to render the filter self-acting by accommodating the supply of liquid to the rate of percolation, so that the pressure upon the porous surface may be always equally great. Upon the small scale, the lamp-fountain or bird's-glass form so generally used for lamps, will be found to answer.

Fig. 859 represents a glass bottle A, partly filled with the fluid to be filtered, supported in the ring of a chemical stand, and having its mouth inverted into the same liquor in the filter funnel. It is obvious, that whenever this liquor by filtration falls below the lip of the bottle, air will enter into it, let down a fresh supply to feed the filter, and keep the funnel regularly charged. If larger quantities are to be operated upon, the following apparatus may be employed. *Fig.* 860, A B, is a metallic vessel, which may be made air-tight; C is the under pipe provided with a stopcock R, for letting down the liquor into the filter *a b*. The upper pipe *t*, through which the fluid

859



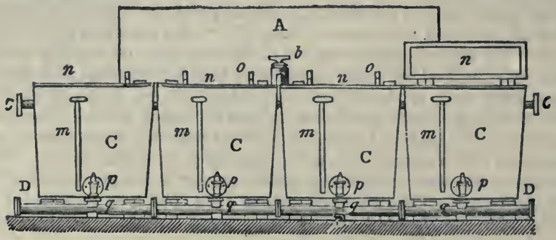
860



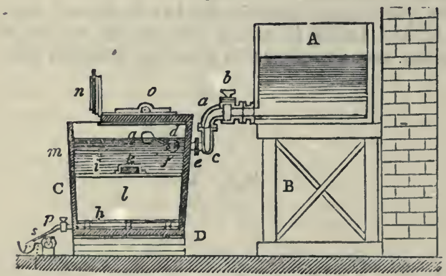
is poured by means of the funnel E, has also a stopcock which opens or shuts, at the same time, the small side tube *u t*, through which, during the entrance of the fluid, the air is let off from the receiver. A glass tube *g*, shows the level of the liquor in the body of the apparatus. In using it, the cock R must be first closed, and the cock S must be opened to fill the receiver. Then the filter is set a-going by reopening the cock R, so as to keep the fluid in the filter upon a level with the opening of the tube C. Both these pieces of apparatus are essentially the same.

In many manufactures, self-acting filters are fed by the plumber's common contrivance of a ball-cock in which the sinking and rising of the ball, within certain limits, serve to open or shut off the supply of liquor as it may be required or not. Dumont has adopted this expedient for his system of filtering syrup through a stratum of granularly ground animal charcoal or bone-black. *Fig.* 861 is a front view of this apparatus with 4 filters C; and *fig.* 862 is a cross section. The framework B supports the cistern A, in which the syrup is contained. From it the liquor flows through the stopcock *b*, and the connection-tube *a*, into the common pipe *c*, which communicates, by the short branch tubes *e*, with each of the four filters. The end of the branch tube, which is inside of the filter tub, is provided with a stopcock *d f*, whose opening, and thereby the efflux of the liquor from the cistern through the tube *a*, is regulated by means of the floating-ball *g*. Upon the brick-work D the filter tub stands, furnished at *h* with a false bottom of zinc or copper pierced with fine holes; besides which, higher up at *i* there is another such plate of metal furnished with a strong handle *k*, by which it may be removed, when the bone-black needs to be changed. In the intervening space *l*, the granular coal is placed. *o* is the cover of the filter tub, with a handle also for lifting it. One portion of it may be raised by a hinge, when it is desired to inspect the progress of the filtration within. *m m* is a slender vertical tube, forming a communication between the bottom part *h*, and the upper portion of the filter, to admit of the easy escape of the air from that space, and from among the bone-black as the syrup descends; otherwise the filtration could not go on. *p* is the stopcock through which the fluid collected in the space under *h* is let off from time to time into the common pipe *q*, *fig.* 861. *r* is a trickling channel or groove lying parallel to the tube *q*, and in which, by means of a tube *s*, inserted at pleasure, the syrup is drawn off in case of its flowing in a turbid state, when it must be returned over the surface of the charcoal.

861



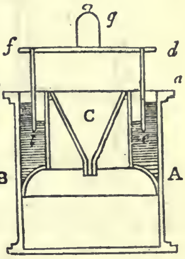
862



The celerity with which any fluid passes through the filter depends,—1, upon the porosity of the filtering substance; 2, upon the pressure exercised upon it; and 3, upon the extent of the filtering surface. Fine powders in a liquor somewhat glutinous, or closely compacted, admit of much slower filtration than those which are coarse and free; and the former ought, therefore, to be spread in a thinner stratum and over a more extensive surface than the latter, for equal effect: a principle well exemplified in the working of Dumont's apparatus, just described.

In many cases filtration may be accelerated by the increase of hydrostatic or pneumatic pressure. This happens when we close the top of a filtering cylinder, and connect it by a pipe with a cistern of fluid placed upon a higher level. The pressure of the air may be rendered operative also either by withdrawing it partially from a close vessel, into which the bottom of the filter enters, or by increasing its density over the top of the liquor to be filtered. Either the air-pump or steam may be employed to create a partial void in the receiver beneath the filter. In like manner, a forcing-pump or steam may be employed to exert pressure upon the surface of the filtering liquor. A common siphon may, on the same principle, be made a good pressure-filter, by making its upper leg trumpet-shaped, covering the orifice with filter-paper or cloth, and filling the whole with liquor, the lower leg being of such length as to create considerable pressure by the difference of hydrostatic level. This apparatus is very convenient either on the small or great scale, for filtering off a clear fluid from a light muddy sediment. The pressure of the atmosphere may be elegantly applied to common filters by the apparatus represented in *fig.* 863, which is merely a funnel enclosed within a gasometer. The case A B bears an annular hollow vessel *a b*, filled with water, in which receiver the cylindrical gasometer *d e f i* is immersed. The filter funnel C is secured at its upper edge to the inner surface of the annular vessel *a b*. In consequence of the pressure of the gasometer regulated by the weight *g*, upon the air enclosed within it, the liquid is equally pressed, and the water in the annular space rises to a corresponding height on the outer surface of the gasometer, as shown in the figure. Were the apparatus made of sheet iron, the annular space might be charged with mercury.

863



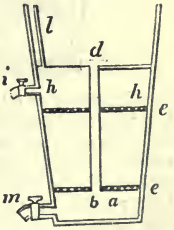
In general, relatively to the application of pressure to filters, it may be remarked, that it cannot be pushed very far, without the chance of deranging the apparatus, or rendering the filtered liquor muddy. The enlargement of the surface is, generally speaking, the safest and most efficacious plan of increasing the rapidity of filtration, especially for liquids of a glutinous nature. This expedient is well illustrated in the creased bag filter now in use in most of the sugar refineries of London. See SUGAR.

An improved method of rapid filtration has been introduced by Professor Bunsen. He facilitates the operation by filtering into a vessel from which the air has been partially exhausted by means of a water air-pump, on the principle of the Sprengel pump. The liquid undergoing filtration is thus forced, by the pressure of the atmosphere, through the pores of the filtering medium, and meets with but little resistance on the opposite side, where it passes into a rarefied atmosphere. Bunsen's paper on this subject has been translated in the 'Philosophical Magazine' for January 1869, p. 1. See ASPIRATOR.

In many cases it is convenient so to construct the filtering apparatus, as that the liquid shall not descend, but mount by hydrostatic pressure. This method has two advantages: 1. that without much expensive apparatus, any desired degree of hydrostatic pressure may be given, as also that the liquid may be forced up through several filtering surfaces placed alongside of each other; 2. that the object of filtering, which is to separate the particles floating in the fluid without disturbing the sediment, may be perfectly attained, and thus very foul liquids be cleared without greatly soiling the filtering surface.

Such a construction is peculiarly applicable to the purification of water, either alone, or combined with the downwards plan of filtration. Of the former variety an example is shown in *fig.* 864. The wooden or zinc conical vessel is provided with two perforated bottoms or sieves *e e*, betwixt which the filtering substance is packed. Over this, for the formation of the space *h h*, there is a third shelf, with a hole in its middle, through which the tube *d b* is passed, so as to be water-tight. This places the upper open part of the apparatus in communication with the lowest space *a*. From the compartment *h h* a small air-tube *l* runs upwards. The filtering substance consists at bottom of pebbles in the middle of gravel, and at the top of fine sand, which may be mixed with coarsely-ground bone-black, or covered with a layer of the same. The water to be filtered being poured into the cistern at top, fills through the tube *b d* the inferior compartment *a*, from which the hydrostatic pressure forces the water upward through the perforated shelf and the filtering materials. The pure water collects in the space *h h*, while the air escapes by the small tube *l*, as the liquid enters. The stopcock *i* serves to draw off the filtered water. As the motion of the fluid in the filter is slow, the particles suspended in it have time to subside by their own gravity; hence there collects over the upper shelf at *d*, as well as over the under one at *a*, a precipitate or deposit which may be washed out of the latter cavity by means of the stopcock *m*.

864



As an example of an upwards and downwards filter, *fig.* 865 may be exhibited. A B C D is a wooden or metallic cistern, furnished with the perforated shelf *c d* near its under part, upon which a vertical partition is fixed through the axis of the vessel. A semicircular perforated shelf is placed at *a*, and a second similar one at *b*. These horizontal shelves rest upon brackets in the sides of the cisterns, so that they may be readily lifted out. The space G is filled with coarse sand, J with moderately fine, and H with very fine. The foul water is poured into the chamber E, and presses through G J H and into the space F, whence it may be drawn by the stopcock *f*.

865

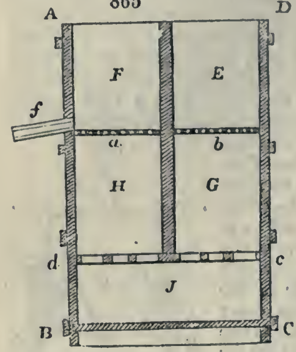


Fig. 866 represents in section a filtering apparatus, consisting of two concentric chambers; the interior being destined for downwards filtration, and the exterior for upwards. Within the larger cistern A, a smaller one B is placed concentrically, with its under part, and is left open from distance to distance, to make a communication between the interior cavity and the exterior annular space. These cavities are filled to the marked height with sand and gravel. The inner cylindrical space has fine sand below, then sharper sand with granular charcoal, next coarse sand, and lastly gravel. The annular space has in like manner fine sand below. The foul water is introduced by the pipe E, the orifice at whose end is acted upon by a ball-cock with its lever *a*; whereby the water is kept always at the same level in the inner vessel. The water sinks through the sand strata of the middle vessel, passes outwards at its bottom into the annular space, thence up through the sand in it, and, collecting above it, is let off by the stopcock on the pipe *b*. When a muddy deposit forms after some time, it may be easily cleared out. The cord *e*, running over the pulleys *f f*, being drawn tight, the ball lever will shut up the valve. The stopcock *d* made fast to the conducting tube E must then be opened, so that the water now overflows into the annular space at A; the tube *c*, in communication with the inner space B, being opened by taking out the stopper *h*. The water thereby percolates through the sand strata in the reverse direction of its usual course, so as to clear away the impurities in the space B, and to discharge them by the pipe *c h*. An apparatus of this kind of moderate size is capable of filtering a great body of water. It should be constructed for that purpose of masonry; but upon a small scale it may be made of stone-ware.

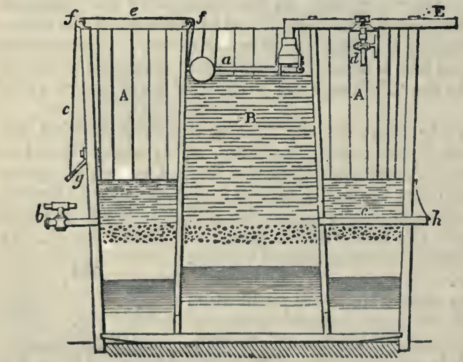
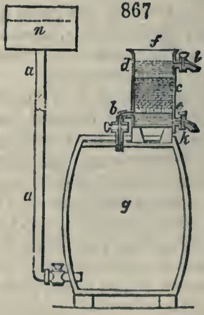
866



867



A convenient apparatus for filtering oil upwards is represented in *fig.* 867. *g* is an oil cask, in which the impure parts of the oil have accumulated over the bottom. Immediately above this, a pipe *a* is let in, which communicates with an elevated water-cistern *n*. *f* is the filter (placed on the lid of the cask), furnished with two perforated shelves, one at *e* and another at *d*, which divide the interior of the filter into three compartments. Into the lower space immediately over the shelf *e*, the tube *b*, furnished with a stopcock, enters, to establish a communication with the cask; the middle cavity *c* is filled with coarsely-ground charcoal or other filtering materials; and the upper one has an eduction-pipe *l*. When the stopcocks of the tubes *a* and *b* are opened, the water passes from the cistern into the oil cask, occupies from its density always the lowest place, and presses the oil upwards, without mixing the two liquids; whereby first the upper and purer portion of the oil is forced through the tube *b* into the filter, and thence out through the pipe *l*. When the fouler oil follows, it deposits its impurities in the space under the partition *c*, which may from time to time be drawn off through the stopcock *k*, while the purer oil is pressed upwards through the filter. In this way the different strata of oil in the cask may be filtered off in succession, and kept separate, if found necessary for sale or use, without running any risk of mixing up the muddy matter with what is clear. According to the height of the water-cistern *n* will be the pressure, and of course the filtering force. When the filter gets choked with dirt, it may be easily re-charged with fresh materials.

It has been for many years the custom of the Water Companies to send the water taken from the river through filter beds, prepared usually of sand and gravel. It was long thought that the effect of these filter beds was merely to separate the solid insoluble matters suspended in the water. It has, however, been shown by the investigations of the late Mr. Henry M. Witt (a chemist of peculiar promise, lost too soon to science, and ere yet the world could recognise his powers), that these filter beds had the power of separating many of the dissolved substances from the water; that, in fact, the soluble salts of lime, and the like, were removed by some peculiar physico-mechanical force, resident, as it appears, as a surface-force, in all porous masses. There are many very remarkable examples in nature of the operation of this power in producing beds charged with metalliferous matter, some of which will be described under the head of MINING.

Mr. H. M. Witt communicated to the 'Philosophical Magazine' for December, 1856, an account of some experiments on filtration, which are of much value. Many of his experiments were made at the Chelsea Water-works, and they appear of such interest that we quote the author's remarks to some extent:—

'The system of purification adopted by the Chelsea Water-works, at their works at Chelsea, consisted hitherto (for the supply has by this time commenced from Kingston) in pumping the water up out of the river into subsiding reservoirs, where it remained for six hours; it was then allowed to run on to the filter-beds. These are large square beds of sand and gravel, each exposing a filtering surface of about 270 square feet, and the water passes through them at the rate of about 6¼ gallons per square foot of filtering surface per hour, making a total quantity of 1687·5 gallons per hour through each filter.

'The filters are composed of the following strata, in a descending order:—

	ft.	in.
1. Fine sand	2	6
2. Coarser sand	1	0
3. Shells	0	6
4. Fine gravel	0	3
5. Coarse gravel	3	3

These several layers of filtering materials are not placed perfectly flat, but are disposed in waves, and below the convex curve of each undulation is placed a porous earthenware pipe, which conducts the filtered water into the mains for distribution. The depth of water over the sand was 4 feet 6 inches. The upper layer of sand is renewed about every six months, but the body of the filter has been in use for about twenty years.

'Samples of water were taken and submitted to examination:—

'1st, from the reservoir into which the water was at the time being pumped from the middle of the river.

'2nd, from the cistern, after subsidence and filtration.'

Experiments were made at different seasons of the year; but one of Mr. Witt's tables will sufficiently show the results.

	1 Originally present	2 After filtration	3 Amount separated	4 Percentage ratio of separated Matter
Total solid residue, including suspended matter	55·60	22·85	32·75	58·90
Organic matter	4·05	1·349	2·70	66·66
Total mineral matter	51·55	21·501	30·049	58·29
Suspended matter	28·93	2·285	26·645	92·10
Total dissolved salts	22·62	19·216	3·404	15·04
Lime	8·719	8·426	0·293	3·36

Col. 1 shows the quantities of the several substances originally present, represented in grains, in the imperial gallon (70,000 grains) of water.

2. The amount present after filtration.

3. The actual quantities separated in grains in the gallon of water.

4. The percentage ratio which the amounts separated bear to the quantities originally present.

'It has been assumed as a principle that sand-filtration can only remove bodies mechanically suspended in water, but I am not aware that this statement has been established by experiment; in fact, I am not acquainted with any published analytical examination of the effects of sand-filtration.

'These experiments supply the deficiency, and show, moreover, that these porous media are not only capable of removing suspended matter (80 to 92 per cent.), but even of separating a certain appreciable quantity of the salts from solution in water, viz. from 5 to 15 per cent. of the amount originally present, 9 to 19 per cent. of the common salt, 3 per cent. of the lime, and 5 of the sulphuric acid.

'Taking the purer water from Kingston, two experiments were made simultaneously with the same water, one filtration being through charcoal alone, and the other through sand alone; the sand filter having an area of 4 square feet, and consisting of the following materials:—

	ft.	in.
Fine sand	1	9
Shells		1½
Gravel		1½
Coarse gravel		9
	2	9

'Apart from its special interest, as compared with the following experiment, made simultaneously through charcoal, the following points are in themselves remarkable in the results obtained by this filtration through sand:—

'1st. That the filter continued increasing in efficacy even till the conclusion of the experiment, *i.e.*, for 376 hours, not having lost any of its power when the experiment was terminated.

'2nd. That no weighable quantity of dissolved organic matter was removed by the sand in this experiment; but it must be remembered that the quantity originally present was but small.

'3rd. Its power of removing soluble salts was considerable; as a maximum, 21 per cent. of the common salt being separated.'

On comparing this experiment with the preceding, the following point comes out as showing the difference between the effects of sand and charcoal as filtering media.

By the charcoal, speaking generally, a considerably larger quantity of the total residue contained in the water was removed than by the sand, their maximum results being respectively as follow:—

Amount originally present	Amount separated in Grains in the Gallon		Amount separated in Percentage of the Quantity present	
	By Sand	By Charcoal	By Sand	By Charcoal

FIRE ANNIHILATORS. This name is given to a portable machine invented by Mr. Phillips, which is adjusted to produce the immediate production of steam, carbonic acid, and other gases, which could be at once directed on the burning mass. The machine is cylindrical in form, and slightly conical. For use it is charged with the following composition: charcoal 20 parts, nitrate of potash 60 parts, and gypsum 5 parts. These materials are boiled together in water, and afterwards dried in a stove at the temperature of 100°. The whole is moulded into the form of a brick, down the axis of which penetrates a hollow cavity for the reception of a bottle, which contains a mixture of chlorate of potash and sugar, surmounted by a globule of sulphuric acid. The charge so prepared is placed in a cylindrical vessel, perforated in many places, which is itself within another cylindrical vessel, also perforated for the passage of the gases; both these are contained in a double cylindrical receiver, the lower part of which contains a quantity of water. The apparatus is closed by two covers, in the outer of which is an opening for the escape of the vapour. In the centre of the cover is placed a spike, for the purpose of breaking the glass bottle deposited in the cavity of the charge. The spike being forced down breaks the bottle, and the sulphuric acid causes the instantaneous combustion of the chlorate of potash and sugar, which fires the charge. The gases now escape through the perforations, and heating the air in the water-chamber, and causing it to expand, forces the water up a tubular passage into the space between and around the cylindrical vessels placed each within each, and being thus converted into vapour, mixes with the gases, and escapes by the discharge-tube, forming a dense cloud, which rapidly extinguishes flame.

Many very successful experiments were made with these fire annihilators, but they have not been much used. There can be no doubt the principle is a correct one. Any arrangement for pouring carbonic acid upon flame would be certain of success, if the cost of production did not stand in the way. A patent was granted in 1873 to Mr. W. B. Dick, of Glasgow, for improvements in apparatus for extinguishing fires. Carbonic acid gas is generated by the action of sulphuric acid on bicarbonate of soda, and is dissolved in water; the solution is projected, by the expansive force of the gas, from a strong vessel through a regulator valve and delivery hose. The bottle of acid is held between a fixed bottom-support and a moveable cap, and is broken by striking an external cap. These 'extincteurs' have been recently supplied to some of the Government offices.

FIRE-ARMS, MANUFACTURE OF. This article belongs properly to a work on mechanical engineering. It cannot be extended as it should be without encroaching to too great an extent upon the space reserved for the articles which legitimately belong to this Dictionary. It has therefore been allowed to remain as it stood in the last edition: all the main principles connected with the construction of fire-arms being fully described.

This art is divided into two branches: that of the metallic, and that of the wooden work. The first includes the barrel, the lock, and the mounting, with the bayonet and ramrod, for military arms. The second comprises the stock, and in fowling-pieces likewise the ramrod.

The Barrel.—Its interior is called the bore; its diameter, the calibre; the back end, the breech; the front end, the muzzle; and the closing of the back end, the breech pin or plug. The barrel is generally made of iron. Most military muskets and low-priced guns were formerly fashioned out of a long slip of sheet-iron folded together edge-wise round a skewer into a cylinder; they were then lapped over at the seam, and welded at a white heat. The most ductile and tenacious soft iron, free from all blemishes, must be selected for this slip. It is frequently welded at the common forge, but a proper air-furnace answers better, not being so apt to burn the iron, which should be covered with ashes or cinders. The shape of the bore is given by hammering the cylinder upon a steel mandril, in a groove of the anvil. Six inches of the barrel at either end are left open for forming the breech and the muzzle by a subsequent welding operation; the extremity put into the fire being stopped with clay, to prevent the introduction of cinders. For every length of two inches, there are from two to three welding operations, divided into alternating high and low heats; the latter being intended to correct the defects of the former. The breech and muzzle are not welded upon the mandril, but upon the horn of the anvil; the breech, being thicker in the metal, is more highly heated, and is made somewhat wider to save labour to the borer. The barrel is finally hammered in the groove of the anvil without the mandril, during which process it receives a heat every two minutes. In welding, the barrel extends about one-third in length; and for muskets, is eventually left from 3 to 3½ feet long; but for cavalry pistols, only 9 inches.

The best iron plates for gun-barrels are those made of *stub* iron; that is, of old horse-shoe nails welded together, and forged into thin bars, or rather narrow ribands. At one time *damascus* barrels were much in vogue; they were fashioned either as above described, from plates made of bars of iron and steel laid parallel, and welded together, or from ribands of the same damascus stuff coiled into a cylinder at a red heat, and then welded together at the seams. The best modern barrels for fowling-pieces and the modern rifles are constructed of stub nail-iron in this manner. The slip or fillet is only half an inch broad, or sometimes less, and is left thicker at the end which is to form the breech, and thinner at the end which is to form the muzzle, than in the intermediate portion. This fillet, being moderately heated to increase its pliancy, is then lapped round the mandril in a spiral direction till a proper length of cylinder is formed; the edges being made to overlap a little in order to give them a better hold in the welding process. The coil, being taken off the mandril and again heated, is struck down vertically with its muzzle end upon the anvil, whereby the spiral junctions are made closer and more uniform. It is now welded at several successive heats, hammered by horizontal strokes, called *jumping*, and brought into proper shape on the mandril. The finer barrels are made of still narrower stub-iron slips, whence they get the name of wire twist. On the Continent, some barrels are made of steel wire, welded together lengthwise, then coiled spirally into a cylinder. Barrels that are to be rifled, require to be made of thicker iron, and that of the very best quality, for they would be spoiled by the least portion of scale upon their inside. Soldiers' muskets are thickened a little at the muzzle, to give a stout holding to the bayonet.

The barrels thus made are annealed with a gentle heat in a proper furnace, and slowly cooled. They are now ready for the borer, which is an oblong square *bit* of steel, pressed in its rotation against the barrel by a lip of wood applied to one of its flat sides and held in its place by a ring of metal. The boring bench works horizontally, and has a very shaky appearance, in respect at least of the bit. In some cases, however, it has been attempted to work the barrels and bits at an inclination to the horizon of 30°, in order to facilitate the discharge of the borings. The barrel is held in a slot by only one point, to allow it to humour the movements of the borer, which would otherwise be infallibly broken. The bit, as represented in *fig.* 868, has merely its square head inserted into a clamp-chuck of the lathe, and plays freely through the rest of its length.

868

869

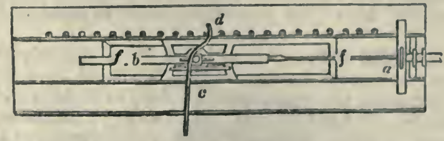

Fig. 869 represents in plan the *boring bench* for musket barrels; *f f* is the sledge or carriage frame in which the barrel is supported; *a* is the revolving chuck of the lathe, into which the square end of the bit, *fig.* 868, is inserted; *b* is the barrel, clamped at its middle to the carriage, and capable of being pressed onwards against the tapering bit of the borer, by the bent lever *c*, worked by the left hand of the operative against fulcrum knobs at *d*, which stand about two inches asunder. Whenever the barrel has been thereby advanced a certain space to the right, the bent end of the lever is shifted against another knob or pin. The borer appears to a stranger to be a very awkward and unsteady mechanism, but its perpetual vibrations do not affect the accuracy of the bore. The opening broach may be of a square or pentagonal form; and either gradually tapered from its thickest part, or of uniform diameter till within two inches of the end, whence it is suddenly tapered to a point.

A series of bits may be used for boring a barrel, beginning with the smallest and ending with the largest. But this multiplication of tools becomes unnecessary, by laying against the cutting part of the bit, slips of wood, called spales, of gradually increasing thickness, so that the edge is pressed by them progressively further from the axis. The bore is next polished. This is done by a bit with a very smooth edge, which is mounted as above, with a wedge of wood besmeared with a mixture of oil and emery. The inside is finished by working a cylindrical steel file quickly backwards and forwards within it, while it is revolving slowly.

In boring, the bit must be well oiled or greased, and the barrel must be kept cool by letting water trickle on it; for the bit, revolving at the rate of 120 or 140 times a minute, generates a great deal of heat. If a flaw be detected in the barrel during the boring, that part is hammered in, and then the bit is employed to turn it out.

Many sportsmen are of opinion that a barrel with a bore somewhat narrowed towards the muzzle serves to keep shot better together; and that roughening its inside with pounded glass has a good effect, with the same view. For this purpose, also, fine spiral lines have been made in their interior surface. The justness of the calibre of a fowling-piece or musket is tried by means of a truly-turned cylinder of steel, 3 or 4 inches long, which ought to move without friction, but with uniform contact from end to end of the barrel. Whatever irregularities appear must be immediately removed.

The outer surface of the barrel is commonly polished upon a dry grindstone, but it is better finished at a turning lathe with a slide-rest.

Rifle barrels have parallel grooves of a square or angular form cut within them, each groove being drawn in succession. These grooves run spirally, and form each an aliquot part of a revolution from the chamber to the muzzle. Rifles should not be too deeply indented, only so much as to prevent the ball turning round within the barrel; and the spires should be truly parallel, that the ball may glide along with a regular pace.

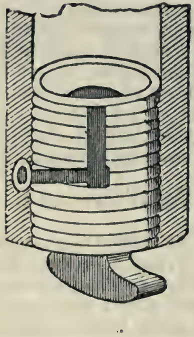
The Parisian gun-makers, who are reckoned very expert, draw out the iron for the barrels at hand forges, in fillets only one-ninth of an inch thick, one inch and a half broad, and four feet long. Twenty-five of these ribands are laid upon each other, between two similar ones of double thickness, and the bundle, weighing 60 lbs., bound with wire at two places, serves to make two barrels. The thicker plates are intended to protect the thinner from the violence of the fire in the numerous successive heats necessary to complete the welding, and to form the bundle into a bar two-thirds of an inch broad, by half an inch thick; the direction of the individual plates relatively to the breadth being preserved. This bar, folded flat upon itself, is again wrought at the forge, till it is only half an inch broad, and a quarter of an inch thick, while the plates of the primitive ribands are now set perpendicular to the breadth of the narrow fillet; the length of which must be 15 or 16 feet French (16 or 17 English), to form a fowling-piece from 28 to 30 inches long. This fillet, heated to a cherry red in successive portions, is coiled into as close a spiral as possible, upon a mandril about two-fifths of an inch in diameter. The mandril has at one end a stout head for drawing it out, by means of the hammer and grooves of the anvil, previous to every heating. The welding is performed upon a mandril introduced after each heat; the middle of the barrel being first worked, while the fillets are forced back against each other, along the surface of the mandril, to secure their perfect union. The original plates, having in the formation of the ultimate long riband become very thin, appear upon the surface of the barrel like threads of a fine screw, with blackish tints to mark the junctions. In making a double-barrelled gun, the two are formed from the same bundle of slips, the coils of the one finished fillet being turned to the right hand, and those of the other to the left.

The barrels forged, as above described, from a bundle of steel and iron plates laid alternately together, are twisted at the forge several times, then coiled and welded as usual. Fifteen workmen concur in one operation: six at the forge; two at the boring mill; seven at filing, turning, and adjusting; yet altogether make only six pairs of barrels per week. In the first instance, it will be understood, that, for the construction of the superior barrels, a bundle of horse-shoe nails is welded into a flat bar, similar bars of scrap steel are made, and these are made up into a bundle—a bar of iron, and a bar of steel—of eight or twelve bars. This is again welded into one bar, and the result is, when the surface is polished, that the difference in the texture of the two metals is distinctly visible. Now, if two bars of iron and one of steel, or two bars of steel and one of iron, or any other combination of the two, be adopted, there will be a variety in the pattern of the finished bar.

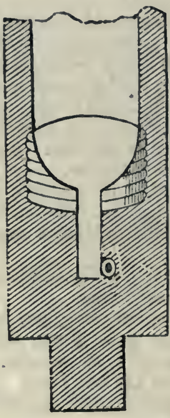
In constructing the barrel this bar may be twisted up singly, as described, or two bars differing in pattern may be welded together, and then twisted. It is usual to place two bars together, to twist one into a screw and leave the other plain, or to give one a right-handed twist and the other a left-handed one; or sometimes three bars are employed, and by twisting or otherwise previously to welding the bars together, and turning or twisting the compound bar into a cylinder, a great variety of patterns are produced on the finished barrel.

The breeching is of three kinds: the common; the chamber, plug, or mortar, *fig.* 870; and the patent, *fig.* 871. The common was formerly used for soldiers' muskets and inferior pieces. The second is a trifling improvement upon it. In the patent breeching, the screws do not interfere with the touch-hole, and the ignition is quicker in the main chamber.

870



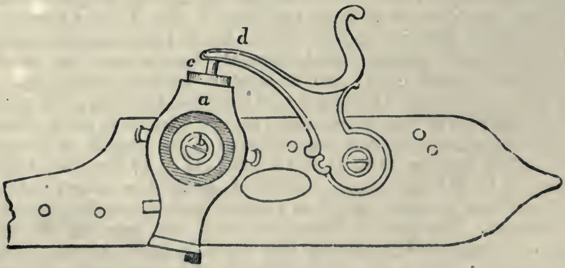
871



The only locks which it is worth while to describe are those upon the percussion principle, as flint locks have ceased to be employed. Forsyth's lock (*fig.* 872) was an ingenious contrivance. It has a magazine *a*, for containing the detonating powder, which revolves round a roller *b*, whose end is screwed into the breech of the barrel. The priming powder passes through a small hole in the roller, which leads to a channel in communication with the chamber of the gun.

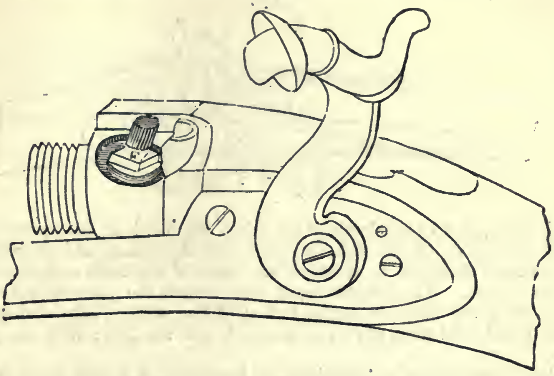
The pan for holding the priming is placed immediately over the little hole in the roller. There is a steel punch *c*, in the magazine, whose under end stands above the pan, ready to ignite the priming when struck upon the top by the cock *d*, whenever the trigger is drawn. The punch, immediately after being driven down into the pan, is raised by the action of a spiral spring. For each explosion, the magazine must be turned so far round as to let fall a portion of the percussion powder into the pan; after which it is turned back, and the steel punch recovers its proper position for striking another blow into the pan.

872



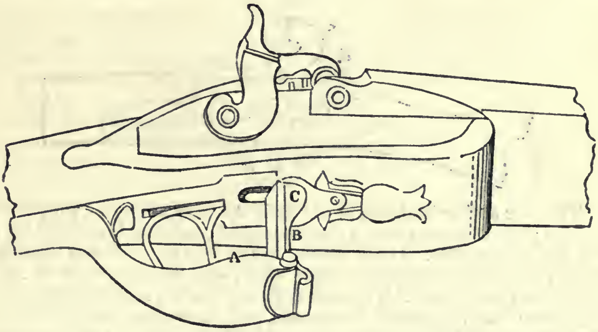
The invention of the copper percussion cap was another great improvement upon the detonating plan. *Fig.* 873 represents the ordinary percussion lock, which is happily divested of three awkward projections upon the flint lock, namely, the hammer, hammer spring, and the pan. Nothing now appears upon the plate of the lock, but the cock or striking hammer, which inflicts the striking blow upon the percussion cap. It is concave, with a small metallic ring or border, called a shield or fence, for the purpose of enclosing the cap, as it were, and preventing its splinters doing injury to the sportsman; as also protecting against the line of flame which may issue from the touch-hole in the cap-nipple. This is screwed into the patent breech, and is perforated with a small hole.

873



The safety lock of Dr. Somerville is, in its essential feature, a slide stop or catch, placed under the trigger, A, *fig.* 874. It is pulled forward into a notch in the trigger,

874



by means of a spring B, upon the front of the guard, which is worked by a key C, pressing upon the spring when the piece is discharged. In another safety plan there is a small moveable curved piece of iron, A, which rises through an opening B, in the lock-plate C, and prevents the cock from reaching the nipple, as represented in the figure, until it is drawn back within the plate of the lock when the piece is fired.

To fire this gun, two different points must be pressed at the same time. If by accident the key which works the safety be touched, nothing happens, because the trigger is not drawn; and the trigger touched alone can produce no effect, because it is locked. The pressure must be applied to the trigger and the key at the same instant, otherwise the lock will not work.

The old French musket is longer than the British, in the proportion of 44·72 inches to 42; but the French bayonet is 15 inches, whereas the British is 17.

	Eng. Dimensions	Fr. Dimensions

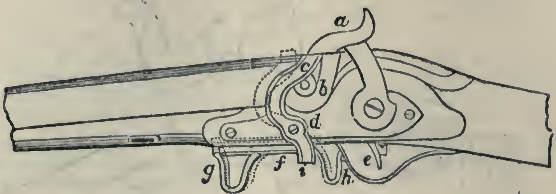
Diameter of the ball	0·676	0·65
Weight of the ball in oz.	1·06	0·958
Weight of the firelock and bayonet in lbs.	12·25	10·980
Length of the barrel and bayonet . .	59·00	59·72

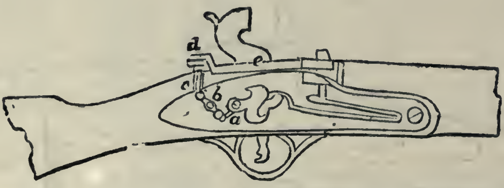
Within these few years a great many contrivances for fire-arms have been brought forward, and several have been patented. The first is that of Charles Random, Baron de Berenger. *Fig.* 875 shows the lock and breech of a fowling-piece, with a sliding protector on one of the improved plans; *a* is the hammer, *b* the nipple of the touch-hole, *c* a bent lever, turning upon a pin, fixed into the lock-plate at *d*. The upper end of this bent lever stands partly under the nose of the hammer, and while in that situation stops it from striking the nipple. A slider *g f h*, connected with the under part of the gun-stock, is attached to the tail of the bent lever at *i*; and when the piece is brought to the shoulder for firing, the hand of the sportsman pressing against the bent part of the slider at *g*, forces this back, and thereby moves the end of the lever *c* forwards from under the nose of the cock or hammer, as shown by the dotted lines. The trigger being now drawn, the piece will be discharged; and on removing the hand from the end *g*, of the slider *f*, the spring at *h*, acting against the guard, will force the slider forward, and the lever into the position first described.

875



Mr. Redford, gun-maker, of Birmingham, introduced a modification of the lock for small fire-arms, in which the application of pressure to the sear spring for discharging the piece is made by means of a plug, depressed by the thumb, instead of the force of the finger exerted against the trigger. *Fig.* 876 represents a fowling-piece partly in action. The sear spring is shown at *a*. It is not here connected with the trigger, as in other locks; but is attached by a double-jointed piece to a lever *b*, which turns upon a fulcrum pin in its centre. At the reverse end of this lever an arm extends forwards, like that of an ordinary sear spring, upon which arm the lower end of the plug *c* is intended to bear; and when this plug is depressed by the thumb bearing upon it, that end of the lever *b* will be forced downwards, and the reverse end will be raised, so as to draw up the end of the sear spring, and set off the piece. For the sake of protection, the head of the plug *c* is covered by a moveable cap *d*, forming part of a slider *e*, which moves to and fro in a groove in the stock, behind the breech end of the barrel; this slider *e* is acted upon by the trigger through levers, which might be attached to the other side of the lock-plate; but are not shown in this figure to avoid confusion. When the piece is brought to the shoulder for firing, the fore-finger must be applied as usual to the trigger, but merely for the purpose of drawing back the slider *e*, and uncovering the head of the plug; when this is done, the thumb is to be pressed upon the head of the plug, and will thus discharge the piece. A spring bearing against the lever of the slider *e*, will, when the finger is withdrawn from the trigger, send the slider forward again, and cover the head of the plug, as shown.

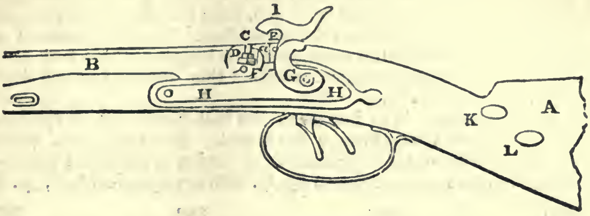
876



The Rev. John Somerville, of Currie, in April 1835, obtained a patent for a further invention to prevent the accidental discharge of fire-arms. It consists in hindering the hammer from reaching the nipple of a percussion lock, or the flint reaching the steel of an ordinary one, by the interposition of moveable safety studs or pins, which protrude from under the false breech before the hammers of the locks, and prevent them from descending to strike. These safety studs or pins are moved out of the way by the pressure of the right hand of the person using the gun only when in the act of firing; that is, when the force of the right hand and arm is exerted to press the butt-end of the stock of the gun against the shoulder while the aim is taken and the trigger pulled. In carrying the gun at rest, the proper parts of the thumb or hand do not come over Mr. Somerville's moveable buttons or studs.

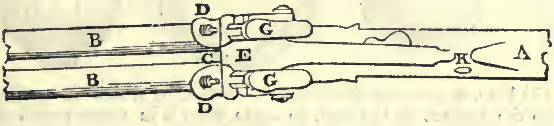
Fig. 877 is a side view of part of a double percussion gun; and *fig.* 878 is a top or plan view, which will serve to explain these improvements, and show one out of many methods of carrying them into effect. A is the stock of the gun; B the barrels; C the breech; D the nipples; E the false breech, on the under side of which the levers which work the safety studs or pins are placed; F is the shield of the false breech; G triggers; H the lock-plate; and I the hammers: all of which are constructed as usual;

877

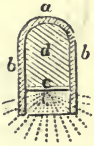


a a are the safety studs or pins, which protrude before the shield F, and work through guide pieces on the under side of the false breech. The button piece is placed

878



879



in the position for the thumb of the right hand to act upon it; but when the pressure of the ball of the right thumb is to produce the movement of the safety studs, it must be placed in or near the position K; and when the heel of the right hand is to effect the movement of the safety studs, the button piece must be placed at L, or nearly so.

In these last two positions, the lever (which is acted upon by the button piece to work the safety studs through a slide) would require to be of a different shape and differently mounted. When the hammers are down upon the nipples after discharging the gun, the ends of the safety pins press against the inner sides of the hammers. When this invention is adapted to single-barrelled guns, only one pin, *a*, one lever and button piece will be required.

Mr. Richards, gun-maker, Birmingham, patented a modification of the copper cap for holding the percussion powder, as represented in *fig.* 879; in which the powder is removed from the top of the cap, and brought nearer the mouth; *a* being the top, *b* the sides, and *c* the position of the priming. The dotted lines show the direction of the explosion, whereby it is seen that the metal case is opened or distended only in a small degree, and not likely to burst to pieces, as in the common caps, the space between *a* and *c* being occupied by a piece of any kind of hard metal *d*, soldered or otherwise fastened in the cap.

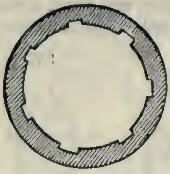
George Lovell, Esq., Director of the Royal Manufactory of Arms at Enfield, introduced an improvement upon the priming chamber. He forms it into a vertical double cone, joined in the middle by the common apex; the base of the upper cone, being in contact with the percussion cap, presents the most extensive surface to the fulminate upon the one hand, while the base of the under one, being in a line with the interior surface of the barrel, presents the largest surface to the gunpowder charge, upon the other. In the old nipple the apex of the cone being at its top, afforded very injudiciously the *minimum* surface to the exploding force.

Guns, Rifling of the Barrels.—The outside of rifle barrels is, in general, octagonal. After the barrel is bored, and rendered truly cylindrical, it is fixed upon the rifling machine. This instrument is formed upon a square plank of wood 7 feet long, to which is fitted a tube about an inch in diameter, with spiral grooves deeply cut internally through its whole length; and to this a circular plate is attached about 5 inches diameter, accurately divided in concentric circles, into from 5 to 16 equal parts, and supported by two rings made fast to the plank, in which rings it revolves. An arm connected with the dividing graduated plate, and pierced with holes, through which a pin is passed, regulates the change of the tube in giving the desired number of grooves to the barrel. An iron rod, with a moveable handle at the one end, and a steel cutter in the other, passes through the above rifling tube. The rod is covered with a core of lead one foot long. The barrel is firmly fixed by two rings on the plank, standing in a straight line on the tube. The rod is now drawn repeatedly through the barrel, from end to end, until the cutter has formed one groove of the proper depth. The pin is then shifted to another hole in the dividing plate, and the operation of grooving is repeated till the whole number of riflings is completed. The barrel is next taken out of the machine, and finished. This is done by casting upon the end of a small iron rod a core of lead, which, when besmeared with a mixture of fine emery and oil, is drawn, for a considerable time, by the workmen, from the one end of the barrel to the other, till the inner surface has become finely polished. The best degree of spirality is found to be from a quarter to half a revolution in a length of three feet.

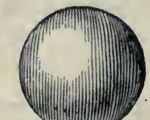
Military Rifles.—An essential improvement in this destructive arm has been introduced into the British service.

The intention in all rifles is to impart to the ball a rotatory or spinning motion round its axis, as it passes out through the barrel. This object was attained, to a certain degree, in the rifles of the old pattern, by cutting seven spiral grooves into the inside of the barrel, in the manner shown by *fig.* 880, the spherical ball, *fig.* 881, being a little larger than the bore, was driven down with a mallet, by which the projecting ribs were forced into the surface of the ball, so as to keep it in contact with their curvatures, during its expulsion. Instead of this laborious and insecure process, the barrel being now cut with only two opposite grooves, *fig.* 882, and the ball being formed with a projecting belt, or zone, round its equator, of the same form as the two grooves, *fig.* 883, it enters so readily into these hollows, that little or no force is required to press it down upon the powder. So much more hold of the barrel is at the same time obtained, that instead of one *quarter* of a turn, which was the utmost that could be safely given in the old way, without danger of stripping the ball, a *whole* turn round the barrel in its length can be given to the two grooved rifles; whereby a far more certain and complete rotatory motion is imparted to the ball. The grand practical result is, that better practice has been performed by several companies of the Rifle Corps at 300 yards than could be produced with the best old military rifles at 150 yards; the soldier being meanwhile enabled to load with much greater ease and despatch. The belt is bevelled to its middle line, and not so flat as shown in the figure.

880



881



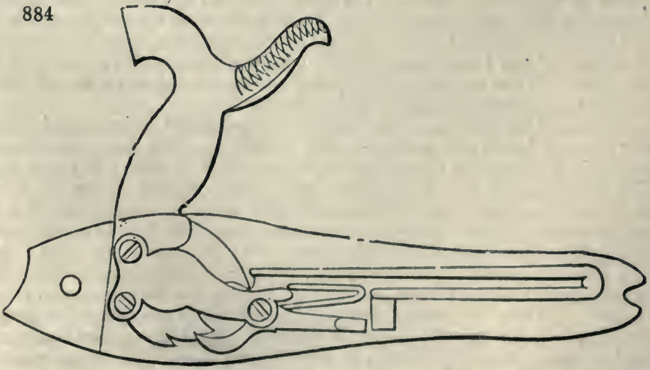
882

883

This mode of rifling is not, however, new in England. In fact, it is one of the oldest upon record; and appears to have fallen into disuse from faults in the execution. The idea was revived within the last few years in Brunswick, and it was tried in Hanover also, but with a lens-shaped (*linsenformig*) ball. The judicious modifications and improvements it has finally received, have brought out all its advantages, and rendered it, when skilfully used, a weapon of unerring aim, even at the distance of 700 yards.

The locks, also, for the military service generally, are receiving important improvements. In Lovell's lock the action of the main spring is reversed, as shown by *fig.* 884; thus rendering the whole mechanism more solid, compact, and convenient;

884



while the ignition of the charge is effected by percussion powders in a copper cap. Mr. Lovell, Inspector of Small Arms for Her Majesty's service, and Director of the Royal Manufactory, at Enfield Chase, directed his attention to the construction of a sure, simple, and strong musket, with which, under his superintendence, the whole of Her Majesty's soldiers were long provided. He has also furnished them with a short, but clear set of instructions for the cleaning and management of these excellent arms, illustrated by a series of wood engravings. From this little work the following notice is copied:—

885

889

Fig. 885. The barrel, reduced to one-seventh size. *a*, the breech; *b*, the nipple-seat or lump; *c*, the back sight; *d*, the back loop; *e*, the middle loop; *f*, the swivel loop; *g* the front loop, with the bayonet-spring attached; *h*, the front sight; *i*, the muzzle.

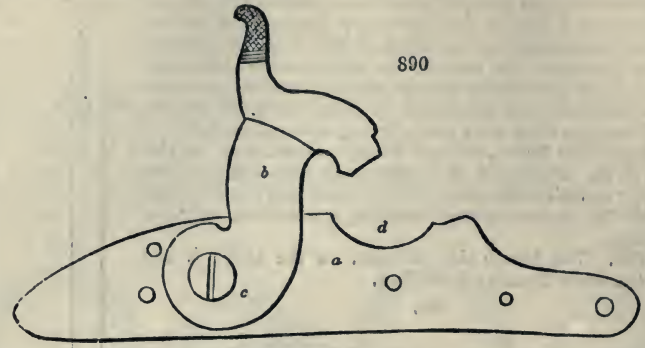
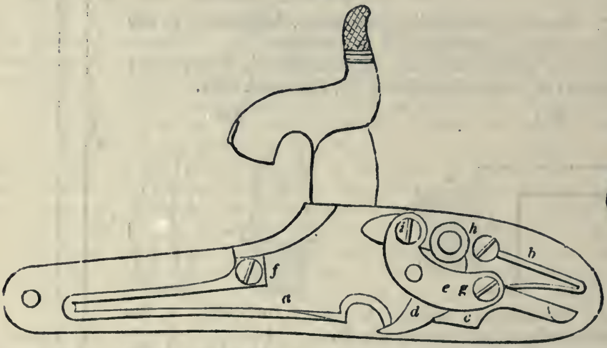
Barrel-welding by Machinery.—The barrels of muskets, birding-guns, &c., or what are called *plain*, to distinguish them from those denominated *stub* or twisted barrels, have of late years been formed by means of rolls: a process in which the welding is first effected on a short slab of thick iron, and then the barrel is brought down to its destined length and form, by repeatedly passing it between a pair of rolls, that have been previously grooved to the exact shape of the barrel intended to be made.

The iron, being thoroughly refined, and reduced into flat bars by the process described, is cut by the shears into slabs or lengths of 10 to 12 inches, and 10 to 10½ lbs. weight, or less, according to the description of gun-barrel that is intended to be made. These slabs are then heated, and bent in their whole length, by means of conveniently-grooved bending rolls, until they assume the form of rough tubes, of the kind of section shown by A, *fig.* 892. They are then placed on the hearth of the reverberatory furnace, and brought to a full welding-heat, and, as soon as the edges of a tube come to a semi-fluid state, it is taken out and passed between rolls having grooves somewhat smaller in diameter than the exterior of the tube, by which means the tube is perfectly welded from end to end; and if care be taken in the management of the heat, and the juncture be kept clear of dirt and cinders, the iron will be found perfectly homogeneous in every part, and there will be no appearance whatever of the seam where the edges came together. These tubes are repeatedly heated, and passed between the barrel rolls, which are of sufficient diameter to admit of gradually decreasing grooves, the whole length of the intended barrel being indented on their surfaces.

890



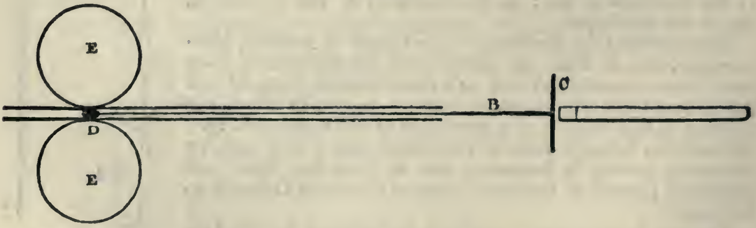
891



892

To preserve the tubular form, and ensure regularity in the size of the bore during the welding process, they are taken out of the furnace, by thrusting into them a tool called a mandril, B, *fig.* 893, which consists of a long rod of iron, having a short steel treblett on its end, of the diameter that the bore of the barrel is meant to be. This rod is so adjusted by means of a strong iron plate C, near its handle, which is of wood, and long, that when passed with the heated tube on it between two transverse holding bars, the short steel treblett D shall be found exactly between the point of impact of the barrel rolls, E, E.

893



The adhesion of the hot iron to the surface of the rolls is strong enough to draw the tube off the mandril, which thus keeps the bore open from end to end; and by repeating the process through the whole series of grooves in the rolls, the barrel is gradually elongated, and brought down to the exact form required; any superfluous length at the muzzle is then cut off. The breech end is then adjusted by the hammer

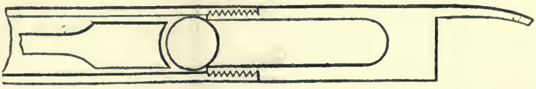
—a triple-seat welded on by hand if it be intended for a percussion lock; and then the barrel is ready to go forward to the mill to be bored, turned, and finished.

Gun-barrels formed by this mechanical method are found to stand proof better than those worked by hand, because the heat is more equalised; and any imperfections in the original mass of iron are more dispersed over the whole extent of the tube.

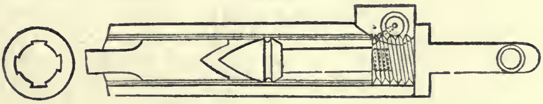
Of late years large strides have been made towards increasing the efficacy of military fire-arms.

The first attempt to improve the rifle in use in the French army was that proposed by M. Delvigne, an officer of the royal ex-guard (*fig.* 894), in which the upper orifice of the chamber that contained the powder took the form of a cup, wherein the ball (somewhat wider in diameter) was received, and by two or three smart blows of a heavy-headed rammer (also cupped out for the purpose) became expanded laterally, and thus the rotatory motion was imparted to it by the spiral grooves of the barrel in passing out. Colonel Poncharra suggested the addition of a wood bottom or sabôt under the ball and a greased woollen patch; and Colonel Thouvesino proposed (*fig.* 895) a steel stem or pillar about 2 inches long inserted into the face of the breech-pin; round this pin the charge of powder was received, and the diameter of the ball, when resting on the top of the pin, was enlarged by the blows of the heavy-headed rammer, as suggested by Delvigne.

894



895

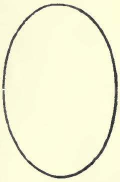


This system took the name of 'Carabine à Tige,' and has been very generally introduced for the service of fusilier battalions in Continental armies; very grave objections, however, have been found against it in use, from the impossibility of keeping the chamber (or part round the pin) clear; and from the severe labour to the soldier in ramming down and enlarging the diameter of the ball sufficiently to ensure the rotatory motion desired.

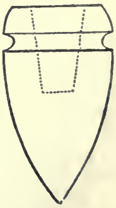
But if the ultimate results thus attained with spherical balls turned out not entirely satisfactory, it was made clearly manifest, in the course of the experiments carried on, that no insuperable difficulty stands in the way of rendering the fire of infantry very much more accurate and powerful, by the use of rifled barrels throughout the army, and thus leading to a verification of the prediction made by Robins above one hundred years ago, that 'whatever state shall thoroughly comprehend the nature and advantages of rifled barrel pieces, and, having facilitated and completed their construction, shall introduce into their armies their general use, with dexterity in the management of them, will by this means acquire a superiority which will almost equal any thing that has been done at any time.'

But besides smoothing the way to such an essential improvement, it has been elicited of late years, that when the accuracy of flight is secured by the rotatory motion derived from the rifling, the bullet, instead of being limited to the form of a sphere as heretofore, may, up to certain limits, be elongated with considerable increase of destructive effect; and with an augmentation of range very much beyond any thing that has hitherto been considered to lie within the reach of small arms—placing them, in fact, with reference to artillery and cavalry, in the first place instead of the last.

896



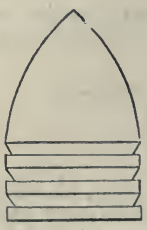
897



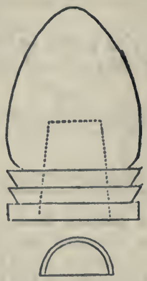
An immensely-extended field has thus been opened to experimenters. 1st. Mons Didion proposed a true oval (*fig.* 896) as the best form of bullet, so that, when shortened by the blows of the heavy rammer and widened in its diameter, it might be brought nearer to the spherical shape before leaving the barrel. 2nd. Mons. Delvigne took out a patent for a bullet (*fig.* 897) under the designation of 'Cylindro-Ogivale;' it had a conical opening behind, in which he imagined that the force of the powder would exert itself with sufficient energy to expand the lead permanently, and so make the ball take the rotatory movement derived from the rifling, without any fatigue to the soldier in loading: with this projectile, indeed, the operation is but slightly more difficult than with the ordinary cartridge and smooth barrels.

The bullet (*fig.* 898) of the 'Carabine à Tige' was called 'Cylindro-Conique,' and was said to possess this advantage over the preceding, that, being brought more to a point in front, it bored its way through the air with greater ease, and thus retained greater velocity, and of course, more extended range; and with this bullet it was that Mons. Tamisier introduced three sharp-edged channels round it, which he stated were necessary to keep its flight steady, by offering a resistance to the action of the air.

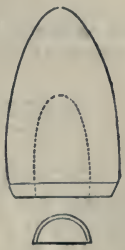
898



899



900



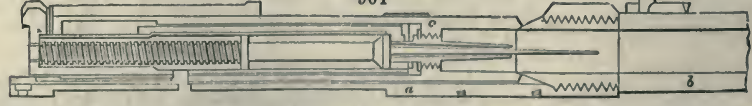
Finally, Mons. Minié, an officer of the French line, suggested (*fig.* 899) the addition of a dénoyau or culot to the hollow ball of Delvigne. This, in the form of a little cup made of sheet iron, is placed in the orifice of the conical hollow of the ball behind, and by the energy of the powder is driven into the ball, enlarging its diameter permanently, and thus giving all the accuracy of the rifle, with nearly the same facility of loading as with the plain barrel.

The principle of the invention, as thus developed, has, we learn, been adopted by our Government for the general use of the army, seeing that it offers so great advantages over the system of plain barrels, but the bullet (*fig.* 900), as modified by the Inspector of Small Arms, has on its exterior no channels, they being found not only useless as to steadying the flight of the projectile, but absolutely injurious in lowering its velocity. The bullet in its improved form too, being more truly balanced in its proportions, and made by mechanical means instead of by casting, has no tendency to the gyrations which appear to have so puzzled French artillerists, and for which they have invented the word 'derivation,' and wasted much learned disquisition.

But even if it were ever to happen, which is not likely, that these various projectors could be brought to agree as to the best form of projectile, they will then find out, that although by the general introduction of rifled and elongated bullets an immense advantage has been realised over plain barrels, their plans, based as they all are upon a system of *loading* at the *muzzle*, are at best but one step in advance; and that a good sound military fire-arm *loading* at the *breech* will, after all, remain the great desideratum —an arm that, without any less accuracy or power to reach masses of artillery or cavalry at a thousand yards' distance, will enable the soldier to triple the quantity of his fire at any moment that he may be called upon to repel a charge of cavalry, or attack or defend a breach at close quarters; of such simple construction, and so easily handled in every position of the body, that the soldier can pour every shot of his most murderous fire upon the enemy with unerring precision, whilst he himself may lie coolly behind a stone or in a ditch in entire security.

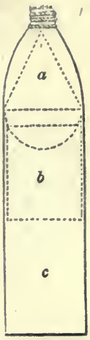
These are no longer wild imaginings, although so many hundreds of attempts towards the same object, from the earliest period to the present day, have been one after another seen invariably to fail. The Germans have been long and steadily pursuing the great object, until at length Herr Dreysa, of Sömmerda in Thuringia, has succeeded, after more than twenty years of continued labour, in establishing a musket, under the name of 'Zündnadelgewehr,' which, if not quite perfect, is so well adapted for the uses to which it is applied that the Prussians have armed the whole of their line and the Landwehr with this weapon.

901



The needle musket (*fig.* 901) consists of a strong socket *a*, open on the upper side and screwed on to the barrel *b*, which is rifled in the usual manner; within this socket is a slider *c*, which in fact constitutes the lock, as it contains the spiral spring and mechanism that produce ignition by percussion; it has a stout hebel, or handle, by which it is moved backwards and forwards freely. The cartridge (*fig.* 902) consists of the ball *a*, the sabot *b*, or bottom of hard paper, and holding the priming matter, and lastly the charge of powder *c*, the whole being made up in paper pasted together. In use, the slider being drawn back, the soldier puts the cartridge with the point of the ball in front into the open breech of the barrel, pushes the slider forward, and secures its close junction by a turn to the right against an inclined edge of the open socket. The spiral spring is then brought into action by pressing the spring case forward with the thumb.

902



To Captain Drayson, R. A., we are indebted for the following. The Enfield rifle, which has lately been approved of for the use of the army, is constructed principally by machinery.

The factory at Enfield, at which this arm is manufactured, is considered one of the most complete establishments in the world.

The barrel, lock, wood-work, furniture, and bayonet are all constructed at Enfield, and, as each portion is made exactly of the same size and shape, a part of one rifle will fit into the same part of another.

The total length of this weapon, including bayonet, is 6 ft. 0½ in., and it weighs 9 lbs. 3 oz.; the barrel is 3 ft. 3 in. in length, and weighs 4 lbs. 2 oz.; the diameter of bore is ·577 inch. The bullet is elongated, and rotates on leaving the piece like a spherical bullet. The general figure of the bullet is cylindrical, but its front end is rounded, and its rear end has a conical-shaped cavity. In the Minié rifle, some of which were introduced into the service, a small iron cap was placed in the hollow at the rear end of the ball for the purpose of causing the bullet to expand, but in the Enfield rifle this opening is filled by a wooden plug instead. This diminishes the fouling of the bore, and answers all the purposes of expansion.

The bullet is ·568 inch, length 1·062 inch, weight 530 grains. The barrel is proved at Enfield, and when flaws are supposed to exist as much as 15 drams of powder have been fired, without bursting the barrel. The service charge is 2½ drams. The weight of 60 rounds of ammunition, including 75 caps, is 5 lbs. 8 oz.

The bore has three grooves; each groove forms a spiral of half a turn in 3 ft. 3 in. The rifle is sighted up to 900 yards, but an effective range may be obtained beyond that distance.

The system of rifling by grooves is the plan which has been generally employed, and many experiments with different numbers of grooves, some of varying depths, being deeper at the breech, and with different turns; some increasing towards the muzzle have been tried and thought advantageous, at various times. The Enfield rifle has three grooves, with a pitch of 6 ft. 6 in., so that the bullet receives half a turn round its axis while moving through the barrel, the length of which is 3 ft. 3 in. The bullet is cylindro-conchoidal; it is wrapped in paper, and made of such a diameter as to pass easily down the barrel. It requires very pure lead, to allow of its being properly expanded, or 'upset,' by the explosion, and is driven partly against the original portions of the bore, called the *lands*, and partly in the form of raised ribs, is forced into the grooves, whose spiral shape gives the required rotation. The Enfield bullet is shown in the annexed figure. It is conical in shape, and has its back end recessed for the insertion of a box-wood plug. This plug, driven forward at the first shock of the explosion of gunpowder, expands the lead until it fills the grooves at the breech. (*Fig.* 903.)

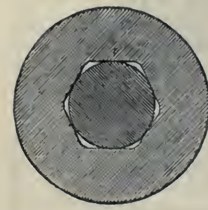
903

The prime cost of a finished Enfield rifle is stated to be about 2*l.* 5*s.*; and from 1,500 to 1,800 rifles per week are at present made at the Enfield rifle factory.

Since the remarkable proof, which has been obtained during the 'seven days' war,' of the advantages possessed by the Prussian needle-gun, our War Office has directed that all the fire-arms supplied to our army shall be breech-loaders, and the Enfield factory is now fully engaged in the conversion of the ordinary Enfield into this form of weapon.

Whitworth's Rifle.—This fire-arm, and the principles on which it is constructed, cannot be better described than by adopting, to a great extent, the words of the inventor: In the system of rifling which I have adopted, the interior of the barrel is hexagonal, and instead of consisting partly of non-effective *lands*, and partly of grooves, consists of effective rifling surfaces. The angular corners of the hexagon are always rounded, as shown in section, *fig.* 904, which shows a cylindrical bullet in a hexagonal barrel. The hexagonal bullet, which is preferred to the cylindrical one—although either may be used,—is shown in *fig.* 905. Supposing, however, that a bullet of a cylindrical shape is fired, when it begins to expand it is driven into the recesses of the hexagon, as shown in *fig.* 904. It thus adapts itself to the curves of the spiral, and, the inclined sides of the hexagon offering no direct resistance, expansion is easily effected. With all expanding bullets proper powder must be used. In many cases this kind of bullet has failed, owing to the use of a slowly-igniting powder, which is desirable for a hard metal projectile, as it causes less strain upon the piece; but is unsuitable with a soft metal expanding projectile, for which a quickly igniting powder is absolutely requisite to ensure a complete expansion, which will fill the bore: unless this is done the gases rush past the bullet, between it and the barrel, and the latter becomes foul, the bullet is distorted, and the shooting must be bad. If the projectile be made of the same hexagonal shape externally, as the bore of the barrel internally, that is, with a mechanical fit, metals of all degrees of hardness, from lead, or lead and tin, up to hardened steel, may be employed, and slowly-igniting powder, like that of the service, may be used. As we have already stated, the Enfield rifle has one turn in 6 ft. 6 in.; that is, the bullet rotates once on its axis in passing over this space. This moderate degree of rotation, according to Mr. Whitworth, only admits of short projectiles being used, as long ones turn over on issuing from the barrel; and, at long ranges, the short ones become unsteady. With the hexagonal barrel much quicker turns are used; and 'I can fire projectiles of any required length, as, with the quickest that may be desirable, they do not "strip." I made a short barrel, with one turn in the inch (simply to try the effect of an extreme velocity of rotation), and found that I could fire from it mechanically-fitting projectiles, made of an alloy of lead and tin; and with a charge of 35 grains of powder they penetrated through 7 inches of elm planks.'

904



905

'For an ordinary military barrel 39 inches long, I proposed a ·45-inch bore, with one turn in 20 inches, which is, in my opinion, the best for this length. The rotation is sufficient, with a bullet of the requisite specific gravity, for a range of 2,000 yards. The gun responds to every increase of charge, by giving better elevation, from the service charge of 70 grains up to 1,200 grains; this latter charge is the largest that can be effectually consumed, and the recoil then becomes more than the shoulder can conveniently bear with the weight of the service musket.'

The advocates of the slow turn of one in 6 ft. 6 in., consider that a quick turn causes so much friction as to impede the progress of the ball to an injurious, and sometimes dangerous, degree, and to produce loss of elevation and range; but Mr. Whitworth's experiments show the contrary to be the case. The effect of too quick a turn, as to friction, is felt in the greatest degree when the projectile has attained its highest velocity in the barrel, that is at the muzzle, and is felt in the least degree when the projectile is beginning to move, at the breech. The great strain put upon a gun at the instant of explosion is due, not to the resistance of friction, but to the *vis inertiæ* of the projectile which has to be overcome. In a long barrel with an extremely quick turn, the resistance offered to the progress of the projectile as it is urged forward becomes very great at the muzzle, and, although moderate charges give good results, the rifle will not respond to increased charges by giving better elevation. If the barrel be cut shorter, an increase of charge then improves the elevation.

There does not appear to have been, even yet, any thoroughly satisfactory experiments on the degree of motion which it is necessary to impart to the ball to ensure a flat trajection, and to overcome the different forces which are continually interfering with the correctness of aim, with even the best rifle. In the experiments with Armstrong's and Whitworth's cannon, some very satisfactory results have been obtained, and much information may be gained by studying the experiments quoted in the article on Artillery.

A professional writer, well qualified to judge of the matter on which he wrote, has made some striking remarks on the Whitworth rifle in the 'Mechanics' Magazine.' After pointing out the small importance of a high prime cost in the case of so durable a weapon as the rifle in question, he refers to the strength of the metal used.

In illustration of its great strength, this fact is quoted. Mr. Whitworth put into a rifle barrel, one inch in diameter at the breech, with a bore of 0·45 inch, a leaden plug 18 inches long, as tightly as it could be driven home upon the charge. It was fired with an ordinary charge of powder, and the leaden plug being expanded by the explosion remained in the barrel, the gases generated by the gunpowder all passing out through the touch-hole. With such strength great durability must of necessity co-exist, unless the quick turn of the rifling should tend to its rapid deterioration. But this is not the case. Mr. Longridge's elaborate investigations having proved that the amount of the force expended upon the rifling of the Whitworth rifle scarcely exceeds two per cent. of the total force of the powder.

Perhaps the most remarkable testimony which has been borne to the merits of this rifle is that of General Hay, the director of musketry instruction at Hythe. After admitting the superiority of the Whitworth to the Enfield in point of accuracy, General Hay said there was a peculiarity about the Whitworth small-bore rifles which no other similar arms had yet produced,—they not only gave greater accuracy of firing, but triple power of penetration. For special purposes, any description of bullet could be used, from lead to steel. The Whitworth rifle, with a bullet one-tenth of tin, penetrated 35 planks, whereas the Enfield rifle, with which a soft bullet was necessary, only penetrated 12 planks. He had found that at a range of 800 yards, the velocity added to the hardened bullet gave a power of penetration in the proportion of 17 to 4 in favour of the Whitworth rifle. This enormous penetration is of the highest importance in a military weapon, in firing through gabions, sandbags, and other artificial defences. Mr. Bidder, President of the Institution of Civil Engineers, says, the Whitworth small-bore rifle, fired with common sporting powder, would never foul so as to render loading difficult. He had himself fired 100 rounds one day, 60 rounds the next, then 40 rounds, and so on, and left the gun without being cleaned for ten days, when it fired as well as it did on the first day. The words of Mr. Whitworth as to the application of his principle to the Enfield weapon must be quoted in answer to the objections of cost, &c., urged against it. 'With regard to the cost of my rifled musket, which has been stated to be an impediment in the way of its adoption for the service, I may state that there would be no difficulty in adapting the machinery and plant already in operation at Enfield, or any requisite portion of it, for making rifles on my system. The change would not cause an increase in the manufacturing expenses; and, supposing the quality of the workmanship and the materials to remain the same, the advantages arising from the use of my bore and turn, and hard metal projectiles, would double the efficiency of the rifle without increasing the cost.'

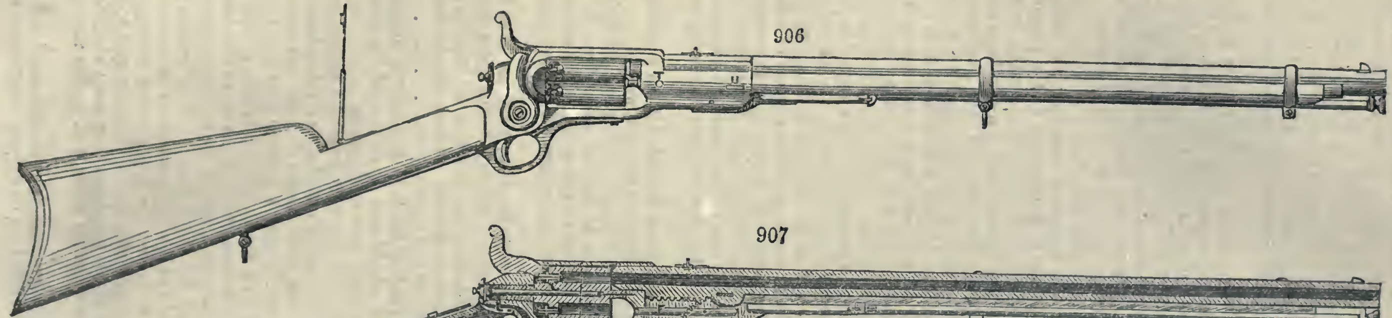
Amongst arms requiring some notice from us, the more remarkable, as involving some excellence in construction, or peculiarity in principle, are the following:—

Colt's Repeating Rifle.—This weapon is constructed mainly on the principle which was introduced by Colonel Colt, in his 'revolvers,' to be noticed presently. The Secretary of War of the United States reported as follows on this arm, which is shown in *fig.* 906, and in section *fig.* 907. *Fig.* 908 is a vertical section of the revolving barrels, and *fig.* 909 the wiping rod.

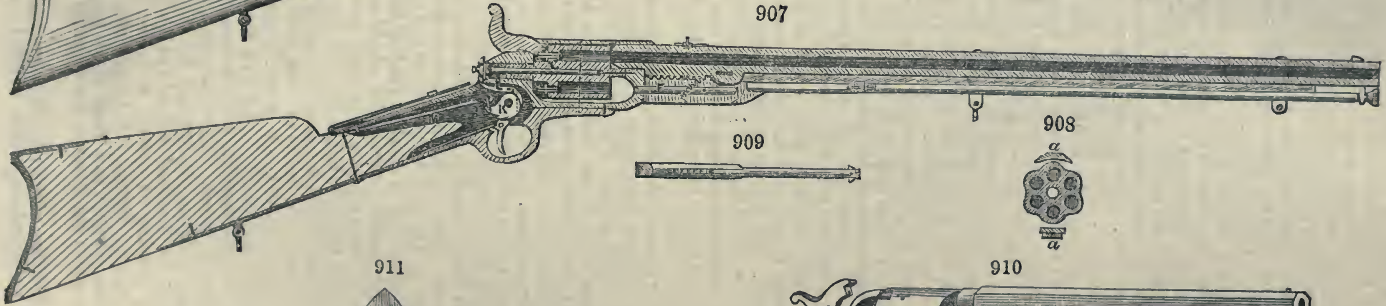
'The only conclusive test of the excellence of the arms for army purposes is to be found in the trial of them by troops in actual service. Colonel Colt's arms have undergone this test, and the result will be found, in some measure, by reports of General Harney and Captain Marcy, who used them in Florida against the Indians. These reports relate only to the *rifle*, but are clear and satisfactory. . . . . A board of officers recently assembled to consider the best mode of arming our cavalry, made a report, showing the present appreciation of the arm by officers of the army standing deservedly high for their services, experience, and intelligence.'

In its internal construction this rifle differs in some respects from the pistols and early revolving rifles. The catch which causes the breech cylinder to revolve, instead of acting against ratchet teeth, and on the cylinder itself, works in teeth cut on the circumference of the cylinder-end of the base-pin, in such a manner that the base-pin rotates with the cylinder itself, being locked by a small mortise in the cylinder; and the stop-bolt gears into corresponding notches, also cut in the end of the base-pin, and thus locks it when required. This is an improvement in the arrangement of these weapons, and by a simple arrangement the small spring catch, which, by means of a circular groove in the front end of the base-pin, keeps it in place, is immediately released by pressing on a small stud, and the cylinder can be instantaneously removed or replaced. Instead of the pin, which, in the pistol, is used to let the hammer down on, when carrying it, a small recess is cut between each nipple, in the cylinder itself, into which the hammer fits when let down, and makes security doubly secure.

The rifle is provided with two sights: the ordinary leaf-sight usually employed is also provided. The hinder sight is adjustable to suit long or varying ranges, and the



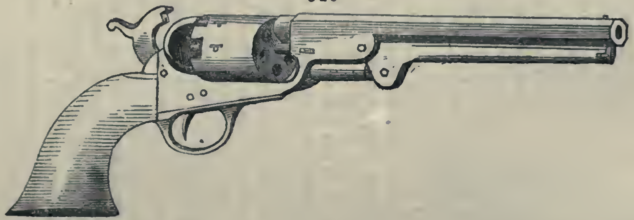
906



907

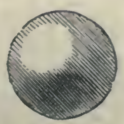
908

909



910

911



912

front sight is that known as the bead-sight, which consists of a small steel needle, with a little head upon it, like the head of an ordinary pin, enclosed in a steel tube. In aiming with this sight, the eye is directed through a minute hole in the sliding piece of the hinder sight, to the small bead in the tube, which bead should cover the mark aimed at; and this sight affords great accuracy in shooting. The wiping rod, which occupies the position usually allotted to the ramrod, in muzzle-loaders, is ingeniously constructed so as to admit of being lengthened. In its interior, which is hollow, slides a slight steel rod, in the end of which a screw-thread is cut; on drawing out the rod, a turn or so of the hand in one direction enables this steel rod to be drawn out to a length as nearly as possible that of the outer case, and a few turns in the contrary direction fasten it firmly in its place; thus enabling it to be used with as much facility as if it were solid. When done with, the reversal of the former motions enables the rod to be restored to its original dimensions, and it can then be returned to its place. This weapon has a real business-like serviceable appearance, and its weight varies, according to the length of the barrel, from 8 lb. to 10 lb. each, with five and six shots.

Colonel Colt has introduced a new shot gun, which is adapted for being loaded alternately with shot and ball. This is adapted for colonists, enabling them to use the gun as an ordinary sporting weapon for birds, &c., or for more deadly purposes. The ball for Colt's rifle is shown by *figs.* 911, 912.

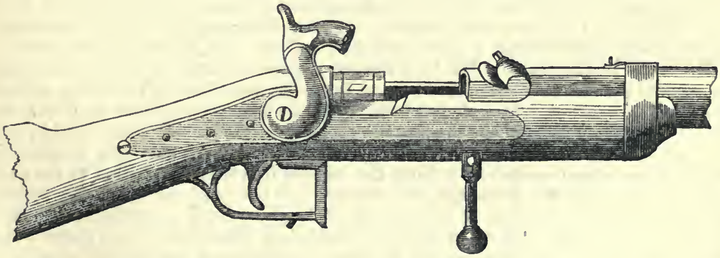
Lancaster's Elliptic Rifle.—So called, although the Elliptical rifle is very old. The bore in this rifle is slightly oblate; the twist found, by experience, to be most advantageous is one turn in 52 inches, the approved diameter of the bore ·498 inches, the length of the barrel being 32 inches. An eccentricity of ·01 inch in half an inch is found sufficient to make the bullet spin on its axis to the extreme verge of its flight. The length of the bullet found to answer best with these rifles is $2\frac{1}{4}$ diameters in length, with a windage of four or five thousandths of an inch.

Major Nuthall's Rifle.—In the ordinary mode of grooving rifles, sharp angles are left between the grooves and 'land' (those parts of the smooth bore left in their original state after the process of grooving has been completed). These create great friction with the projectile, both in loading and discharging. Major Nuthall removes these objections by rounding off the 'lands' into the grooves; that is, making them a series of convex and concave curves, the bore assuming a beautiful appearance to the eye, from the smoothness and evenness with which the lands and grooves blend into each other.

There are also General Boileau's rifle, and some others, which our space will not admit of our noticing.

Breech-loading Rifles have been introduced, and they prove so satisfactory that the principle of breech-loading is applied to ordinary fowling-pieces. Prince's breech-loader has been highly recommended. In this rifle, *fig.* 913, the barrel has attached to it a lever with a knob at its end, kept in its place and locked by a little bolt attached to the bow of the guard. In order to load, the stock being firmly grasped under the right arm, the catch is released, and the knob attached to the lever is drawn to the right, and almost simultaneously pushed forward. The lever being firmly connected with the breech-end of the barrel, the whole of the barrel is thus slipped forward in the stock, to the extent of about 3 inches, disclosing a steel cone, provided on either side with inclined planes, forming a segment of a screw, and locking tightly into slots at the breech-end of the barrel. The cartridge is dropped into the open space at the extremity of the cone, the lever is depressed, pulled backward, and then pushed into its place. The barrel and cone are thus tightly locked together, and until they are in this position the gun cannot possibly be fired. It is, therefore, obvious, that in strength and security this rifle is not inferior to any. At a

913



trial at Hythe, Mr. Prince fired 120 rounds in less than eighteen minutes, showing the rapidity of loading which this weapon admits of. The rifling preferred by the inventor is a five-grooved bore rather deeply cut, the twist being three quarters of a turn in three feet. The London gunmakers have certified to the great merits of Prince's breech-loading rifle.

Prince's cartridge is an ingenious invention; it can be used either with a muzzle or with a breech-loader. The cartridge is made of gun-paper, produced in the manner described for making gun-cotton. The spark fires this with the powder, and if the paper is pure there is no ash left from its combustion. Mr. Prince has brought out a new breech-loading rifle which is simpler than any yet produced. His practical experience in such matters, extending over more than a quarter of a century, combined with the success he has already attained, causes any fresh arm emanating from him to be regarded with considerable attention. The breech is opened by a half turn of a lever, and closed by a corresponding movement. Either common ammunition or a flask can be used in loading. The barrel is a fixture; a chamber being attached to the breech-end, so that existing muzzle-loaders may be readily converted. For cavalry a simple addition is made to the arm, so that the caps are placed on the nipple in the act of loading.

Terry's Breech-loading Rifle differs from Prince's in having the barrel fixed. There is an opening at the base of the breech, which being lifted by a lever discloses a receptacle for the cartridge.

Mr. Westley Richards, *Mr. James Leetch*, and some others have introduced breech-loading rifles. Of the former, Colonel Wilford says: 'The weapon manufactured by Mr. Westley Richards is a perfect wonder. I saw a small carbine, weighing only 5½ lbs., fire better at 800 yards than the long Enfield.'

In the rifle by Leetch the opening for the admission of the charge is in front of the chamber; consequently the shooter has all the security that the solidity of the breech can import.

Revolvers or Repeating Pistols.—The fame attached to Colt's revolvers, *fig.* 910, renders them so well known as to require but little introduction necessary. Although the invention of revolvers, of course, cannot be ascribed to Colonel Colt, their adaptation to modern requirements, and their general use, are undoubtedly due to his extreme energy, perseverance, and skill, and to him, therefore, every credit ought to be given. This make is now extensively used in the United States, and indeed in almost every corner of the world, and seems not to lose favour anywhere. In Turkey, Egypt, Brazil, Peru, Spain, Holland, Prussia, Russia, Italy, and Chili, as well as the United States, and our own country, they have been and are extensively used and approved; and we are given to understand that 40,000 of them have been supplied to our authorities, and have been served out and used in the Baltic, in the Crimea, in China, and in India, with the utmost effect. The shooting with Colt's arms is highly satisfactory. With Colt's revolver you can make first-rate shooting, and be perfectly satisfied with its action. As a proof that it is not liable to get out of repair, we need only state that the American Board of Ordnance had a holster pistol fired 1,200 times, and a belt pistol 1,500 times, without the slightest derangement. The penetration of the first-named was through 7 inches of board, and the second through 6 inches.

The barrel is rifle-bored. The lever ramrod renders wadding or patch unnecessary, and secures the charge against moisture, or becoming loose by rough handling or hard riding. The hammer, when at full cock, forms the sight by which to take aim, and is readily raised at full cock by the thumb, with one hand. It has been tested by long and actual experience, that Colt's arrangement is superior to those weapons in which the hammer is raised by pulling the trigger, in which, in addition to the great danger from accidental discharge, the strength of the pull necessary for cocking interferes with the correctness of aim, which is of so much importance. A very effectual provision is made to prevent the accidental discharge of this pistol whilst being carried in the holster, pocket, or belt. Between each nipple (the position of which secures the caps in their places) is a small pin, and the point of the hammer has a corresponding notch; so that if the hammer be lowered in the pin, the cylinder is prevented from revolving, and the hammer is not in contact with the percussion cap, so that, even if the hammer be struck violently by accident, it cannot explode the cap.

The movements of the revolving chamber and hammer are ingeniously arranged and combined. The breech, containing six cylindrical cells for holding the powder and ball, moves one sixth of a revolution at a time; it can only be fixed when the hammer and the barrel are in a direct line. The base of the cylinder being cut externally into a circular ratchet of six teeth (the lever which moves the ratchet being attached to the hammer); as the hammer is raised in the act of cocking, the cylinder is made to revolve, and to revolve in one direction only; while the hammer is falling the chamber is firmly held in position by a lever fitted for the purpose; when the hammer is raised the lever is removed, and the chamber is released. So long as the hammer remains at half-cock, the chamber is free and can be loaded at pleasure. Revolvers by Daw, by Adams and Dean, and others, have been introduced. They are all so similar in principle, that they need not be described.

FIRE-BLENDE. A rare mineral containing about 62 per cent. of silver, with sulphur and antimony. It is found at Andreasberg in the Hartz, at Freiberg in Saxony, and at Przibram in Bohemia.

FIRE-BRICKS. See Bricks.

FIRE-CLAY. Those clays which are termed *fire-clays* are such as are of a very refractory character—resisting the highest temperatures of the blast-furnace without melting. The conditions which are necessary for the production of a good fire-clay have rarely been sufficiently explained. The best fire-clays are hydrated silicates of alumina, not unfrequently containing silica uncombined; they should not contain soda, potash, or lime in any quantities, as those alkalis combine at high temperatures with the silica, and form glasses. The presence of iron is also exceedingly injurious to a fire-clay. Under the direction of Dr. Percy, an extensive series of analyses of fire-clays were made in the laboratory of the Museum of Practical Geology. From these, as published in Dr. Percy's 'Metallurgy,' the following more important have been selected :—

See Clay.

FIRE-DAMP, the carburetted hydrogen of coal-mines, produced, in some cases, by the slow decomposition of the coal itself; in others, it is probably the result of the changes in the constitution of the vegetable matter of which the coal itself is formed, which has been confined under great pressure in the interstitial spaces of the coal or rocks immediately in connection with them. The accumulation of this gas in the 'goaf,' or waste spaces of a coal-mine, is probably due to the changes which the coal itself undergoes. The sudden outbursts of this gas, known as 'blowers,' are no doubt the result of the liberation of the gas by suddenly removing the pressure under which it has been confined. This gas is the constant product of the decomposition of carbonaceous bodies under water; it has hence been also called 'marsh gas.' It is a protocarburetted hydrogen, its formula being C^2H^4 (**CH^4**).

This carburetted hydrogen gas does not explode when mixed with air in a proportion much above or below the quantity necessary for complete combustion. With three or four times its volume of air it does not explode at all, with five and a half or six volumes of air it detonates feebly, and with seven or eight most powerfully. When mixed with fourteen volumes of air the mixture is still explosive, but with larger proportions of air the gas only burns about the flame of the taper. See Safety Lamp and Mining.

FIRE-DAMP INDICATOR. Fire-damp or *Grisou* of the French is a great source of danger to the coal-miner, for, when mixed with certain proportions of air, it forms a mixture which, meeting with a naked light, explodes, occasionally causing great destruction to life and property, while its products of combustion poison those who, although stunned by the concussion, would yet recover if conveyed into a pure atmosphere; therefore its presence is a twofold source of danger. To make these two sources of danger more easily comprehended, it may be explained that if fire-damp be present to a very large extent, it naturally reduces to such an amount the oxygen, because two substances cannot occupy the same space at one time, and oxygen being thus excluded leaves in its place fire-damp, which is not poisonous, but simply incapable of supporting life, that is of oxidising the blood, since life simply goes out. The other source of danger is, however, of a different character, for when an explosion of such a mixture takes place the carbon which is hidden in the compound called fire-damp or mine-gas becomes converted, by its combustion with oxygen, into carbonic acid or choke-damp, which is actually poisonous, so that if a man should breathe an atmosphere mixed with it, and be then removed into pure air, he would not be capable of resuscitation, for his life is gone; whereas in the case of suffocation by fire-damp it comes to be simply a case of suspended animation, for if the lungs be artificially inflated with pure air before a great expiration of time life may be saved, as in the case of persons who have been immersed in water; hence as a precautionary measure in all pits where fire- or choke-damp is known to occasionally or habitually be present, casks of lime-water should be placed at intervals, with coarse cloths suspended in them, so that men in the event of an explosion could seize a cloth as they run from their stall after an explosion, and holding this loosely to their mouths in the manner of a respirator they would find that the lime had removed the carbonic acid, and permitted only the remaining mixture of air and fire-damp to pass into their lungs; and these gases not being poisonous would enable the men to pass through the dangerous space occupied by the products of the explosion, and then to reach a place of safety; whereas if they should fall down and lie in the atmosphere of the explosion, the lime respirator would prevent them being poisoned, and when their bodies were reached by the searchers they would be removed, and the ordinary means of restoration being applied many would be recovered, while the searchers themselves would benefit by the aid of the respirators. If fire-damp to the extent of 5 per cent. be mixed with atmospheric air, and be long inhaled, it produces no remarkable effect, except perspiration, which becomes profuse if the amount of fire-damp reach 10 per cent.; if it still increase to 15 per cent., and be inhaled for half an hour, a peculiar bodily helpless feeling supervenes, which makes one feel disposed to lie on one's back, and the eyelids tingle and smart. These feelings pass off in a few minutes, if fresh air be breathed. In an atmosphere containing 22 per cent. of fire-damp a man may still breathe for some considerable time. The writer of this article remained in such an atmosphere for five minutes making experiments, without other inconvenience than a feeling of mental lassitude—other words do not convey the exact sensation; but in an atmosphere more fully charged with fire-damp, probably 33 per cent., he became helpless before he could determine the amount per cent. present, even in three attempts; that is, in shorter time than sixty seconds.

The physical characters of fire-damp vary greatly in different mines; in some cases, being present to exactly the same amount per cent., it will explode violently in the lamp with a click, in others quite quietly; the miners call it a 'sharp gas,' or a 'slow gas,' as the case may be. Its odour varies greatly; and a circumstance of much importance in another point of view is that its diffusion-rate as regards time varies in different pits; in one pit it will diffuse into a vessel in forty-five seconds, in another in fifty, while in a third it may take sixty seconds; the hygrometric state of the gas appears to cause these variations, for in dry pits the time is longer, or appeared to be so in these cases, than in pits whose atmosphere was at the dew point. The writer of this paper is of opinion that the circumstances attending the production of fire-damp in mines require investigation, as there are many points to be elucidated, by experiments to be made in the pits.

Fire-damp is a mechanical mixture of carburetted hydrogen, nitrogen, and carbonic acid, in varying proportions. The carburetted hydrogen is the only substance with which we have to deal in fire-damp, because it is this substance that, when mixed with atmospheric air, becomes explosive; in the act of combustion its carbon forming carbonic acid, and its hydrogen water, both of which at the moment of formation are gaseous, and being at a high temperature, they therefore occupy a larger space than was formerly occupied by the mixed gases: in other words, it explodes, and gives rise to all the phenomena so well known.

In speaking, then, in future of fire-damp, we allude only to the carburetted hydrogen, or marsh-gas, contained in the mixture, that alone being the combustible substance; a proposition to be noticed, because our figures will appear to be different from those obtained by some who have taken the compound substance. Fire-damp is a chemical compound, otherwise known by the name of mine-gas, or as marsh-gas, and is composed of one equivalent of carbon, with two equivalents of hydrogen; it is a light substance of specific gravity 0·559, air being 1·000, and, by its levity, has a tendency to rise to the uppermost part of a gallery. Notwithstanding the law of diffusion, the lower contain less than the upper strata in a chamber, but the writer found, in a return air-way in the Hetton colliery, a uniform atmosphere of 3 per cent. of fire-damp. It is combustible, forming carbonic acid and water.

In the same manner, while speaking of 'choke-damp,' 'after-damp,' 'black-damp,' 'dampie,' &c., we allude only to the carbonic acid which is contained in the compound which passes under so many names, according to the source whence it occurs, for in all cases it is a mixture of carbonic acid, watery vapour, and nitrogen, in varying proportions.

Carbonic acid gas is a chemical substance, composed of one equivalent of carbon and two equivalents of oxygen; it is a dense gas of a poisonous nature, having a specific gravity 1·524; its density causes it to flow to and accumulate upon the floor of a chamber. In an atmosphere, containing 10 per cent. of carbonic acid, life can be maintained for a short time only, and a candle for a still less time; indeed, Dr. Angus Smith has observed that 3 per cent. is fatal, if the amount of oxygen falls below 18 per cent. in the same atmosphere.

We have thus spoken of fire-damp and of carbonic acid, because we are about to explain Mr. Ansell's proposition for giving warning of the existence of these substances through the agency of *diffusion* by means of a simple system of telegraphy. Mr. George F. Ansell, late of the Royal Mint, in a recent lecture on this subject, said: 'Possessing this information, I visited some pits, that I might see the precise conditions to be met, and I placed before myself the problem, how to make known, by their own agency, the existence of substances so varying as carbonic acid and fire-damp; it was perfectly manifest that the specific gravity, as specific gravity which had been proposed by others, must fail, because of the dust and currents of air in the pits; but these thoughts developed the idea that specific gravity, as a diffusive agent, would be the plan, and I have up to this date been unable to improve the first-formed idea, although I have been enabled to greatly simplify the mode of operation. I felt all along that if the existence of dangerous gases could be made known to the master without the man's agency, then the servants would be more particular to observe the laws laid down by the master, and so conduce to the welfare of all.'

The diffusion of gases may be described as an intermingling of them when placed in such circumstances as to admit of the natural motion of their particles extending itself into space or into other gases; for this explanation, it is well to consider that matter in every form, whether solid, liquid, or gaseous, that is liquid in a higher sense, is formed of minute particles, just as the ocean is formed of drops of water. Those minute particles have been called atoms or molecules, and there are reasons for believing that these atoms have motion amongst themselves in either the solid, liquid, or gaseous form of matter. In the case of gases, the law governing one particular motion was eliminated by the late Mr. Thomas Graham, who demonstrated that gases diffuse into each other and into space in the inverse ratio to the square root of their densities; in other words, a light gas diffuses itself rapidly, while a dense gas diffuses itself slowly into space, or into another gas.

If we take the following substances, and compare them with atmospheric air, as the standard of specific gravity, they will illustrate our meaning, for—

	Specific gravity.	Cubic in.		Grains.
Air being taken as of	1·0000	100	will weigh	31·0117
Hydrogen being taken as of	0·0691	,,	,, ,,	2·1400
Marsh gas being taken as of	0·5590	,,	,, ,,	17·4100
Carbonic acid being taken as of	1·5240	,,	,, ,,	47·2600

The barometer registering 30 inches, and the thermometer 60° F. If, therefore, a vessel of a given capacity be filled with each of these different gases under precisely similar circumstances, and weighed carefully, the variations of weight would be as indicated above.

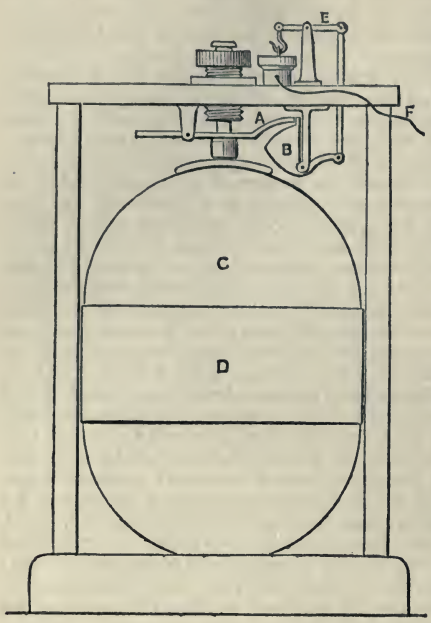
If, then, we imagine the containing vessel to be made of such a substance as will admit of diffusion, we should find that the gas would diffuse out of that vessel in a period of time relative to its specific gravity: hydrogen most quickly, marsh gas next in its place, air following, and lastly carbonic acid; each gas being replaced by its diffusion-equivalent of air; but in the case of air, although diffusion would take place, its amount would not be registered, because air would replace air, volume for volume.

To demonstrate this with one experiment, it will be sufficient to fill a glass tube, whose one end is closed by a plug of plaster of Paris, with coal-gas, and then to place its lower end in water, when the water will gradually rise in the tube, because the gas diffuses out into space, leaving a partial vacuum, while the atmosphere presses the water into that space.

But we find that the whole space is not exhausted, yet there is no gas remaining; for while the gas has diffused out, air has diffused into the tube (the gases have passed each other within the interstices of the plaster of Paris), and thus we come to the relative movement of gases under the circumstances of diffusion, or endosmose and exosmose, as it was formerly called.

The same gas, diffusing through different substances, occupies varying times, being quicker through unglazed pottery ware of Wedgwood than through Sicilian marble. The force or power of diffusion is considerable, as will be evident if the little apparatus about to be described be placed in an atmosphere of coal-gas. The instrument consists of a porous cell, surmounted by a cylinder, in which is placed a piston of brass, the piston being free to move, just as in the case of steam. Immediately that this instrument is placed in an atmosphere of coal-gas, diffusion commences; the gas passing into the porous cell through its walls more rapidly than the air passes out, causes an increase of volume, which exerts its pressure on the lower side of the piston and carries it up through the cylinder.

914



Fire-damp and choke-damp accumulate slowly under some conditions, and rapidly under others; there are, therefore, two main divisions to be met, and we will first explain how Mr. Ansell proposes to indicate the existence of a slowly-accumulating mass of gas in a goaf, or other place.

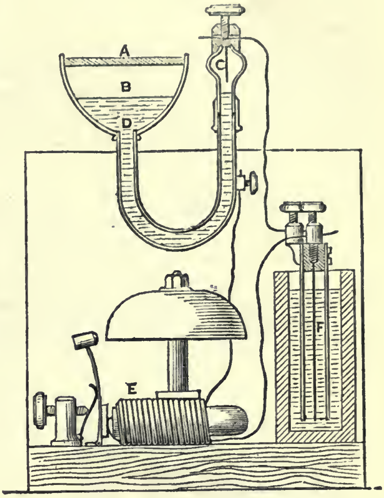
For the purpose of indicating by signal a slowly-accumulated mass of fire-damp, or of carbonic acid, he uses a balloon of thin India-rubber; for, singularly enough, he found that both these gases cause an *expansion* of the balloon. At first sight one can understand how marsh gas expands the balloon, by the law of diffusion; but that carbonic acid should also expand it, is so surprising, that the effect will require to be explained by a law not yet discovered.

The balloon is filled with atmospheric air, and its neck tied tightly with silk, or wax-end, and a piece of linen is bound round the equator of the balloon to prevent lateral expansion. The balloon C, *fig.* 914, so prepared, is placed under a small lever A upon a stand of wood, so that it exerts a gentle pressure on the lever; if now any fire-damp or carbonic acid accumulate round it, either of these gases passes through the substance of the India-rubber balloon, and, accumulating inside, causes it to expand, thus to press against the lever, and raising it releases a detent B, E, by which the terminal poles of a battery F are connected, whereby we get telegraphic communication with a distant place, or a warning on the spot at will. It must be stated that the temperature of a given place in a mine does not vary from year's end to year's end. The action of gases through India-rubber has been explained, by assuming that the gases dissolve in the outer coats of the India-rubber, and in solution pass through and evaporate from the inside. This proposition is rather fascinating, but Mr. Ansell refuses to regard it as the true explanation; he is, therefore, engaged in investigating the facts in a larger field, and at a future time hopes to discover the law which regulates the passage of gases through thin India-rubber.

These balloon instruments can be so arranged as to tell if the accumulation be still free from danger, or if it be explosive.

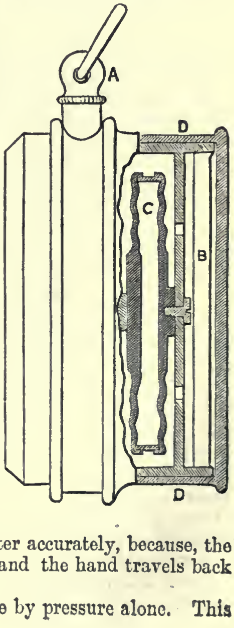
In the event of a sudden irruption of fire-damp, he applies the law of diffusion in all its simplicity; for by an instrument, *fig.* 915, he shows at once, if there be gas, no irruption can be so sudden that this instrument cannot tell of its approach—say, in from 5 to 10 seconds—according to the percentage of fire-damp contained in the dangerous rush. It may be so delicately set as to give warning if the mixture be still below the explosive point. The instrument consists of an iron funnel, B, whose stem is bent into a U, the funnel being closed with a plate, A, of unglazed Wedgwood ware (but, in his first experiments, he used a broken flower-pot), the stem being closed by a cap of brass, C, through which is passed a platinum-tipped copper-wire, capable of just dipping into the mercury, D, previously placed in the bend of the funnel. The distance between the platinum-pointed wire and the mercury regulates the point at which the indication shall be given as regards the irruption; that is to say, if a non-explosive mixture is to give its warning, the wire must be brought almost to touch the mercury; but if it be intended to give its alarm for an explosive amount, then it may stand a little farther off; but in no case to exceed the thickness of a shilling. If, when the instrument be ready, gas impinge on the porous tile diffusion takes place, and the pressure of the accumulating gas forces the mercury against the platinum-pointed wire, and the circuit being thus completed, telegraphic warning is given on the spot, as well as in the manager's room, if such be desirable, either by a needle or by a bell.

915



In the case of known accumulations, Mr. Ansell considered that, if the amount per cent. could be readily ascertained, measures in proportion could be taken to sweep out by ventilation such a dangerous mass. He tried instruments upon many systems, all acting by diffusion, and with many obtained splendid results, such, for instance, as with a column of water or of mercury; but in all cases temperature would be fatal, unless in the hand of a scientific man. Then, again, there is another action depending on the exchange of the proportions of the gases composing the atmosphere, which leads to errors; he has, therefore, been led to use the aneroid barometer, which, although far from a perfect instrument, is still reliable, and may be depended on till a better is discovered. In this place we may mention that Mr. Ansell is now at work at a most beautiful pocket indicator, which we have reason to believe will avoid all the difficulties of the aneroid, and be simply an indicator, not a compound instrument answering three purposes, as does the aneroid indicator. That marvellous arrangement, the Davy lamp, gives magnificent indications, and it may be asked, why try to go beyond it? Mr. Ansell says, 'I hope to supplement it by another indicator, for it must still be used with my proposed instrument; yet I am not without hope that I shall soon make my instrument self-registering; then I shall hope it will be even more useful than in its present form.'

916

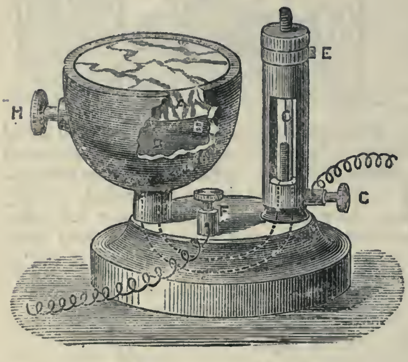


The instrument, *fig.* 916, about to be explained, is an aneroid barometer of the most delicate construction, the brass back of which has been removed, and its place occupied by a porous tile, B. There are besides one or two minor alterations, such, for instance, as a small valve, A, to be used at pleasure. This instrument acts by pressure on the outside of an aneroid chamber, C, which, by a system of levers, causes a hand to travel over a dial face, which is graduated in inches just as the ordinary aneroid, so that it can be used as a barometer, and as such can be relied upon. If we desire to experiment for fire-damp, or for choke-damp, by means of this indicator, it must be taken into the neighbourhood of the suspected atmosphere, and held by the ring handle, A, till it has become of the same temperature as the new place. It is absolutely necessary to follow these directions, because, when the valve is closed, the instrument is affected by temperature; when the temperature is equalised, which is usually in a short time, it may be known by the fact that the hand remains stationary after the valve is closed. The valve, which is simply a hole bored through the handle A, so that by turning the handle the atmosphere is admitted or excluded at will, is closed by screwing it tightly, and the position of the hand recorded. Then the brass cap D, which protects the porous tile, is removed, and the instrument held up into the suspected atmosphere, when in about 45 seconds the maximum effect is produced; at this time it is necessary to read the barometer accurately, because, the maximum point having been reached, effusion takes place, and the hand travels back to zero.

Effusion is the mechanical passage of gas through the tile by pressure alone. This action proceeds with the diffusion, hence we never obtain all the effect calculated upon; but directly diffusion ceases, effusion going on empties the chamber of gas, so that if the instrument be held long enough in the *same* atmosphere, the hand will return to zero, whence it started, and remain there till the instrument is taken into a purer atmosphere, or into one more fully charged. If into an atmosphere more fully charged, the barometer will rise, and this increased reading must be added to the other reading, so as to obtain the amount present at the new place. Thus in one reading it gives 3 per cent. of fire-damp; this atmosphere remains, and the hand returns to zero, but the instrument is placed in an atmosphere which gives 7 per cent. on its face, therefore the true reading is 7 + 3 = 10 per cent., which can be confirmed by taking the instrument into the intake gallery for a few minutes, and then putting on the cap; carry back the instrument to the suspected atmosphere, and it will at once indicate the 10 per cent.

Effusion has been a source of great trouble in the elimination of a suitable substance for a diffusion septum, but Mr. Ansell has just now happily found that Sicilian marble supplies his wants, for this substance permits *diffusion* to take place while it almost entirely arrests *effusion*. This will have a very important bearing on the indication of fire-damp, because it is now only necessary to fit a plate of Sicilian marble into the iron funnel of *fig.* 915 in the place of the porous tile A, and that instrument may be used instead of the delicate instrument shown at *fig.* 916, which, it must be admitted, is extremely delicate and liable to destruction. By regulating the thickness of the marble from one-eighth of an inch to one inch, Mr. Ansell meets the cases of the varying times required for the various rates at which gas accumulates. Instead, however, of using the instrument, *fig.* 915, which is proposed only as a means of warning to those on the spot, he wishes to place in the pits an instrument shown as *fig.* 917, which is about a third of the actual size. This is made of a thick cup of cast iron, screwed into a stand of the same metal, and from the other side of which an upright pillar rises to a height just above the top edge of the cup, as will be seen in the illustration. The top of the iron cup is closed by a solid disc of Sicilian marble three quarters of an inch thick, shown at A, where the iron is torn away for the sake of demonstration. The cup contains mercury as represented by D, while between B and A is a space B, occupied by atmospheric air. If the cup be examined it will be seen that the mercury D flows by a bent tube into the upright pillar where of course it assumes the same level as in the cup. In the event of fire-damp accumulating around the cup (and this instrument is to be placed near the roof at a fitting place in the pit) it at once diffuses through the marble, and by the law above explained accumulates in the space B, and thereby presses on the mercury D and causes it to flow and rise into the pillar till it touches the needle C, and thus to complete the circuit between the poles of a battery, and to ring a bell which may be placed miles or yards off in the viewer's office or in the lamp-cabin. The distance between the mercury and the needle C determines the point of mixture between the gases of which warning should be given; and this may be fixed at above or below the point of explosion at will, by regulating, by means of the screw which passes through the top, where a pin E is placed, to enable a man to regulate the distance in the dark by feeling the pin; H is a valve which should be securely closed as soon as the instrument has been steadily fixed in its proper position, while F and G are the wires which terminate in a cable going to the office, &c., so that twenty of these instruments communicate with the one bell, just as in the case of the telegraph bells at hotels, where the bell rings and a number drops to show which instrument is communicating the state of the pit.

917



All the time the valve A of the aneroid indicator is open, the instrument is a barometer, therefore it indicates change of altitude; at the spot one wishes to test the valve is closed; a knowledge of this will preclude the possibility of *mistaking change of altitude* for *gas*. It is well to remember that this instrument is not intended *to detect gas:* its inventor intends it to be used only to determine how much gas exists in any place where it has been shown to exist. A few intelligent observations will make any man as perfectly acquainted with the indicator as with his watch.

It is imperative that the instrument be held by the ring handle, else its action cannot be depended on. Mr. Ansell has found that the following figures are to be relied upon for fire-damp, and for carbonic acid :—

With Rising Barometer.

Fire-damp.

Per cent.	Inches.	
1 per cent.	=0·010	
3 ,,	=0·030	
5 ,,	=0·060	
7 ,,	=0·080	
7½ ,,	=0·090	explosive
10½ ,,	=0·130	
12½ ,,	=0·170	
15 ,,	=0·220	
20 ,,	=0·320	
50 ,,	=0·800	
100 ,,	=1·680	

With Falling Barometer.

Carbonic Acid.

Per cent.	Inches.
1 per cent.	=0·015
3 ,,	=0·050
5 ,,	=0·080
10 ,,	=0·160
15 ,,	=0·240
20 ,,	=0·330
50 ,,	=0·820
100 ,,	=1·640

Mr. Ansell was much assisted by Mr. Thomas W. Short (of the firm of Short and Mason, 62 Hatton Garden, E.C.), who practically realised the ideas Mr. Ansell conveyed to him, and so produced the apparatus in a simple and practical form.

The following actual experiments were made by Mr. Ansell in a coal-pit at the Ince Hall Colliery, on the 7th June, 1866, in the presence and with the assistance of some officials of the Ince Hall Colliery Company.

Two aneroid barometers were used, each with tiles of different thicknesses, with a view to determine the proper thickness. The instrument denoted by the * had the thinner tile.

Time occupied by experiments	Aneroid Barometer Indicator		Difference	Amount of gas indicated	Distance from floor	Davy Lamp giving to the Underviewer indications as follows—
	Before experiment	After experiment				
Seconds	Inches	Inches	Inches	Per cent.	Inches	
50	30·65	30·71	0·06	5·00	...	Small cap
*50	30·40	30·53	0·13	10·50	...	Very explosive

60	30·50	30·74	0·24	16·00	42	Lamp could not be held in this gas without fear of extinction
*50	30·41	30·62	0·21	14·50	42	

Note.—It was remarked by the underviewer, that the lamp indicated a varying amount of gas within a few seconds at the same place. These changes were attributed to the heat from our lamps and from our bodies; and it was found that the lamps and indicators most nearly agreed when both were taken into the gas at the same instant.

---

[1] It was agreed that this was held 10 seconds too long, as the index-hand travelled backwards.

FIRE-OPAL or *Girasol.* A lustrous variety of opal. See OPAL.

FIRESTONE signifies a stone which will bear the heat of a furnace without injury. In geology the term is generally applied to the sandstone which occurs at the top of the Upper Greensand in the south of England, which, from its power of withstanding the effects of heat, is frequently used for lining kilns and furnaces. It is a greenish calcareous sandstone, soft, and easily worked in any direction when first taken from the quarry; but, on exposure, it becomes extremely hard and durable, and well suited for building purposes. Many of the older churches in Dorsetshire are built of this stone.—H.W.B.

FIRE-WORKS. See PYROTECHNY.

FIR-WOOD. The wood of several species of conifers, the most important of which are the Silver Fir, *Abies excelsa*, or the *Pinus abies* of Linnæus (*Sapin commun*, Fr.; *Weiss* or *Edel Tanne*, Ger.); and the Scotch Fir, *Pinus sylvestris* (*Pin d'Ecosse*, Fr.; *Kiefer*, or *Föhre*, Ger.). These are valuable as timber-trees, and for the resinous juices which exude from them. See ABIES; TURPENTINE.

FISCHERITE. A hydrous silicate of alumina, from Nischne-Tagilsk in the Urals.

FISH. Many of the parts of fish enter into manufactures, and, prepared, become articles of commerce. The 'sound' or swimming-bladder of the sturgeon yields isinglass, but the true isinglass is sometimes sophisticated by the gelatin of common fish. Fish-oil finds employment in many ways, and manures prepared from fish-offal are much used.

Owing to the arrangements made relative to our less important imports, it is not possible to give—as was given in the last edition—our importation of fish. See CAVAIRE; ISINGLASS; MANURE.

FISH-SKIN. The skin of the dog-fish, shark, and other ganoids, used occasionally in polishing and in cleaning rounded and irregular works in pattern making.

FISSURE. A crack or rent in rocks. See DYKE.

FIXED AIR. An old name for carbonic-acid gas.

FLAGSTONE. A stone which splits freely in a particular direction along the original lines of deposition of the rock. These are generally sandstones, and the splitting surfaces are frequently produced by thin laminæ of mica; but thin bedded limestones also furnish flagstones, of which some beds of Purbeck limestone and the Stonesfield slates are examples. Flagstones are also obtained from Lias limestones, which are, in fact, thin beds of indurated clay.—H.W.B.

Most of our common flagstones are micaceous sandstones from the coal-measures of Yorkshire.

FLAKE-WHITE. This name is applied indiscriminately to pure white lead, and to the trisnitrite of bismuth.

FLAME (*Flamme*, Fr. and Ger.), in the ordinary acceptation, is the combustion of a mixture of an inflammable gas or vapour with air. That it is not, as many suppose, combustion merely at the exterior surface where the gas and the air come in contact with each other, is proved by passing a fragment of phosphorus or sulphur into the centre of a large flame. Either of these bodies ignited in passing through the film of flame will continue to burn there with its peculiar light; thus proving that oxygen is mixed with the vapour in the interior. If we mix good coal-gas with as much atmospheric air as can convert all its carbon into carbonic acid, the mixture will explode with a feeble blue light; but if we mix the same gas with a small quantity of air, it will burn with a rich white flame: a knowledge of this fact has led to the practice, in many of our large gas-works, of pumping air into the gasometers with the coal-gas—a dishonest and a dangerous system. In the latter case, the carbonaceous particles are precipitated, as Sir H. Davy first showed, in the interior of the flame, become incandescent, and constitute *white light.* Towards the interior of the flame of a candle, a lamp, or a gas-jet, where the air is scanty, there is a deposition of solid charcoal, which, by its ignition, increases in a high degree the intensity of the light. If we hold a piece of fine wire gauze over a jet of coal-gas close to the orifice, and if we then kindle the gas, it will burn above the wire with its natural brilliancy; but if we elevate the gauze progressively higher, so as to mix more and more air with it before it reaches the burning point, its flame will become fainter and less white. At a certain distance it becomes blue, like that of the above explosive mixture. If a few platina wires be held in that dim flame they will grow instantly white hot, and illuminate the apartment. On reversing the order of this experiment, by lowering progressively a flat piece of wire gauze from the summit towards the base of a gas flame, we shall find no charcoal deposited at its top, because plenty of air has been introduced there to convert all the carbon of the gas into carbonic acid; but, as we descend, more and more charcoal will appear upon the meshes. At the very bottom, indeed, where the atmospheric air impinges upon the gauze, the flame is blue, and no charcoal can therefore be deposited.

The fact of the increase of the brilliancy and whiteness of flame by the development and ignition of solid matter in its bosom, illustrates many curious phenomena. We can thus explain why olefiant gas affords the most vivid illumination of all the gases; because, being surcharged with carbon, this is deposited in the middle of the flame, as it would be in an ignited porcelain tube, whereby its solid particles first get ignited to whiteness, and then burn away.

The explanation given above was originally advanced by Sir H. Davy, and has, until recently, been universally accepted by chemists and physicists. Dr. Frankland has, however, brought forward a body of evidence tending to show that the presence of incandescent solid particles is by no means essential to the luminosity of a flame. Indeed, many flames of high illuminating power cannot possibly contain solid particles; thus, when the vapour of bisulphide of carbon is burnt in nitric oxide gas, it produces a dazzling light, yet without the presence of any solid matter. Frankland maintains that the luminosity of a flame is directly connected with the density of the burning vapours. He finds that dense vapours and gases become luminous at much lower temperatures than do those of less density; and that a rare gas, when not luminous at a given temperature under ordinary atmospheric pressure, may become so when suddenly compressed. The passage of electric sparks through different gases produces an intensity of light varying with the density of the gas. With respect to ordinary flames, it is believed that glowing particles of precipitated carbon are not the true source of luminosity, and that soot is far from being a deposit of mere carbon. Frankland maintains that 'incandescent particles of carbon are not the source of light in gas and candle-flames, but that the luminosity of these flames is due to radiations from dense but transparent hydrocarbon vapours.'—*On the Source of Light in Luminous Flames*, *Proc. Roy. Inst.*, June 12, 1868.

In the blowpipe flame from an oil-lamp or a candle, the inner blue flame has the greatest heat, because there the combustion of the whole fatty vapour is complete. The feeble light of burning hydrogen, carbonic oxide, and sulphur, may, upon the principles above expounded, be increased by simply placing in them a few particles of oxide of zinc, slender filaments of amianthus, or fine platina-wire. It is now many years ago since Dr. Ure demonstrated, in his public lectures in Glasgow, that by narrowing the top of a long glass chimney over an argand flame either from oil or coal-gas, the light could be doubled, at the same cost of material. The very tall chimneys used by the lamp-makers are wasteful, as they generate a strong current of air, and the combustion of the solid matter is carried on with great rapidity. With a narrow chimney of half the length we can have nearly as good a light, and save 30 per cent. of the oil. See BLOWPIPE; LAMPS.

FLANDERS BRICKS, commonly called Bath bricks. These are made in large quantities at Bridgewater, from the silty clay deposited in the estuary, which contains a large proportion of fine sand. These bricks are much used for domestic purposes, also in making founders' cores, and for polishing some steel articles.

FLANNEL. A plain woollen stuff of a rather open and slight fabric.

Wales is the country in which flannel was originally made, and the Welsh flannel is still held in much estimation. Hand labour is rarely employed in the production of Welsh flannel; and, though it is not so cheap as some others, the quality and finish of this fabric generally cause it to be preferred for vests worn next the skin and similar purposes. Flannels are now made more extensively at Rochdale than in any other part of the world. In that neighbourhood the manufacturers produce the greatest variety of widths, finish, and substance, viz., the thin, the medium, the thick, double-raised, and swanskin. Saddleworth produces the so-called Saxony flannels, which are much admired; and some varieties are produced at Leeds, and finished the natural colour of the wool. In the West of England flannels are made, but not extensively; and in Ireland a few varieties of low flannels and coatings, called Galways, are manufactured from Irish-grown wool. See WOOLLEN MANUFACTURES.

FLASHINGS. Pieces of lead or other metal let into the joints of a wall so as to lap over the gutters, and prevent the splashings of rain from injuring the internal work. When glass is coated with a thin layer of coloured glass it is said to be 'flashed,' and the operation is called 'flashing.'

FLASK. In foundries, a shallow iron frame, without top or bottom, used for moulding. The lower flask is called a *drag*. See FOUNDING.

FLAT. The name of a river boat, usually flat-bottomed, and carrying from 80 to 120 tons. This term is also applied to baskets in which butter is now sent from all parts of the country to the London markets.

FLAT RODS. In *mining*, a series of rods for communicating motion from the engine, horizontally, to the pumps or other machinery in a distant shaft.

FLATS. *A mining term.* Flats are the decomposed parts of limestone strata, and often contain deposits of lead ore and other minerals, all of which are spread out horizontally. Similar horizontal beds occur in our tin mines, and they are sometimes very productive. The 'carbonas' of the tin mines near St. Ives are little more than flats. Hooson, in his 'Derbyshire Miner,' published in 1747, thus defines a flat:—'it is neither vein, pipe, rake, nor screw.'

FLATTING. The operation of finishing house-painting so as to prevent the unpleasant glare which arises from a surface left in simple oil colour. The flatting colour should be incorporated with a large quantity of spirits of turpentine. This drying leaves a dull surface, which is produced by the resin of the turpentine. Unfortunately, from the high price of turpentine, naphtha is now commonly employed. As naphtha contains no resin, the colour is not so permanently placed upon the surface; it washes off readily, and is liable, after a season, to fall off as dust. This substitution of naphtha should therefore never be allowed.

FLATTING MILL. A mill for rolling out metals into plates. Cylinders of great power are employed for this purpose.

FLAUGHTS. Tools for carding wool, used chiefly in Scotland.

FLAVIN. A yellow dye-stuff imported from America, and used as a substitute for quercitron bark. It is prepared by dissolving it in hot water, with which it makes a somewhat turbid solution. It should be used when newly dissolved, for if allowed to stand it deposits a brownish-yellow mass, in consequence of its not being all completely soluble in water. If boiled in distilled water until all the soluble matter is taken up, and the clear solution decanted, it soon yields a deposit. The colour produced by flavin is never good until raised. A colour dyed by it weakens gradually when a little sulphuric acid has been added; but what remains retains its brilliancy by raising, and in respect of this property it differs from bark.

Adolph Ott, of New York, makes the following remarks on Flavin in the 'American Chemist':—

'The flavine handed to me for examination came from the Stamford Manufacturing Company, 157 Maiden Lane, New York. It represented a light yellow powder, but sparingly soluble in hot water, and separating again on cooling. The supernatant liquid remained slightly coloured. Warm alcohol, even when diluted, dissolved it quickly; not so ether. Tartrate of potassa and copper was not reduced by an aqueous solution, showing the absence of sugar. The solution remained clear on adding a solution of glue, thus indicating the absence of tannin. Sodium-amalgam, when added to an alcoholic slightly-acidulated solution, gave rise to the well-known purple reaction indicative of quercetrin; this reaction was, by the way, also obtained with the deposit of a decoction of yellow bark. The watery solution of flavine decoloured permanganate of potassa, proving the presence of gallic acid (test of Monier). The absence of tannin and the presence of gallic acid are to be considered as proof that the alkaline decoction of the bark had been treated for some time with sulphuric acid.

'The above-mentioned tests satisfied me that the sample was a remarkably pure flavine.

'The late Professor Bolley, who first made us acquainted with the method of manufacture of flavine, discovered tannin and sugar in flavine analysed by him. My specimen was free from both, but contained gallic acid, the derivate of tannic acid. Since a solution of crude quercitrin assumes a beautiful yellow colour, when protochloride of tin is added, this being not the case with my flavine, I drew the conclusion it was free from quercitrin. This fact was also to be inferred from the presence of gallic acid.

'Prompted by the results of this investigation, I began to search whether there existed other analyses of flavine besides that given by Bolley. My researches in this direction remained without result; but I obtained, on the other hand, some notes which strikingly illustrate how slow industries sometimes progress when they are unaided by science. According to James Napier, who published a book on the art of dyeing in 1853, the flavine must have become a commercial commodity in or about the year 1850. Aside from describing its behaviour towards mordants and vegetable fibres, the author states that it contains 4·4 per cent. ashes. They consisted doubtless of sulphate of soda. Supposing that the dye-stuff had not been washed out, and that to make the decoction the same quantity of water had been employed as prescribed in the patent specification of Leeshing, it would be very easy to calculate how much soda was used. The quantity was doubtless very large. In 1856 ("Repertory of Patent Inventions") Leeshing, in Glasgow, secured a patent for the treatment of yellow bark, weld (the herb of *Reseda luteola*), and flavine, for the purpose of enhancing their colouring power. He terms "quercitrin," the material obtained from quercitron; "flavetin," the one obtained from flavine. His first process consists in boiling the pigment-yielding substance, either with dilute sulphuric or hydrochloric acid, and then washing it out with cold water; a second process consists in previously boiling the dye-woods or dye-stuffs in a weak soda-solution, saturating with sulphuric or hydrochloric acid, and boiling for half-an-hour. The inventor claims that the products thus obtained differ from the original substances in being free from tannin and lime (?), and in having acquired new properties, viz. a greater affinity for mordants and a more vivid and richer colour. Being less soluble in water, they are preferable for the dyeing of such tissues as require a boiling heat in the vat.

'Since particular stress is laid upon the increase of the intensity of the colour, it is to be assumed that the flavine contained then a larger proportion of quercitrin. Although the patentee fails to give hints with regard to this point, my supposition has been confirmed by the results of an examination of flavine imported in 1858 into Germany, made by Kœnig. I am unfortunately not in possession of the original paper, yet according to Gmelin, Kœnig obtained quercitrin in minute crystals by treating the flavine with very dilute boiling sulphuric acid, and by purifying the separated flocculent precipitate—the ordinary manner. However, it will always remain a disputed point whether Leeshing was or was not acquainted with the papers on quercitrin by Rigand, who first communicated the fact that this substance is split up if acted upon by dilute mineral acid. This paper appeared in the "Chemical Gazette," two years previous to the date of Leeshing's patent. I would remark that Rigand was well aware of the fact that mordanted cotton assumes a purer yellow when dyed with quercetin than when dyed with quercitrin.

'With regard to the process of Leeshing for enhancing the colouring power of the yellow oak, Bolley, in his "Chemische Technologie der Spinnfasern," says that it was not rational, the quercetin formed being deposited on the bark. But the learned technologist failed to consider that the process in question was also applied to flavine, which was already then a commercial commodity; and, moreover, we may well accept that it was not the intention of Leeshing to extract the colouring matter, partly because the weighty bark with enhanced colouring power brought a proportionally higher price than the pure dye-stuff, and partly because the demand for the latter (the flavine) was undoubtedly not yet sufficiently large. When considered in this light, the inventor certainly deserves credit. One of the processes is quite analogous to the preparation of garancine from madder. In both cases a substance combined with glucose must be set free to be converted into a dye-stuff. In short, the "quercitrin" of Leeshing is a technical product from quercitron.

'After the beautiful researches of Bolley and Rigand on quercitrin had already been published, it is incomprehensible that Muspratt (*vide* his "Chemistry applied to the Arts and Manufactures," edition of 1860), in treating of the above-mentioned dyes, states that their intensity was probably enhanced because the colouring matter had become more soluble in water. Yet on the very same page, in giving an abstract of the Patent Specification of Leeshing, he mentions that the derivates in question upon being treated with hot as well as cold water, yield much less colouring matter than the materials from which they had been produced. Schlumberger, according to Grothe, treats the bark of the yellow oak as follows:—100 kilos of the ground wood are mixed with 280 litres of water, acidulated with 25 kilos of oil of vitriol. This mixture is boiled for two hours, whereupon the bark is washed out, pressed and dried. For the same quantity of bark Schlumberger takes four times the quantity of acid (of only one-third the strength) of that of Leeshing, but extends the time of treatment to twice the length. These are the only points in which these two methods differ from each other. In speaking of this process, Grothe, in his "Katechismus der Bleicherei, Färberei, und des Zeugdrucks" (p. 103), remarks:—"All the tannin having been separated by treating the bark with sulphuric acid, the colours produced with *quercetin* are much purer and brighter than those obtained with flavine." I am at a loss to comprehend this, for it must be evident to every one that the ground bark, when directly treated with acids, must always contain a larger amount of intermediary products than flavine, even when this latter has not been washed out. Grothe, moreover, observes: "Dye-extracts from quercitron, which contain mainly quercitrin, yield with alum a beautiful yellow." I ask, how is it possible that extracts from quercitron, among which Grothe includes the flavine, dye a beautiful yellow, if yet containing tannin, which, according to Grothe, acts injuriously? And why have extracts of quercitron been produced "with a high percentage of quercitrin," since "recent investigations have demonstrated that they contain quercetin, which is principally effective?"

'Immediately after this, Grothe remarks:—"For this reason the quercetin is now especially made." If Grothe designates with this name the prepared bark of Schlumberger, he will excuse me for asking why it is that it is not preferable to produce the flavine, which, with regard to purity and intensity of colour, is to the yellow bark as the purpurine of Kopp to the madder of Alsace?

'With regard to the behaviour of the peculiar kind of tannic acid contained in the bark of *Quercus tinctoria*, many erroneous views seem still to exist. Bolley, in his above-mentioned treatise, observes, for instance, that it was probable that the flavine furnishes a purer yellow than the bark of quercitron, because it has been freed from the greater part of tannic acid. It appears to me that it would have been more correct to state that the flavine produces a purer colour because it consists chiefly of quercetin, as Bolley himself has demonstrated, while the bark contains only the less colouring quercitrin. It is, moreover, not quite clear to me in what manner the tannic acid referred to could act injuriously, since, for dyeing yellow, the goods are not mordanted with iron salts. Besides, the tannic acid from quercitron, according to Schlossberger, yields green, not black, when coming in contact with salts of peroxide of iron. This was already known by Dr. Bancroft when he wrote in his Patent Specification, bearing date of 1775:—"This species of bark may be distinguished from all others by its giving with alum a fine yellow colour, and not striking a black upon the addition of iron."

'According to Grothe ("Katechismus," &c., p. 103) flavine yields a dark, greenish-black precipitate with salts of protoxide of iron, and citron-yellow with salts of protoxide of tin. This can be comprehended only when it is known that Grothe compiled from the above-mentioned book of Napier, who evidently examined a kind of flavine containing much tannic acid. With salts of protoxide of iron, pure flavine yields a green colour with olive tint; with tin salt the liquid only assumes a brighter colour. A decoction of bark, however, from which quercitrin has already separated, produces, with salts of protoxide of iron, a greenish-black; with tin salt, a light yellowish precipitate. In this latter case the supernatant liquor grows reddish.

'In dyeing with a decoction of the bark, the brown colour discovered by Chevreul acts undoubtedly more injuriously than tannin does. If, therefore, one chooses, with Bolley, to ascribe the purer yellow of the flavine to the absence of a foreign substance, it would certainly be more correct to seek the cause of this fact in the absence of the brown colour of Chevreul. Every dyer knows that in dyeing with the bark of quercitron high temperatures are not desirable, the brown dye being then absorbed by the fibre, just as in dyeing with aniline violet the real colour contained therein is withdrawn at a high degree of heat.'

The quantity of colouring matter in flavin is very great, its value as compared with bark is 16 to 1, or one ounce of flavin is equal to one pound of quercitron bark. A portion burned left 4·4 per cent. of ash, and a solution of it gives the following reaction with salts:—

Persalts of iron	Orange black precipitate.
Protosalts of iron	Deep greenish black precipitate.
Protosalts of tin	Lemon yellow precipitate.
Persalts of tin	Orange yellow precipitate.
Alumina	A rich yellow precipitate.

Acids lighten the colour of the solution, and alkalis deepen it, rendering it redder.—*Napier.*

FLAVINDIN. A substance isomeric with indin and Indigo blue. It is produced by the action of potash on indin. Flavindin may be obtained in large quantities by continuing the ebullition of indin with solution of potash for a long time. It is purified by solution in water containing a few drops of ammonia, and precipitation with hydrochloric acid. Flavindin is of a pale yellow colour, and is sparingly soluble in alcohol. See Watts's 'Dictionary of Chemistry.'

FLAX (Latin, *linum;* French, *lin;* Italian and Spanish, *lino;* Portuguese, *linho;* German *Flachs;* Dutch *vlas*), the *Linum usitatissimum*, a plant of the class Pentandria, order Pentagynia, in the system of Linnæus, and the type of the order Linaceæ, in the natural system of Botany, largely cultivated for its fibre and seed, and, next to cotton, the most extensively used raw material for textile manufacture in the vegetable kingdom. This plant was primarily a native of Asia, and was introduced at an early period into Europe. Frequent mention is made of it in Scripture history, as grown both in Palestine and in Egypt, as well as of the fabrics manufactured from its fibre. It was probably introduced into Europe by the Phœnician traders, or the Greek colonists of Egypt and Syria. Homer alludes to the linen manufacture of Greece.

At the present day, the flax plant is grown for fibre alone, for seed alone, or for both products together, in many countries of the eastern, and in some of the western hemisphere. For seed alone, in Hindostan, Turkey, and the United States of America; for fibre and seed in Russia, Belgium, Holland, France, Germany, Scandinavia, Italy, Switzerland, the Iberian Peninsula, Great Britain, and Egypt; in Ireland, chiefly for the fibre, without utilising the seed.

The average annual production of fibre, in the chief countries where flax is grown, is as follows:—

	Tons
Russia	130,000
France	48,000
Belgium	18,000
Holland	9,000
Austria	60,000
Prussia	32,000
Ireland	35,000
Egypt	10,000

and adding all other countries, we may estimate the entire annual weight of fibre produced throughout the world, at 400,000 tons.

The quantity of seed may be taken at nearly 2,000,000 of quarters. At the average value of fibre and seed, the annual production in all countries, of the former, may be given in value at 20,000,000*l*., and of the latter at 5,000,000*l*., making in all, 25,000,000*l*. as the worth of the raw produce, before its conversion into woven fabrics and feeding-stuffs.

From all we can learn relative to the earliest annals of the flaxen trades of the United Kingdom, it would seem that the great object of those who took most interest in their progress was to secure ample supplies of raw material. Long before the manufacture of cotton gave such impulse to enterprise in Great Britain the governments of the day and the great landowners in each shire or county successively patronised the growth of flax. In many of the old English leases it was made a matter of actual covenant that farmers should every season set apart certain sections of land for that purpose, and at most of the country fairs there were premiums offered for the largest and best-finished parcels of flax. Two centuries ago, Scotland was especially famed for the production of the finest description of material to be found in either England or Ireland; and as she too had her Board of Trustees whose duty it was to encourage the growth as well as the manufacture of flax, a large quantity of that article was annually raised there. This system of home growth was kept up on both sides the Tweed until the last quarter of the past century, when the introduction of the Asiatic fibre, and the mechanical contrivances of Hargreaves, Crompton, and Arkwright, gave a new turn to British enterprise. In a few years the manufacture of cotton had extended so rapidly that it took the lead of all the clothing trades.

From that period demand for flax fell away, and English farmers, finding more difficulty in making sale of that variety of crop, ceased to grow it for fibre; but a few men in Dorset, Devonshire, and Somersetshire sow flax almost solely for seed. All that time, however, and on to the present, the Irish people, and especially Ulstermen, continued to grow the 'national fibre,' for although the cotton manufacture had made some progress there, the demand for linen rose rapidly and the cry for larger supplies of raw material was heard on all sides. The culture of flax in Ireland formed a large field of local enterprise at a very early period of that country's history. Cormac O'Conn, who reigned there in the third century, is described as wearing 'a girdle of fine flax;' and five hundred years afterwards, when Niall the Third was in power, exports of flax formed the most prominent features of Ireland's trade with England. During succeeding ages the Irish farmer seems to have forgotten his cunning, as in the days of Lord Strafford's vice-regal government in that island the growth of flax as well as the make of linen had degenerated very much. Whatever may have been the faults or failings of the unfortunate Earl, in other phases of his political career, the Irish linen trade owes more to him than to any other of the English deputies, not only of his own time, but of any that succeeded him. When Lord Strafford made his first tour of the Irish provinces, the average yield of the plantation acre, which in point of area was more than one and a half that of the English acre, did not exceed fifteen stones, and the length of fibre was about twelve inches. The Earl sent orders to Holland for supplies of seed in the spring of 1633, the year after his appointment, and he also brought over a number of Dutch farmers to teach Irishmen the most successful mode of cultivating the plant. These foreigners were kept at work for several seasons, and the result of their exertions was that in 1638 the turn-out was thirty stones to the acre, and the length of flax stem had increased to 2½ feet. Fifty years afterwards Arthur Dobbs wrote a history of Ireland's Commerce and Agriculture. There was then an area of thirty thousand acres under flax, and the yield had gone up to an average of forty-four stones to the Irish acre. We should here state that the settlement of the Huguenots in different parts of the island had by that time given powerful impetus to every branch of the linen trade. In nearly all the northern counties the culture of flax began to be studied as an art, and the more enterprising growers prided themselves very much on the quality of the article they were able to produce.

A board, consisting of nobles and gentry, was appointed to sit in Dublin, under the title of 'Trustees of the Linen and Hempen Manufactures,' and ample means were placed in the hands of members for the purpose of encouraging the trade. Five and twenty years afterwards a similar institution was established for Scotland; and in both cases much good was done, though the principle on which they were founded could scarcely be justified in rightly-regulated economy. Foreign flax seed was largely imported into Dublin and Dundee, and bounties awarded to growers of the largest and finest lots of fibres. But the breadth of lands under that crop north of the Tweed never exceeded 10,000 acres, or little more than one-fourth of the area sown at that time in Ireland. In 1809 there were only 5,000 acres in all Scotland against 35,000 acres in Ireland, but of that aggregate 23,000 acres were raised in Ulster. There were 148,000 acres sown in that county in 1815, and about the same extent of area in 1820, while in 1825 the sowing occupied 139,400 acres. After the dissolution of the Linen Board in 1828 no reliable record of crops was kept, and until 1847, when a regular system of agricultural statistics was got up in Ireland, all was left to mere conjecture. In the meantime the imports of foreign flax into the United Kingdom had been making enormous progress. We give the figures for different periods of the first half of the present century:—

Year	Cwts.
1801	273,720
1821	498,653
1831	936,440
1841	1,346,843
1851	1,194,184

Flax-spinning by machinery has accomplished wonders for flax-growers. Some attempts had been made to produce linen yarn by water-power in Lurgan, so early as 1717. A carpenter, Thomas Turner, of that town, who was much patronised by Louis Crommelin, invented a machine to spin flax and for which the Board of Trustees awarded him 100*l.*, but the death of the inventor took place before the work had been brought to perfection. Louis Paul, a Birmingham blacksmith, tried his hand at a machine in 1740, and John Kendrew and Thomas Porthouse of Darlington brought out in 1787 a still superior invention. But until John Marshall, son of a Leeds shopkeeper, took the matter in hand, all had proved complete failures. The Leeds mill was commenced about the close of the past century, and some time afterwards the trade was started in Dundee. These mills imported Irish flax very largely, and this gave fresh stimulus to growers in that island. Ireland had been trying the new principle of yarn spinning for some years, and although the Board of Trustees paid a premium of 30*l.* for every spindle erected, no permanent good resulted. The bounty system ceased in 1828, and two years afterwards T. and A. Mulholland, of Belfast, erected in that town their famous York-street mill, which, like that of the Marshalls of Leeds, gradually grew into gigantic proportions. In 1833 there were nine flax-spinning-mills at work in Belfast, thereby creating an immense increase in the consumption of raw material. Imports of foreign fibre were not keeping up to the requirements, and about that time a number of Belfast spinners and linen merchants began to feel that a famine in flax would arise if extra exertions were not made to extend home-growth. In 1841 a society was formed for that purpose, and so well did it do the work that the breadth of land which for that year was only 83,750 acres had been extended in 1844 to 122,680 acres. But the great good effected by the Flax Improvement Society did not end there. Besides that enlargement of area, the farmers were taught by experienced instructors better modes of preparing the soil and a more careful system of choosing seed. The effect of these lessons was to improve the skill of growers so much that the article produced was superior in quality and the yield equally improved.

A terrible prostration of energy in the ranks of Irish agriculturists followed the famine of 1847, and the breadth of flax lands was narrowed one-half. For some seasons afterwards this state of affairs continued, the total area in 1849 only extending to 60,070 acres. But, as better days set in, a great improvement took place in flax-growing, and in 1852 there were 137,000 acres under the crop; the succeeding season showed a much wider area, 174,529 acres having been sown. Then came a reaction, and in 1857 the breadth was only 97,720 acres. By this time the demand for first flax had been rendered still greater in consequence of the extension of spinning-mills in Dundee and Leeds; so that, besides the home requirements, Irish farmers had a stirring appeal for further supplies made to them from the sister isle. All this cry for more flax did not fall unheeded on the ears of the people engaged in the different departments of the trade. After the final suppression of the Sepoy mutiny, the tide of public interest had set strongly towards India, and much attention was aroused as to the best mode of turning to good account the immense capabilities of that magnificent appanage of the British Crown. The House of Commons, as the reflex of popular feeling outside, took up the subject, and a Select Committee was appointed to inquire into and 'take evidence on the Colonisation and Settlement of India.'

In course of that inquiry Mr. James Dewar, of the house of D. Dewar, Son, and Sons, Cheapside, London, stated, that of all Britain's possessions none equalled the land beyond the Ganges in the variety and value of its fibrous products. He said that in 1854 the Indian Government, at the suggestion of the Punjaub Agricultural Society, had induced the native farmers to cultivate 60,000 acres of land in flax; and so well did that crop succeed that in the following year 250,000 acres were sown. In 1858 Colonel Burnett brought over large lots of India-grown fibre, part of which, after having been examined and approved of by the Belfast Chamber of Commerce, was sold in that town at 45*l.* a ton. At a moderate computation of the average yield of the India flax lands, the value of the crop for 1855 was about 2,250,000*l.* In 1859 several of the leading linen merchants on both sides the Channel held conference as to the practical opening up of a field of industry beyond the Ganges, and ultimately Mr. James Dewar and other men in the trade formed 'The India Flax Company.' Ample means were subscribed to start the project of flax culture in the Punjaub on a scale of extended dimensions, and a large tract of land was acquired by the directors on very favourable terms. Practical instructors—men well schooled in the art of flax-growing—were sent out to watch over the preliminary proceedings, and teach the natives how to prepare the ground, sow the seed, and attend to the crop in every stage of its growth. For a few seasons the work went on favourably. In the south-east transept of the second Industrial Exhibition held at Kensington in 1862, several samples of Indian flax were shown, and these were considered as very hopeful evidences of what might be done in that phase of Indian enterprise. But from various causes, probably want of perseverance as the leading one, the India Flax Company was dissatisfied, and the whole affair was given up. There had, some time before, been much attention directed to Canada, where the prospects of abundant supplies were said to be most favourable. Some lots of flax grown in Ontario were sent to Belfast, some to Dundee, and some to Leeds, and in each case mill-owners were well pleased with the article; but after all the assertions made by sanguine projectors, Canada's flax culture has not done much for the spinning trade.

We have seen that England and Scotland have all but ceased to supply fibre for flax-spinning; to Ireland, therefore, and continental Europe, mill-owners must look for raw material. The uncertain nature of the crop and the very unfavourable state of the climate in some seasons cause great diversity of feeling among the Irish farmers as to the flax culture. A small extent of area marked the season of 1857, but in 1861 there were 147,950 acres sown; in 1862, 150,000 acres; in 1863, 214,000 acres; and in 1864, 301,942 acres, by far the widest area ever known. Of this last-noted total, Ulster alone had 278,254 acres, while Connaught had cultivated 8,688 acres; Leinster, 7,383 acres; and Munster, which for soil and climate could compete with Belgium itself, had only 7,620 acres. We hear much about utilising Ireland's resources, and of the necessity of creating more remunerative fields of enterprise for capitalists and work-people; but in the most fertile province of that nation, and where there might annually be produced some 250,000 acres of flax, we find that only a mere fractional part of such breadth had been thus occupied. And if so much had been sown every single pound weight of the entire crop would have been taken up by our mill-owners.

An unprecedented demand for flaxen products was created by the scarcity and dearth of cotton during the American War. Not only were the spindles of every mill in the kingdom taxed to their extreme power, but vast lots of French yarns were imported to meet the requirements of that time of extra activity. Of course there was great demand for flax, and fortunately the yield of 1864 was above the average. From that season, however, the growth of flax in Ireland declined. In 1865 there were 251,433 acres sown; in 1867, 253,257 acres; in 1869, 229,252 acres; and in 1871, 156,764 acres, or little more than one-half the breadth under flax in 1864. The yield of 1870 averaged about 40 stones of fibre to the acre, that of 1871 was less than 20 stones to the acre; but that year is well known as the most unfavourable of any season for the last sixty.

There were 430,000 spindles in England's flax mills in 1864, and 350,000 in Scotland; at the same time Ireland had 750,000 spindles set up in her mills. Very little change has since then taken place in the trade of Great Britain, while that of Ireland has increased to more than 900,000 spindles. Foreign supplies of raw material have been making up for defective produce in home lands, as will be seen by the annexed figures of imports:—

Year	Cwts.
1861	1,133,979
1865	1,913,132
1871	2,597,900

Some time after Sir Robert Peel's last accession to power, he proposed that duties should be thrown off all raw materials. Foreign flax then paid a tax of 10*l.* a ton, and when the minister mooted his intention to let such material come in free, a great outcry was raised against the proposition, which, it was said, would, if carried into law, ruin the Irish farmers. At that time (1842) milled flax sold at 5*s.* 6*d.* to 10*s.* 6*d.* the stone of 16½ lbs., and hand-scutched flax at 4*s.* 6*d.* to 6*s.* 6*d.* the stone. The average prices of flax for the first half of 1872 were 5*s.* 6*d.* to 8*s.* 6*d.* for hand-scutched, and 7*s.* to 12*s.* 6*d.* for milled, per stone of 14 lbs.

The flax plant has a single slender stem, varying from 2 to 4 feet in height, according to the nature of the soil and the season, with the difference of climate, and mode of culture. It has lanceolate, sessile leaves, of a rich green colour, and branches out, at the top, into two or more small stems, each of 2 or 3 inches in length, and bearing light blue flowers, succeeded by globular capsules, pointed at the apex, and bearing eight to ten seeds of a reddish brown, when ripe. The stem of the plant consists of an inner part, or core, sometimes hollow, but more frequently solid, composed of ligneous matter, surrounded with a bark of fibres, which are united to each other by a gum, the whole being sheathed in a fine epidermis. The plant arrives at maturity in fourteen or fifteen weeks after the seed is sown. It has then changed to a pale yellow or straw colour, and the seeds have become brown. The usual period of sowing, in European countries, is from March to May, although in some parts of the Continent the seed is put in the ground in autumn; but in this case nothing is gained, as the plant becomes mature very little earlier than when the sowing is done in spring. It is grown on a wide range of soils, sandy, calcareous, clay, loam, peaty, &c., but that best adapted to it is, either a deep, friable, clay loam, or the alluvial deposit of rivers, whether along their banks, their deltas, or where reclaimed from the sea, as in the case of the polders of Holland. Deep tillage, good drainage, and repeated pulverisation of the soil, are very requisite. The preparations for the crop are begun in winter, by ploughing the surface, and turning it up to the action of frost: they are completed in spring, by ploughing and harrowing. The seed is sown at the rate of 2½ bushels per statute acre, the best season being April. In the British Isles, Belgium, and Holland, the favourite seed is obtained from Russia, Riga being the port of shipment. Dutch seed is also extensively in use in Ireland, and a good deal of home-grown seed—the first year's growth from Riga seed (one year from the barrel), which is considered quite equal to the parent. No manure is used in Ireland, but in Belgium and France rape cake dissolved in urine is considered very useful. The seed is sown broadcast, and the soil is afterwards rolled. When the plant is a few inches high, weeds are carefully removed, and no further attention is necessary until the season of pulling. Flax is not cut with the scythe or sickle, but is pulled up by the roots. About the middle of August it is generally ready for pulling in the British Islands, but in Belgium and France it is in a fit state two to three weeks earlier.

The after treatment varies in different countries. In Russia, part of Belgium and Holland, and in France, the plant, after being pulled, is dried in the sun, being set up on the root end in two thin rows, the top interlacing in the form of the letter V inverted. The sun and air soon thoroughly dry the stems, and they are then made into sheaves, and the seed afterwards beaten off. The stems are steeped subsequently. Another mode, in general use in Ireland and in part of Flanders, is to steep the green stems immediately after they are pulled. In Flanders, the seed is invariably separated from the stems before the latter are immersed in water. In Ireland, although this is practised to some extent, yet the great bulk of the flax crop is put in the water at once, with the seed-capsules attached, and consequently there is a very considerable annual loss to the country by this waste of a most valuable product of the plant. In the Walloon country of Belgium, in its eastern provinces, and in the greater part of Germany, *dew-retting* is practised. That is, in place of immersing the stems in water, they are spread thinly on short grass, and the action of the dews and rains ultimately effects what immersion in a running stream or pool accomplishes in a much shorter time, namely, the decomposition of the gum which binds the fibres to the stem and to each other. Fibre obtained by this method is, however, of very inferior quality and colour.

If the fibre of flax be separated from the stem, without the decomposition of this matter, it is found to be loaded with impurities, which are got rid of afterwards in the wet-spinning, the boiling of the yarn, the subjection of the woven fabric to the action of an alkaline lye, and the action of the atmosphere—of rains and of alternate dippings in water, acidulated with sulphuric acid, and of a solution of chloride of lime, which are all required to perfect the bleaching. The great object, therefore, is to obtain the fibre as nearly free from all foreign substances as possible, and, consequently, the mechanical separation of it from the woody pith of the stem is not to be recommended.

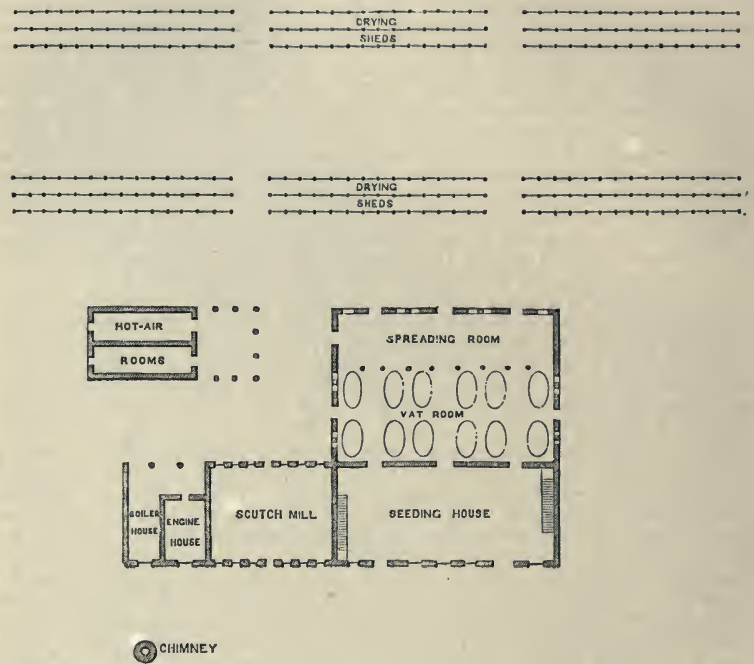
At various periods attempts have been made to prepare flax fibre without steeping. Weak acids, solutions of caustic potash, and of soda, soap lye, and lime, have all been tried, but have all been found objectionable. In 1815 Mr. Lee brought before 'the Trustees of the Linen and Hempen Manufactures of Ireland' his system of separating the fibre without steeping. He alleged that a large yield was thus obtained, that the colouring matter could afterwards be discharged by the most simple means, and that the fibre possessed greater strength. But it was found that the system was practically worthless. In 1816, Mr. Pollard, of Manchester, brought forward a plan of the same nature, and proposed to make an article from flax which could be spun on cotton machinery. This also fell to the ground. In France and Belgium, at different periods, similar projects were found equally impracticable. In 1850, and again in 1857, Mr. Donlau revived the same, but the same fatal objections prevented the success of the system. The fibre was loaded with impurities, and the apparently larger yield over steeped fibre consisted solely of these very impurities, which had to be got rid of in the after-processes of manufacture. At the same time it must be recognised that the 'dry separated' fibre can be rendered useful for one class of manufactures, viz., those where no bleaching is necessary, and its great strength is here an object. For ropes, rick-covers, tarpaulins, railway-waggon covers, &c., where pitch or tar is used to prevent the decomposing action of moisture and of atmospheric changes, this mode of obtaining flax fibre is highly useful.

The immersion of the flax stems in water, either as pulled full of sap, or after drying, appears, as yet, to be the best mode of effecting the decomposition of the gum, and obtaining the fibre pure, or nearly so. The water most suitable for this purpose is that obtained from surface-drainage, springs generally holding more or less of mineral matters in solution. Spring-water from a calcareous soil is peculiarly unsuitable, the carbonate of lime which it contains being adverse to the putrefactive fermentation of the vegetable extractive. In Russia, much of the flax grown is steeped in lakes. In Holland, it is always steeped in pools filled with the surface-drainage. In France and Belgium, it is either steeped in pools or rivers. In England and Ireland, generally in pools, though occasionally in rivers. The most celebrated steep-water in the world is the river Lys, which rises in the north of France, and flows through the west of Belgium, joining the Escaut at Ghent. Although the water of this stream has been analysed, chemists have not been able to discover why it should be so peculiarly favourable to the steeping of flax. All along its course flax is steeped. The trade is in the hands of factors, who purchase the dried stems from the growers, and undertake all the after-processes, selling the fibre to merchants when it has been prepared for sale. The apparatus in use consists of wooden crates, 12 feet long, 8 wide, and 3 deep. The sheaves of flax-straw are placed erect in the crates, and the root ends of one are tied to the top ends of another, to secure uniformity of packing. The crate, when filled, is carried into the river, and anchored there, the upper part being sunk by the weight of stones, 6 inches underneath the surface. The period of steeping begins in May, and ends about September. The previous year's crop is thus steeped, having lain over in the state of dried straw during the winter. All the flax thus treated produces fibre of a yellowish white colour, very soft and lustrous, with very finely divided filaments, and strong. From it almost exclusively are made cambric, the finest shirtings, and damask table-linen. It is a strange fact that flax-straw is brought to the Lys, from a great distance, and even from Holland, as no other water has yet been found to give such good fibre.

In 1847 a new system of steeping was introduced in Ireland, by Mr. Schenck, of New York. It had been successfully tried in America on hemp, and the inventor crossed the Atlantic to try its efficacy on flax. His plan consisted in hastening the putrefactive fermentation of the vegetable extractive by artificially raising the temperature of the water to 90° F. By this means instead of an uncertain period of seven to twenty-one days being required for the steep, according to the state of the weather and the temperature of the atmosphere, the flax was retted uniformly in sixty hours. The flax-straw, after the separation of the seed, is placed in wooden or brick vats, and the heat is communicated by forcing steam into a coil of iron or leaden pipes, placed under a false bottom perforated with holes.

The annexed plan (*fig.* 918) of a retting on Schenck's system, capable of consuming annually the produce of 400 acres of flax, and employing, in all the operations of seeding, steeping, drying, and scutching, 30 men and 55 girls and boys, or an aggregate of 85 persons, will give an idea of the arrangements. The seeding-house requires to be of large size, as flax-straw is a bulky article. It is on the ground floor, for the convenience of carting-in the flax. The loft above it is used for cleaning and storing the seed. The vat- and spreading-rooms are in a building of one story only, built with a vaulted roof resting on pillars. That part of the roof which is over the vats has lower windows to aid the escape of the vapours from the vats. The drying sheds at the top of the plan are on an open space, well exposed to the wind, and 50 or 60 feet apart. The hot-air rooms, or desiccating house, are fire-proof, each room being capable of containing the flax turned out in one day's work. The scutch mill, with engine and boiler-house, complete the plan.

918



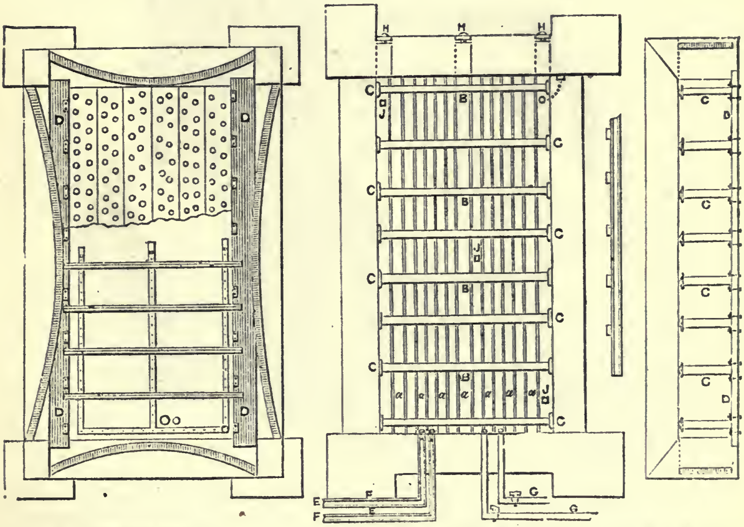
The advantages of this system were so manifest that it was speedily adopted in many parts of the United Kingdom and of the Continent. It was found, however, to have some defects. The small quantity of water soon became thoroughly saturated with the products of decomposition, and the fibre of the flax, when dried, was, consequently, found loaded with a yellow powder, offensive to the smell, causing inconvenience in the preparing and spinning, and, worse still, acting prejudicially on the quality of the fibre itself, rendering it harsh and dry.

To obviate these defects, Mr. Pownall, of London, conceived the idea of pressing the flax-straw, immediately when taken out of the steep, between a pair of smooth cast-iron cylinders, while, at the same time, a stream of water played upon the rollers. By these means the foul water of the vat is pressed out of the flax stems, which are flattened and bruised, thus tending to aid the separation of the bundles of fibres into minute filaments, while the stream of water effectually washed away all remaining impurities.

It has recently been found that better fibre can be obtained by reducing the temperature and extending the time of steeping. The most perfect adaptation of Schenck's system is at the rettery of M. Auguste Scrive, near Lille, and *fig.* 919 is a representation of it. Tanks of wood or stone are used, each to contain two and a half tons of flax-straw. The straw is classified according to quality and length before being packed in the tank. It is put in erect, the root ends resting on the perforated false bottom, and slightly pressed together, but not so much as to prevent a free circulation of water, and a free exit for the gases germinated by the fermentation. The tank being filled with water, the whole is secured at the tops of the sheaves by narrow strips of wood four inches thick *a*, catching the tops on the whole length of each row of bundles.

These strips of wood are kept firm by cross iron holders B, secured by iron bars C, fastened to pieces of wood D, worked into the side walls of the tank, leaving a surface four inches deep of water over the top of the flax. When the tank has been filled with cold water through the wooden shoot E, the whole is rapidly heated to 78° Fahrenheit, by means of steam-pipes coiled under the false bottom. A second open shoot F carries heated water at 90° to discharge on the surface, besides two closed pipes G G, one of which brings hot water of the same temperature, and the other cold water. When fermentation sets in, which is ordinarily in eight hours, the pipe, as well as the shoot of water at 90°, is set at play; the first to create a continual current of fresh water through the mass of flax, clearing off the products of decomposition, and bringing them to the surface; the second to drive this foul water to the openings H H, where it is discharged by the overflow. The two pipes with heated and cold water going to the bottom of the tank, as well as the two shoots containing cold and hot water, to go to the surface, are also made use of to equalise the temperature during the whole operation, which is ascertained by the use of a thermometer in the square wooden box J J. The steeping of coarse straw requires 36 to 48 hours, medium qualities 50 to 60 hours, and the finer descriptions 60 to 72 hours. The 'wet rolling' between cylinders after the steep is accompanied by a shower of water at 78°, not on the flax but on the top of the cylinders. This removes the remaining impurities, and prepares the straw for being easily dried. The heated water may be obtained from the waste water of a spinning-mill, or from a condensing steam-engine.

919



Ground Plan. Top of Tank. Side of Tank.

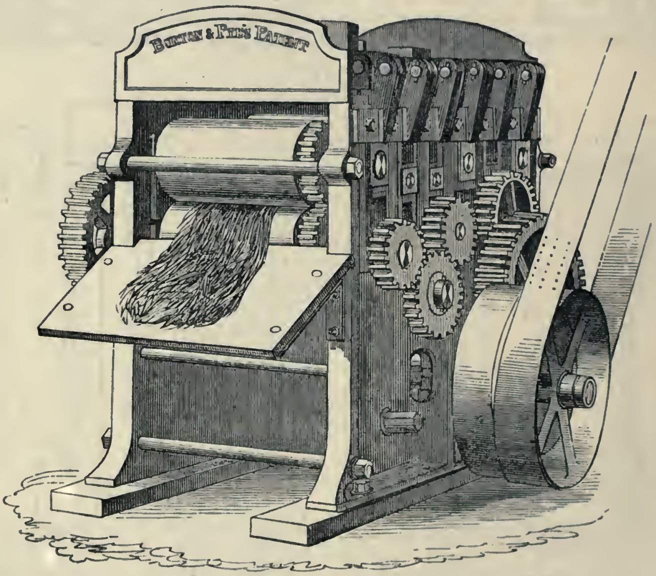
Flax steeped by Schenck's system is dried in various ways. Some retters have drying houses with heated air; others set up the flax loosely on the root end, in the field, or spread it thinly on the grass; while others, again, clasp it between two slender pieces of wood about a yard in length, and hang these up in a building open at the sides, so that a current of atmospheric air is constantly passing through.

In 1852 another mode of retting flax was introduced by Mr. Watt, of Glasgow. Instead of immersing the stems in water, he subjected them to the action of steam. Square iron chambers were employed, in which the flax-straw was packed. The door by which it was introduced was then fastened by bolts or nuts, and steam was then driven in. The steam penetrated the stems of the flax, and being partially condensed on the top and sides of the iron chamber, a constant drip of water, lukewarm, fell upon the flax. In twelve to fourteen hours the stems were removed, and, after being dried, the fibre readily separated from the woody core, the water remaining in the iron chamber being of a dark brown colour, without offensive odour. The fibre obtained by this method was of a greyish colour, and was at first well thought of by manufacturers; but, in the end, on more extended trials it was found to possess several defects, and Watt's system is not now carried out.

Another system of treating flax was introduced by M. Claussen, a Belgian, and for some time it attracted much attention. He separated the fibre from the stem without steeping, and then, by the employment of acids and alkalis, he got rid of the vegetable extractive and other impurities, and produced a fibrous mass strongly resembling cotton. He professed to make an article capable of being spun with cotton or wool. The higher value of flax fibre, however, was a great obstacle, and at present the only use made of his process is to convert scutching tow—the refuse flax fibre—into an article to be spun with wool, and even this is practised to but a very small extent.

Messrs. Burton and Pye's patent (*fig.* 920) is a modification of the hot-water steep. By this process the flax-straw, after the seed is removed, is passed through a machine composed of plain and crimping rollers, by the combined action of which the woody part is rendered easily separable from the fibre. The latter is then placed in a vat, holding about a ton, which is subsequently filled with cold water (*fig.* 921). This vat has a perforated false bottom, under which steam, with a pressure of 50 lbs. to an inch, is introduced and disseminated by perforated tubes. Another tube conveys into the vat a cold mixture of fuller's earth in water. The introduction of the mixture and the steam is continued until the liquid in the vat reaches 80° Fahrenheit. The flax remains in it at this temperature for thirty hours, when the surface of the liquid is covered with a saponaceous froth. Then an apparatus of cross bars of wood, closely fitting into the interior of the vat, and pressed by two powerful screws, expresses the impurities from the fibre. The supply of the fuller's earth is stopped, and cold water is alone supplied with the steam, so regulated that the temperature is by degrees raised to 150°, the pressure being continued until the water appears free from impurities. The water is then withdrawn from the vat through a valve in the bottom, and a pressure equal to 200 tons is applied to the mass of the flax. It remains under this pressure for four hours, when it is half dry. It is then taken out and dried in sheds open at the sides to the air. The fibre produced by Mr. Pye's method appears of good quality and strong, but the system has not as yet been carried out on a sufficiently large scale to admit of a decided opinion on its merits.

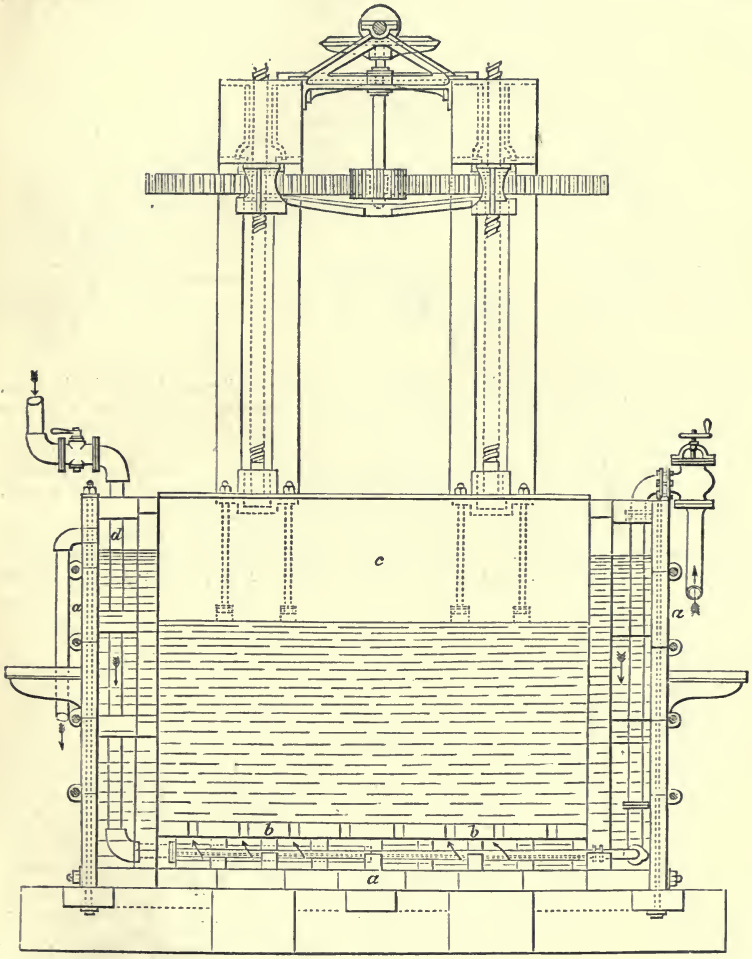
920



The same may be said of the plan of M. Terwangue, of Lille, who employs hot water at a temperature of 15° to 17° Centigrade (60° Fahr.), in which chalk and charcoal have been placed. His process requires seventy-two hours on the average, and he employs brick tanks. The water is, as in all the preceding cases, heated by steam.

Before leaving the subject of steeping, reference may be made to a process patented by Mr. F. M. Jennings, of Cork, by means of which coarse flax fibre is rendered capable of being subdivided into minute filaments, or, in other words, made fine. While the fibre of cotton is incapable of subdivision, that of flax, as viewed through the microscope, is seen to consist of a bundle of extremely delicate filaments adhering together, so that fine and coarse flax are really relative terms. Mr. Jennings throws down upon the flax fibre, as it appears in commerce, a small quantity of oil, say half an ounce to the pound of fibre. He effects this by boiling the fibre in an alkaline soap-lye, washing with water, and then boiling in water slightly acidulated with pyroligneous acid, which decomposes the soap, and leaves its fatty constituent on the fibre. It is afterwards washed once more, and is then found to be soft and silky, and the coarse fibres capable of being readily separated on the hackle, while the strength is not apparently reduced. There is also a greater facility in the bleaching of the linen made from flax fibre so treated, and less loss in weight in the bleaching process.

921

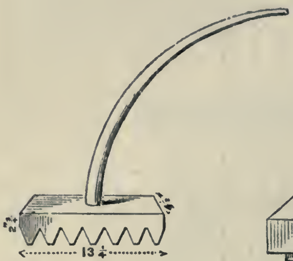


While some of the inventions referred to for hastening and equalising the time of steeping are being carried out to a considerable extent, and promise well, when brought to a greater degree of perfection by experience in practical working, to be yet more largely employed, the great mass of the flax grown throughout the globe is steeped in pools, rivers, or lakes. It will, therefore, be most advisable to follow the processes, as practised by the growers or factors.

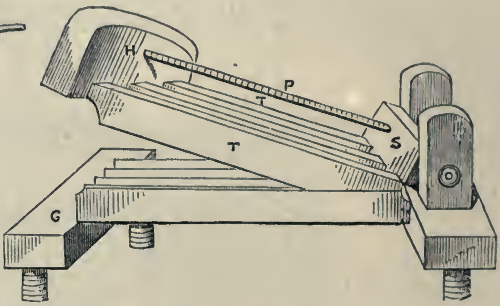
When the flax has been sufficiently retted, *i. e.* when on taking a few stalks out of the water the fibre can be readily separated by the fingers along its entire length from the woody interior, it is removed from the water, and placed to drain on the banks of the pool or river. It is then taken to a closely-shorn grass-field or old pasture land, and spread thinly and evenly on the ground. In Flanders, however, the system of drying is somewhat different. Instead of being spread flat on the ground, the sheaves are divided into four portions, and these are set upright in *capelles*, *i. e.*, the butt ends are spread widely out in a circle on the ground, and the tops are kept close together. By this means the sun and air soon dry the flax. When thoroughly dried it is tied up in sheaves, and after remaining a few days in the usual form of a grain stack, it is ricked. In this state it may remain for years without the fibre being deteriorated.

The next process is termed scutching (French, *teillage*), and is intended to separate the fibre from the woody matter of the stem, and thus to make it fit for the spinner.

922



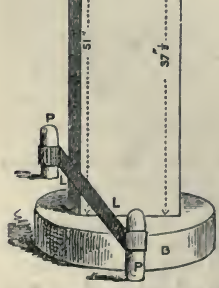
923



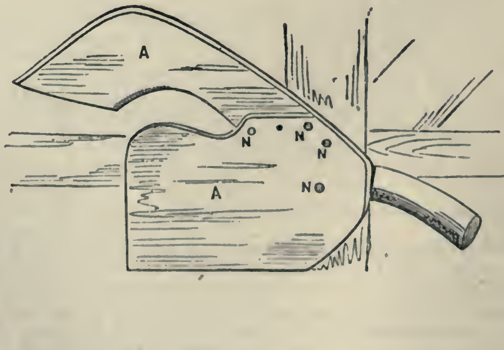
The first part of this process is to bruise the stems thoroughly, so that while the fibre, from its tenacity, is intact, the brittle woody part is flattened and broken in such a manner as to admit of its easily being beaten off by the action of the scutch-blade or scutch-mill. In most countries the bruising is done by hand. In Flanders and France the flax-straw is first laid flat on the ground, the sheaf being untied and spread thinly, and the workman, placing his foot upon it, beats it with an instrument called a *mail*, having a curved handle and a heavy square indented mallet, *fig.* 922.

The next part of the process is to give the flax repeated blows in a machine termed a *bracé* or *braque*, *fig.* 923. This is generally made of wood, but sometimes of iron, and consists of two rows of grooves T T, the upper one moving on a pivot at the socket S. A stout pole P runs from end to end of the upper row of teeth. The latter are wedge-shaped, 4¾ inches deep, 1½ inch thick at top, and 33½ inches long from the head H to the socket S. The head weighs about 8 lbs. and is 10 inches long, and 3¼

924



925



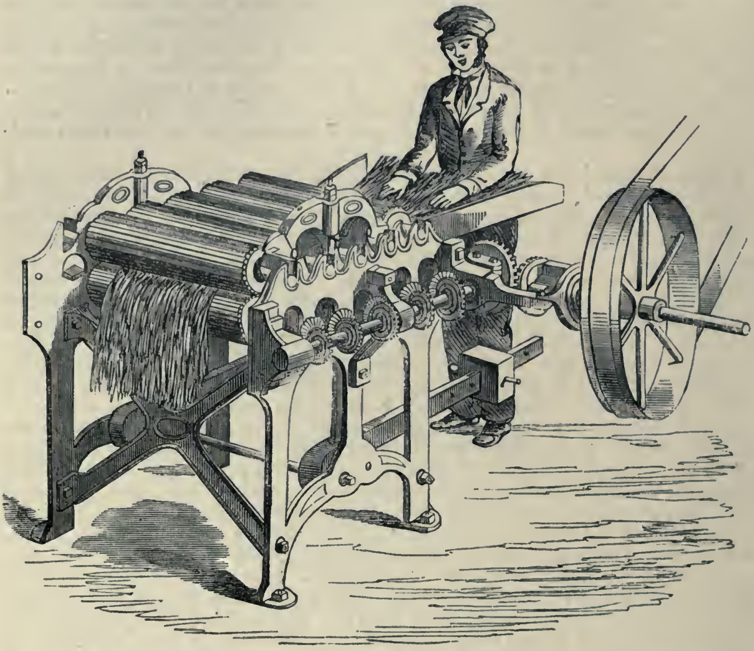
inches thick. The lower row of teeth consists of four, while the upper is three, fitting into the interstices. The best wood for the machine is that of the apple-tree.

Next comes the scutching proper, still following the Belgian, French, and Dutch method of hand-work. After the flax has been bruised by the *mail*, and crushed by the *braque*, it is ready for the scutching process. In Belgium and France the method pursued is by the employment of a wooden stand (*fig.* 924). A broad plank of pine or beech, about 4 feet high, and rather more than a foot broad, about $\frac{3}{4}$ inch thick, is fixed in a wooden sole B. 3 feet from this sole is a cut in the wood of the upright plank, about $1\frac{1}{2}$ to 2 inches wide. This cut serves for the introduction of a handful of the flax-straw, bruised as before described, and the workman, holding it three-fourths exposed through the slit, beats it with a tool called the scutch-blade, *fig.* 925. It is made of walnut wood, and is very tough and flexible. In Ireland the system of scutching by hand is very rude, and prevails chiefly in the western counties. A brake similar to that of Belgium is employed; but instead of the Belgian scutch tool, a rude instrument is employed, generally of ash-wood, in the form of a sword-blade.

It must be stated that the system of hand-scutching is only to be recommended where the quality of the flax fibre is so superior as to render economy in waste of primary importance, or else where the wages of labour are so low as to render the power of machinery of little consequence as regards economy. But, where wages are high, and flax of medium or low quality, there is no question that machine-scutching is the most advisable, and the most economical. This has been especially recognised in Ireland, where in 1870 there were 1540 scutch-mills in operation, when the growers sent their crops to be prepared for market, at a reasonable rate, much less than hand-scutching would have cost. Scutch-mills have been introduced with advantage into Russia, Prussia, Austria, Denmark, Holland, Belgium, France, Italy, and Egypt. In Ireland, although in several districts flax is scutched by hand, machine or mill scutching has been for more than half a century in operation. As in the hand-scutching, the operation consists of two processes: first, the bruising of the stems; and secondly, the beating away of the woody parts from the fibre. The original system of bruising is still very general. It consists of a set of three smooth wooden rollers, one underneath and the two others above it, parallel to each other, and one of them horizontal to the lower roller. The labourer sits opposite the lower roller, and inserts a handful of flax-straw between the latter and the upper one, which is horizontal to it. The flax being drawn in and bruised between these, passes up between the two upper rollers, and reappears at the outside. It is again put through, once or twice, according to its thickness, or to its being more or less steeped, and the fibre, consequently, more or less easily freed from the ligneous part. The scutching apparatus consists of a wooden shaft, to which are attached, at intervals, like radii of a circle, short arms, to which are nailed the *stocks*, which are parallelogram-shaped blades of hard wood, with the edges partially sharpened. The labourer stands beside an upright wooden plank, very similar to that figured in the description of the Belgian hand-scutching apparatus (*fig.* 924), and through just such a slit exposes one half of the handful of bruised flax-straw to the action of the stocks, which revolve with rapidity along with the shaft, and strike the flax-straw, beating off the ligneous matter, and leaving the fibre clear. When the end exposed to the stocks is cleaned, the workman turns the handful, and exposes the other end. It is usual to have a set of either two or three men, at as many different stands, and instead of each thoroughly clearing out the handful of flax, he only partially does so; the second then takes it up and finishes it; or, if there be three in the set, he does not quite clean it, but hands it over to the third to do so. In the latter case, the first workman is called the *buffer*, the second the *middler*, and the third the *finisher*. The motive-power in these scutch-mills is generally water; in some cases they are wind-mills, and in a few instances they are driven by horses. Latterly, the use of steam-engines has considerably increased, as being more to be depended upon than water, which frequently fails in a dry season. It has been found that the woody waste produced in the scutching is quite sufficient fuel for the boiler, without its being necessary to purchase coal or peat, and this waste had hitherto been applied to no useful purpose, being with the greatest difficulty decomposable for manure.

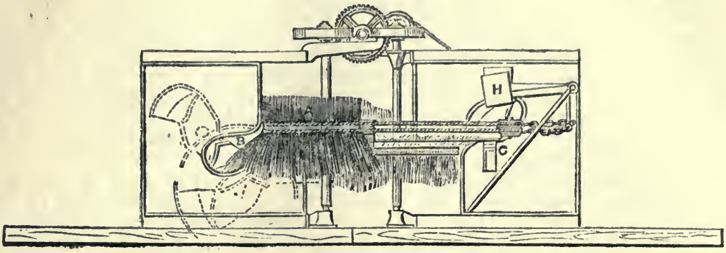
The first improvement on this old scutch-mill apparatus was the introduction, by Messrs. MacAdam Brothers, of Belfast, of a machine for bruising the flax-straw, prior to steeping, and it has since been extensively employed, with very satisfactory results. It consists of a series of fluted rollers, running vertically on each other, the flutings varying in width, the widest set being the first through which the flax-straw passes, and the others diminishing in width, until the finest is the last. While acting strongly on the ligneous matter, at the same time bruising and crimping it, and reducing it almost to powder, it does not injure or disarrange the fibres. One breaking machine of this construction is capable of supplying twelve scutching-stands of the ordinary mill. It is attended by two boys, one to feed the flax-straw into the machine, by means of a feeding table, and the other to remove it at the opposite extremity. Once passing through the machine is quite sufficient to prepare the flax-straw thoroughly for being scutched. The force required to drive it is one horse-power. *Fig.* 926 will best show its construction and mode of action.

926

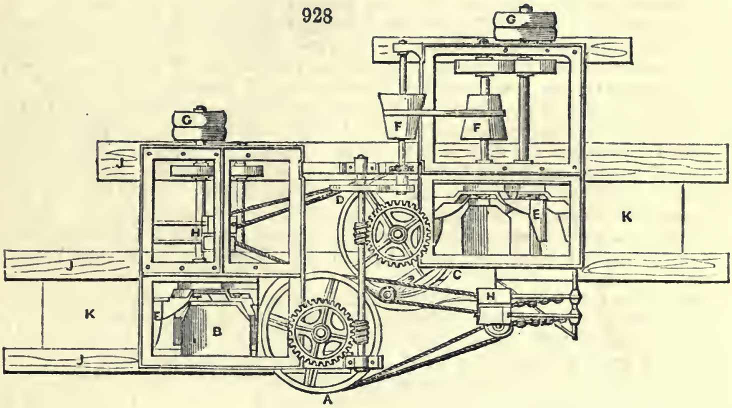


It having been found that many disadvantages were inherent in the old scutch-mill, several persons have set themselves to work to supply a machine which would reduce the cost of labour, obviate the necessity of obtaining skilled workmen, and diminish the great waste of fibre, which was but too frequent in the ordinary mill. Among the most successful of these scutching machines, is an invention of Mr. MacBride, of Armagh, Ireland, *figs.* 927, 928. It consists of a cast-iron frame, at each end of which is a compartment, enclosing a double set of beaters, of peculiar construction, which revolve rapidly in a contrary direction, striking alternately on each side of the flax, as it is submitted to their action, and thoroughly removing the woody part, which falls down in dust into a pit or hollow under the machine. In order to carry the flax gradually through the machine, and present it in a proper manner to the beaters, in succession, an endless double rope is introduced, carried in the hollow of a large grooved wheel, in which it is kept tight, by means of tension-weights. The flax-straw, made into handfuls, is introduced at A, under the double rope, at one end of the machine, and is at once grasped by it firmly rather above its middle, and carried along slowly, by the movement of the grooved wheel, until it enters, hanging downwards, the compartment B, containing the first set of beaters. By the time the flax-straw has been carried through them, all its lower half, which has been exposed to the action of the beaters, is cleaned out, and the rope, passing on a short way farther, arrives at a point where a second grooved wheel is revolving, furnished with ropes in like manner, but arranged at a rather lower level. By a simple arrangement, the flax is here transferred from one set of ropes to the other, the second set grasping it near its lowest end, thus leaving all the uncleaned part, or upper half, ready to be scutched. The second wheel moves on, and carries the flax towards the compartment containing the second set of beaters, cleaning all the upper portion of the flax. It then issues out at D, cleaned throughout, and is received by a person placed there for that purpose, who makes it up into the usual package for sale, of 16½ lbs. A constant succession of similar handfuls of flax-straw is thus kept pass ing through the machine without interruption. E E are the beaters; F F are two cones, carrying a leather band, which gives the motion to the ropes, or carrying-apparatus.

927



928



By shifting the position of this band towards one end or the other of the cones, the speed of the carrying-ropes may be varied at pleasure, so as to keep the flax a longer or shorter time under the beaters. Some kinds of flax require more scutching than others. G G are the driving pulleys, for giving motion to the machine by means of a band from motive power, which may be steam, water, wind, or horses. Each pair of pulleys drives one set of beaters separately from the other set, and hence, if requisite to drive one set faster than the other, which is sometimes the case when the top end of the flax is hard to clean, this is easily done by using a similar pulley on the machine, or a larger drum on the driving shaft. H H are the tension-weights and levers for keeping tight the carrying-ropes. J J are bearers of wood for carrying the frame of the machine. K K are pits underneath the compartments containing the beaters, and are for receiving the woody dust as it falls from the flax-straw. The machine occupies a space of 11½ feet, by 10 feet, but some space is required round it for handling the flax. The height of the machine is 6½ feet. The power required is three-horse.

M. Mertens, of Gheel, Belgium, has invented a scutching-machine, which merits notice. It is portable and cheap, and requires the attendance of only boys or girls, to put the flax-straw in and take the scutched fibre out. The action is something similar to that of the Irish scutch-mill, but the bruised flax-straw is placed in iron clasps, one end being first cleaned out, and then the clasps opened, the flax-straw reversed, and a second insertion in the machine clears out the other end.

Messrs. Rowan, of Belfast, have recently introduced a scutching machine, whose action differs from all hitherto in use. The flax-straw is not previously bruised, but is at once fastened in iron clasps, which are placed in a slide, the action of the machine carrying them on along one side, while two parallel bars of iron, toothed, comb the straw and separate the woody part from the fibre. The first portion of these bars have coarse teeth, and the teeth become closer by degrees upto the end of the slide. There a workman or boy takes out the clasps, unscrews the nuts fastening them, and reverses the position of the straw, so that the portion not previously subjected to the action of the machine is now presented to it, while that already cleaned out is untouched. The machine is double, *i.e.* has two sides of combs, each capable of containing twelve of the clasps, and each cleaning out one end of the flax-straw. Hence, after the workman or boy has unclasped the half-cleaned straw, turned it upside down, and presented the uncleaned end to the other side of the machine, the same action of combing, already described, clears out that end thoroughly, and by the time the progressive movement of the mechanism brings the slide to the extreme end, the flax fibre appears free from woody refuse, and in a fit state for market. It is then unclasped and made up into bundles.

There have been a great number of other scutching machines invented, but it is not necessary to particularise them.

In the operation of scutching, however carefully it may be done by hand or by machine, there occurs more or less waste, *i.e.* the beating of the flax-straw, in order to separate the marketable fibre from the useless wood, causes a portion of the former to be torn off in short filaments mingled with the wood, and this torn fibre is very much less valuable than the long filaments when finally cleaned out. In general, it will not average more than an eighth or a tenth of the value of the long fibre. It is termed *scutching-tow* or *codüla*, and when properly cleaned is dry-spun for yarns employed in making coarse sacking, tarpaulins, &c. Being very much mixed with the woody matter of the flax stems, it is necessary to get rid of the latter before the scutching-tow can be spun into yarn. To accomplish this, shaking by hand is the first process, and subsequently the stuff is put into a wooden machine termed a 'devil,' in which, by a mechanism something resembling the shakers in a threshing machine, the woody particles and dust are got rid of. The tow is sorted into different qualities, and, in some cases, it is *hackled* before being sold. In France and Belgium it is chiefly retained at home, spun by hand, and woven into such fabrics as coarse trowsers and shirts, for the labouring classes, aprons, table-covers, &c. What is produced in Russia, is partly used for similar purposes among the lower classes, but the great mass is exported, Great Britain and Ireland being the chief mart, and Dundee especially.

The great aim in all the different methods of scutching, has been to obtain the largest possible yield of long fibre from the flax-straw, and to waste as little as possible in scutching-tow. The French and Flemish system of hand-scutching is most successful in this respect, but as the quality of fibre there produced is very much finer, and consequently more valuable than all others, the additional expense of hand-labour is compensated by the larger yield of long fibre; whereas, in Ireland, the fibre being generally coarser and less valuable, occupying an intermediate place between the Flemish and Russian, the cheapness of mill-scutching turns the scale, and, except in remote districts, it is now universal. In Egypt, until some fifteen years ago, the method of scutching was of the most primitive form. The fellahs, after steeping their flax in the Nile, and drying it on the banks, proceeded to clean out the fibre, by first beating the straw between two flat stones, and then striking it against a wooden post. Mehemet Ali and his successors, however, introduced Irish scutch-mills, driven by steam-power, and since then a marked improvement has taken place in the state in which Egyptian flax has been brought to market. It may be interesting to note here, that in the early period of Egyptian civilisation, the dwellers by the Nile were able to manufacture cambrics of a finer texture than the most finished modern mechanism can produce—as is evidenced by the cerecloths wrapping the mummies—and that from a fibre so coarse in comparison to European flax, that while the latter may be spun by machinery to 300 or 400 leas, and by hand to 1,200 leas, the former cannot be put higher than 40 to 50 leas, and rarely even to that.

In the scutching operation, three several matters are obtained from the flax stems. The first is the fibre, which is the primary object, and which is the really valuable portion, that known as 'flax' in commerce. The second is the woody refuse of the stems, hitherto applied to no other use than as fuel, or occasionally in Ireland as a covering for cuttings of potatoes, when planted, to protect them from frost. Mr. Pye, of Ipswich, however, proposes to make it available as an auxiliary food for cattle, having the authority of Professor Way that a sample analysed by him yielded 7·02 per cent. of oil and fatty matter; 7·93 of albuminous matter (containing 1·25 nitrogen), and 26·29 of starch, gum, sugar, &c. He (Mr. Pye) recommended its use for feeding live stock, in conjunction with ground oats or other farinaceous food. Professor Hodges, nevertheless, in analysing another sample of this ground ligneous matter, gave quite a different result, his estimate of the nutritive constituents being as follows:—nitrogenised flesh-forming matters, 3·23 per cent.; oil and fatty matters, 2·91; gum and soluble matters, 14·66; and he compared this with the average results of seven analyses of oil-cake, giving nitrogenised matters, 28·47; fatty matters, 12·90; gum and other soluble matters, 39·01.

The third portion separated by the scutching process is termed '*scutching-tow*,' in Ireland; in Russia and Prussia, '*codilla*;' in France and Belgium, '*étouppe de teillage*,' described above. These branches of the trade consume annually many thousand tons, imported chiefly into Scotland, from Russia and Prussia. In France, Belgium, and Holland, the codilla or scutching-tow is chiefly retained by the growers or factors at home, for a domestic manufacture of similar goods, and of coarse blouses and trowsers. It has also been employed for conversion, by Claussen's process, into a finely-divided mass of fibres, capable of being mixed with wool and spun along with it into yarn, the fabric made from this yarn being chiefly hose.

Before proceeding to treat of the processes to which flax fibre is subjected subsequent to scutching, it may be well to glance at the uses to which the seed is applied. This valuable product of the plant furnishes two articles of much utility, and of very extensive use,—the oil and the cake. When the seed has been separated, dried, and threshed out, it is either sold again for sowing or for conversion into cake and oil. Of course the former purpose only consumes a small proportion of the seed produced throughout the world, and in many countries it is not of a quality suitable to the chief flax-growing localities. Thus, while northern Russia, Germany, the Low Countries, and France either export seed for sowing, or consume their own produce to a considerable extent for this purpose, the southern provinces of Russia, the States along the Mediterranean, Egypt, Turkey, Greece, and the East Indies, while large exporters of seed for crushing, cannot sell any for sowing. The supply of the seed-crushers of the United Kingdom is more largely obtained from Russia and Hindoostan than from any other countries. The entire annual import of seed into the British Islands averages 600,000 to 800,000 quarters, value between a million and a half and two millions sterling. The conversion of flax seed into oil and cake is carried out by different methods. In France, Belgium, Holland, and the north of Europe generally, where a large quantity is crushed, the apparatus employed is very simple and yet very effective. Lille, in France, Courtrai and Ghent, in Belgium, Neuss, in Prussia, and the province of Holstein, are the great seats of this manufacture. See LINSEED.

The seed is pounded in a kind of wooden mortar, cut out of solid timber, and at the bottom lined with thick copper. By means of a revolving shaft, furnished with projecting notches of wood, beams of oak 20 feet high, having the ends shod with channelled iron, are alternately raised up and let fall into the mortars, where, in a short time, they convert the seed into a pulpy mass. When sufficiently pounded, this is removed and put into woollen bags, which are then wrapped up in a leathern case, lined with a hard twisted web of horse-hair, covering both sides and ends, but open at the edges. These are then ready to be pressed, and for this purpose are packed perpendicularly in an iron receptacle, narrow at the bottom, and widening towards the top. Packings of metal are then put in, and in the centre of the bags is inserted a beech wedge. A beam similar to that employed in pounding the seed is then set in motion, and at each descending stroke it drives the wedge in tighter, thus squeezing the bags of seed against the iron sides of the press. When the wedge has been driven home, another is introduced and battered by the beam, until it will drive no farther. At the bottom of the press are holes through which the oil thus pressed out of the seed runs into a receptacle beneath. In order to loosen the wedges and admit of the bags being removed from the press, a wedge of a different form, wide at bottom and narrow at top, and already a fixture in the press, but raised up and fastened by a rope during the driving of the other wedges, is released from the rope, and another beam drives it home, thus partially starting the differently-constructed wedges and loosening the mass. The bags with the pressed seed are then taken out, and the latter, having lost the greater part of its oil while subjected to so considerable a pressure, is found in a thin hardish cake, taking the form of the leathern case, and off it the woollen bag is readily stripped by the workman's hands. The oil obtained by this process is the purest and most limpid; but another process has to be performed before the seed yields all that the pressure is capable of extracting from it. The cakes, therefore, when taken out of the bags, are broken up and put into the mortar, where the same pounding operation takes place. When again brought into a comminuted state, the powder is put into a circular iron pan or kettle, under which is a fire, and slowly roasted in it, being kept from burning by means of an iron arm which is moved round inside by the machinery, constantly turning the ground seed. When sufficiently warmed by this operation, during which it is made to part more freely with the oil, the mass is again filled in bags and pressed as before, after which they are finally, the bags being stripped off, pared at the edges, put in a rack to dry, and stored for sale. The oil thus obtained is darker in colour than that by the cold process, and contains more mucilaginous matter. Many foreign oil-millers, however, only employ the hot plan, believing that they have thus a larger yield than when the cold pressure is first used. See LINSEED OIL.

In England, the cold pressure is little, if at all, practised, the seed being almost invariably warmed before pressure. The system of crushing, formerly universal here, had some resemblance to the Flemish method above detailed, the chief difference being in the mode of preparing the seed, prior to its being put in the press. The first process is to pass slowly from a hopper the whole seeds into a pair of smooth or fluted metal rollers, which, in turning on each other, crack the seeds. Heavy edged stones then grind them into a meal, a little water being added during the operation, which facilitates the comminution of the seed. The meal is then put in the *kettle* before described, and while heated and stirred in it, the water mixed with it is evaporated. It is then bagged and put in the press, where the *stampers*, falling on the wedges, effect the desired results. The most recent improvement in the mode of pressure, and one now largely adopted, is the hydraulic press, and it is generally considered that a larger yield of oil can be obtained by its use than by the wedge and stamper-beam method. Blundell's (of Hull) patent is that most generally employed, and Messrs. Samuelson of that place are distinguished as makers of it, having themselves introduced some modifications and improvements. The oil obtained from flax-seeds or linseed, as it is generally termed, is of very extensive use in the arts, and is the chief vehicle for paints. To suit it for this purpose, and to make it dry quickly, it is mostly boiled in an iron pan, and during the operation a quantity of litharge is dissolved in it. The cake is a very favourite article with stock-feeders, being combined, as containing much nutriment in small bulk, with roots or other vegetable food, having large bulk with small nutriment. So extensively is it consumed in Great Britain, that besides the very large quantity made from imported seed, fully 80,000 tons of foreign cake are annually imported. On the Continent inferior qualities of cake are ground to a coarse powder, and either applied to the soil as a top-dressing, or steeped in a liquid manure, and the mass spread out on the land in that state.

Scutched flax fibre appears in the market made up in different ways. Russian is in large bales or bundles; Dutch and Flemish in bales weighing 2 cwts., the fibre being tied in 'heads,' each of which is about as much as the hand will grasp. Irish is made up in bundles termed 'stones,' the weight of which is either 16¼ lbs. or 24½ lbs. In this state it is piled in the stores of the spinner, care being taken that it be placed on a ground-floor, flagged or tiled, and not in a boarded loft, as the humid atmosphere of the former is conducive to the preservation of the suppleness and 'spinning quality' of the fibre, whereas it deteriorates considerably when exposed to a drier air.

The first operation which it undergoes in the spinning factory is *hackling*.

This process is required to comb and straighten the fibres, to get rid of any knots, and to lessen and equalise the size of the filaments. The action of the hackles necessarily divides the scutched flax into two portions, the long, straight ones, which remain after the flax has passed through the operation, being termed 'line,' and the woolly- or cottony-looking mass which remains, being designated 'tow.' Both of these are spun, but the line produces the finer and better qualities of yarn, and is consequently much more valuable than the tow. The great object, therefore, is to obtain the largest possible quantity of the former from a given weight of scutched flax, and the yield of line varies considerably according to the nature of the season. Spinners, therefore, are anxious, as each new crop of flax is brought to a marketable state, to test the yield of line, so as to guide them in their purchases. They are thus enabled to ascertain more clearly the suitability of the samples for 'warp' or 'weft' yarns, and for thread-twisting. Warp-yarns, being those which constitute the long threads of a linen fabric, require to be harder and stronger than weft-yarns, which form the cross or short threads.

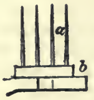
The yield of line, as well as the general economy of the operation, is, of course, greatly dependent on the nature of the hackling-machine employed, and great scope for care and ingenuity is thus given to the machine-makers. A great number of hackling-machines have, from time to time, been brought out, employed in the factories, and subsequently abandoned, when others, having greater merit, have been invented.

In the early period of the linen manufacture, when spinning was done exclusively by hand, no hackling-machines were employed. The process was exclusively effected by hand-hackles. Even after the introduction of machine-spinning, they were, for a long period, the sole means of hackling. Of late years, the machine has been more and more brought into use, and, although hand-hackling still exists to a considerable extent, the other method is by far the more extensively employed.

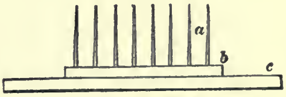
For hand-hackling, the tools used consist of a surface studded more or less thickly with metal points, called hackle-teeth, through which teeth the flax is drawn by the operator.

The hackles ordinarily used for hand-hackling in this country are in the form of rectangular parallelograms, presenting a line of 7 inches towards the worker, and 4 to 5 inches deep. The first tool employed is called the 'ruffer,' the pins of which are about ¼ inch square at their base, and 7 inches long, and brought to a fine point; the second is the 'common 8,' which is always used after the 'ruffer;' then the 'fine 8,' the '10,' the '12,' the '18.' The pins of all these tools are similarly placed to those of the ruffer, but are somewhat shorter in length, and are more slender as the tools increase in fineness. In all these tools the pins are held in wooden stocks of about ¾ inch in thickness and covered with sheet tin. This sheet tin, through which the pins are driven, helps to support them and prevent the wood from splitting. These tin-covered stocks are only of a size necessary for the extent of pins employed, and are themselves screwed to other larger pieces of board, a little broader and some inches longer than themselves, and by which they are ultimately fixed to the hackler's bench, inclining somewhat backward with their points from the worker, and a sloping board behind to prevent the flax entering too much in the pins thus:

929



930



931

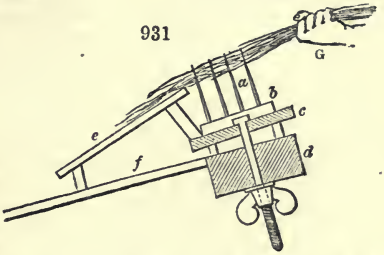


Fig. 929, end view of a hackle; *fig.* 930 front view of hackle; *fig.* 931 hackle, &c., fixed up for working. *a* pins; *b* tin-covered stock; *c* foundation board; *d* beam of table or bench; *e* backboard; *f* table to receive the tow, &c.; G hand of workman. Such is the form of hackle used in England, and also the manner in which they are, of whatever description, fixed for work.

The operation of manual hackling is simple in principle, although it requires much experience to acquire dexterity.

The workman having first divided the flax into handfuls or stricks, of which there are 300 to 400 to the cwt., proceeds to grasp one as flatly spread as possible between his forefinger and thumb, by about its middle, and wind the top end round his hand in order the better to prevent the slipping of the fibres; he then begins by a circular swing of his arm to lash the root end into the hackle; taking care to commence as near the extremity as possible, now and then collecting the fibres by holding his left hand in front of the tool, turning the strick from time to time. He thus gradually works up as near as possible to his right hand, when he seizes the ruffed part of the strick and holds it in the same manner as at first, and proceeds by a similar treatment to 'ruff' the top end; when this is finished the 'ruffed' work is taken to the tool called a 'common 8,' the pins of which are much closer placed than those of the ruffer, and are only 4 or 5 inches long. This '8' is always used after the ruffer, but from it the work can be taken to any of the finer tools, viz. 8, 10, 12, and sometimes 18. It is usual and better to dress both ends over each tool before taking the work to the next. The pins of all these tools are 4 inches long, in order, as was supposed, to have sufficient spring. The flax is not lashed into them as into the ruffers, neither are the ends required to be wound round the hand. But the root end of the flax is always the one to be first worked, and the hackling begun at nearly the extremity of the strick, which on being drawn through the hackle is received by the left hand of the workman, and by it carried back and laid upon the backboard and over the point of the pins, for the angle of inclination of the hackles and a slight lowering of the right hand causes it to enter sufficiently on being drawn forward. As it is impossible to ruff or dress entirely up to the hand, when the hold is changed in either operation, there must of necessity be left a certain space to be repassed through the tools; this is called the 'shift,' but the less length that is required for this purpose the better for the yield of line. The numerous long fibres that slip from the strick in ruffing must be collected and drawn from the mass of tow attached to them, when they can be relaid in the strick, or kept to be dressed separately under the name of 'shorts,' and from time to time the short fibres or tow sticking to the teeth of the finer tools are removed. Whenever one-half of the length of the strick of flax is hackled, it is turned round to hackle the other half. This process is repeated upon each hackle. From 100 pounds of well-cleaned flax, about 45 or 50 pounds of hackled line may be obtained by the hand labour of 12 hours; the rest being tow, with a small waste in woody particles of dust. The process is continued till, by careful handling, little more tow is formed.

To aid the hackle in splitting the filaments, three methods have been had recourse to: beating, brushing, and boiling with soap-water or an alkaline lye.

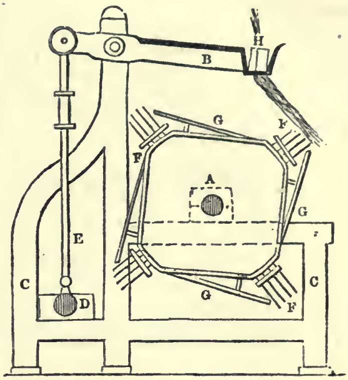
Beating flax either after it is completely hackled, or between the first and second hacklings, is practised in Bohemia and Silesia. Each hackled tress of flax is folded in the middle, twisted once round, its ends being wound about with flaxen threads; and this head, as it is called, is then beaten by a wooden mallet upon a block and repeatedly turned round till it has become hot. It is next loosened out, and rubbed well between the hands. The brushing is no less a very proper operation for parting the flax into fine filaments, softening and strengthening it without risk of tearing the fibres. This process requires, in tools, merely a stiff brush made of swine's bristles, and a smooth board, 3 feet long and 1 foot broad, in which a wooden pin is made fast. The end of the flax is twisted two or three times round this pin to hold it, and then brushed through its whole length. Well-hackled flax suffers no loss in this operation; unhackled, only a little tow; which is of no consequence, as the waste is thereby diminished in the following process. A cylindrical brush turned by machinery might be employed here to advantage. These have been tried in establishments for machine spinning, but not found advantageous.

The object of all hackling being to produce a good yield of line with tow of good quality—that is to say, free from broken, unsplit fibres, lumps and knots—the care and attention necessary to do this, with the expense and uncertain result of the individual skill of workmen, urged manufacturers to attempt the establishment of machines for effecting the process. Therefore many contrivances were invented with this view, but it was long doubted whether any of them made such good work, with so little loss, as hand labour. In hackling by the hand it was supposed that the operator would feel at once the degree of resistance, and be able to accommodate the traction to it, or throw the flax more or less deeply among the teeth, according to circumstances, and draw it with suitable force and velocity. For a considerable period these ideas, or rather prejudices, as they may now be called, seemed to be confirmed: for the earlier attempts to supersede hand-hackling, like those in many other undertakings, though partially favourable, were, on the whole, rather discouraging. In attaining one point desired another was lost, for too much still depended on the care and attention, if not on the actual skill, of the persons attending the machines.

It will be desirable, therefore, to give particulars respecting some of those which have been from time to time invented, although they are not now in use, as a lesson for preventing the repetition of things already known, as well as to illustrate the steps successively taken. The first machine invented, or, at least, published, was called the 'Peter,' and was intended to illustrate, as clearly as possible, the movements of the hand hackler. The flax was first divided into small convenient portions or handfuls, about 4 oz. each, called 'stricks,' which, before being taken to the machine, were slightly straightened and dressed over the ordinary hand 'rougher.' Each of these was then placed between a pair of short iron bars, called a 'holder,' one of which had an indentation in the middle, and the other a corresponding projection. Thus when tightened together by screws 4½ inches apart (such length being equal to a man's grasp), the strick of flax was firmly held while exposed to the action of the hackles. The holder was then suspended from moveable levers over a truncated rectangular cylinder, upon the angles of which were fixed, at a certain angle, hackles similar to those used in the manual operation. The levers supporting the holders received from a crank a short up-and-down motion, so timed in their oscillations as to strike the holder nearly against the points of the pins at the time they were passing under, coming thus as nearly as possible to the effect of a man striking in and drawing through the hackles, except that the flax remained nearly stationary, and the hackle was drawn through it by the rotation of the cylinder, whereas in the hand-process the hackle was stationary, and the flax drawn through it by the operator. Each machine carried two holders. The tow made and collected from the holders was seized and taken off by boys stationed for that purpose, while another, at the ringing of a bell, took out and changed the sides of the stricks to be presented to the action of the hackles, and subsequently withdrew them from the first machine to another similar but with finer hackles, and thus continued until the root end—always the first operated on—was dressed to the desired degree of fineness, when they would be taken to a table where another set of boys, previously to removing the first holder, put on a second to the already-hackled part, leaving about 2½ to 3 inches to be re-hackled. This operation is termed 'shifting,' and the space left, 'the shift;' it is thus performed and remains so called at the present day, the only change being that in the holder now in use one screw is used for two stricks instead of two screws for one strick.

Fig. 932 will more clearly show the construction of this machine. A, square truncated cylinder carrying the hackles; B, oscillating arm or lever for supporting the holder; C C, framing; D, crank and shaft; E, connecting rod from crank to oscillating arm; F F F, hackles; G G G, back board; H, holder. The first motion was given by pulleys on the shaft D, which revolved 4 times to 1 of the hackle cylinder, by the intervention of suitable wheels. The worm and wheels for the bell motion were attached in the usual manner to the shaft of the cylinder.

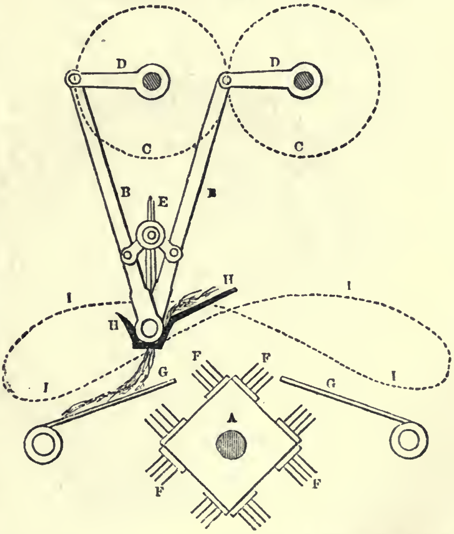
932



Machines of this construction continued in rather limited use without any change or competition till about the year 1825, when a patent was taken for a machine known as the pendulum machine. The flax in the holder being suspended and swung backwards and forwards while the hackle remained fixed, the flax was thus hackled, stroke for stroke, on each of its sides; the boys, as in the last described, snatching off the tow as it was formed, and at certain times, that is at each rise of the pendulum (for it had a rising and falling motion to imitate the hand workers in commencing at the extreme end of the flax), passing the holder from one recess to another of the pendulous table, so as to arrive at the progressively finer tools when ranged along the machine; but sometimes the different tools were fixed upon the angles of a square cylinder that presented a finer range, the whole length of the machine, by turning up a new angle at each rise of the pendulum, when the labour of the boys was simply to put in the tow and take out from it the flax. The adjoining diagram (*fig.* 933), without entering on any details of a machine that was so little used, will make the theory of its action quite clear.

A, hackle bench sometimes revolving so as to present different degrees of hackles at its various angles, sometimes stationary with the gradation of hackles upon its length; B B, pendulum arms; C C, equal wheels working into each other; D D, crank arms; E, radial slide-bars to preserve the holder table; H, holder table; F F F F, hackles; G G, back boards; I I, direction in which the holders swing; there were the same wheels, &c., at each end of the machine, and the holder table H reached from one to the other. The wheels, C C, with all attached to them, were made to rise and lower upon the hackles, and the back-boards C to rise when the hackle bench turned.

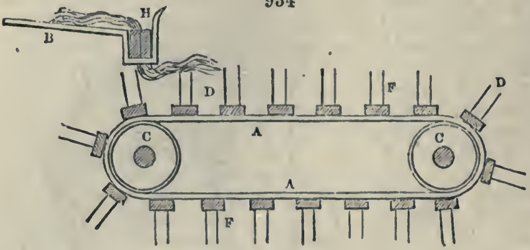
933



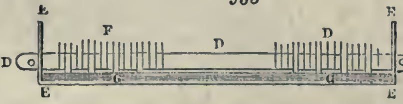
About the same time another patent was taken out for a machine where the holders were suspended above one end of a travelling sheet of hackles. This machine also required hand labour to turn and transfer the stricks, though the tow was caused to fall clear from the hackles by mechanical means. The following sketch (*fig.* 934) shows the principle upon which this machine works, and, though never much employed at the time of its appearance, it has subsequently served as foundation for those that are now in the zenith of their prosperity.

A A (*fig.* 934), sheet of hackles; B, support for holders; C C, carrier pulleys for the sheet of hackles. *Fig.* 935, a larger view of the hackle bar G G, in order better to show the faller D D D, in the staples or grooves E E, at the end of the hackle-bar G G; F F, pins of the hackles, between the rows of which the faller D D D acts to push the tow off the pins. There is a clearing faller D to each hackle, which is kept to the bottom of the hackles at that part of their course where they are in contact with the flax, but at the turn F D fly beyond the points, as shown by the effect of the centrifugal force.

934



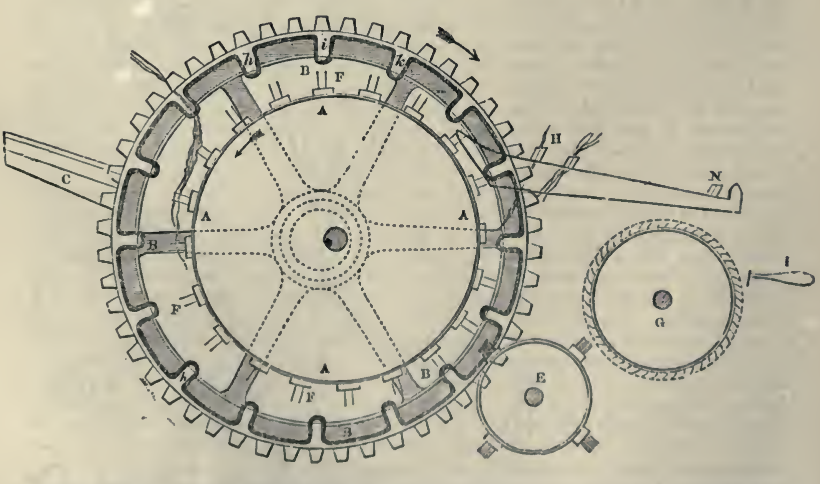
935



936

All these machines, possessing great similarity of features in regard to the personal attention required, never came into such general operation as to supersede entirely hand-dressing, either from their own defects, or prejudices against their employment. About the year 1830, in consequence of the new mode of spinning being carried on with considerable energy, it was found advantageous to cut the flax into two, three, or more lengths previously to hackling, which rendered it necessary to have machines peculiarly adapted for this new short description of material. This machine, known as the excentric or circular machine, deserves considerable attention for its own inherent merits, and the extensive utility it has proved to be of in suggesting the principal parts of those by which it has been supplanted. In its original form it was made of a breadth suitable for only one strick, and consisted of a cylinder 3 ft. diameter, upon the whole circumference of which at intervals of 3 or 4 inches were fixed the hackles. As each machine could only carry one description of hackle, it was necessary to employ a series of these machines, called a 'class,' when the flax required to be dressed over a succession of finer tools, each succeeding machine carrying a finer tool than its predecessor. The hackles were cleared of tow by coming in contact at one part of their revolution with a brush roller, which also revolved in contact with a cylinder covered with card clothing, the points of the pin being in such a direction as to clear the brush from tow, and allow itself to be in its turn cleared by

937



the oscillations of a comb, whence by rollers the tow was brought into a sliver. In order to preserve the continuity in the supply of tow, and maintain the regularity of the sliver produced by it, the holders with the flax were presented to the hackle cylinder in a manner peculiar to this machine, and in endless succession by means of certain circular carriers placed at each end of the hackle cylinder, but excentric thereto, and at such a distance apart as each should bear one end of the holder as it extended across the cylinder parallel to its axis. Thus, the holders introduced at that part of the circumference of these carriers furthest from the hackles were carried forward, while the flax was in operation, till they were brought almost into contact with the points of the pins, when, by the intervention of a slide, they were withdrawn from the machine, but with one side only of the flax dressed, and that but on one tool; therefore the holder required replacing in the same machine, in order that the second side of the strick should be dressed as was the first. The holders then required to be carried by hand to each succeeding machine of the class.

The preceding figure (937) shows the leading features of these machines: A A, hackle cylinder; B B, excentric wheel to carry holders in its recesses, *h h*; C, slide upon which the holders were laid so as to fall into the recesses *h h* of wheel B; D, slide for taking out holders; E, brush cylinders with brushes; G, cylinder covered with card clothing; H, holder come out; I, doffing comb. The space of the holder-carrying wheel was filled with holders, and so maintained in endless succession, and thus each served in some measure to keep the end of its preceding one down into the hackles.

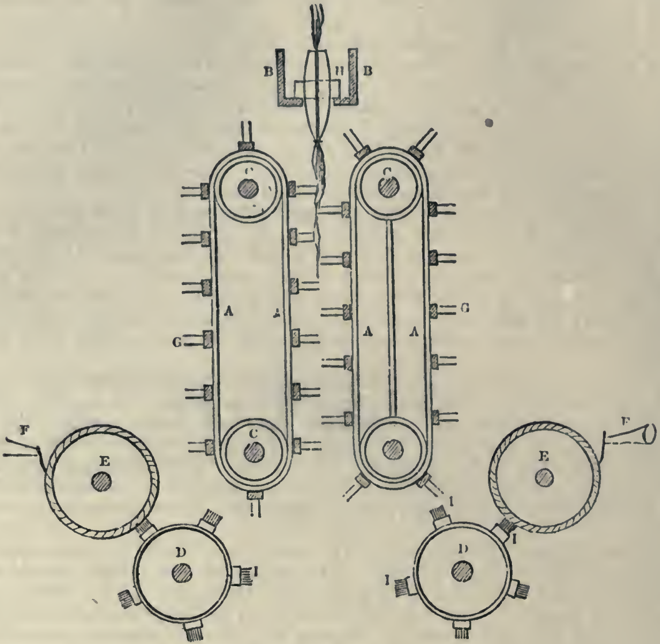
About 1833, a machine was patented consisting of two parallel cylinders, over which the flax was carried, revolving in its progress so as to present the alternate sides of the strick to the hackles, the progressively finer tools being ranged along these cylinders, so that having passed the length of one cylinder one end was completely finished. When the holder was taken out, 'shifted,' and replaced, it was carried back along the second cylinder, and thus returned to where it commenced, finished. This machine, however, never was carried further than the experimental one for the patent.

Another machine (Wordsworth's) the same year made its appearance, and for some time enjoyed much celebrity. It consisted of two parallel vertical sheets of hackles running together, and so geared that the hackles of one intersected the interstices of the other. The flax suspended in its holder from a species of trough passed between these two sheets, and was thus hackled simultaneously on each side in its course through the progressively finer hackles from one end of the machine to the other.

A A (*fig.* 938), hackle sheets; B B, holder trough or slide; C C C C, pulleys for carrying the hackle sheets; D D, brush rollers; E E, rollers covered with card clothing to clear the brushes; F F, doffer combs; G G, hackles; H, holder; I I, brushes.

It is unnecessary to notice more at length the different machines brought out, employed for a time, and then rejected. Although the hackling and spinning of flax, in the full length as it grows, was what was first practised by hand, the first really successful machine for hackling was what was known as the 'circular machine' for hackling 'cut line,' as it is called, or the long flax fibre broken into several lengths. It had always been known that the top and root ends of the fibre were of very inferior quality to the middle, and of course when all was spun in one length the yarn produced was inferior to what the middles could be spun to, while superior to what the tops and roots would produce. It therefore occurred that in the general qualities of flax the division of the fibre, so as to separate the different portions named, would be advantageous to the spinner. The operation of cutting was performed by a simple machine consisting of a pair of jaws, so constructed that when the flax is introduced between them the different parts, instead of being clearly cut off, are, so to speak, bitten off, leaving ragged ends. This is desirable in order that the ragged ends might interlace in the spreading prior to going through the preparing machines, which precede the spinning operation. The machine for hackling cut line was brought out about forty years since, and underwent, before it was finally set aside, a considerable number of modifications for the purpose of economising the labour in working it. About the same time the 'flat machine' was introduced, which was more particularly intended for hackling long flax. The nature of the operation of these machines was the same, the flax being acted on by different series of hackles fixed in the circumference of a cylinder in the one machine, and on an endless sheet in the other. The curvature of the cylinder was no objection in hackling cut flax; but for acting on long fibres it was necessary to put the hackles on a sheet, for the purpose of getting sufficient length of flat surface. The most successful machines, and which displaced all previous ones, have been modifications of these of different kinds, some of them being simply contrivances for saving manual labour, and giving certainty to the action, and others combining other improvements with this object. Carmichael's patent machine (*figs.* 939, 940) was, as brought out at first, simply the old flat machine with

938



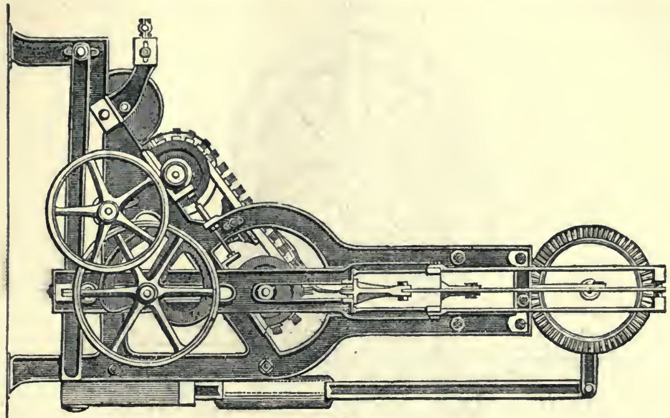
self-acting motions for actuating the holders applied to it. It was afterwards much improved by the adoption of an inclined sheet in imitation of a very successful self-acting modification of the old flat machine which was brought out by Combe, of Belfast, whose machine, at this time, is considered by many to be the best one in use for long line.

The distinguishing feature in these rival machines is, that in Carmichael's the motions are all performed by the descent of ponderous weights, while in the other they are performed by the direct action of the machine.

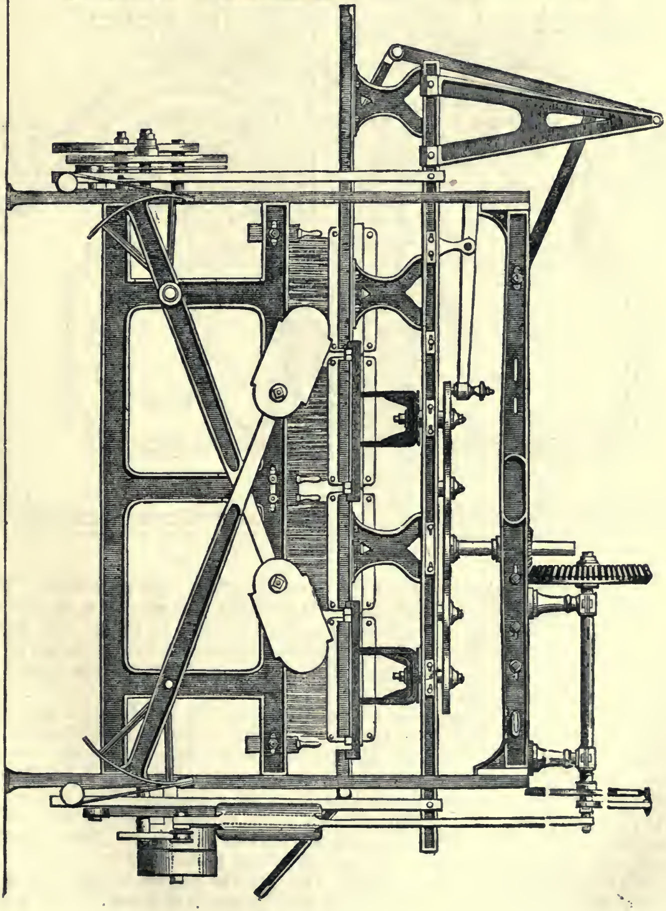
There are other differences affecting the working of the machines, which are by practical hacklers considered of great importance, and as giving more value to Combe's machine. The most important of these is the facility of adjusting the place where the holders approach the flax, which greatly affects the yield of line.

The same principles of actuating the holders were applied to cylinder machines for hackling cut flax, but, as these have been displaced by more recent inventions, it is not necessary further to refer to them. Wordsworth's machine, already figured (*fig.* 938), was of importance, as being the basis of several other valuable machines. Its essential feature was arranging the hackles on two sets of endless sheets placed opposite each other, and driven and connected by wheel-work so as to revolve together, the surfaces being placed so close together that the hackle pins penetrated the flax from both sides, and hackled at the same time. The large circle described by the points of the hackles in this machine, which prevented them cutting the flax close to the holders, and other imperfections, led to its abandonment. Some years since, Combe of Belfast designed for the eminent flax-spinning firm of Marshall and Co., of Leeds, a modification of this machine, which since has been known as Ardill and Pickard's machine, and has come into extensive use. The principal new feature in this machine was the introduction of cranked wheels for supporting and carrying the hackles, for the purpose of making the points of the hackles describe a small circle, and thus enable them to cut close to the holders. Although successful, this invention did not fully accomplish the object aimed at. About the same time, Marsden's intersecting machine was brought forward, and possessed a great reputation for a length of time. Its success was a good deal owing to the flax hackled by it having an apparent fineness; but this was not found to be of practical value, as the spinning quality was not improved thereby. For this reason it has gone greatly out of use.

The next machine which came into extensive use was Combe's reversing cylinders,



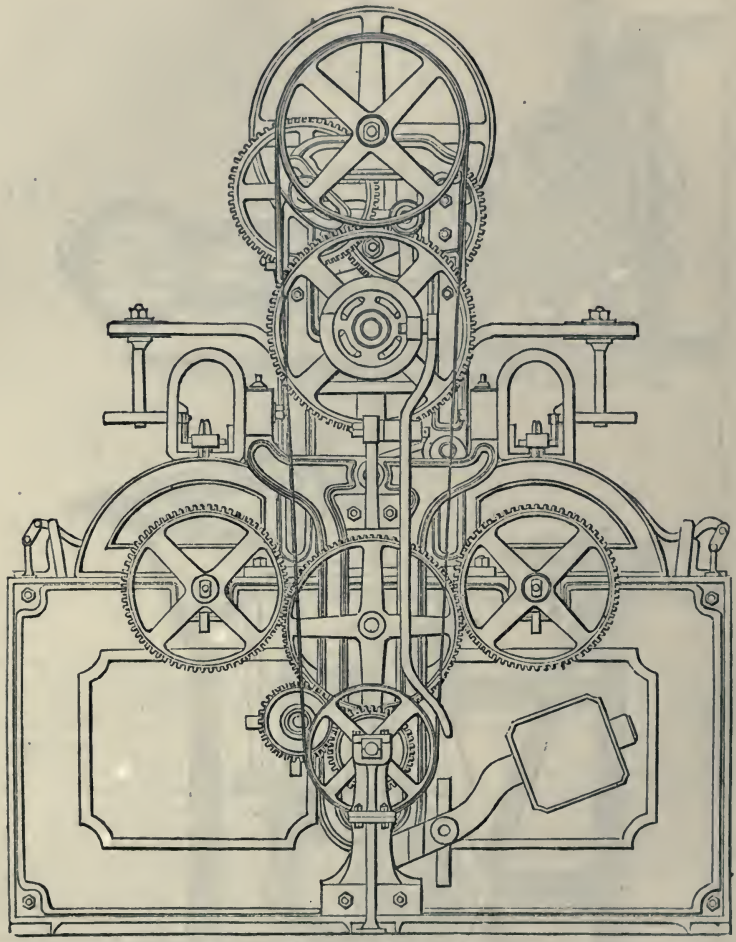
939



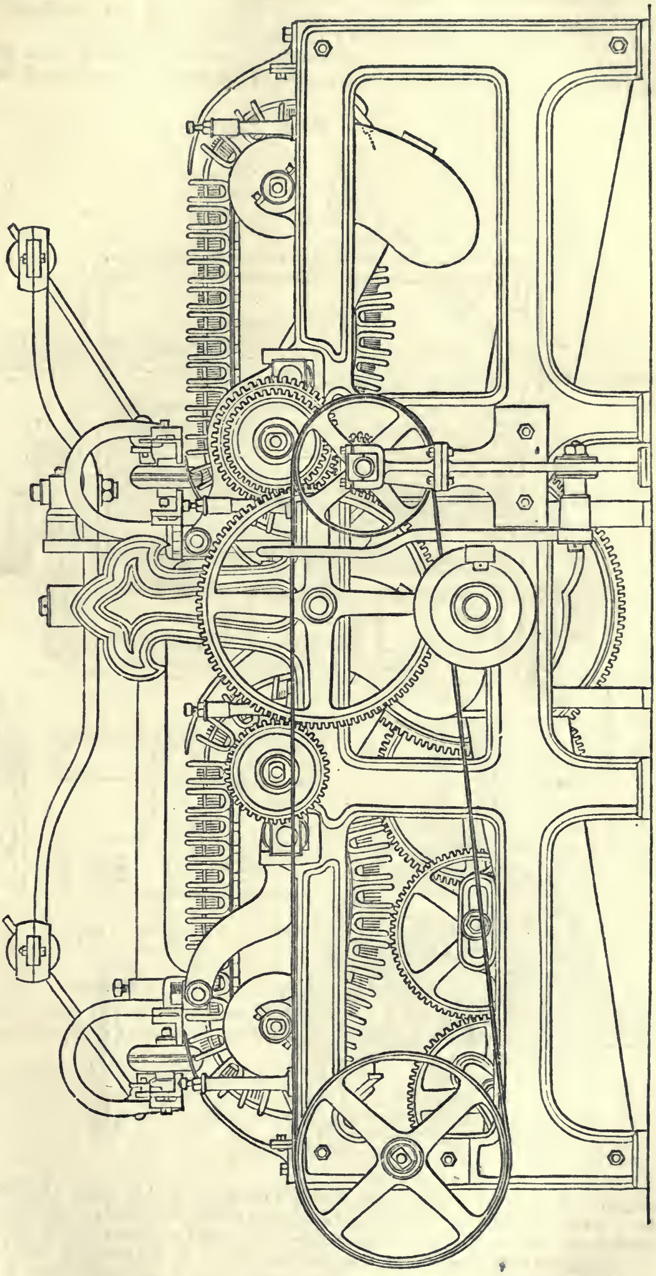
940

fig. 941. These machines are constructed in a great variety of forms for different kinds of work, and seem to give very good results. They are simple in their construction, and give little trouble, acting lightly on the flax and making very wiry fibres. They are made of all sizes, from 12 to 30 inches in diameter, and with 4, 6, or 8 graduations of hackles, according to the kind of work to be done on them. The flax is hackled on each side, or each graduation of hackles, by reversing the direction of the rotation of cylinders. The tow, or short fibre, is thrown off the hackles by stripper rods, placed between the rows of pins.

941



The next machine to be named is by the same inventor, and is styled the patent reversing sheet-hackling machine. It is for long line, on the same principle as that just described, except that it has the hackles fixed on flat sheets, as in the 'old flat' machine. It is simple and complete, easily driven and attended; and a considerable number are now in use. From the hackles being on a flat sheet, it is necessary to make the holders descend, first on one side while the sheets are moving in one direction, and then on the other while they are moving the other way. This is done by supporting the channels which carry the holders on four levers fixed on two oscillating shafts, to which motion is communicated by a shaft. The holders are slid through by a lever on the top, which acts on a sliding bar, by means of a ball, which forms a universal joint and actuates the holders, whatever position the channels are in. The drawing here given, *fig.* 942, will show the mechanism.



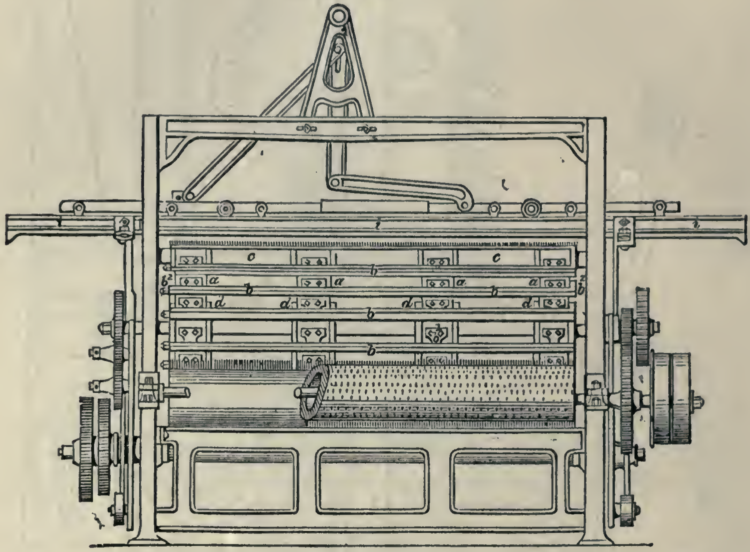
942

Both the machines last described are made double, or in fact, the construction of each is that of two machines in one. The table for filling and changing the flax in the holders is attached to the machine. One side hackles one end of the flax, and the other side the other end.

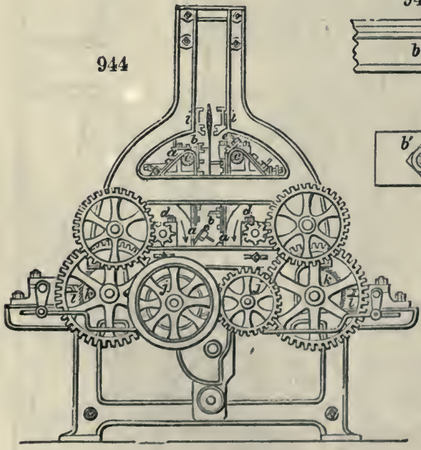
We now have to describe a machine for hackling cut line, patented by Mr. Lowry, of Manchester, and now extensively in use at home and on the Continent. It is virtually a modification of Wordsworth's machine, already described.

Fig. 943 is a side elevation of a sheet-hackling machine to which these improvements are applied; *fig.* 944 is an end elevation of the same; *fig.* 945 is a front view;

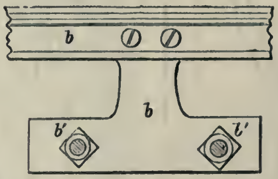
943



944



945



946

947

and *fig.* 946 an end view of one of Lowry's improved hackle bars. In *figs.* 943 and 944, *a a* represent the belts, sheets, or chains to which the hackle bars *b* are attached. These belts, sheets, or chains pass around the small drums *c c*, and larger drums *d d*, which are turned round by the gearing, shown in the drawing, or by any other suitable arrangement of gearing. The hackle bars *b* are made with a recess to receive the stock of the hackles *e*.

The hackle bars *b* are connected to the belts, sheets, or chains *a*, *a*, by means of rivets or screws, passing through the flanges *b*, and through the belts, sheets, or chains *a*; and at each end of each hackle bar is a stud or guide pin *b′*, which, when the hackles arrive near the small drums *c*, *c*, take into the groove in the guide plates. The object of these guide plates is to support the hackle bars in passing over the small rollers *c*, and during the operation of striking into the strick of flax or other fibrous material to be operated upon. The holders, with the stricks depending from them, are placed within the rails *i*, *i*, and these rails are made to rise and fall and the holders are made to pass from one end of the machine to the other, in the usual manner. When the machine is at work, the drums *c* and *d* revolve in the direction of the arrows in *fig.* 944, and the hackle bars being attached to the belts, sheets, or chains *a*, and supported by the guide plates, cause the hackles to enter the stricks of fibrous material at or nearly at right angles to the fibres thereof, and to retain that position at the commencement of their downward motion; whereby as the belts, sheets, or chains continue to descend, the hackles are drawn through the fibrous material for the purpose of removing the short fibres and extraneous matter. Another great advantage resulting from this improved mode of attaching the hackle bars *b* to the belts, sheets, or chains *a*, is, that the hackles can be made to enter the fibrous material at a point closer to the holder than in any of the sheet machines now in use. When the hackles are passing round the drums *d*, *d*, they are cleansed by the revolving brushes *j*, *j*, which deposit the material removed from the hackles on to the card drums *k*, *k*. These drums are cleansed or doffed by the combs *l*, *l*, or in any other convenient manner.

This machine is also used to a very large extent, and well liked for dressing half-line and full-length flax. For this purpose the sheets require to be made 6 inches longer from centre to centre, and the head or trough to lift 3 inches higher, and the top rollers to approach and recede from each other simultaneously with the rising and falling of the head.

Combe, of Belfast, has produced another edition of Wordsworth's machine. Its novel feature consists in dispensing with bars altogether, in carrying the hackles and in fixing them directly on the leather sheets. By this means a very true action is obtained, and the working parts are so light that the machine bears any speed with scarcely any wear and tear. In this invention there are also combined convenient modes of regulating the lift and severity of the cutters to suit different kinds of flax, and the holders are carried through the machine by a separate apparatus for that purpose, while they are at their highest elevation, instead of during the whole process of lifting, as had always been the case in other machines.

The cutting of flax already referred to, is effected by a machine consisting of a species of circular saw about 20 in. in diameter; but, instead of a single blade, it is constructed of 3 or 4 plates of steel, each about $\frac{1}{4}$ in. thick, and having angular projections from their circumference. This revolves at a considerable velocity, while the flax, firmly grasped in each hand by its ends, is still further held and slowly carried against the saw by two pair of grooved pulleys pressed together by a considerable weight. It is thus partly sawn and partly broken through. Flax may be cut into 2, 3, and sometimes 4 divisions: and sometimes the dead harsh fibres that are frequently found at each of its ends only are cut off and used as tow; but more generally the different portions are hackled and used for the purposes they are sorted for.

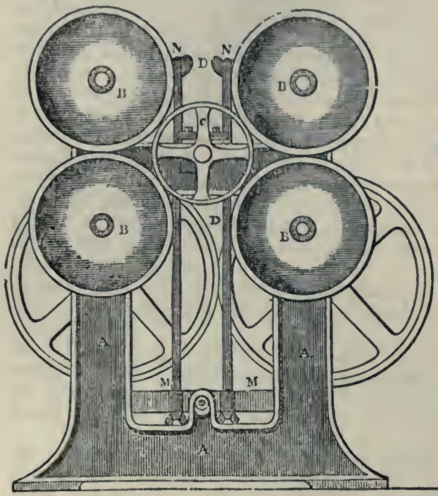
Description of flax-cutting machine (*figs.* 948, 949). A A, framing; B, the grooved pulleys for holding and carrying the flax; C C, the driving pulley; D, saw or cutter; E, F, wheels for gearing together the pair of holding pulleys; G, H, I, K, pinions and wheels for producing the proper relative speeds between the cutter and pulleys; L, weight, which by levers M and N, causes the pressure of the holding pulleys.

Preparing.—By this term are understood those preliminary operations through which both line and tow must pass after the hackling and before the spinning process.

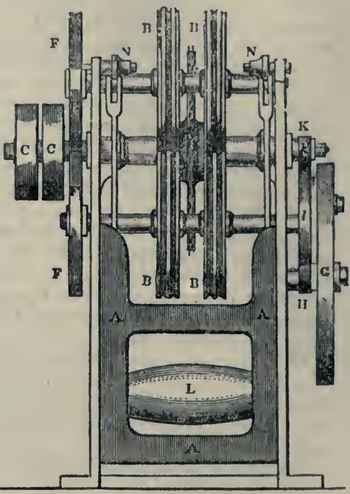
The mechanism and modes of proceeding for this purpose, which consist of repeated drawings, are similar for 'long' line or 'cut;' though the dimensions and fineness of the machinery must be made suitable for their various lengths and qualities. But in the preparation of tow a peculiar additional operation is demanded, as a consequence of the different state of the fibres of which the material is composed; this operation, termed 'carding,' has for its object to bring the highly irregular and entangled mass into a somewhat more homogeneous and uniform state, previously to its being afterwards drawn and equalised in a manner similar to line.

In the preparation of line the first operation is called 'spreading,' or first drawing; and the machine employed a 'spreader:' those subsequently are the second and third 'drawings' (sometimes a fourth is used), and lastly the 'roving.' It is upon the spreader that the separate stricks of line are first combined and drawn into long uniform bands or ribbons, called 'slivers,' of determinate lengths. This is effected by subdividing the stricks into two or three portions, and then placing them consecutively, slightly elongated, and overlaying each other about ¾ths of their length

948

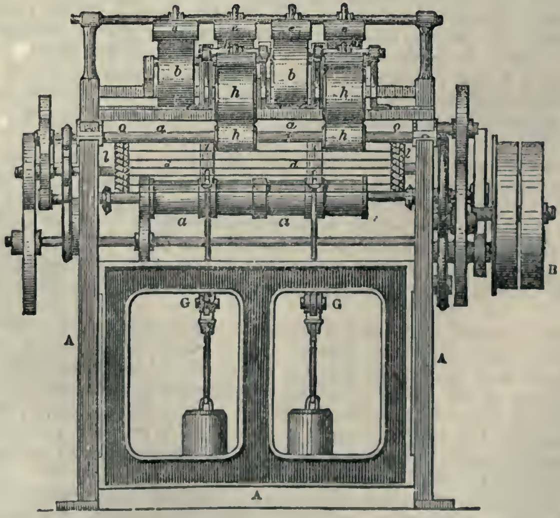


949



upon and in the direction of an endless creeping sheet or apron. The machines are generally made with two of these creeping sheets or aprons, and upon each sheet are thus laid two distinct lines of stricks; each of which forms a thick uniform body of line, and capable of being maintained to an indefinite length. These endless creeping sheets supply continuously another part of the machine, where the body of 'line' is drawn out to between 20 and 60 times its original length, according to whether it is composed of cut or long flax. This part of the machine comprises a pair of holding

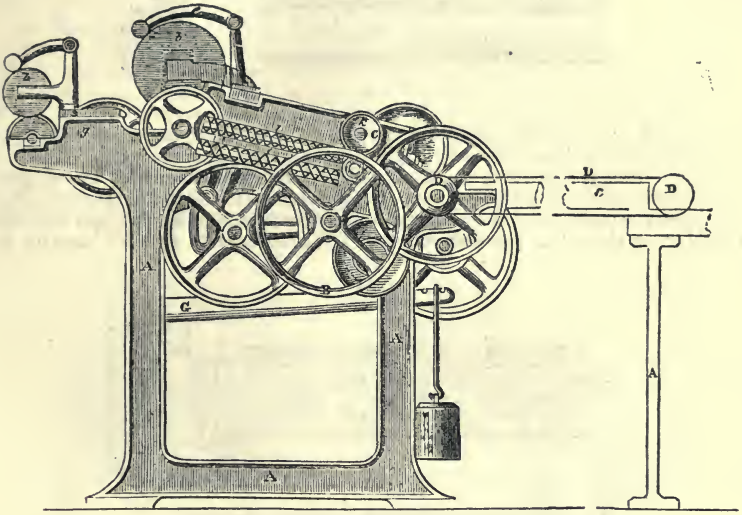
950



or back rollers; an endless succession of bars called fallers, bearing combs of closely-ranged steel pins, through which the slivers are drawn; a pair of drawing rollers; an arrangement of diagonal or doubling bars; and a pair of delivering rollers. It is generally termed the 'gill frame,' or 'gill head,' probably from the French word *aiguilles* (needles), as descriptive of the combs, and to distinguish this machine from those formerly used for the same purpose, which simply consisted of a series of rollers, under and over which the line was passed.

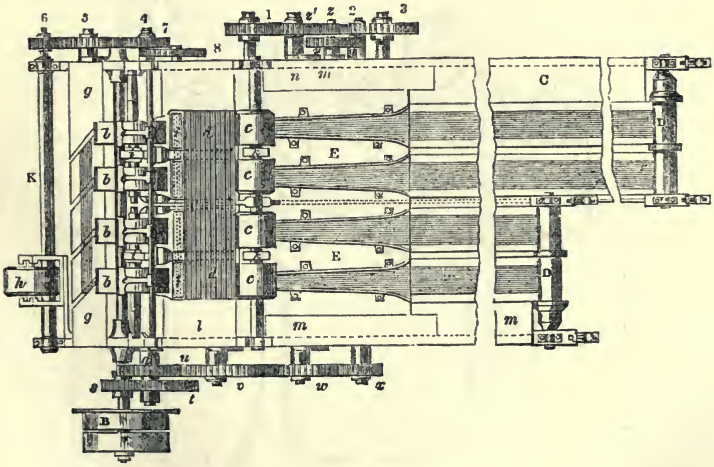
Figs. 950, 951, 952, show the outline of the present most approved gill spreader or first drawing.

951



A A, general frame of the machine; B, driving pulleys; C, auxiliary frame for endless sheets; D D D D, rollers for carrying the endless sheets or aprons; E E, conductors to guide and slightly condense the four bodies or slivers of line; F, can for receiving the sliver; G, lever for weight on front or drawing roller; H, lever for weight on back roller; K, delivering-roller shaft, spring, and bell, which, by the

952

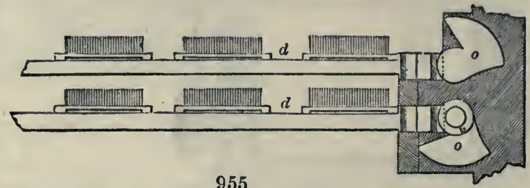


intervention of gearing between it and the front roller, is caused to ring when any desired length of sliver is delivered.

a a, the iron drawing roller or boss; *b b b*, the wooden or pressing roller, by the pressure of which upon *a a* the sliver is held during the greater velocity of these rollers over that of *c*; the holding or back rollers elongate in exact proportion to its augmentation; the holding roller *c* is in like manner pressed against another in order to assist the 'gills' in retaining the fibres; *k k*, hooked rods to connect the weighted lever *h* with the holding roller *c*, and by the pressure thus caused insure its effect; *d* the sheet or surface of 'gills' composed of separate bars, as seen at *figs.* 954, 955; *e*, rubber or cleaner of pressing roller *b*; *f f*, conductors to contract laterally the sliver at the moment of drawing; *g*, plate of metal having diagonal openings at an angle of 45° (this plate is sometimes called the 'doubling bars,' having been first made of separate bars) to the original course of the sliver, in order to enable it to be turned in a rectangular direction and guided to the delivering rollers *h h*; this direction of the sliver is more distinctly seen at *fig.* 952; *i*, hanger or connector of pressing

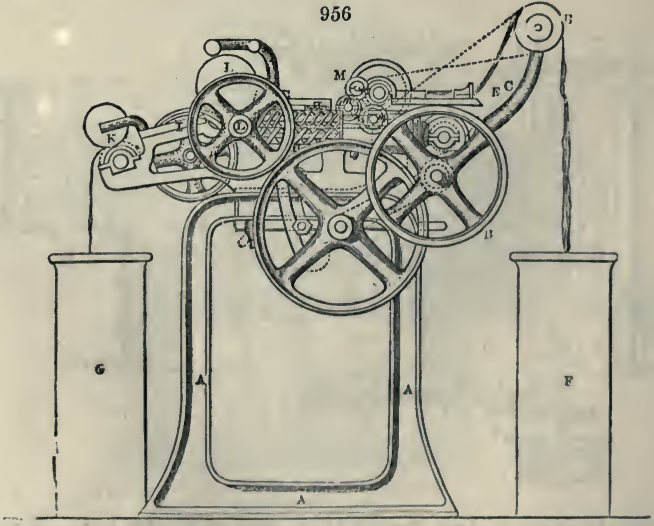
953

954



955

956

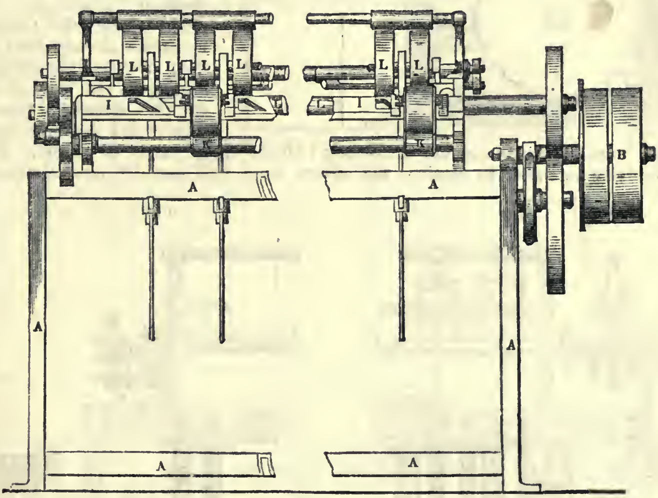


roller *b* to its weight lever *c*; *l l*, the screws or worm shaft for carrying the gill bar *d d*; *m m*, the shaft with bevel wheels by which the screws at opposite sides of the frame are caused to move simultaneously; *n n*, pinions for connecting the upper and lower spirals of each pair; *o o*, the cams or excentrics for lowering and raising the gill bars; *p p*, weighted guide lever or bell cranks for guiding the faller in its descent, and moderating the shock caused by its weight when coming in contact with the lower slide or support; *q* and *r*, worm and wheel for bell motion; *s*, *t*, *u*, *v*, *w*, *x*, line of wheels from pulley to front roller and from front roller to back; 1, 2, 3, line of gearing from back roller to sheet; 4, 5, 6, 7, line of gearing from roller to delivering roller; 8, from roller to brush; *y y*, from back shaft to back roller.

The machines for the second, third, and fourth drawings, though in principle essentially the same, yet differ in some of their minor details from the foregoing, as they do not require the feeding sheet to supply them, the sliver, from the spreader, having sufficient coherence to allow itself to be drawn from the cans direct by the back rollers of these machines; neither is a bell motion requisite to determine the length of slivers produced by them. The subjoined sketches show the general parts requisite.

A A (*figs.* 956, 957), framing; B, driving pulley; C, support of sliver carrier; D, roller for carrying sliver; E, conductors; F, can containing the slivers from the first drawing; G, receiving can; H H, the hackle carrying spirals; I, the diagonal or doubling bars; K, the delivering rollers; L, the drawing rollers; *m*, *m*, *m*, the retaining rollers.

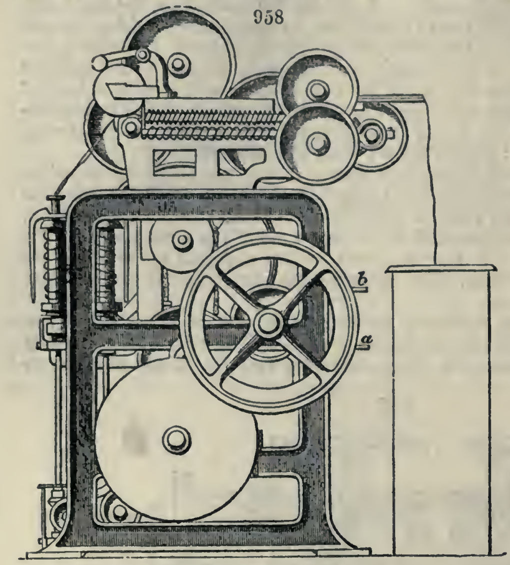
957



The roving frame is the same in regard to the arrangement of its back and front rollers and gills as the drawing frames; and, as the position and manner of regulating the poles are generally the same as adopted for cotton, the description of these parts, therefore, does not require to be repeated; but an improvement patented a few years since by Sir P. Fairbairn, of Leeds, of that part of these frames which relates to regulating the taking-up movement of the bobbin merits particular attention, as by it the inconveniences of the older method of a weighted belt and cone, and those of the more recent disc frames, are entirely overcome. The principle of this improvement consists of driving a pulley by pressure between two discs running at equal speeds in opposite directions, as seen at *figs.* 958, 959, 960.

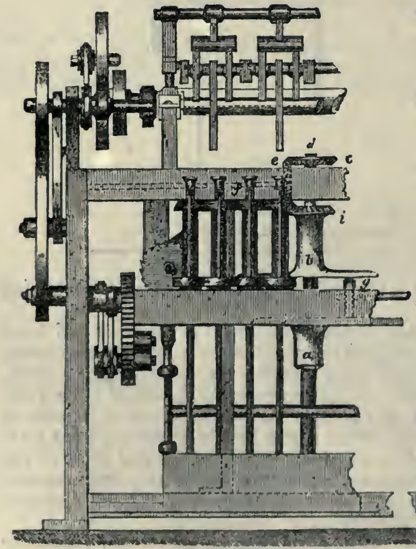
To obtain the variable speed, instead of using a cone and belt as in some frames, or the pulley and single disc as in others, we have the following parts: *a b*, the horizontal driving discs; the lower one *a* is keyed to the shaft *d*, while the upper *b* is free to turn upon it; *i*, bevel wheel fitted to or forming one piece with the upper disc *b*; *c*, bevel wheel keyed to shaft *d*; *e*, intermediate bevel wheel gearing in the bevel wheels *c* and *i*, so as to turn them in opposite directions, and consequently the discs to which they are directly or indirectly attached; *g*, the variable pulley covered with leather and resting upon the lower disc *a*, and itself pressed upon by the weight of disc *b*; it is thus driven at speeds varying according to its approach to or from the shaft *d*, thus answering the purpose of the traversing leather belt of the cone movement; *h*, shaft keyed in the pulley *g*, from which the variable motion is transferred to the bobbins.

958

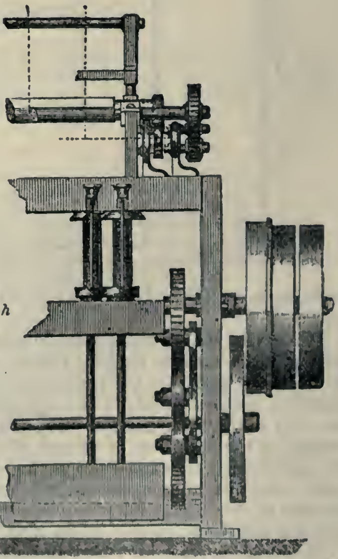


A series of preparing machines, termed a 'system,' consists in general of 1 spreading of 4 slivers at the drawing rollers, united into one by the doubling bars at the delivering roller, 2 frames of second drawing, in all 24 bosses 2 frames, third drawing containing together 36 bosses; if a fourth drawing is required, 2 frames of 24 bosses each, or 48 bosses in all. 180 spindles of roving in 3 frames will well supply 3,000 spindles of medium spinning. The mode of using this 'system is, as has already been said, first to spread the stricks of line upon the feeding-sheet of the spreader, then to receive the sliver or slivers there produced into cans capable of holding 1,000 to 1,200 yards of slivers. Those cans specially intended to receive the slivers from this machine are all made to one regular weight; thus, when filled, the weight of line each contains is correctly ascertained, and by the bell motion the length is also known. Upon this basis is founded the method of producing any desired number of yarn, and by doubling the slivers, a degree of equalisation that the simple spreading would be unable to effect; for at each drawing, and at the roving, several of the slivers from the preceding drawing are put together, to be again reduced to one for this object alone.

959



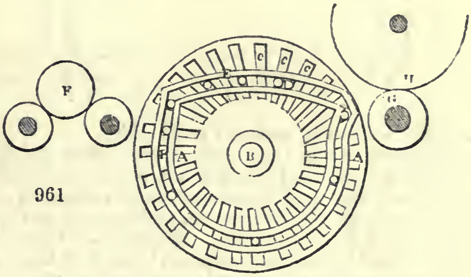
960



Hence, the weight of a determinate length in yards of the desired yarn being known, a calculation is made, combined of the drafts and number of doublings the material has to undergo, to determine what the weight should be of that length of slivers contained in the cans from the spreader. It is ordinary to put 10 or 15 of these cans together, to form what is called a 'set,' the slivers of which are united at the second drawing with the subsequent drawings and rovings. The combination of two or three slivers at each boss is sufficient.

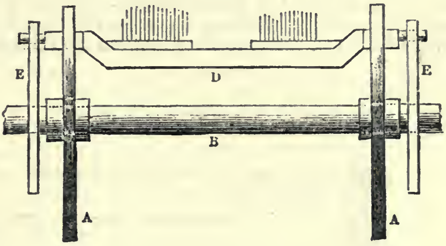
Though the above is descriptive of the 'gill' frames now in use, yet it should be understood they are by no means the first or only results of the attempts made to correct the defective principle of the original roller machines, which were incapable of holding or retaining the flax with a sufficient degree of regularity, owing to its unequal lengths and unadhesive nature. The consequences were that the yarns produced were 'lumpy' and unlevel, making it evident that some improved means were necessary for more completely restraining and regulating the drawing of the fibres. The most obvious way to do this was to introduce some mode of partial detention by creating a friction among the fibres to imitate the action of the fingers in hand-spinning. This led to causing the slivers to pass through and among several ranks of serrated pins, which was found very nearly to attain the object, and certainly greatly improved the levelness and uniformity of the slivers. Thus the use of 'gills' became general about forty years since.

Those first brought into general use were constructed with circular discs or plates for carrying the faller or gill bar, which at the same time were guided by their ends passing in fixed slides, so as to bring the gill in as vertical a position and as near the drawing roller as possible. The figures (961, 962) are profile and front views of the working parts of one of these gills:—A, slotted plate or disc, of which a pair were keyed upon a shaft B, so as to carry each end of the faller D, passing through the slots *c c*; E, the fixed excentric slide; G, H, the drawing rollers; F, the holding rollers.



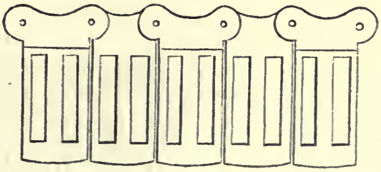
961

962



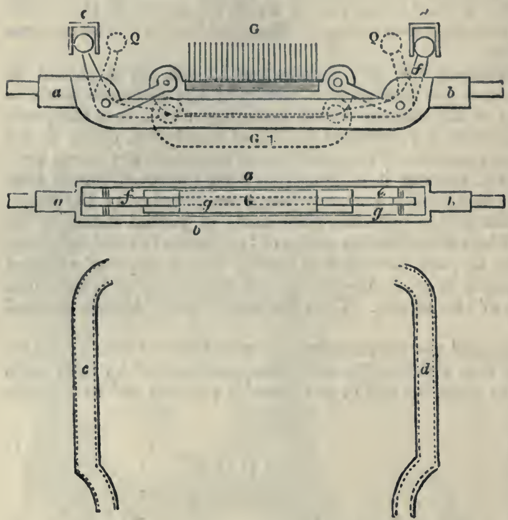
This was succeeded by the 'chain gill,' in which the fallers were carried forward by an endless series of connected links, or jointed together 'slotted plates,' instead of the simple circular. The object of this was to increase the flat surface of gill bars between the holding and drawing rollers, making it more suitable for the longer descriptions of material. The slides and rollers, being similar in these machines to those in the former, are not repeated, but the sketch of five slotted plates is given in *fig.* 963.

963



From the evident importance of bringing the retaining effects of the gills as closely as possible to the point where the movement of the drawing fibres is greatest, several attempts have been made to improve the above-described gills in this respect. With this view, Messrs. Taylors and Wordsworth patented a gill of considerable ingenuity (*fig.* 964), which therefore deserves mention, though it never came into use. Its description is as follows:—*a*, *b*, the faller or 'gill bar' in one piece, which was carried forward by an endless chain; *c*, *d*, slides placed horizontally over the gill sheet guiding the ends of certain bell-cranks *e*, *f*, joined at their angle in the recess *f*, *g*, *e*, of the gill bar, and at their other end to the gill or comb G. By this arrangement, as long as the bell-cranks are in the parallel parts of the slides *c*, *d*, the gill teeth will be above the faller *a*, *b*, but when they arrive at the contracted part the guided ends will be brought into the position Q Q, and consequently the gill depressed is G 2; this is so timed as to cause them to clear the drawing roller, when, on again continuing their course, they are again caused to rise and penetrate the sliver by the reversed inclination of the slides *c*, *d*, at the back roller.

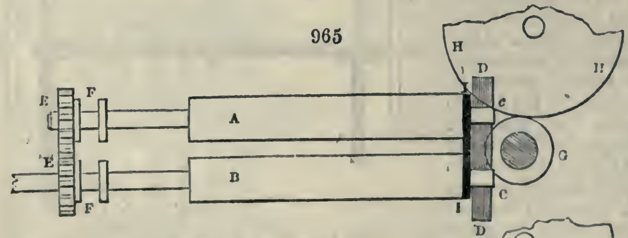
964



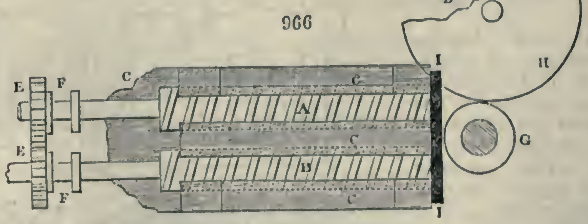
The objection to this ingenious machine was the largeness of the space suddenly left open by the descent of the gill, as the double faller, bell-crank, and gill necessarily occupied great width.

The screw or spiral movement of the fallers, which was soon afterwards invented, quickly superseded all others in use, as by these means the faller was caused, even in the manner they were first constructed, to approach closer than even in the most perfected construction of the others, to the side of the drawing roller, and still maintain the pins in a vertical position. Recently this object has been more perfectly attained by a patented improved construction adopted by Messrs. P. Fairbairn and Co., whereby the obstacle to the faller wholly touching the roller has been removed, and thus producing the full holding effect of the gill to the latest possible moment. This is effected by employing a method of supporting the spirals by their working in tubular recesses in the side plate of the machine; along these recesses are longitudinal openings through which the faller end passes to enter between the threads of the spiral, and which serve also as slides to support the faller. As by this means the supports or plummer blocks that intervened between the end of the spirals and the roller are suppressed, the faller

965



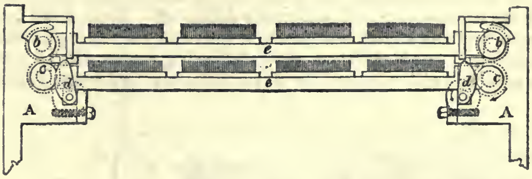
966



is enabled to advance to the place they formerly occupied. *Figs.* 965 and 966 show this comparison of the older and more recent methods. A, B, spirals; C C, the parts by which they are supported, being in *fig.* 965 small pivots in plummet block D D, and in *fig.* 966 hollow tube-like recesses in frame plate C C; E E, pinions to work the upper and lower spiral together; F, bearings; G, drawing-rollers; H, pressing rollers; I I, passage of the faller's descent.

Here it may be as well to observe that the same parties have still more lately introduced another important amelioration in these machines for remedying the noise and wear and tear which ordinarily attend them by the abrupt and violent descent of the faller. *Fig.* 967 shows a sectional front view of a head having this improvement applied. A A, supports for screws; *b*, *c*, top and bottom screws; *d d*, the new cams fixed on shafts parallel with the screws, and revolving at the same speed. Thus, these cams *d d* receive the faller *e e* at their largest diameter, at the moment they are free to descend, and guide them gradually down to the lower slide.

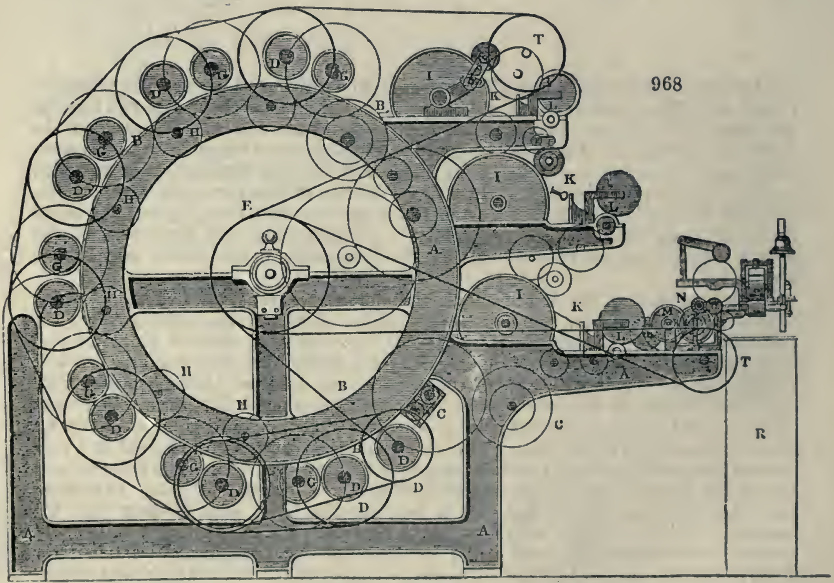
967



Thus constructed, the 'screw gill' continues to be the most esteemed in principle, though not without some serious objections in practice. For the abrupt and angular movement of the faller even here not only liberates too suddenly a portion of the fibres that should be but gradually relaxed at the moment of being drawn, but causes considerable wear and tear to itself, the slides, and the gills attached to it; to which cause of destruction must be added the great friction of the worm movement; these, however, in 'line' preparing, where the fibres are long and straight, and the drafts employed large, and where, consequently, a comparatively slow movement of the gills is required, are not so much felt as in the preparation of tow, where they become serious.

In 'tow preparing' the first operation, as before stated, consists of 'carding,' which is generally repeated over two separate machines, which are respectively called the 'breaker' and the 'finisher' cards. They are essentially the same in principle, and vary but little in construction, the only difference being that the 'breaker' is fed or supplied by the disjointed parcels of tow from a creeping sheet (as the spreader with 'line') and delivers its slivers into a can, whereas the 'finisher' is fed from a bobbin upon which several of the slivers from the breaker are united by a machine expressly for that purpose, called a 'lap frame;' this card thus receives its supply of work in a very regular form, and previously to delivering it in the form of slivers causes them to pass over a gill, to consolidate and strengthen them before delivering them into the receiving can; it is also generally clothed with a finer description of wire filleting than the breaker. Though it is the better method to card thus the tow twice, yet this second carding is sometimes dispensed with; in that case this auxiliary gill is similarly fixed to the first card or breaker. The cards employed for tow are machines of considerable weight and importance, the main cylinder, or, as it is sometimes called, 'swift,' being from 4 to 5 feet diameter and 4 to 8 feet long; those most generally employed are 6 feet long. Previously to entering upon the detailed description of a card, it may be as well first to trace in general terms the progress of its operations, as tending to elucidate the explanation of the machine itself.

The tow is first divided by weighing into small parcels of 10 to 20 drams; these are then shaken out and spread so as to cover certain definite portions of the creeping feeding-sheet, by which they are conducted to the first pair of rollers called the feeders, These rollers are covered with a leathern band, in which are fixed in close array a number of wire points about ½ an inch long, and having a tangential inclination to the circumference of the rollers, which are about 2½ inches diameter. The tow passing at a slow rate of progression between these rollers, is by them gradually presented to the points with which the swift is likewise covered, also set in leathern bands, but which are about 2 inches wide; these points, the same length as those of the feeders, have an inclined direction pointing to that in which the cylinder turns. The much greater velocity of the 'cylinder' combs and somewhat opens and breaks the tow as it slowly arrives in contact, and the inclination of the pins at the same time carries it forward. All such lumps and fibres as are not sufficiently opened and straightened by this first contact, remaining prominent on the surface of points on the cylinder, are carried by it against another roller, whose axis is parallel, and whose wire-covered circumference is brought as near as possible, without absolute contact, in order to catch and retain these prominent lumps and fibres; the points of this roller (called a 'worker') are inclined in a direction opposed to the movement of the swift, and, therefore, hold the tow to be again combed and straightened as at first it was by the feeders: this is repeated eight or nine times, by having that number of workers to the card; each of these workers has its attendant roller also covered with wire points, by whose inclination in a contrary direction, and by the greater velocity of the roller, the tow is stripped from the workers, to be again laid on to the cylinder. The strippers, though running at a greater velocity than the workers, are still slower than the cylinder. The tow thus carried forward gradually improving in openness and regularity as it passes each pair of 'workers and strippers,' finally arrives at the roller called a 'doffer,' of which there are two or three upon a card, the wire points of which are in such a direction as to hook or catch the tow 'as it flies.' The use of these several doffers is, that by placing each succeeding one progressively nearer the swift, the longer and shorter fibres are successively and separately taken off. Each doffer is cleared by an oscillating comb, and the slivers conducted, if intended for the lap machine into a can by delivering rollers; but if finished, these delivering rollers are, as it were, the back rollers of the auxiliary gill, patented for this application by Messrs. Fairbairn and Co.;



968

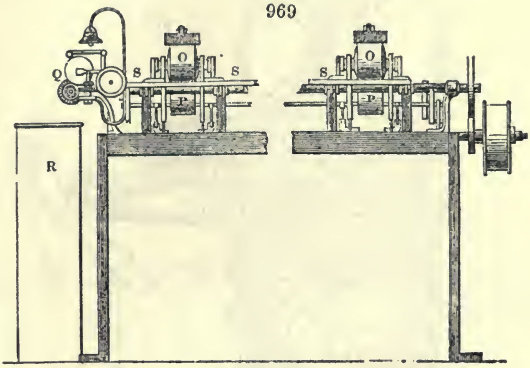
whereby the slivers are not only saved from all danger of derangement in their loose and porous state as direct from a card, but the hitherto double expense of carding and first drawing is reduced to that of carding alone.

A A A (*fig.* 968), framing; B, swift or main cylinder; C, feed rollers; D D D, strippers to feed rollers and workers driven by one belt from pulley E, and maintained tight by the moveable pulley F; G G G, workers; I I I, the three doffers; H H H, intermediate wheels to connect the movement of the doffers with one another; K K K, oscillating combs for their respective doffers; L, delivering rollers; M, back roller of auxiliary gill; N, gill surface; O, P, drawing rollers; Q, delivering rollers and bell motion for measuring the sliver in the cans R; S S, doubling plate; T, pulley for driving auxiliary gills by bell from the pulley E.

The lap frame, to which allusion has already been made as the necessary adjunct to the cards when double carding is to be performed, is employed to collect together a number of slivers from the breaker by winding or lapping them upon a cylindrical piece of wood, which may be described as a bobbin shank, thus producing an equalisation of the slivers of tow as the making up of sets effected in line preparing; from

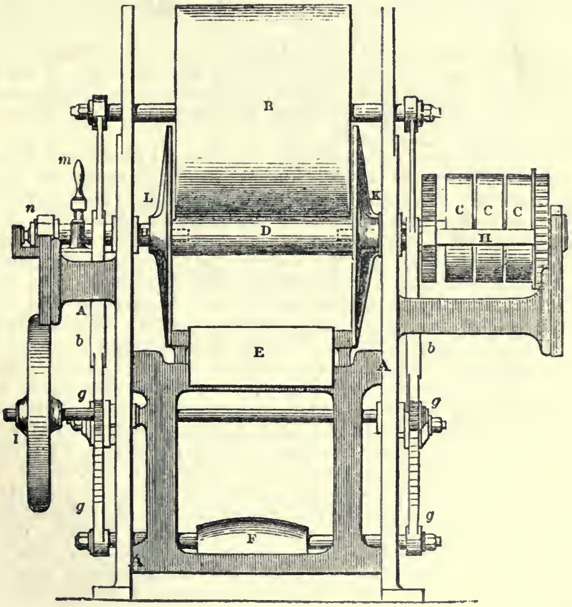
50 to 60 lbs. of tow is the usual complement of one of these bobbins; the length and the diameter, when full, about 22 inches; thus, a 6-feet wide finisher card will take off these bobbins at once; from 15 to 20 is the number of slivers usually wound together, and the completion of a bobbin by the ringing of a bell, connected with the measuring cylinder of the machine. The following is a descriptive drawing of the lap machine:—

969

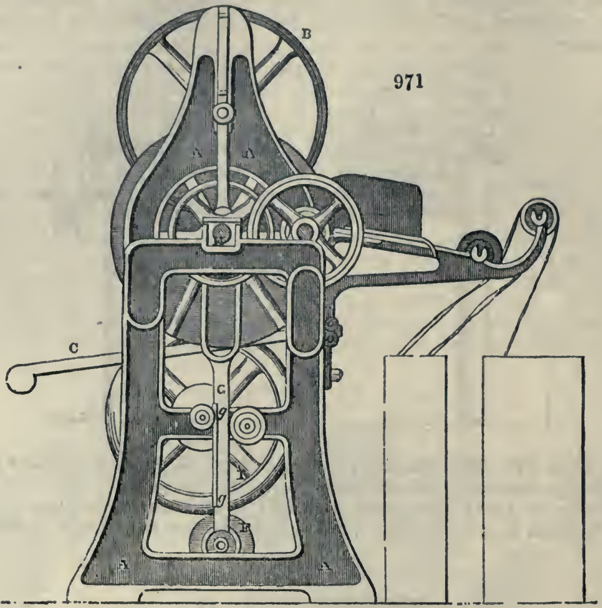


A A A (*figs.* 970, 971), framing; B, measuring and pressing cylinder; C C C, driving pulleys connected with different gearing to change the speed as the bobbins fill; D, bobbin or shank intended to be filled; E, table to receive the bobbin when about to be taken from the machine; F, weight to increase the effect of pressure of the measuring cylinder by the connecting rods G G, which are split for part of their length in order to pass the shaft H, and at another, *g g*, have racks into which work pinions keyed on the shaft of the hand wheel I, for the convenience of raising and lowering the cylinder and weight. The shaft H is divided at the plates K and L, and provided with sockets to receive the end of the bobbin shank D, which is introduced

970



by sliding back the piece H *n*, and returning it by lever *m*, and thus is coupled and turns together with two pieces of shaft H, as also the disc plates K and L, which are



971

to serve as temporary ends to the bobbin during the time of its filling, and thus by turning with it avoid that rubbing and felting effect upon the edges of the tow so injurious in the machines formerly constructed, and by the bobbin acting as the driver to the cylinder the slivers are drawn tighter, and thereby avoid those plaits that the other machines were so liable to produce.

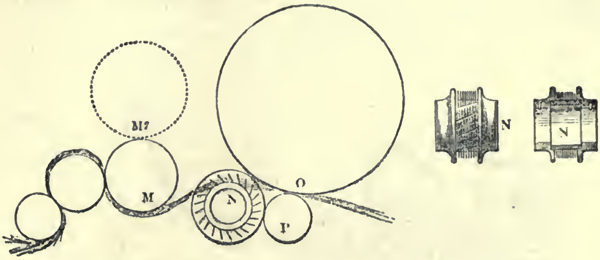
As before mentioned, some objections were found to the working of the screw-gill, of a nature detrimental to the machines themselves, which, though not of great importance in 'line,' were much aggravated in tow preparing, as the lesser drafts there employed cause a greater wear and tear of the fallers and gills. The objection to these machines, however, is not confined to this point only, but extends also to their effect upon the material itself. The fibres of the tow sliver, as coming from the card, are in a light and much confused state, which renders them liable to be easily separated; so that the faller, by its sudden descent, has a tendency to draw some down, and become lapped by them, as well as to make so marked a difference in the thickness of the sliver, by the withdrawal of the retaining comb, as materially to injure the quality of the yarn. Thus this 'gill' was not enabled to hold its place in tow spinning, when other circumstances led to greater attention being paid to this important branch of the flax business, and it became a desideratum to have a machine free from these defects, and capable of working without derangement, at much greater velocity than was safe with the screw-gill. These desiderata the 'rotary' gill, patented by Messrs. Fairbairn and Co., amply supplies. For in this gill the circular form of the gill sheet obviates the necessity of having several fallers, and the simple motion creates neither friction nor abruptness of effect, while, the retention of the fibres being continuous, the slivers produced are perfectly level and uniform; consequently, these gills are extensively applied, as the auxiliary gill explained in carding, as well as for the subsequent drawings and rovings of tow, and sometimes, as will be afterwards seen, to coarse spinning. The theoretical construction of these rotary gills will be seen by the annexed sketch.

M (*fig.* 972), back rollers, but when applied to a card at top and bottom holding-rollers are again employed; N, the rotary gill sheet having the pins inclined backwards, so as to insure the impalement of the sliver when the fibres begin to draw; P and O, the drawing and pressing rollers; the doubling bars or plates are the same to these gills as to the screw gills.

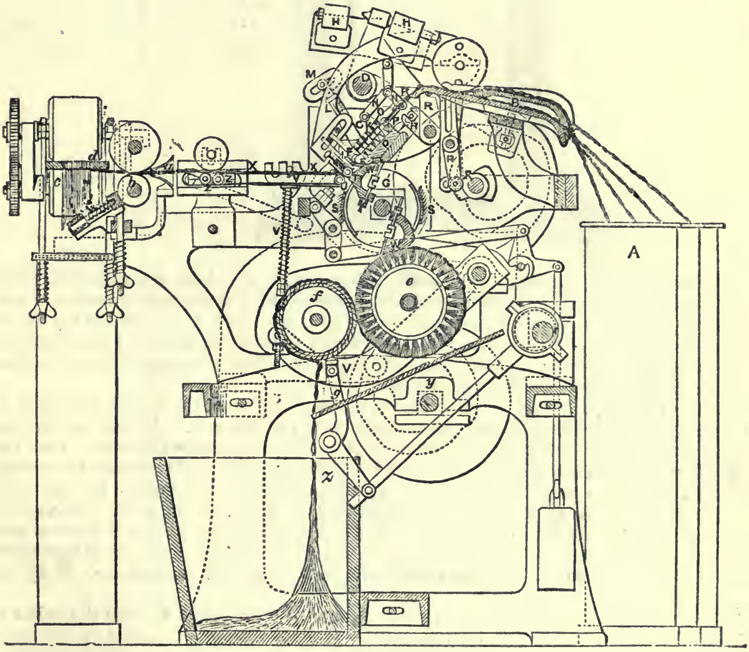
A machine has been invented, and brought out by Sir P. Fairbairn and Co.

of Leeds, called Heilmann's tow-combing machine (*fig.* 973), which, on trial, is much approved of. The tow is first carded in the ordinary way, say on a breaker-card, and then on a finisher-card; the latter delivers the tow in the shape of a sliver into cans, which are next placed at A, or back of the tow-combing machine.

972



973



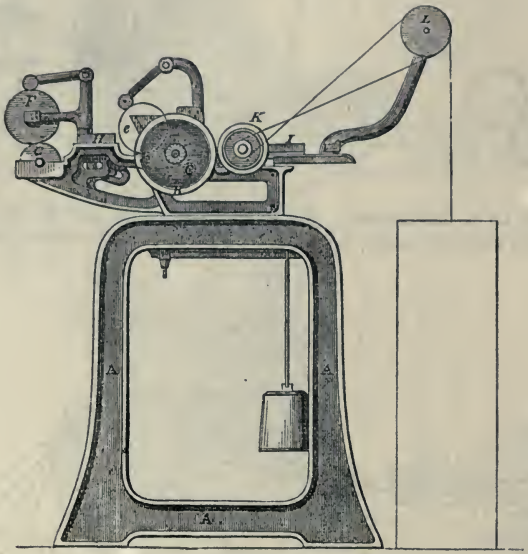
From the cans A the tow goes to the back conductor B, divided into as many compartments as there are slivers; and from the conductor B, to the feeding box C suspended on shaft D, without being keyed to it. The front lip E of the feeding box is fluted and fitted with leather, and a corresponding nipper F hung from the same shaft D, and keyed upon it, completes the jaw which has to hold fast the tow, while the cylinder G combs it.

The feeding box C derives its motion from the nipper F, which is moved by lever and excentric as shown, and follows that nipper by its own weight, until stopped by india-rubber buffers H; when the nipper F in going further back leaves it, and the jaw E F opens for more tow to be fed, and the tow already combed to be drawn through the detaining comb I, as explained hereafter.

The top K of feeding box is moveable up and down, by means of the connecting rod L, hung on a fixed centre M, so that the top part K opens or shuts as the body of the box goes backwards or forwards. The levers N N N are only used to keep the top and bottom of the box parallel to each other.

As shown in the drawing, the top of the feeding box is fitted with hackles passing through two grates O and P, fast on bottom of feeding box, and leaving between them a space through which the sliver has to pass.

974



By the above arrangement, the hackles are caused to withdraw from the tow, while the whole box is drawn backwards on slides of table Q, by the excentric motion R R R. The last backwards motion takes place while the jaw F is yet shut, and the top of the box up; but when the latter has got closed again, then the whole box slides down on the table Q to its former position, bringing with it the sliver of a quantity equal to that move: this completes the feeding motion.

Now as the feeding box recedes, the lip E comes nearer to the combing cylinder G, the hackles S S cleaning the tow projecting outside the nipper F. As soon as they are passed through, the feeding box comes back to the most forward position, when the nipper F leaves it, and the jaw E F opens: at the same time the two rollers T U have reached their top position. The top one T is then thrown forwards (by the lever arrangement shown in V V V) upon the leather W, stretched on parts of surface of cylinder G; this roller T is thus driven, and takes hold of the points of the tow presented to it by lips or bottom jaw E; a fine detaining comb I being just before interposed between them to keep back the 'noils,' that have not been carried off by the combing cylinder.

In that way the points of the tow are driven upon the sheet X, until the roller T, by being thrown back again off the leather W, their motion is stopped at the same moment, the two rollers U and T are allowed to drop down by excentric V, drawing with them (through the detaining comb I, and quite out of the rest of the sliver) the other ends of the fibres of which they have got hold.

While this has been going on, the feeding box has advanced the sliver a step, the nipper closed, and forced the said feeding box forwards so as to bring the lip E within the reach of hackles S on cylinder G, which then met it, cleansed the tow, and so on as before.

At that time the rollers T and U come up again, and during that upwards motion the latter ends of the fibres partly combed and overturned by the cylinder hackles, as shown in drawing, are combed by them in their turn, Then the roller T is once more driven round by the leather W stretched on cylinder, the new points place themselves above the back ends of the fibres combed before, and are carried forwards into a continuous sliver on the leather sheet X, from the leather sheet to the rollers Z Z, then to the trumpet conductor A, the front delivery roller C, and (when more than one head to the machine) from C to the end delivery *c*, over the conducting plate *d*.

In *e*, *f*, *g*, and *h*, are the usual brush, doffer, comb, and tow box for the noils.

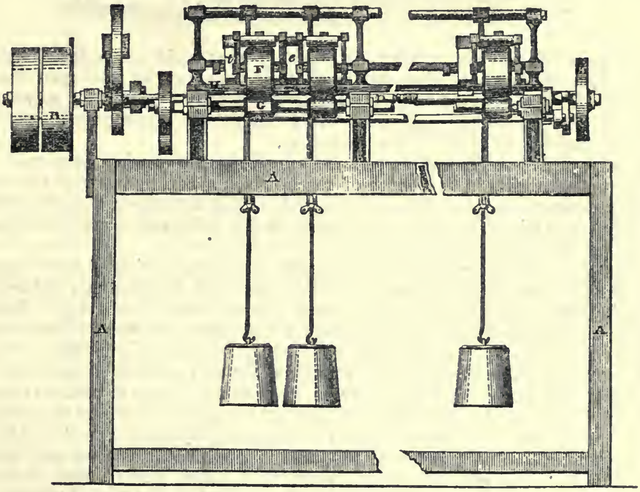
These combing machines are made of different sizes to suit all sorts and lengths of tow; the yarn produced from them is much finer than that produced by the ordinary carding system alone. The combed tow can generally be spun to as high numbers as the line from which it has been combed, and in some instances has produced good yarn, even to higher numbers. The combed tow, after the combing machine, is passed through a system of drawing, roving, and spinning, similar to that used for cut line.

Subsequently to the carding the preparation of tow is completed by making up sets of cans for the second drawing, as explained for line; these slivers are doubled and drawn once or twice more, and then roved. The drafts used in tow-preparing are from 9 to 8, for, as the fibres are shorter, it necessitates the employment of less draft. In both line and tow preparing, lesser drafts are employed as the stages advance, the gills finer, and the conductors narrower: also for both materials much attention is requisite to keep the various parts of the machines in good order, free from bent or broken pins, and chipped or indented rollers, for no subsequent operation can cure the defects that may be produced by negligence in these particulars. The drawing and roving frames for tow are shown in *figs.* 974, 975, 976.

A A (*fig.* 974), drawing frame; B, driving pulleys; C, rotary gill sheet; D, drawing roller; E, pressing; F, G, pairs of delivering rollers; H, doubling plate; I, back conductor; K, back roller wheel with pulley to turn the sliver rail L.

A A (*figs.* 975 and 976), roving frame; B, pulley and fly wheel combined; C, drawing roller; D, rotary gill; *a a*, stand for gill movement. The regulation of the bobbins is effected in the same manner as already described for line roving.

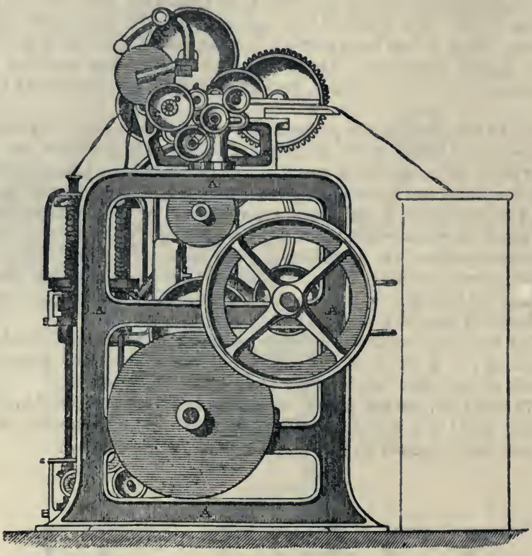
975



Spinning.—This operation consists in drawing the rovings down to the last degree of tenuity desired, and twisting them into hard cylindrical cords, which are called 'yarns.'

There are three modes of performing this operation: the first, and perhaps oldest, is that where the drawing and twisting are performed altogether, with the material preserved dry, and without breaking or shortening the fibre; the second is that which likewise, without changing the length of the fibres, draws them while dry, but wets them just at the moment before twisting. This method is the nearest imitation of hand spinning, and makes the yarn more solid and wiry than the first; as the fibres of flax losing their elasticity while wet, unite and incorporate better with one another. The third mode of spinning has been much more recently introduced than either of the others, and by it the fibres are wetted to saturation previously to being drawn, whereby they are not only much reduced in length, but their degree of fineness is increased by the partial solution of the gummy matter inherent in the flaxen material: owing to these circumstances equally good turns can be produced by this mode of spinning from line and tow of inferior quality, to what could be employed upon either of the others, and not only that, but much finer yarns can be now spun than were possible previous to its introduction. It has therefore not only nearly superseded all other methods of spinning for yarns from 20's to the finest, but has much increased the extent and importance of the flax manufacture.

976



The only difference in spinning frames for line or tow, when employed for the older methods, consists in the length of reach, which generally involves the necessity of having separate machines for each material, though sometimes they are made with a capacity to be adapted to either purpose. In the third method the same machines are used promiscuously for line or tow.

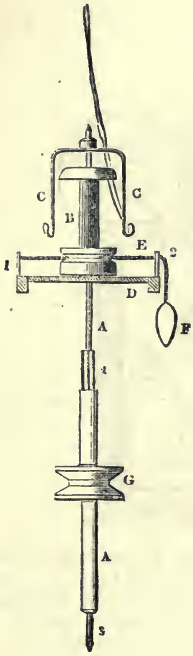
The yarns spun wholly dry are used for the coarse description of woven goods, as packing canvas, corn sacks, and when partially bleached, for sheetings and towellings, as from its greater elasticity and openness it fills up better in weaving. Those spun partially wetted are employed for a somewhat superior description of linen goods, and the solid silky appearance qualifies them for drills, damasks, &c., as well as for sewing and shoe threads; a somewhat inferior material, by this manner of treatment, makes an equally good yarn as a better material spun dry. The yarn produced from this wet principle is rather inclined to have a cottony appearance; and from the comparative ease with which an inferior material can be made to present an apparently fine good yarn, the application of yarns thus produced is exceedingly various and sometimes deceptive, though, when good materials are used, these yarns afford durable and handsome drills, shirtings, lawns, and cambrics, as well as fine sewing threads.

The mechanical arrangements for twisting, and then winding the yarn upon a bobbin, is called the 'throstle' principle, supposed to be so called from the whistling noise they create when working at full speed, which is from 2,500 to 4,000 revolutions a minute. The following diagram will explain the principle, which is applied alike to all the modes of spinning above described.

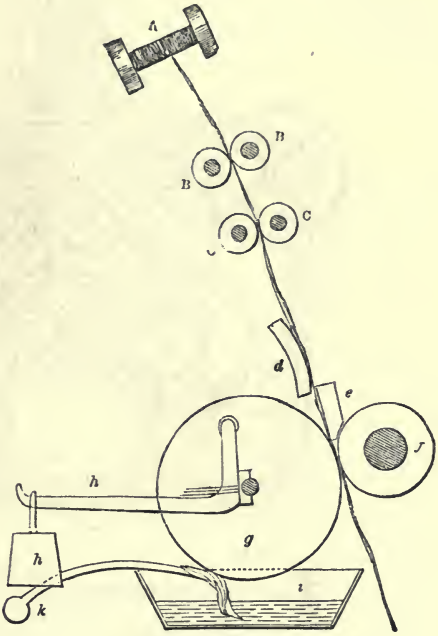
A A (*fig.* 977), the spindle; B, the bobbin, loose and independent of the spindle in regard to turning, and rising, and lowering, but through which the spindle passes; C C, the flyer screwed to the spindle top; D, table called 'bobbin lifter,' as while at work it rises and lowers to lay the yarn on the whole bobbin equally; E, a small cord to press on the bobbin by the weight F; G, pulley by which the spindle is driven.

Many attempts have been made to improve upon this principle, in order to avoid or lessen the strain upon the thread in its passage from the drawing rollers to the flyer eye; but, till recently, without any degree of success. The only improvement at present known, and which promises to become general, is that where the necessity to have a top to the bobbin is avoided. It will be seen from the diagram (*fig* 977),

977



978



that the yarn is compelled to rub the top of the bobbin, and the friction thereby created quickly causes it to become rough; and therefore it has a tendency to catch and break the thread. The desirableness, therefore, of having a clear course for the yarn was evident, and this improvement that we are about to explain produces the effect by employing what is called a coping motion, which, like that used in mule-spinning, preserves the layers of thread upon the bobbin ever in a pointed or conical state, and therefore self-supporting without the aid of the wooden end of the bobbin. See COTTON SPINNING.

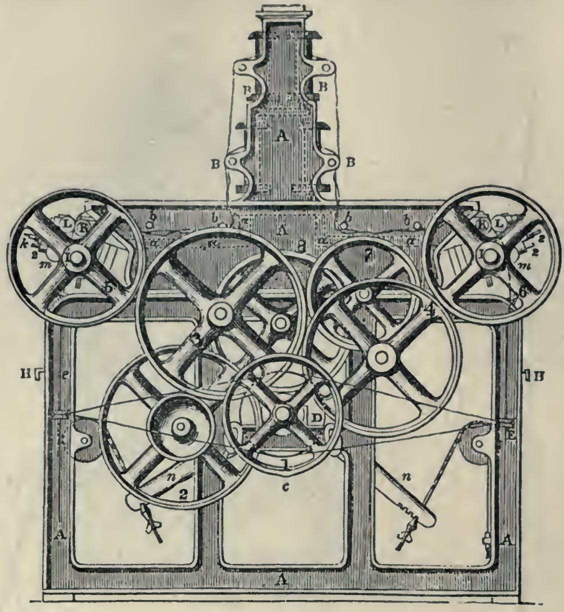
The arrangement of the rollers for holding and drawing the slivers or rovings, as well as the plates and rollers for aiding to retain the twist of the rovings, in order to render their elongation more equable when to be drawn dry and spun upon the older methods, will be seen in *fig.* 978.

A (*fig.* 978), roving bobbin; B, back or holding roller; C, carrying roller; *d*, flat plate with a slightly curved face; the carrying roller and plate are so placed as to cause a degree of friction to the roving when passing over them, so as to retain the twist, and thus act as the pins in the 'gill frames;' *e*, tin conductor for contracting the roving at the moment of being drawn; *f*, metal roller; *g*, wooden roller pressed against the drawing roller in order to pinch the roving; *h*, lever and weight. When it is intended to wet the yarn previously to twisting, the trough *i* is used, in which is water, which is supplied to the roller *g* by the capillary attraction of a piece of cloth immersed therein, and bearing against the roller by lever *k*.

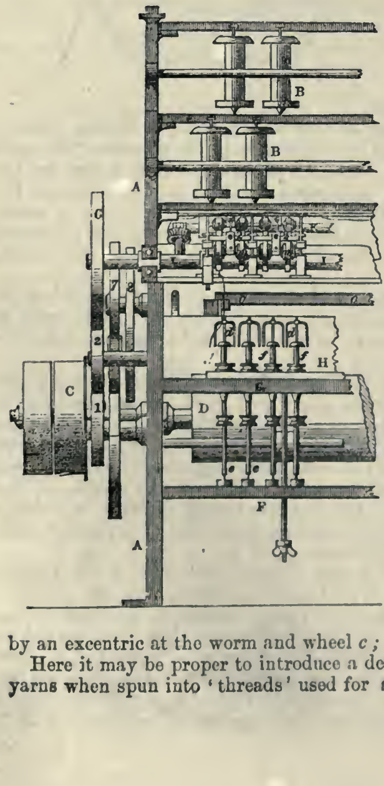
The machines for 'wet' spinning are of a very different construction and appearance; as the close proximity of the holding and drawing rollers prevents the intervention of holding rollers or friction bars, while the force requisite to draw the rovings at the short reaches used, varying from 2½ to 4 inches, requires each pair to be deeply and accurately fluted into one another. The water used is heated, in order by the expulsion of the fixed air more rapidly and completely to saturate the rovings while passing through it. The following drawings and description will be sufficient to give an accurate idea of the principle of these machines, which are generally 20 to

30 feet in length, and contain 200 to nearly 300 spindles; that is, 100 to 150 on each side.

979



980



A A A A (*figs.* 979 and 980), framing; B B, stand for roving bobbins; C, driving pulleys fixed upon the axle of cylinder D, from which pass endless cords to drive the spindles *e e;* F, step-rail of spindles; G, collar rail for ditto; H, bobbin lifter; I I, front roller; K K, back roller; L, back pressing roller; M, top pressing roller (these are generally made of box wood, but sometimes of gutta-percha); N N, levers in connection with the excentric to produce the rise and fall of the bobbin lifter; O O, thread-plate; Q Q, saddles or transverse bars resting on the axles of the back and front pressing rollers, so that one lever and weight acts for both by the connecting rod and lever *r r*, which, in order to cause more pressure on the drawing than on the back roller, is placed on the saddle nearer the former than the latter. 1, 2, 3, 4, 5, 6, 7, 8, train of wheelwork, by which the movements are distributed. *a a a*, the trough of hot water maintained by steam-pipes at the desired temperature; *b b*, guide rods or pipes to cause the roving to pass under the water. In order to avoid the rollers becoming indented by the roving always passing on the same place, they are caused to traverse the breadth of the rollers by a traversing guide rail, moved by an excentric at the worm and wheel *c;* *d*, flyers, and *f*, spindles.

Here it may be proper to introduce a description of the machines for twisting the yarns when spun into 'threads' used for sewing, &c. The yarns spun for this purpose should always be made of a somewhat superior description of line to that employed for the same number of yarns for weaving, and have rather less twist. They are generally taken while wet on the spinning bobbins to the twisting frame, and, when combined together, the union is effected by a torsion in the opposite direction to the original twist of the separate yarns.

Reeling.—This operation consists in winding the yarn off the bobbins of the spinning or twisting frames, and forming it into hanks or skeins. The various denominations of the skeins into which yarn is reeled, and then the forms or combinations they are made up into, are as follow:—

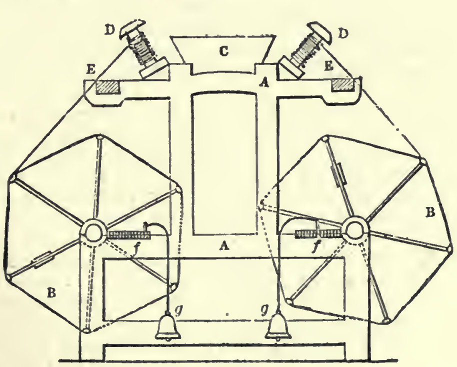
The lea containing 300 yards
10 leas making 1 hank
20 hanks „ 1 bundle
6 bundles „ 1 packet.

It is by the standard lea of 300 yards that the description of yarn is known from the number contained in 1 lb. weight; thus, No. 20 contains 20 leas or 6,000 yards for 1 lb. weight. In Scotland, the subdivisions are rather different from the foregoing, which are employed in England and Ireland; the lea, however, remaining the same:—

38 leas make 1 spindle
6 „ „ 1 rand
12 rands „ 1 dozen.

The reeling is performed upon exceedingly simple machines, generally put in motion by the hand of the person attending them, though sometimes they are driven by the motive power of the factory. The reel is made sufficiently long to receive twenty bobbins, and the barrel upon the yarn is wound in one length; the diameter, however, varies so as to suit the different sizes yarned to be reeled. For the coarsest yarns and down to 16 and 20, the largest circumference is used of 3 yards; from that to about No. 100, 2½ yards; and for the finest yarn 1½ yard is found most convenient. These various circumferences are compensated either by putting a great number of threads into each 'tye,' or increasing the number of tyes, so that opposite to each one of the 20 bobbins an entire hank should be formed before taking the yarn off; thus at each 'stripping,' one bundle is turned off. To facilitate the stripping, one of the rails of the barrel is made to fall in, and thus slacken the hanks; care is taken to leave the lea bands very loose, in order to allow the yarn to be spread out in drying and bleaching. The determinate lengths of yarn, when wound on the reel, are notified by the ringing of a bell connected with the axle of the barrel. *Fig.* 981 below shows the form of an ordinary hand-reel.

981

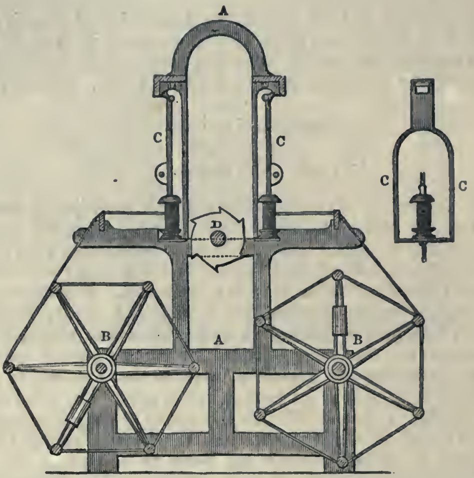


A A (*fig.* 981), framing; B B, reel barrels; C, box or trough to receive empty bobbins, &c.; D D, bobbins in position of being reeled; E E, guide rails, moveable so as to place the leas side by side on the reel; *f f*, bell wheels; *g g*, bells for each reel barrel suspended on springs.

To these hand-reels there are many objections; for it is evident that the correctness of measure depends entirely upon the attention of the reeler, and the stoppages arising from the breaking of a thread or the finishing of a bobbin interrupt the work of all the others. These objections rendered it necessary to attempt some ameliorations of the system by the introduction of a reel that should automatically prevent these causes of error. Such a reel was patented a few years since, and is now in general use in Scotland; it is so contrived as to have the capacity of stopping itself when a thread breaks, when a bobbin finishes, and leas and hanks are completed; and having but four or five bobbins in one compartment, the stoppages affect but few at a time; and as this machine can be worked by less skilful persons without possibility of error, much saving is effected both in wages and material. The annexed figure (982) shows the principle of this improved reel.

A A (*fig.* 982), framing; B reels; C C, pendulums on which are hung the bobbins to be wound off; D, driving shaft with ratchet wheels opposite to each pendulum, so that when a thread breaks, the pendulum to which it is attached falls into the ratchet wheel, and thus stops it.

982



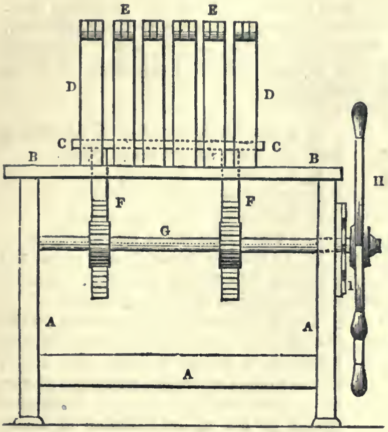
The drying of wet spun yarns should always, when possible, be done in the open air by spreading the hanks upon horizontal poles through them, with another similar pole resting inside upon their lower extremities, in order to keep them straight. If artificial heat is employed, that from steam or hot water is preferable, and it should never exceed 90° Fahr., as otherwise the yarn is apt to become harsh.

Making up.—By this operation is first produced upon the yarns a certain softness and suppleness, and then the hanks are folded and tied up in conveniently-sized packages.

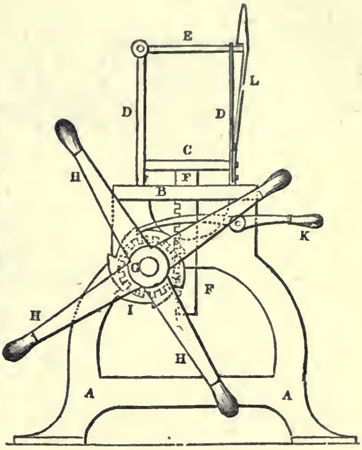
In order to give the yarns that soft and mellow feel so agreeable and characteristic of flax yarns, the hanks when brought from the drying are what is called slaken down and pin-worked. This is done by separating a few at a time, and passing them on to a strong arm of wood fixed to a wall or pillar, when, with a heavy baton put through them, the workman proceeds to stretch the hanks with a sudden check or jerk, which operation he repeats in two or three places so as to thoroughly straighten and shake them loose; he then, using the same baton as a lever, twists them lightly backwards and forwards till the desired degree of suppleness is obtained. A brush is sometimes used to aid the straightening and separating, as well as to increase the gloss on the yarn. The hank or hanks will then be found to have assumed a flat shape, as on the reel, which facilitates their folding with a dexterous twist by their middle, when they are laid in square piles upon a table with their twisted folds one upon another. They are maintained in the perpendicular by a few supports fixed in the table. Sometimes these packages, which, according to the sizes of the yarn, consist of from quarter of a bundle to five or six bundles, are bound together by some of their own hanks, but sometimes by cords in three or four places of their length. It is, however, better to employ a bundling press than an ordinary table, as the yarn can then be made up more solidly, thus both improving its appearance, and causing it to occupy less space for packing and stowage. The bundling presses are made upon the same principle, but on a smaller scale, than those used for making up the small packets in which sewing threads are generally presented for sale, and are upon the following construction (*figs.* 983, 984):—

Fig. 983, front view; *fig.* 984, profile. A A A, frame; B, table or flat top of frame; C, rising table; D D, iron uprights fixed to B; E E, bars hinged at one end to uprights D D, to shut across the press, and be caught and latched down by the spring catch L, fixed to the upright D along one side of the press; F F, racks for lifting the table C by the pinions on shaft G; H, crossed levers for turning the shaft G; I, ratchet wheel engaging the detent K, and thus retaining the shaft G in any required position, and thus of course maintaining the pressure of table C against the top cross-bars E.

983



984



Weaving is the operation by which the yarns are combined into textile fabrics, such as canvas, linens, lawns, drills, damasks, &c., and a great variety of other denominations of articles for use and ornament.

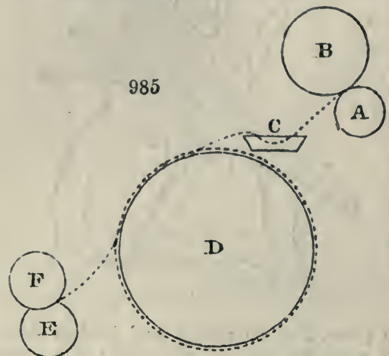
Hitherto the weaving of linens has been carried on by the ancient and well-known hand process, so ancient and so well known as to place the operative practising it among the worst paid of any other art. Now, however, there are several extensive and thriving establishments where machinery has taken the place of much squalid misery, and at much cheaper rates produce to consumers superior articles, and still afford good payment to the operative. The improvements in power-weaving which have led to this result are not founded upon one or even a few successful inventions or contrivances, but are the combination of a great many that have occupied much time to mature. Many difficulties had to be overcome in the weaving of flax, that did not exist in that of other materials; and for a considerable period the expense of linens rendered their consumption so limited, as to make their production by power-weaving but a very secondary object. The greatest obstacle of a practical nature to the introduction of the power-loom weaving of linens was, the stubbornness or want of elasticity in the yarn, which caused frequent breakages and much confusion. In woollen or cotton goods, if a thread or yarn should chance to be a little tighter than the others in the warp, its elasticity will allow it to come up to the general bearing of the others when the weft is struck up by the reed; but in linen, from the want of that elasticity, a thread so situated would break, and by crossing some others, cause those also, if not to be broken direct by that circumstance, at all events to produce an obstruction to the shuttle that would lead to further mischief. Hence it was most material in linens to have such a method of winding the yarns upon the warp beams that should insure the greatest regularity; but strange to say, that point, though now attained, was at first wholly lost sight of. That circumstance, as well as the great mistake of attempting to use the same looms as are found suitable for cotton, produced so much discouragement in the earlier attempts as to give rise to a high degree of prejudice against the possibility of success in this undertaking, which may account for the backwardness in which this branch of the flax manufacture was found till quite recently.

The roving machine, called by the ingenious inventor, Mr. W. K. Westley, of Leeds, the *Sliver Roving Frame*, seems to be a philosophical induction happily drawn from the nature of the material itself, and accommodated to its peculiar constitution. It is remarkable for the simplicity of its construction, and, at the same time, for its comprehensiveness: requiring no nicety of adjustment in its application, and no tedious apprenticeship to be able to work it.

It is known that the mucilaginous matter of the plant may be softened by water, and hardened again by heat; of this fact advantage is taken, in order to produce a roving wholly without twist; that is, in the form of a ribbon or sliver, in which the fibres are held together by the glutinous matter which may be natural to them; or which may, for that purpose, be artificially applied. The sliver roving, as long as it remains dry, possesses all requisite tenacity, and freely unwinds from the bobbin, but on becoming again wetted in the spinning frame, it readily admits, with a slight force, of being drawn into yarn, preserving the fibres quite parallel.

The diagram, *fig.* 985, shows this in explanation:

985



A, is the drawing roller of the roving frame in front of the usual comb.

B, the pressing drawing roller.

C, a shallow trough of water.

D, a cylinder heated by steam.

E, a plain iron roller for winding.

F, a bobbin lying loose upon the winding roller, and revolving upon it by the friction of its own weight.

The roving, or sliver, as shown by the dotted line, after leaving the drawing rollers A, B, passes through the water, in the trough C, which softens the gluten of the fibres: and then it is carried round by the steam cylinder D, which dries it, and delivers it hard and tenacious to the bobbin F, on which it is wound by the action of the roller E.

This is the whole of the mechanism required in producing the sliver roving. All the complex arrangements of the common cone roving are superseded, and the machine at once becomes incomparably more durable, and easier to manage; requiring only half the motive power, and occupying only half the room. A frame of 48 bobbins is only 6 feet long, and affords rovings sufficient to supply 1,200 spinning spindles.

This machine, though here described, is but little used, being capable of but very limited application.

Combe of Belfast has lately introduced an improvement in the roving frame. It consists in the application of a peculiar expanding pulley, instead of the cones or discs and runners which have hitherto been always used for the purpose of regulating the 'take-up' of the bobbins. It is evident that a strop of 2 or 3 inches broad, working over the cones, placed with the small end of one opposite the large end of the other is an imperfect and rude mechanical contrivance, and that there must be a constant straining and stretching of the belts. There is the same imperfection attending the discs and runners. The expanding pulley is free from these objections, as its acting surface is a line; and therefore it works with the greatest accuracy, while it is also a great simplification of the machine generally. In rovings for flax and tow it is generally driven directly from the front roller, by which means a large number of wheels and shafts are avoided (*fig.* 986).

The following sketch shows the arrangement of the machinery in the most important rooms in a modern flax mill of 7,000 to 8,000 spindles, capable of producing, weekly, about 1,900 bundles of line yarn, No. 25's to 120's; and about 700 bundles of tow yarn, No. 10's to 40's.

There are three systems of long-line machinery for No. 25's to 70's; two systems of cut-line machinery for No. 10's to 120's; and three systems of tow machinery for No. 10's to 40's.

The building is 56 feet wide and 162 feet long; which is a very suitable and convenient size, and which admits of the most economical arrangement of the machinery. The following is a description of the machines shown in the preparing room (*fig.* 987):—

A A, two of Baxter's patent sheet hackling machines for long tow.

B, a flax-cutting machine.

C, one of P. Fairbairn and Co.'s patent double line of holder hackling machines for cut line.

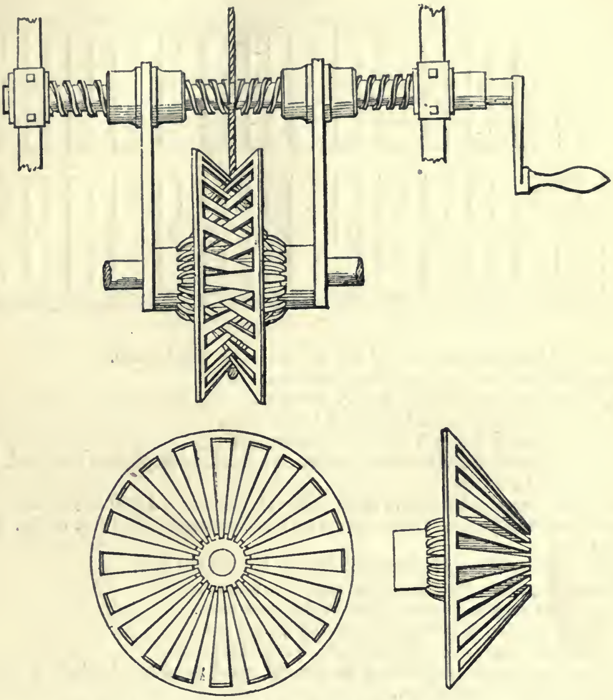
D D, are two breaker cards, 4 feet diameter × 6 feet wide.

E, lap machine.

F F F, are three finisher cards, 4 feet diameter × 6 feet wide, with P. Fairbairn and Co.'s patent rotary gill drawing heads attached.

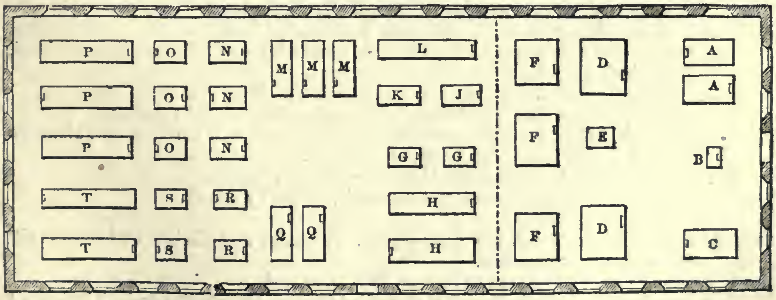
G G, are two patent rotary gill drawing frames for long tow, 12 slivers each.
H H, two ditto regulating roving frames, 48 spindles each, for long tow.

986



J, is a screw gill second drawing frame of 3 heads for cut-line tow.
K, is a screw gill third drawing frame of 3 heads for cut-line tow.
L, a screw gill regulating roving frame of 72 spindles for cut-line tow.
M M M, are three long-line first drawing frames or spreaders of 4 bosses each.

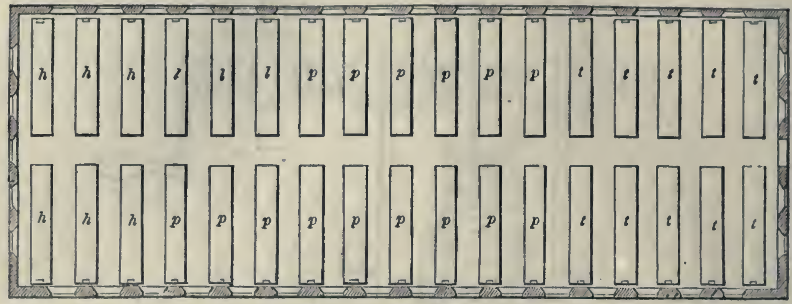
987



N N N, are three long-line second drawing frames of 2 heads each.
O O O, are three long-line third drawing frames of 2 heads each.
P P P, three long-line regulating roving frames, 60 spindles each.
Q Q, are two cut-line spreaders of 4 bosses each.
R R, two cut-line second drawing frames, 2 heads each.
S S, two cut-line third drawing frames, 2 heads each.
T T, two cut-line regulating roving frames, 72 spindles each.

The spinning room (*fig.* 988) contains 34 spinning frames of 184 to 244 spindles each, apportioned to the several systems as described below.

988



I. System of long-line machinery for spinning No. 25's to 40's.
1 Baxter's patent sheet hackling machine, 6 tools.
1 spreader or first drawing frame, 4 bosses.
1 second drawing frame, 2 heads, 4 bosses each.
1 third drawing frame, 2 heads, 6 bosses each.
1 patent disc regulating roving frames, 60 spindles, 10 spindles per head, 8 inches × 4 inches bobbin.
5 spinning frames, $2\frac{3}{4}$ inches pitch, 200 spindles each, 1,000 spindles.
The production of this system is about 66 bundles, or say, 420 lbs. of No. 30's yarn per day.

II. Two systems of long-line machinery for No. 40's to 60's.
1 Baxter's patent sheet hackling machine, 8 tools.
2 spreaders or first drawing frames, 4 bosses each.
2 second drawing frames, 2 heads of 6 bosses each.
2 third drawing frames, 2 heads of 8 bosses each.
2 patent disc regulating roving frames, 60 spindles each, 12 spindles per head, 6 inches × $3\frac{1}{2}$ inches bobbin.
10 spinning frames, 220 spindles each, $2\frac{1}{2}$ inches pitch, 2,200 spindles. Production about 130 bundles, or 472 lbs. of No. 55's yarn per day.

III. Two systems of three cut-line machinery for No. 40's to 120's (one for 40's to 70's, and one for 70's to 120's).
1 flax cutting machine.
1 P. Fairbairn and Co.'s patent double line of holder hackling machine.
2 spreaders or first drawing frames, 4 bosses each.
2 second drawing frames, 2 heads each, 6 slivers per head.
2 third drawing frames, 2 heads each, 8 slivers per head.
2 patent disc regulating roving frames, 72 spindles each, 12 spindles per head, 6 × $3\frac{1}{2}$ inches bobbin.
5 spinning frames, 220 spindles each, $2\frac{1}{2}$ inches pitch = 1,100 spindles.
5 spinning frames, 244 spindles each, $2\frac{1}{4}$ inches pitch = 1,220 spindles.
Production about 65 bundles or 236 lbs. of No. 53's yarn per day, and about 50 bundles or 105 lbs. of No. 95's yarn per day.

IV. Two systems of long-tow machinery for No. 10's to 25's.
1 breaker card, 4 feet diameter, 6 feet wide, doffed by rollers.
1 lap machine.
2 finisher cards, 4 feet × 6 feet, with P. Fairbairn and Co.'s patent rotary gill drawing frames attached.
2 patent rotary gill drawing frames, 12 slivers each.
2 patent rotary gill disc regulating roving frames, 48 spindles each, 8 inches × 4 inches bobbin.
3 spinning frames, 184 spindles each, 4 inches pitch for No. 10's to 18's = 552 spindles.
3 spinning frames, 200 spindles each, $2\frac{3}{4}$ inches pitch for No. 16's to 25's = 600 spindles.
Production about 39 bundles, or 488 lbs. No. 16's per day, and about 39 bundles or 312 lbs., No. 25's per day.

V. One system of cut tow machinery for No. 25's to 40's.
1 breaker card, 4 feet diameter, 6 feet wide, doffed by combs.
1 finisher card, with P. Fairbairn and Co.'s patent rotary gill drawing frame attached.
1 screw gill second drawing frame, 3 heads each, 4 bosses per head.
1 screw gill third drawing frame, 3 heads each, 6 bosses per head.
1 screw gill patent disc regulating roving frame, 72 spindles, 12 spindles per head, 6 × 3½ inches bobbins.
3 spinning frames of 220 spindles each, 2½ inches pitch = 660 spindles.
Production about 36 bundles, or 240 lbs. of No. 30's per day.

The reeling is generally carried on in the attic above the spinning room, and the number of reels required is about the same as the number of spinning frames.

Summary view.

There are 3,200	spindles	long line,	producing	196	bundles, or,	890	lbs. of yarn per day.

7,332	spindles			425	bundles	2,270	lbs. of yarn per day.

A more effective system of economy, as well in the finish of raw flax as in the make of yarn, has been satisfactorily carried on for years past.

The old mode of hand-scutching, as was usual in farming circles in earlier times, had many drawbacks. It was not only very costly, but exceedingly wasteful. No matter how well skilled may have been the operators, or how careful they were of the flax straw, serious damage was often done to the fibre in course of the scutching process; the actual weight of material produced having rarely exceeded twenty per cent. of the original produce.

Nearly two hundred years ago the native Irish, as well as the various settlers from England and Scotland who had become nationalised in every peculiarity of taste and habit, were still plodding on as their fathers had done in the ancient track. Lands were only partially prepared for flax culture; and, although a few of the more forward growers retained the traditional desire for improvement handed down from the days of Lord Strafford, the general rule was to take little more pains in the management of the flax crop than was then usual in relation to corn or root culture. About that time the cruelty of Louis XIV. was thinning France of some thousands of its Protestant people. Persecution waved the flag of intolerance, Tyranny held its carnival, and whole districts were depopulated. Many of the fugitives fled to Ireland, and the greater number of those French exiles had been connected with manufacturing industry. Dublin, Waterford, Portarlington, and Limerick welcomed numbers of these people, and in the north, Lisburn and Lurgan formed the respective resting-places of others. After the battle of the Boyne large accessions were made to the ranks of the Huguenots, and King William, having taken great interest in the well-being of the settlers, induced Louis Crommelin, a gentleman of immense experience in the linen manufacture, to leave his asylum in Amsterdam and come over to Lisburn, where he set him at the head of the people. A number of Hollanders had also settled there, and those men, being well skilled in the art of flax-growing, were placed in farms which the lord of the soil had given at low rents, and which lands were set apart for the special culture of flax. With the native population of that wide district of Ulster, the Dutchmen and Huguenots formed amicable brotherhood. Difference of creed and of country was never permitted to create social warfare, and the result was that the improvements in the mode of cultivating the flax grounds, as suggested by the foreigners, were readily adopted by the Irish, many of whom, in the course of a few years, showed by their skill and forethought how much they had profited by the lessons of their teachers. M. Crommelin, as director of the linen manufacture, watched with intense interest every phase of progress, and with the means placed in his hands for that purpose rewarded to the utmost of his power the leaders of his industrial army.

The law enacted in 1701 for the encouragement of the Irish linen trade not having been carried into effect, a new Act was passed by Queen Anne in 1711, and a number of nobles and other gentry were appointed to form a Board, the head-quarters of which was in Dublin. This body immediately set to work, and in the first instance commenced operations by directing special attention to the growth of a quality of flax, finer and more silky in texture than any that had ever before been raised in Ireland. Better machinery for scutching purposes had been introduced by M. Crommelin; his

Dutch assistants and the French women having been offered large premiums for spinning, great stimulus was given to the culture of fine flax. In 1718, M. Crommelin, with the assistance of James Turner, a Lurgan carpenter, succeeded in effecting considerable improvements in the mechanism of the wheel then used by spinsters. This machine, we need scarcely state, was that which succeeded the ancient distaff and spindle. The leader of the Huguenot colony had previously purchased some hundreds of spinning wheels in France, and when these came to hand he had them distributed among the women and girls most celebrated for ability in producing fine yarn. But in the French wheels he found it necessary to make certain changes in order to adapt them more especially to the wants as to the peculiar ideas of the spinners. On the improved wheel, however, the native Irish as well as the French settlers spun yarns of a degree of fineness far exceeding anything ever before seen in Ulster.

We have no authentic data on which to found a correct opinion of the area under cultivation in Ireland during M. Crommelin's directorship. Mr. Dobbs, who wrote in 1728, says there were then grown in the different provinces 30,000 Plantation, say about 47,000 English acres. Towards the close of the century the breadth had been largely extended, and the imports of foreign flax, which did not exceed 50,000 cwts. in 1700, had increased to 260,000 cwts. in 1799.

A new era was then setting in on the flax manufacture. The Messrs. Marshall of Leeds had successfully established the enterprise of spinning that fibre by mechanical power, and from that time rapid improvements were made in the finish of material for the spindles. The preparing process known as hackling was then in a comparatively backward state; but, as the new system of producing yarns extended to Scotland and Ireland, the inventive genius of the different sections of the British Isles was called into play, and before the first half of the nineteenth century had gone by every single department of the trade showed its evidence of progress. Among the leading makers of hackling machines we have the Messrs. Lowry of Manchester. To Mr. George Lowry the trade is indebted for the invention of that great improvement, the vertical wheel hackling machine. Then we have Messrs. Combe and Barbour, S. Cotton and Co., and Mr. George Horner of Belfast. Each of these makers has contributed some special improvement in easy working and simple mechanism, and several of them show a high rate of yield of line per cent. compared with other machines.

Flax-spinning by steam-power had been preceded by the same system, but in which the works were driven by water; and these works, generally on a small scale, were attempted in various parts of the isles of Britain before the end of last century. To the Messrs. Marshall of Leeds, the Messrs. Baxter of Dundee, the Messrs. Murland of Castlewellan, and Messrs. Mulholland of Belfast, the trade is indebted for the first effective introduction of the steam-driven flax-spindle. For a long period, however, the enterprise of mill-spinning in the higher numbers of yarn was confined to Leeds, and in the coarse numbers to Dundee. In 1828 the mill at Castlewellan, Co. Down, was started by the brothers Murland, and in 1830 the first bundle of flax yarn produced in Belfast was turned off the spindles of the brothers Mulholland. In 1869 there were in England and Wales 437,623 spindles; in Scotland, 256,228 spindles; and in Ireland, 894,273 spindles. Forty-four years ago—1830—the imports of foreign flax into the United Kingdom amounted to 944,500 cwts.; and in 1873 2,194,473 cwts. were landed. In the meantime, Ireland had become the chief source of home supply, Great Britain having gradually contracted her breadth of flax-lands until the total area for 1873 was narrowed to 14,683 acres, the vast proportion of which was grown for seed rather than for fibre. In course of last year there were 122,432 acres of land under flax in Ireland, producing an aggregate of 406,950 cwts. of marketable material. From various causes, but more especially unfavourable seasons and neglect on the part of some growers of preparing the soil with due care, as well as want of care in selecting the seed, the yield of flax-lands in Ulster fell off considerably. In the famous season of 1853 the average produce was 41 stones to the acre. That rate of yield fell off until in 1869 only 19½ stones were raised, and in the disastrous season of 1871 the average had declined to about 15 stones to the acre. This caused the utmost depression in farming circles, and the very unguarded assertion made by a member of the linen trade that Ireland was 'flaxed out' began to be looked upon as a practical truth. But in the season of 1873 flax crops in most parts of the country were abundant in yield, and superior in quality. Many of the more skilful flax growers in Down raised 80 stones to the Plantation acre, and in other counties equally large produce was reported.

We have thus given full details of the flax and yarn trades down to 1874. Under the head of LINEN we shall note the latest improvements in the make of goods and the mechanism of steam-looms.

Our trade in flax will be seen by the following tables;—

FLEXIBLE SANDSTONE. A micaceous or talcose sandstone, possessing considerable elasticity, so as to bend to and fro with gentle pressure. It is found in the diamond-bearing districts of Brazil, in the United States, and near Delhi. See Articulite; Itacolumite.

FLEXIBLE SILVER ORE. A name for Stephanite. See Silver.

FLINT. (*Pierre à fusil*, Fr.; *Feuerstein*, Ger.) A massive impure variety of silica allied to chalcedony. It forms a connecting link between quartz and opal, since it consists, according to Fuchs, of an intimate mixture in varying proportions of the two forms of silica—the crystalline or insoluble, and the non-crystalline or soluble; the latter being readily separated by solution of caustic potash. The colours of flint, which are usually various shades of grey, brown, or black, are entirely removed by calcination, the flint thus becoming white and opaque: whence the colour is commonly referred to the presence of organic matter, derived probably from the associated fossils. Although sufficiently hard to strike copious sparks with steel, flint is very easily broken, splitting with a flat conchoidal fracture, usually dull on the surface. It is feebly translucent, and has so fine and homogeneous a texture as to bear polishing, but possesses little lustre.

Flint is found chiefly in the form of nodular masses, of very irregular and frequently fantastic shapes; and of various sizes up to a foot in diameter. These masses occur embedded in calcareous, never in siliceous strata; and are especially abundant in the upper beds of the chalk, which have hence been termed 'Chalk-with-flints.' Although occasionally arranged in layers running across the plane of bedding, as in the 'potstones' of Norfolk, yet as a rule the nodules have a notable tendency to dispose themselves in lines parallel to the direction of the stratification; occasionally they occur so close together as to unite, and thus form continuous horizontal bands or flat tabular masses.

Externally the flint nodules are usually coated with a white opaque crust, apparently siliceous; whilst internally they are often hollow, the cavities sometimes containing pulverulent silica, and sometimes being lined with chalcedony, or with crystals of iron pyrites or other minerals; whilst almost universally they enclose the remains of some marine organism, commonly a sponge. Indeed, the study of the microscopic structure of flint has led Dr. Bowerbank to the conclusion that all flints, both nodular and tabular, contain the remains of spongeous tissue, which appears to have acted as a nucleus or centre of attraction around which the silica was deposited from solution.

Flints when first quarried are exceedingly brittle, and are commonly humid when broken, but by exposure to the air they gradually acquire toughness; hence, when used as road-material, they should never be laid down on immediate removal from the quarry.

Flints calcined and ground to a powder enter into the composition of all kinds of fine pottery, and were formerly employed in the manufacture of the finer varieties of glass, hence termed 'flint glass.'

Flints form excellent building materials; because they give a firm hold to the mortar by their irregularly rough surfaces, and resist, by their nature, every vicissitude of weather. The counties of Kent, Essex, Suffolk, and Norfolk contain many substantial specimens of flint-masonry.

Formerly an important application of this siliceous substance was in the formation of gun-flints, for which purpose it was cut in a peculiar manner. The following characters distinguish good flint nodules from such as are less fit for being manufactured: the best are somewhat convex, approaching to globular; those which are very irregular, knobbed, branched, and tuberose, are generally full of imperfections. Good nodules seldom weigh more than twenty pounds; when less than two they are not worth the working. They should have a greasy lustre, and be particularly smooth and fine grained. The colour may vary from honey-yellow to blackish brown, but it should be uniform throughout the lump, and the translucency should be so great as to render letters legible through a slice about $\frac{1}{50}$th of an inch thick laid down upon the paper. The fracture should be perfectly smooth, uniform, and slightly conchoidal; the last property being essential to the cutting-out of perfect gun-flints. Although flint locks are now but rarely employed, the process of cutting the flints to shape possesses much interest.

Four tools are employed by the gun-flint maker.

First, a hammer or mace of iron with a square head, from 1 to 2 pounds weight, with a handle 7 or 8 inches long. The tool is not made of steel, because so hard a metal would render the strokes too harsh, or 'dry,' as the workmen say, and would shatter the nodules irregularly, instead of cutting them with a clean conchoidal fracture.

Second, a hammer with two points, made of good steel well hardened, and weighing from 10 to 16 ounces, with a handle 7 inches long passing through it in such a way that the points of the hammer are nearer the hand of the workman than the centre of gravity of the mass.

Third, the disc hammer or roller, a small solid wheel or flat segment of a cylinder, parallel to its base, only 2½ inches in diameter, and not more than 12 ounces in weight. It is formed of steel not hardened, and is fixed upon a handle 6 inches long, which passes through a square hole in its centre.

Fourth, a chisel tapering and bevelled at both extremities, 7 or 8 inches long, and 2 inches broad, made of steel not hardened; this is set on a block of wood, which serves also for a bench to the workmen. To these four tools a file must be added, for the purpose of restoring the edge of the chisel from time to time.

After selecting a good mass of flint, the workman executes the four following operations on it:—

1. *He breaks the block.* Being seated upon the ground, he places the nodule of flint on his left thigh, and applies slight strokes with the square hammer to divide it into smaller pieces of about a pound and a half each, with broad surfaces and almost even fractures. The blows should be moderate, lest the lump crack and split in the wrong direction.

2. *He cleaves or chips the flint.* The principal point is to split the flint well, or to chip off scales of the length, thickness, and shape adapted for the subsequent formation of gun-flints. Here the greatest dexterity and steadiness of manipulation are necessary; but the fracture of the flint is not restricted to any particular direction, for it may be chipped in all parts with equal facility.

The workman holds the lump of flint in his left hand, and strikes with the pointed hammer upon the edges of the great planes produced by the first breaking, whereby the white coating of the flint is removed in small scales, and the interior body of the flint is laid bare; after which he continues to detach similar scaly portions from the clean mass.

These scaly portions are nearly 1½ in. broad, 2½ in. long, and ⅛th of an inch thick in the middle. They are slightly convex below, and consequently leave in the part of the lump from which they were separated a space slightly concave, longitudinally bordered by two somewhat projecting straight lines or ridges. The ridges produced by the separation of the first scales must naturally constitute nearly the middle of the subsequent pieces; and such scales alone as have their ridges thus placed in the middle are fit to be made into gun-flints. In this manner the workman continues to split or chip the mass of flint in various directions, until the defects usually found in the interior render it impossible to make the requisite fractures, or until the piece is too much reduced to sustain the smart blows by which the flint is divided.

3. *He fashions the gun-flints.* Five different parts may be distinguished in a gun-flint: 1. The sloping facet or bevel part, which is impelled against the hammer of the lock. Its thickness should be from two to three twelfths of an inch; for if it were thicker it would be too liable to break; and if more obtuse, the scintillations would be less vivid. 2. The sides or lateral edges, which are always somewhat irregular. 3. The back or thick part opposite the tapering edge. 4. The under surface, which is smooth and rather concave. And, 5. The upper face which has a small square plane between the tapering edge and the back for entering into the upper claw of the lock.

In order to fashion the flint, those scales are selected which have at least one of the above-mentioned longitudinal ridges; the workman fixes on one of the two tapering borders to form the striking edge, after which the two sides of the stone that are to form the lateral edges, as well as the part that is to form the back, are successively placed on the edge of the chisel in such a manner that the convex surface of the flint, which rests on the forefinger of the left hand, is turned towards that tool. Then with the disc hammer he applies some slight strokes to the flint just opposite the edge of the chisel underneath, and thereby breaks it exactly along the edge of the chisel.

4. The finishing operation is the *trimming*, or the process of giving the flint a smooth and equal edge; this is done by turning up the stone and placing the edge of its tapering end upon the chisel, in which position it is completed by five or six slight strokes of the disc hammer. The whole operation of making a gun-flint, to describe which so many words are here used, is performed in less than one minute. A good workman is able to manufacture 1,000 good chips or scales in a day (if the flint balls be of good quality); or 500 gun-flints. Hence, in the space of three days, he can easily cleave and finish 1,000 gun-flints without any assistance.

The manufacture of gun-flints is still carried on to a limited extent at Brandon, in Suffolk, where the trade has been established for several centuries. In 1870 there were three masters and thirty workmen engaged in flint-working at Brandon.

An excellent paper on flint-knapping by Mr. J. Wyatt of Bedford, is published in Stevens's 'Flint Chips' (1870). A description of the processes still in use is also given in Evans's 'Ancient Stone Implements, Weapons, and Ornaments of Great Britain' (1872).

The facility with which flint, in spite of its hardness, may, with sufficient practice, be fractured in almost any given direction, yielding fragments with sharp-cutting edges, has led to its employment as one of the commonest materials of those rude stone implements which have in all ages been fashioned by savage tribes ignorant of the use of metal. The antiquary has long been familiar with the occurrence of such implements in tumuli or ancient burial-mounds; and of late years they have also been found in the Pfahlbauten or pile-dwellings in the Swiss lakes; in the Kjökkenmöddings or Danish shell-mounds; in bone-caverns, &c. The worked flints found in these situations are referred, in most cases, to an early pre-historic period known to archæologists as the 'stone-age;' a period apparently anterior to the knowledge of any metal, excepting gold. The so-called stone-age, which indicates a phase of civilisation rather than an epoch of definite date, has been divided by Sir John Lubbock into a *newer* and an *older* period, termed respectively the *neolithic* and the *palæolithic* age. The neolithic implements, although commonly of flint, are by no means exclusively so; blood-stone, jade, porphyry, and indeed any stone sufficiently hard, having been also employed. In form they present considerable variety, comprising axes or celts, knives, scrapers, sling-stones, spear-heads, arrow-heads, and the like; many of them, especially the celts, being wrought into highly-finished forms, and even ground and polished to a cutting-edge.

Of a far higher antiquity and of a much ruder type than any of these polished relics of the newer stone-period are those primitive flint implements of palæolithic age which within the last few years have been found in deposits of drift-gravels, frequently at considerable depths and, in many cases, associated with the remains of extinct mammalia—discoveries which have excited an intense interest from their bearing upon the much-vexed question of the antiquity of the human race. To these early flint implements attention was first directed by the late M. Boucher de Perthes, a French antiquary, who had from time to time discovered them in the gravel-pits in the valley of the Somme, chiefly in the neighbourhood of Amiens and of Abbeville. Although the first discovery was made as early as 1841, the subject attracted but little notice until the year 1859, when the locality was visited, and the instruments and their mode of occurrence described, by Messrs. Prestwich and Evans. The deposits in which these worked flints are found consist of stratified sands and gravels, often of considerable thickness, resting upon an eroded surface of chalk, and referred by geologists to the pleistocene or post-pliocene period; a time when the climate of Northern Europe was considerably colder than at present, and when these latitudes were inhabited by the mammoth, the woolly rhinoceros, the cave-bear, and other mammalia now extinct. The flint implements have been found chiefly in the lower beds of these drift deposits, immediately overlying the chalk, and frequently beneath a thickness of more than 20 feet of undisturbed sand, brick-earth, &c., containing shells in some places marine, in others land and freshwater, together with the bones and teeth of certain extinct mammalia, but never with the remains of man. It should be remarked that these drift-implements, unlike those of the more recent stone-age, are formed exclusively of flint, and that they never exhibit the slightest trace of having been either ground or polished. The form of these implements is, moreover, quite characteristic. But, although of an extremely rude type, they bear quite sufficient evidence of design to verify them as the results of human workmanship; whilst, on the other hand, their extreme antiquity is attested not only by the position in which they occur, but also by the glossy varnish-like character of their surface, totally unlike that of recently-fractured flint. The possibility of their having been modern forgeries is further precluded by the fact that many of them are coated with a calcareous incrustation, and that they occasionally exhibit on the surface dendritic markings produced by the slow action of the oxides of manganese and iron.

Since these discoveries have been made in the valley of the Somme, flint-hatchets of the drift-type have been recognised in several localities in this country and elsewhere. Among the more productive English localities may be mentioned the valley of the Little Ouse, Thetford, Fareham, Bournemouth, the Reculvers, and the valley of the Thames.

FLINT GLASS. See Glass.

FLINTY SLATE. A very siliceous black schist, often containing 75 per cent. of silica. It is used as a 'touchstone' for testing gold, by a comparison of the colour of the streak made by the metal. See Assay.

FLITTERN BARK. The bark of young oak trees, which is distinguished from *coppice bark* by its superior quality, and also from the bark of old oak trees, known as *timber bark*. Flittern bark is much used by the tanner.

FLOAT-STONE. (*Quartz nectique*, Fr.; *Schwimmstein*, Ger.) A light concretionary or cellular form of silica, sufficiently open in texture to float on water.

FLOCK and **FLOCKS.** The first is finely-powdered wool, used when dyed of various colours to prepare paper hangings.

The second is a name given to the refuse or waste of cotton and wool, and is used for stuffing mattresses.

FLOCK PAPER. Paper prepared for walls by being sized in the first instance, either over the whole surface or over special parts, constituting the pattern only, and then powdering over it flock or powdered wool which had been previously dyed.

FLOOKAN or **FLUKAN.** The name given by the Cornish miners to veins filled wholly with clay. This is usually applied to such veins or lodes as are at right angles, or nearly so, to the true metalliferous lodes.

FLOOR-CLOTH MANUFACTURE has become of late years a very large branch of trade. The cloth is a strong somewhat open canvas, woven of flax with a little hemp, and from 6 to 8 yards wide, being manufactured in appropriate looms, chiefly at Dundee. A piece of this canvas, from 60 to 100 feet in length, is secured tight in an upright open frame of oaken bars, in which position it is brushed over with glue size, and rubbed smooth with pumice-stones; it next receives the foundation-coats of paint, two or three in number, first on the back side, and then on the front. The foundation-paint, made with linseed oil and ochre, or any cheap colouring matter, is too thick to be applied by the brush, and is therefore spread evenly by a long narrow trowel, held in the right hand, from a patch of it laid on just before with a brush in the left hand of the workman. Each foundation-coat of the front surface is smoothed by pumice-stone whenever it is hard enough to bear the operation. When both sides are dry, the painted cloth is detached from the frame, coiled round a roller, and in this state transferred to the printing room, where it is spread flat on a table, and variously figured and coloured devices are given to it by wooden blocks, exactly as in the block printing of calicoes or papers. The blocks of the floor-cloth manufacture are formed of two layers of white deal and one of pear-tree timber, placed with their grain crossing one another alternately. There is a block for each colour in the pattern, and in each block those parts are cut away that correspond to the impressions given by the others; a practice now well understood in the printing of two or more colours by the press. The faces of the blocks are so indented with fine lines, that they do not take up the paint in a heavy daub from the flat cushion on which it is spread with a brush, but in minute dots, so as to lay on the paint (somewhat thicker than that of the house painter) in a congeries of little dots or teeth, with minute interstices between. Applied in this way, the various pigments lie more evenly, are more sightly, and dry much sooner than if the prominent part of the block which takes up the colour were a smooth surface. The best kinds of floor-cloth require from two to three months for their production.

From the use of the sulphate of baryta with the white lead, sometimes to the extent of 75 per cent. of the former, not merely in the foundation-paint, but in the subsequent colours with which the canvas is painted, there is a very general complaint that the floor-cloths for halls, &c., where they are necessarily exposed to washing, very soon lose their colours and become bare, the barytes washing out, and, of course, removing at the same time the lead and other colours.

The same principle in colouring floor-cloth is now applied to *paper*, and is carried on to a very large extent at Egham under the patent of Mr. Walton. The oil is there first dried or oxidised, then dissolved in naphtha with the colouring; as the naphtha dries, the paper is ready for use. See OXIDISED OIL; WHITE LEAD.

FLORAN. A mining term; tin ore scarcely perceptible in the stone; tin ore stamped very small.—*Pryce.*

FLOS FERRI. Coral-like forms of aragonite, or carbonate of lime, occurring especially in the iron mines of the Eisenerz in Styria.

FLOSS, of the puddling furnace, is the fluid glass floating upon the iron produced by the vitrification of the oxides and earths which are present. See IRON.

FLOSS-SILK (*Filoselle, Bourre de soie, Fleuret,* Fr.) is the name given to the portions of ravelled silk broken off in the filature of the cocoons, which is carded like cotton or wool, and spun into a soft coarse yarn or thread, for making bands, shawls, socks, and other common silk fabrics. The floss or fleuret, as first obtained, must be steeped in water, and then subjected to pressure, in order to extract the gummy matter which renders it too harsh and short for the spinning wheel. After being dried it is made still more pliant by working a little oil into it with the hands. It is now ready to be submitted to the carding engine, and it is spun upon the flax wheel.

The female peasants of Lombardy generally wear clothes of homespun floss silk. Of late years, by improved processes, fine fabrics of this material have been produced, both in England and France. M. Ajac, of Lyons, manufactures a variety of scarfs and square shawls of *bourre de soie,* closely resembling those of *cachemire.*

FLOTSAM. See JETSAM.

FLOUR. The finely-ground meal of wheat, and of any other corns or *cerealia.* See BREAD.

Since the analysis of grain represents the total chemical constituents of the flour, and the cell in which it is contained, a few analyses from the researches of Way and Ogston are given:—

	WHEAT			BARLEY		
	Hopeton	Red Straw	Old Red Lammas	Chevalier	Unknown	Moldavia
Potassa	30·32	29·75	32·46	27·43	21·14	31·55
Soda	0·07	0·64	4·53	0·05	...	1·06
Lime	2·51	3·27	3·21	2·79	1·65	1·21
Magnesia	12·38	13·75	9·56	8·67	7·26	10·17
Sesquioxide of iron	0·08	0·23	2·06	0·09	2·13	1·02
Sulphuric acid	0·18	0·60	0·32	2·72	1·91	0·27
Silica	3·60	2·14	5·49	23·60	30·68	24·26
Phosphoric acid	49·22	49·58	40·57	26·01	28·53	28·64

The produce of one quarter of wheat weighing 504 lbs. is, according to Mr. Hard of Dartford—

Flour	392 lbs.
Biscuit or fine middlings	10
Toppings or specks	8
Best pollard	15
Fine pollard	18
Bran and coarse pollard	50
Loss	11
	504 lbs.

Vauquelin has given the following as the results of his examination of wheat flour:—

	French	Odessa hard	Odessa soft	Paris Flour	Inferior Flour
Starch	71·49	56·5	62·00	72·8	67·78
Gluten	10·96	14·55	12·00	10·2	9·02
Sugar	4·72	8·48	7·56	4·2	4·80
Gum	3·82	4·90	5·80	2·8	4·60
Bran	...	2·30	1·20	...	...
Water	10·00	12·00	10·00	10·0	12·00

Adulterations of, to detect.—The first method is by specific gravity. If potato flour be added, which is frequently done in France, since a vessel which contains one pound of wheat flour will contain one pound and a half of the fecula, the proportion of this adulteration may be easily estimated. If gypsum or ground bones be mixed with the flour, they will not only increase its density still more, but they will remain after burning away the meal as ashes.

The second method is by ascertaining the quantity of gluten which the suspected sample will afford, as described in the article BREAD. The two following chemical criteria may also be employed:—

1st. Nitric acid has the property of colouring wheat flour of a fine orange yellow, whereas it affects the colour neither of fecula nor starch.

2nd. Muriatic acid colours good wheat flour of a deep violet, but dissolves fecula or starch, and forms with it a light and colourless viscous fluid, decomposable by alkalis.

Sulphate of iron renders an infusion of pure flour somewhat yellow, and imparts a bottle-green to that which is adulterated with bean meal.— (*Lassaigne.*) Nitric acid and ammonia poured successively on good flour shows nothing remarkable; but bean meal strikes a deep red colour.— (*Donny.*)

The amount of ash left by the flour has been proposed by Louyet as a test of its purity. He says, 'Wheat flour yields on the average 0·8 per cent.; rye flour, 1·0; bean and pea meal, 3; linseed meal, 10 per cent. of ash.'

FLOWERS. The name formerly given to those substances which were obtained by sublimation; as the flowers of sulphur, the flowers of Benjamin, &c.

FLOWERS, ARTIFICIAL, *Manufacture of.* The art of representing by flowers, leaves, plants, &c., vegetable nature in her ornamental productions, constitutes the business of the artificial florist. The Italians appear to have been the first people in Europe who excelled in the art of making artificial flowers; but of late years the French have been most ingenious in this branch of industry.

Ribbons folded in different forms and of different colours were originally employed for imitating flowers, by being attached to wire stems. This imitation soon gave way to that by feathers, which are more delicate in texture, and more capable of assuming a variety of flower-like figures. But a great difficulty was encountered in dyeing them with due vivacity. The savages of South America manufacture perfect feather flowers, derived from the brilliant plumage of their birds, which closely resemble the products of vegetation. The blossoms and leaves are admirable, while the colours never fade.

The Italians employ frequently the cocoons of the silkworm for this purpose; these take a brilliant dye, preserve their colour, and possess a transparent velvety appearance, suitable for petals. Of late years, the French have adopted the finest cambric for making petals, and the taffeta of Florence for the leaves. M. de Bernardière employs whalebone in very thin leaves for artificial flowers; and, by bleaching and dyeing them of various hues, he has succeeded in making his imitations of nature very remarkable.

Gutta-percha dissolved in benzole, and freed from all impurities, will, when spread out on a sheet of glass, dry into a beautifully white and delicate film, of great strength, and capable of receiving any colour. This has been employed in Paris in the manufacture of flowers. Vegetable parchment (paper prepared by the action of sulphuric acid) has been employed for the same purpose in this country. See VEGETABLE PARCHMENT.

The colouring matters used in flower-dyeing are the following:—

For red; carmine dissolved in a solution of carbonate of potash.

For blue; indigo dissolved in sulphuric acid, diluted and neutralised in part by Spanish whitening.

For bright yellow; a solution of turmeric in spirit of wine. Cream of tartar brightens all these colours.

For violet; archil, and a blue bath. For lilac; archil.

The aniline colours are now largely used.

Some petals are made of velvet, and are coloured merely by the application of the finger dipped in the dye.

Artificial flowers imported were of the values given in each year:—

	Value		Value		Value
1868	341,176*l.*	1869	365,407*l.*	1870	266,502*l.*

In 1872 we imported from—

	Value
Germany	4,657*l.*
Belgium	18,966
France	387,768
Other countries	149
Total	411,510*l.*

FLUATES. A term formerly applied to the compounds now called *fluorides*, on the supposition that they contained fluoric acid. When, however, the true constitution of this acid, as a hydrogen-compound, was determined, it became evident that the substances called fluates must belong to the class of so-called haloïd salts, and consist therefore of the element fluorine united directly with a metal or radical; whence they are properly termed fluorides. Thus, fluor-spar, formerly known as fluate of lime, is, according to the new nomenclature, a fluoride of calcium; containing—fluorine, 48·7; calcium, 51·3.

It may be remarked that fluorine has a strong tendency to form double salts, many of which occur native. Thus, the minerals called cryolite and chiolite are double fluorides of sodium and aluminium.

FLUE CINDER. The cinder from the reheating furnace. See IRON MANUFACTURE.

FLUELLITE. A rare mineral, containing fluorine and aluminium, found at Stennagwyne in Cornwall.

FLUKES. See ANCHOR.

FLUOR. See FLUOR-SPAR.

FLUORESCENCE, the name given to a peculiar phenomenon rendered evident by many crystals of fluor-spar. If we look through a crystal of fluor-spar it will appear yellow or green as the case may be; now, if we look at it, the light falling upon the surface upon which we look, it will appear beautifully blue or purple. Prof. Stokes, to whom we are indebted for a very exact examination of the whole of the phenomena of this class, refers this effect to an alteration of the refraction of the ray by the first surface upon which it falls. Sir John Herschel first drew attention to this peculiar condition as exhibited in a solution of sulphate of quinine in water slightly acidulated with sulphuric acid. Here we have a perfectly colourless solution when we look through it, which sends back to the eye fine blue rays when we look at the surface on which the solar rays fall. Sir John Herschel referred this to epipolic dispersion, or dispersion from the first surface of the fluid on which the light fell. There are many substances which appear to possess this property of altering the refraction of rays, or are fluorescent. Beyond this brief explanation, we cannot afford space in this dictionary to deal with the subject. We must refer those interested to the *Philosophical Transactions*, in which Prof. Stokes's communications appeared.

FLUORINE. (*Symbol*, F.; *Atomic weight*, 19.) The elementary base of hydrofluoric acid, which has never yet been isolated.

The power of liberating a principle from fluor-spar which would etch glass was known as far back as 1670; Scheele, in 1771, examined hydrofluoric acid, and regarded it as an oxygen compound with an unknown element. Ampère, in 1810, determined that hydrofluoric acid was a compound of hydrogen and fluorine.

Fluorine combines with most of the metals, and with hydrogen, boron, silicon, sulphur, and phosphorus; with chlorine, bromine, iodine, and oxygen, it exhibits no tendency to unite. It has been suggested to employ hydrofluoric acid in the purification of beet-root sugar; the alkalis present in the juice being effectually removed by the acid, while the organic matter remains unaffected.

FLUOR-SPAR. (*Chaux fluatée*, Fr.; *Fluss-Spath*, Ger.) This mineral often exhibits a variety of vivid colours. It crystallises in the cubic (monometric) system, with regular octahedral cleavages; spec. grav. 3·14 to 3·19; hardness = 4·0; scratches calc spar, but is scratched by a steel point; usually phosphorescent with heat; at the blowpipe decrepitates and fuses into an opaque bead; acted on by the acids with disengagement of a vapour which corrodes glass; its solution affords precipitates with the oxalates, but not with ammonia. Its constituents are, fluorine, 48·7; calcium, 51·13 in 100.

Fluor-spar occurs subordinate to metallic veins; as to those of lead, in Derbyshire and Cumberland; of lead and copper, in Cornwall, and in Saxony and Bohemia; but it is found also in masses or veins, either in crystalline rocks, associated with quartz, barytes, &c., as in Auvergne, Forez, Vosges, Norberg in Sweden; Norway; Petersburg; Gourock, in Scotland, &c.; or among limestones, slates, and sandstones, in Derbyshire, Cumberland, Cornwall, and New Jersey. It exists also in the amygdaloids of Scotland, and in the volcanic products of Monte Somma at Vesuvius. The variously-coloured specimens, called Derbyshire spar, are worked upon the turning lathe into vases and other ornamental objects.

A very beautiful variety, which has been much used for ornamental purposes, known from its colour as 'Blue John,' has been obtained from Tray Cliff, near Castleton, Derbyshire. The beautiful colour of the natural fluor has been successfully imitated by exposing some of the common varieties to heat.

Fluor-spar is employed to a considerable extent in the production of hydrofluoric acid and for etching on glass. It is also used by lead smelters as a flux. The beautiful phenomenon of *fluorescence* is so named from the fact that many of the fluor-spars have the power in a high degree of thus affecting the rays of light. See FLUORESCENCE.

FLUVIATILE (*fluvius*, a river), belonging to a river.

FLUX (Eng. and Fr.; *Fluss*, Ger.) signifies any substance capable of promoting the fusion of earths or metallic ores by heat. White flux is the residuum of the deflagration, in a red-hot crucible, of a mixture of two parts of nitre and one of cream of tartar. It is in fact merely a carbonate of potash. Black flux is obtained when equal parts of nitre and tartar are deflagrated. It owes its colour to the carbonaceous matter of the tartaric acid, which remains unconsumed; the quantity of nitre being too small for that purpose. The presence of the charcoal renders this preparation a convenient flux for reducing calcined or oxidised ores to the metallic state. Limestone, fluor-spar, borax, and several earthy or metallic oxides, are employed as fluxes in metallurgy. See METALLURGY.

FLY POWDER. Under this name there is sold on the Continent the black coloured powder obtained by the spontaneous oxidation of metallic arsenic in the air. Various preparations of white arsenic are used for the same purpose in this country. King's yellow is much used; it should be made by boiling together sulphur, lime, and white arsenic, but much that is sold is merely arsenic and sulphur mixed.

Objecting on principle to the familiar use of arsenic and dangerous substances, a preference may be given to a substitute for the above, made by boiling quassia chips into a strong decoction and sweetening with loaf sugar. This seems to have deadly power over the flies, who can scarcely quit the liquid without imbibing a deadly potion, and they are seen to fall from the ceilings and walls of the rooms soon afterwards. Many of these compounds for killing flies are supposed by their odour to attract flies into the rooms.

The inconvenience to manufacturers and others from flies, may be obviated in many cases where apartments are required to be kept as free as possible from them, by reference to facts recorded by Herodotus, of fishermen surrounding themselves with their nets to keep off the gnats. We are indebted to William Spence, Esq. F.R.S., for some very curious particulars respecting the common house fly communicated in a paper to the Entomological Society. The common house fly will not in general pass through the meshes of a net. The inhabitants of Florence and other parts of Italy are aware of this fact, and protect their apartments by hanging network up at the windows; thus at all times the doors and windows may be kept wide open by hanging a light network over the aperture. The meshes may be of considerable width, say enough for several flies on the wing to pass through, and no fly will attempt to pass, unless there be a strong light (another window opposite, or reflection from a looking-glass). A knowledge of this simple means of protection from flies on the wing may prevent inconvenience from these intruders, and obviate the necessity for poisons to destroy them.

FODDER, is the name of a weight by which lead and some other metals were sold in this country; but it is now rarely used. It varied in its amount in different parts of the kingdom, being 19½ cwts. at Hull; 21 cwts. at Newcastle; 22 cwts. at Stockton; 24 cwts. in Derbyshire.

FOILS. Thin sheet copper silvered and burnished, and afterwards coated with transparent colours mixed with isinglass, employed by jewellers to improve the brilliancy of pastes and inferior stones. The foil is inclosed in the setting, and entirely covers the back of the stone, to which it imparts much of its own brilliancy.

FOLIATED TELLURIUM. See NAGYAGITE.

FONDUS. The name given by the French to a particular style of calico-printing resembling the rainbow, in which the colours are graduated or melted (*fondus*) into one another, as in the prismatic spectrum. See CALICO PRINTING for a description of the process.

FONTAINEBLEAU SANDSTONE. This stone consists of grains of siliceous sand, agglutinated by carbonate of lime: the carbonate, in spite of its association with the sand, crystallises in bold rhombohedral forms. In specimens from the forest of Fontainebleau, in France, the proportion of silica may reach 50 or 60 per cent.

FOOD. See NUTRITION.

FOOL'S-PARSLEY. The *Æthusa cynapium*, a very poisonous umbelliferous plant, common in Britain, and occasionally mistaken for parsley.

FOOT-WALL, *a mining term.* The 'wall' or side of the rock under the mineral vein: it is as commonly called the *under-laying wall.*

FOOT-WAY, *a mining term.* The ladders by which the miners descend and ascend.

FORBESITE. A hydrous arsenate of nickel and cobalt, from the Desert of Atacama, in South America. It has been named after Mr. David Forbes, by whom it was described.

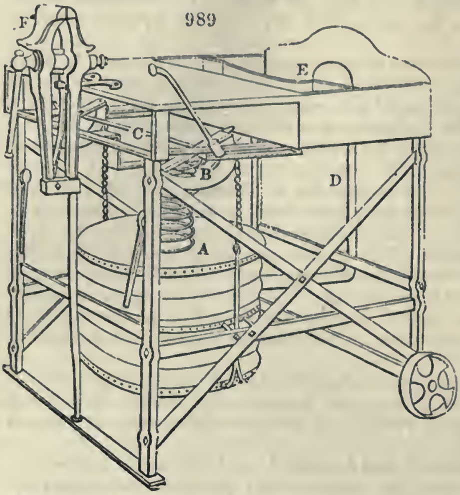
FORBIDDEN FRUIT. The large orange-like fruit of the *Citrus Paradisi* is often sold under this name.

FOREST-BED. The name given by some English geologists to the stratum underlying the glacial drift at Cromer, in Norfolk.

FOREST-MARBLE. An argillaceous laminated shelly limestone, alternating with clays and calcareous sandstones, forming one of the upper portions of the Lower Oolite. In Whichwood Forest, in Oxfordshire, the finer bands are quarried as marble, hence its name.

FORGE (Eng. and Fr.; *Feuer*, Ger.) is the name either of the furnace, where wrought iron is hammered and fashioned with the aid of heat, or the great workshop where iron is made malleable. The former is called a smith's forge, the latter a shingling mill. See IRON.

Fig. 989 represents a portable truck-forge of a very commodious construction. A is the cylindric leather bellows, pressed down by a helical spring, and worked by means of the handle at B, which moves the horizontal shaft C, with its two attached semicircular levers and chains. D is the pipe which conducts the blast to the nozzle at E. The hearth may be covered with a thin fire-tile or with cinders. F is a vice, fixed to the strong rectangular frame. This apparatus answers all the ordinary purposes of a smith's forge; and is peculiarly adapted to ships, and to the execution of engineering jobs upon railways, or in the country. The height is 2 feet 6 inches; the length is 2 feet 9 inches; the width 2 feet; weight about 2 cwts.



989

Holtzapffel describes another portable forge of his own construction, possessing many advantages.

With the manipulations of the forge, it is not the province of this work to deal.

FORK, *a mining term.* A mine is said to be 'in fork,' or an engine to have the 'water in fork,' when all the water is drawn out.

FORMATES. Compounds with formic acid. See Watts's 'Dictionary of Chemistry.'

FORMATION. When employed in a geological sense it signifies a group of rocks, referred to a common origin, or belonging to the same period.

FORMIC ACID. (*Acide formique*, Fr.; *Ameisensäure*, Ger.) The acid which exists in the bodies of ants, associated with malic acid.

Formic acid was obtained artificially, originally by Fisher of Leeds in 1670, and subsequently by Dr. Hulse, by distilling red ants.

It may be prepared by boiling 1 part of starch with 4 of sulphuric acid, and 4 of water, allowing the liquor to cool, and adding gradually 4 parts of the black oxide of manganese, and distilling. For the reactions which take place, see Watts's 'Dictionary of Chemistry.' Its formula is C^2HO^3,HO ($\mathbf{CH^2O^2}$). It is a clear colourless fluid, which crystallises below 32° Fahr., into brilliant plates.

FORMULÆ, CHEMICAL. The term *formula*, in ordinary chemical language, is always understood to mean the collection of symbols indicating a compound substance. Thus, if we allude to the letter or letters indicating an element, we say its *symbol*; but if we are speaking of a compound, we say its *formula*. It appears that some short notice of the principles upon which the construction of chemical formulæ depends is necessary to enable those who are not familiar with chemical language to understand the few formulæ employed in these volumes. For a complete account of the philosophy involved in the construction, consult 'Watts's Dictionary of Chemistry.' The symbols of all the elements will be found under the head 'ATOMIC WEIGHTS.' In constructing formulæ there are several rules to be observed, the neglect of which will lead to misapprehension of the meaning intended to be conveyed. Substances in the most intimate union are expressed by placing the symbols in juxtaposition. Thus oxide of lead is represented by PbO, dry sulphuric acid (sulphuric anhydride) by SO^3, acetic acid by $C^4H^4O^4$. But where a compound is to be expressed which is itself formed by the union of two compounds of the class first mentioned, such as an acid and a base, a comma is placed between them; thus, sulphate of lead is PbO,SO^3, nitrate of copper CuO,NO^5. The number of atoms, when more than one enters into a compound, is expressed by writing the number on the upper part of the right hand of the element. But if only one atom is to be expressed, the mere symbol is written. Thus oxide of copper is CuO, but the suboxide is Cu^2O. If preferred, the number multiplying the atom may be written at the lower right-hand corner of the symbol; Cu_2O, and Cu^2O are identical in meaning. If it be intended to multiply a formula not containing a comma or any other sign, such as SO^3; $C^4H^4O^4$, &c., the number is to be written on the left hand of the formula, and is to be made larger than would be the case if it merely multiplied the atoms of an element. Thus two atoms of oxide of lead are written $2PbO$; three atoms of acetic acid, $3C^4H^4O^4$. But it is to be remembered that a number placed on the left hand of a symbol or formula only multiplies as far as the first comma or sign, so that if we wish to multiply a formula containing a comma or other sign, the formula must be placed between parentheses. Thus two atoms of sulphate of lead are written $2(PbO,SO^3)$. If it be intended to express the fact that one substance is to be added to another, with a view to the production of a given compound or reaction, the substances to be added together are connected by a plus sign. For example, suppose it be necessary to express the fact that one equivalent of oxide of lead added to one equivalent of sulphuric acid produces sulphate of lead, we write, $PbO + SO^3$ forms sulphate of lead. But it is more usual and brief to put down the terms connected by the plus sign followed by the sign of equality, and then the formula of the resulting compound, thus:—$PbO + SO^3 = PbO,SO^3$. A collection of symbols expressing the nature of a reaction or decomposition, the two terms being united by the symbol of equality, is called an equation. Equations are of the highest value to the chemist, as enabling him to express in the simplest possible manner the most complicated reactions. Moreover, these equations enable us to see at a glance the true nature of a decomposition. To take a simple case, namely, that of the decomposition of terchloride of antimony by carbonate of ammonia, we have

$$SbCl^3 + 3(NH^4O,CO^2) = SbO^3 + 3NH^4Cl + 3CO^2.$$

Or, in words, terchloride of antimony plus three equivalents of carbonate of ammonia, yields one equivalent of teroxide of antimony, three of chloride of ammonium, and three of carbonic acid (carbonic anhydride).

The above illustrations will suffice to show the principles upon which formulæ and equations expressive of chemical decompositions are constructed. In writing equations showing the metamorphoses of substances with which it may be supposed the reader of them may not be very fully acquainted, it is proper to place beneath them the names of the substances in full; thus: in writing the change supposed to be experienced by amygdaline under the influence of a ferment which does not itself contribute any substance to the reaction, we might say:—

$$\underbrace{C^{40}H^{27}NO^{22}}_{\substack{\text{Amygdaline}\\\text{oil.}}} + 4HO = \underbrace{C^{14}H^6O^2}_{\substack{\text{Bitter almond}\\\text{oil.}}} + \underbrace{C^2NH}_{\substack{\text{Prussic}\\\text{acid.}}} + \underbrace{2C^{12}H^{12}O^{12}}_{\text{Grape sugar.}}$$

In writing the formulæ of substitution-compounds, it is convenient to place the replaced and replacing substances in a vertical line, so as to indicate at a glance the substitution which has taken place. As an illustration, we shall place side by side the chemical type ammonia and some bodies derived from it by substitution.

$$\underbrace{N\left\{\begin{matrix}H\\H\\H\end{matrix}\right.}_{\text{Ammonia.}} \quad \underbrace{N\left\{\begin{matrix}C^2H^3\\H\\H\end{matrix}\right.}_{\text{Methylamine.}} \quad \underbrace{N\left\{\begin{matrix}C^2H^3\\C^2H^3\\H\end{matrix}\right.}_{\substack{\text{Bimethy-}\\\text{lamine.}}} \quad \underbrace{N\left\{\begin{matrix}C^2H^3\\C^2H^3\\C^2H^3\end{matrix}\right.}_{\substack{\text{Trimethy-}\\\text{lamine.}}} \quad \underbrace{N\left\{\begin{matrix}C^{12}H^5\\H\\H\end{matrix}\right.}_{\text{Aniline.}} \quad \underbrace{N\left\{\begin{matrix}pt\\pt\\H\end{matrix}\right.}_{\substack{\text{Platina-}\\\text{mine.}}} \quad \underbrace{P\left\{\begin{matrix}C^2H^3\\C^2H^3\\C^2H^3\end{matrix}\right.}_{\substack{\text{Triphosphme-}\\\text{thylamine.}}}$$

In the first of the above formulæ we have the type or starting point, ammonia itself. In the next we find one atom of hydrogen (two volumes) replaced by one atom (two volumes) of the radical methyle. In the third we find two atoms of hydrogen replaced; and in the fourth illustration all three have been replaced by methyle. The fifth formula is that of ammonia, in which one atom of hydrogen is replaced by phenyle, forming phenylamine, or, as it is more usually termed, aniline. The sixth illustrates a very peculiar substitution. In it we find two atoms of hydrogen replaced by the *platinicum* of the late illustrious chemist, M. Gerhardt, who regarded platinum as entering into substitutions with two atomic weights, as if it were two metals. The one being the platinum of chemists generally, its atomic weight being 99 (and its symbol Pt); this he calls *platinosum*. The other being *platinicum* (pt), with an atomic weight half that of *platinosum*, namely, 49·5. The last formula is that of the singular base, triphosphmethylamine. In it we see the nitrogen of the original type replaced by phosphorus, and each atom of hydrogen by methyle.

It will greatly assist the student in his endeavours to recollect chemical formulæ, if he commits to memory the principal types and the substances which are regarded as formed on their model. The following are those which are best established:—

Type, two atoms of water.—This type is written in such a manner that the replacement of the hydrogen can be distinctly seen. By its side are placed a few of the substances formed on the same model.

$$\overbrace{O^2\left\{\begin{matrix}H\\H\end{matrix}\right.}^{\substack{\text{Two atoms}\\\text{of water.}}} \quad \overbrace{O^2\left\{\begin{matrix}C^4H^3O^2\\H\end{matrix}\right.}^{\text{Acetic acid.}} \quad \overbrace{O^2\left\{\begin{matrix}C^4H^5\\H\end{matrix}\right.}^{\text{Alcohol.}} \quad \overbrace{C^2\left\{\begin{matrix}C^4H^5\\C^4H^5\end{matrix}\right.}^{\text{Ether.}} \quad \overbrace{O^2\left\{\begin{matrix}K\\H\end{matrix}\right.}^{\substack{\text{Hydrate of}\\\text{potash.}}} \quad \overbrace{O^2\left\{\begin{matrix}K\\K\end{matrix}\right.}^{\substack{\text{Anhydrous}\\\text{potash.}}}$$

In the above simple illustrations of the type water we have, in the case of acetic acid, one atom of hydrogen replaced by the oxidised radical acetyle, $C^4H^3O^2$, and the other by one atom of basic hydrogen. By 'basic' hydrogen is meant, that it acts the part of, and can be replaced by, a metal. The opinions of chemists with regard to the nature of the radical existing in acetic acid are divided. Some consider the acid as the hydrated teroxide of the non-oxidised radical acetyle (C^4H^3), and therefore write its formula $C^4H^3O^3 + HO$. But as the chloride of the oxidised radical can be isolated, we cannot doubt its existence. Moreover, there is no doubt of the existence of the other radical, C^4H^3, because we find it replacing hydrogen in the base acetylamine. See ACETYLAMINE. But the conclusion must be drawn from these facts that there are two radicals, one existing in acetic acid $C^4H^3O^2$, which Williamson calls *othyle*, and another, sometimes called *vinyle* C^4H^3, which exists in aldehyde, in olefiant gas, and several other bodies. The radical in acetic acid is, consequently, not C^4H^3, but $C^4H^3O^2$.

The next illustration is that of alcohol, which consists of two atoms of water, in which one atom of hydrogen is replaced by ethyle, and the other by hydrogen. Ether, on the other hand, is derived from the same type, both atoms of basic hydrogen being replaced by ethyle. Hydrate of potash and anhydrous potash will, after what has been said, explain themselves. It will be seen that in all these illustrations, the same vapour-volume is preserved, and by this means the apparent anomaly of ether and alcohol being of different vapour-volumes is removed. While the type two atoms of water (=4 volumes) has an actual existence, it remains for chemists to discover whether we are justified in receiving as types bodies which have no real existence, such as three atoms of water.

Type, two atoms of hydrogen.—The type ammonia has already been sufficiently illustrated; it remains, then, only to show what substances are to be regarded as formed on the type hydrogen. M. Gerhardt, in addition to these, adopts hydrochloric acid as a type; but when we consider that that acid is itself formed on the hydrogen model, it appears unnecessary to raise it to the dignity of a separate type.

Two atoms of hydrogen.	Olefiant gas.	Marsh gas.	Hydrochloric acid.	Benzole.	Prussic acid.	Chloride of ethyle.
$\overbrace{H}$	$\overbrace{C^4H^3}$	$\overbrace{C^2H^3}$	$\overbrace{Cl}$	$\overbrace{C^{12}H^5}$	$\overbrace{C^2N}$	$\overbrace{C^4H^5}$
H	H	H	H	H	H	Cl

The above will be sufficiently plain after what has been said, it being remembered that C^2H^3 is methyle, C^4H^5 ethyle, $C^{12}H^5$ phenyle, and C^2N cyanogen.

It is a fruitful source of annoyance to students and others to find, on looking through chemical works, the same substance represented by different authors with totally different formulæ. We shall endeavour to give a few instances and such explanations as will assist in enabling the student to overcome the difficulty. It is often the case that the differences in the formulæ arise from the works consulted having been written at different dates; the older one is then, in most cases, to be rejected, because it is probable that the formulæ in it have been corrected by subsequent and more accurate researches. It not unfrequently happens that an author writes nitrous acid NO^4, and the true nitrous acid (NO^3) is called hyponitrous acid. It may serve to assist the student in correcting any errors on this point, to consult a list of the oxides of nitrogen according to the nomenclature at present employed: such a list will be found in the article NITROGEN.

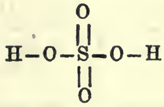
A still more common cause of difficulty is to be found in the different theoretical views of certain chemists regarding the constitution of certain chemical substances. It is explained under the article ATOMIC WEIGHTS that many of the elements have within the last few years had their atomic weights doubled; and this alteration has of course greatly affected chemical formulæ. But even with the same atomic weights, the formula of a given substance may admit of considerable variety of expression, which becomes a source of perplexity to those who are not accustomed to such changes. It may be instructive to show in how many ways the formula of a simple compound like sulphuric acid may be written, according to the different views which may be taken of its constitution. Thus, it may be supposed that this acid is a compound of water (H^2O)[1] and sulphuric anhydride (SO^3); hence the formula of sulphuric acid may be written $H^2O.SO^3$. Another chemist may regard this acid as a compound of a radical (SO^4) with hydrogen; for example, when sulphuric acid is acted upon by zinc, the zinc replaces the hydrogen, which is set free, and zinc sulphate is formed; hence we may formulate sulphuric acid as H^2SO^4. But by the reaction of peroxide of barium and sulphuric acid, peroxide of hydrogen (H^2O^2) is set free; hence there is a reason for writing its formula, $H^2O^2.SO^2$. Yet another mode of expressing

---

[1] It will be convenient for the purposes of this illustration to employ the modern atomic weights, O=16, S=32.

the constitution of this acid is suggested by the system introduced by Dr. Frankland. According to his method, sulphuric acid should be thus formulated: $\mathbf{S}^{vi}O_2Ho_2$. In this expression, sulphur being the element of highest atomicity is placed at the head of the formula, and written in thick black type, whilst its hexatomic character is indicated by the Roman numerals at the upper right-hand side. These six bonds, or units of equivalence, are satisfied partly by the two atoms of diatomic oxygen, and partly by the two atoms of the monatomic radical hydroxyl (HO), which is written by Dr. Frankland Ho. This hydroxyl may be replaced by other radicals; for example, in zinc sulphate the two atoms of monatomic hydroxyl are replaced by one atom of diatomic zincoxyl, and this salt will be represented by the formula: $\mathbf{S}^{vi}O_2Zno^{ii}$.

The modern doctrine of atomicity has also introduced other forms of constitutional formulæ. Thus, many chemists would now express the composition of sulphuric acid in this form:—



$$H-O-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-O-H$$

Such a formula is not intended to indicate the relative positions of the several atoms in the compound, but the lines connecting these atoms are supposed to represent the number of units of equivalency enjoyed by each atom, and the manner in which these bonds of affinity are engaged with those of other atoms. Looking, for example, at the centre of this formula we see that the atom of sulphur has six combining bonds, and how these are engaged with the four atoms of oxygen, each of which has only two such bonds.

Instead of indicating the atomicity in this way, other chemists prefer to enclose each symbol in a circle from which lines diverge to represent the units of equivalence. Professor Kekulé, Dr. Crum Brown, and Dr. Frankland have been foremost among modern chemists in devising these *graphic* formulæ.

For the purposes of lecture-illustration material expressions may be constructed by means of solid balls representing atoms, and rods representing bonds of union. These concrete systems, called *glyptic* formulæ, were introduced by Dr. Hofmann.

For reasons given under the article ATOMIC WEIGHTS, it has been considered desirable to employ generally throughout this Dictionary the old atomic weights, and a system of dualistic formulæ; but for the convenience of those who are familiar with modern formulæ, most of the expressions are also constructed with the modern atomic weights, and these formulæ are printed, for the sake of distinction, in thick black type.

On the modes of determining the empirical and rational formulæ of substances from the results of their analysis.—It now remains to show how the formulæ of bodies are determined. There are two kinds of formulæ—the *empirical* and *rational*. An empirical formula merely indicates the simplest ratio existing between the elements present; a rational formula shows the absolute constitution of an atom or equivalent of any substance. Sometimes the expression rational formula is used in a more extended sense, and then signifies the actual manner in which the elements are arranged in a compound molecule, but this happens so seldom, that we shall in this work understand the term in the sense first given.

An empirical formula can always be deduced from the mere result of an accurate analysis. A rational formula, on the other hand, demands a knowledge of the atomic weight of the substance. The latter datum can be best determined—1st, by the analysis of a compound with a substance the atomic weight of which is well established; 2nd, by determining the density of its vapour.

Empirical formulæ.—The percentage composition of a compound having been accurately found, the empirical formula may be deduced from the following rule:—Divide the percentage of each constituent by its atomic weight, and reduce the number so obtained to its lowest terms. Suppose, for example, the empirical formula of nitric acid to be required, the percentage being:—Nitrogen, 25·9; oxygen, 74·1.

These numbers, divided by their respective atomic weights, give—

$$\frac{25{\cdot}9}{14}=1{\cdot}85.$$

$$\frac{74{\cdot}1}{8}=9{\cdot}26.$$

To reduce these numbers to their lowest terms, it is merely necessary to divide 9·26 by 1·85. The simplest terms being:—Nitrogen, 1·00; oxygen, 5·00. Nitric acid consequently consists of one atom of nitrogen, and five of oxygen.

Rational formulæ.—In the above illustration we found the simplest ratio existing between the elements of nitric acid. But it will be seen that, for aught that appears there, it may consist of *n* times NO^5. It becomes necessary, therefore, to find the atomic weight of the acid, and then to find the number of atoms of the elements (combined in the above ratio), which will make that atomic weight. In order to do this, it will be proper to determine the atomic weight of the acid from the data procured by the first method, given above. In order to accomplish this, a salt was analysed for the percentages of soda and nitric acid, with the annexed result:—Soda, 36·47; nitric acid, 63·53.

The required datum, namely, the atomic weight of the acid can easily be obtained by saying,—*As the percentage of base is to the percentage of acid, so is the atomic weight of the base to the atomic weight of the acid.* In the instance given we have, therefore:—

$$\underbrace{36{\cdot}47}_{\substack{\text{Percentage of}\\ \text{base.}}} \;:\; \underbrace{63{\cdot}53}_{\substack{\text{Percentage of}\\ \text{acid.}}} \;::\; \underbrace{31}_{\substack{\text{Atomic weight of}\\ \text{base.}}} \;:\; \underbrace{53{\cdot}999}_{\substack{\text{Atomic weight of}\\ \text{acid.}}}$$

It is evident that 53·999 may be written 54·0 without any inaccuracy. If, therefore we add together the equivalents of nitrogen and oxygen in the ratio found in the empirical formula, we shall have—

$$\begin{array}{lr} \text{1 equivalent of nitrogen} = & 14 \\ \text{5 equivalents of oxygen} \;\; = & 40 \\ \hline & 54 = \text{the atomic weight of the acid.} \end{array}$$

We will now consider the mode of determining the rational formula of a substance from the results of the analysis and the density of the vapour. Suppose a hydrocarbon to have yielded on analysis:—Carbon, 85·714; Hydrogen, 14·286 (=100):

$$\text{And—} \qquad \frac{85{\cdot}714}{6} = 14{\cdot}286 \qquad \frac{14{\cdot}286}{1} = 14{\cdot}286$$

The quotient being the same, the empirical formula becomes C^nH^n. It remains, therefore, to determine the value of ^{n}. The density of the vapour was found to be 2·9064. Now the hydrocarbons always possess a condensation to four volumes. In the article EQUIVALENTS, CHEMICAL, rules are given for ascertaining the equivalents of substances from the densities of their vapours. For four-volume formulæ the rule is:—Divide the density of the gas by half the density of hydrogen. Applying this rule, we have—

$$\frac{2{\cdot}9064}{{\cdot}0346} = 84{\cdot}00$$

It is therefore necessary to find what multiple of the atomic weight of CH will make 84·00. Now $C + H = 6 + 1 = 7$, and $7 \times 12 = 84$. Consequently, the formula is 12(CH), or as it is always written, $C^{12}H^{12}$.

The above rules will suffice to enable any person to determine the empirical and rational formulæ of substances from the results of analysis.

For further information on the subject of Chemical Formulæ, the reader may consult Watts's 'Dictionary of Chemistry.'

FORMYLE. The hypothetical base of formic acid.

FOSSIL. (*Fossilis*, anything dug from the earth.) Formerly all minerals were called fossils, but the word is now restricted to express the remains of animals and plants found buried in the earth.

FOSSIL IVORY. The bones and tusks of elephants and mammoths are found in eastern Siberia, and along the shores of the Arctic sea in great abundance. The tusks are collected for sale, but are much less valuable than the recent ivory.

FOSSIL PAPER, or *Wood*, or *Flax*, or *Cork*. Terms used to distinguish familiar varieties of Amianthus, according as they resemble one or other of the substances named.

FOUNDING; FOUNDRY. In foundries attached to blast-furnaces where from 20 to 30 tons of iron are made *per diem* the moulds are generally mere troughs cut in the sand, into which the melted metal flows and cools in contact with the air. The surfaces of the castings made in this manner present appearances which vary according to the quality of the iron.

The kinds of iron adapted for founding purposes are those which are most fluid when melted, and which contain most carbon, and are called Nos. 1 and 2. They are distinguished by the surface of the pig of iron, which was exposed to the air during cooling, being smooth, and presenting a slightly convex figure. The surfaces of Nos. 3 and 4 pig-iron, and of the white crystalline pig-iron (most suitable for making into wrought iron) present a concave figure, and the surfaces are very irregular and pitted with holes. The colour of the fracture, and the closeness of the grain, also indicate the proportion of carbon in pig-iron.

The mixtures of metal, melting temperatures of metal, &c., require the closest observation on the part of the workmen and foremen who practise iron-founding, and these mechanics are in the practice of observing differences so minute that they cannot be appreciated by the chemist, or expressed in words.

Machinery has enabled the modern founder, by means of railways, turn-tables, travelling-cranes, and steam-power to move at will the heaviest masses without confusion and with great expedition; but nothing but the traditions of the factory, and the constant habit of observation will enable him to conduct properly the melting and casting of metal so as to arrive at certain results.

This is proved by the constant failures of those who undertake to make descriptions of castings, of which they have had no previous knowledge.

Each branch of foundry work must be studied in detail, and we can only pretend to indicate those directions in which progress has been and is being made.

Foundry.—The process of iron smelting and the construction of furnaces having been described under other heads, the remaining part of the business of a foundry, viz., that which relates to the preparation of the moulds and moulding, will now be described.

Moulding.—The art of moulding is one of the most important processes carried on in a foundry, and the success of the founder is directly proportioned to the skill and ingenuity brought to bear upon the production of the patterns and the system of moulding.

Before metals can be cast into the variety of shapes in which they are wanted, patterns must be prepared of wood or metal, and then moulds constructed of some sufficiently infusible material capable of receiving the fluid metal, and retaining it without uniting with it until it has solidified.

A mixture of sand and loam (packed tightly into metal boxes, called flasks) is generally chosen as the material for making moulds, and is employed advantageously for several important reasons.

Flasks.—In modern foundries a system has been invented, by which flasks of any dimensions may be constructed by means of bolting together a number of rectangular frames of cast iron, so arranged as to admit of being easily connected together.

When the particular castings for which the flask has been constructed, or rather compounded, are completed, the separate pieces are unbolted, and are ready to be combined in some new form appropriate to the dimensions of the pattern next to be moulded in them.

The loss of capital, &c., invested in flasks, only occasionally used, is thus saved, as well as loss of time in searching for the size required. The space devoted, on the old system, to the reception of flasks belonging to a foundry was very large, and this may now be appropriated to other purposes.

Sand and loam.—Founders formerly used, on account of price, the description of sand most accessible to them, but at the present time, the convenience and cheapness of railway carriage has enabled special qualities of sand to be delivered to all parts of England.

For founding purposes sand is much improved by the admixture of coke, crushed and reduced to a fine powder, and a mill for this purpose is as necessary in every large foundry as those for grinding and mixing loam.

Moulding-sand must be a mixture of a large quantity of silex and a small quantity of alumina—the property of the latter material being to cement the grains of silex together. Loam consists of the same materials mingled in opposite proportions.

The preparation of loam for those purposes for which sand is not adapted, is an important duty in a foundry, for a great quantity of loam cores have to be made and dried in proper ovens, which is a tedious operation.

Many castings, such as the screws for steamers, are more conveniently cast in moulds constructed of wet loam. These are shaped to the required form when the clay is moist, and then carefully dried afterwards.

Other castings are of such peculiar shapes that they can only be produced in moulds that take in a vast number of pieces. These moulds are then formed of a number of pieces of hardened sand, held together by strips of iron or of plaster, if the sand used is not coherent enough in itself.

Compounds of silex and alumina are very infusible, and when moistened with water and faced with carbonaceous matter, they are capable of receiving the most delicate impressions from the patterns which the founder employs.

Grains of sand are so irregular in shape themselves that they leave innumerable irregular spaces between them, and these intervals form a network of channels which permit the rapid escape of the gases, which are so violently generated by the contact of hot metal falling upon wet sand.

Machine Castings.—Every year, engineers order castings to be prepared of more difficult and complicated forms, and with greater perfection of surface than they have required before.

The reason of this is, that with the progress of the mechanical arts larger and stronger machines are continually being introduced. In these machines greater steadiness of cast-iron framework is necessary than can conveniently be obtained when the frame is made out of a number of pieces of iron cast separately and then bolted together. It would be impossible to mould large frames with pieces projecting on all sides (prepared to receive the moving parts of the machines), and jutting out in contrary directions, in any flasks filled with wet sand, for the pattern never could be removed without destroying the impression. To meet these difficulties, the modern ironfounder has had to follow those plans which were first proved practicable to those who have devoted themselves to casting bronze statues. In founding, as in so many other branches of manufacture, the discoveries made in prosecuting the fine arts have been advantageously adopted by those engaged in works of utility.

False Cores.—The introduction of the drawbacks, or false cores, made of sand pressed hard (and admitting of taking to pieces by joints, at each of which a layer of parting sand is prepared), using for figure casting, enables the moulder to work at his leisure, without fearing that his mould may tumble to pieces, and also enables him to fashion these drawbacks or cores into the most complicated forms, with the power to remove them while the pattern is removed, and build them up again round the empty space (formerly occupied by the pattern) with the greatest facility and accuracy.

The workmen, whose occupation is to knead the sand into the forms required by the founder, are termed moulders, and they form a very numerous body of mechanics, demanding and receiving high wages.

The moulder has often only his sand, his flasks, cranes, and a few simple tools (for smoothing rough places, and for repairing the places in the sand where the mould has broken away during the lifting of the pattern); he has to make proper arrangements for the exit of the atmospheric air which leaves the mould as the fluid metal takes its place; and he is expected to produce an exact copy in metal from any pattern, simple or complicated which may be brought before him.

It will be evident that to produce a good result with such imperfect appliances as the ordinary moulder uses, a skilful workman must be employed, and time expended in proportion the difficulty of the operations to be performed.

Where only a few impressions from a model are required, it is not worth while to spend money in making expensive patterns, or providing those appliances which may enable patterns to be moulded with facility and little skill; but where thousands of castings are wanted of one shape, it is expedient to spend money and skill on patterns and tools, and reduce the work of the moulder to its minimum.

Management.—The best managed foundry is not that in which good castings are obtained by the employment of skilled workmen at a great expense, and without trouble or thought on the part of the principal, but rather that in which the patterns have been constructed with a special reference to their being cast with the minimum of skill and the maximum of accuracy. It is only by the forethought and calculation of the manager that subsequent operations can be reduced to their smallest cost: and in the foundry, as in all other manufactories, the true principles of economy are only practised where the head-work of one person saves the manual labour of a large number.

Improvements.—The attention of founders has been turned—1st, to the methods by which the labour of making moulds in sand might be reduced; 2nd, to the introduction of improvements in the mode of constructing patterns and moulds; and 3rd, to the manufacture of metallic moulds for those purposes for which they could be applied. A great progress has been made during the last twenty years in these different directions.

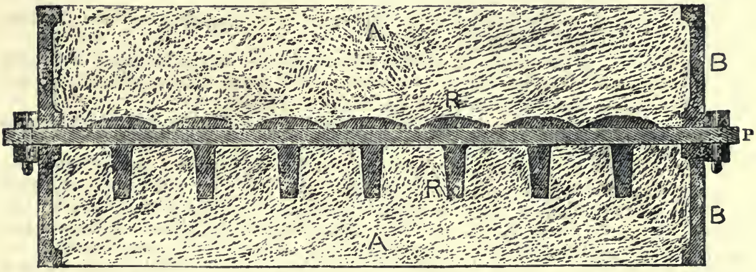
Machine Moulding.—In the large industry carried on for the production of cast-iron pipes for the conveyance of water and gas, machinery has been applied so that the operation of pipe-moulding is performed almost without manual labour, with great rapidity and precision. The cost of pipes at the present time is only about 2*l.* per ton above the value of pig-iron, out of which they are made; a sum very small when it is considered that the iron has to be re-melted, an operation involving both a cost of fuel and a loss of 5 to 20 per cent. of the iron in the cupola. An ingenious machine for moulding in sand, spur and bevel wheels of any pitch or diameter has been employed in Lancashire; the advantage being that the machine moulding tool acts directly upon the sand without the intervention of any pattern or mould. In any large foundry there is an enormous accumulation of costly wheel-patterns, taking up a great deal of space, and these can now be dispensed with by substituting the wheel moulding-machine. Railway chairs are moulded in a machine; and ploughshares, which although only weighing a few pounds each, are sold at the low rate of 8*l.* a ton, are moulded in a machine.

Plate Casting.—Under the next class of improvements the introduction of plate-casting has been the most fruitful of good results.

One great source of expense and trouble in a foundry is the injury done to patterns and to their impressions in the sand by the necessity, under the ordinary system of moulding, of striking the pattern, or pushing it first in one direction and then in another in order to loosen it. Now, the object of the machinist is to construct all his spindles, bearings, bolts, and wheels, of specified sizes, and then to cast the framing of his machine so accurately that the working parts may fit into the frame without any manual labour. In order to effect this, every projection and every aperture in the casting must be at an exact distance, and this can only be attained by employing such a system as that of plate-casting, where the pattern is attached firmly to a plate, and it is impossible for the moulder to distort or injure the impression. Plate-casting has been long known, but was practically confined for many years to the production of small articles, such as cast nails and rivets.

In a plate-mould for rivet-casting, the shafts of the rivets are attached to one side of the plate, which is ¾-in. thick, and planed on both sides. The heads of the rivets are on the opposite side of the plate. The guides on the upper and lower flask admit the plate to fit between them, and when the plate is withdrawn the upper and lower flasks close perfectly, and are in all respects like ordinary moulders' flasks. The principle of moulding is very simple, and can be performed without skilled labour ten times as fast as ordinary moulding, and with far greater accuracy. The plate is inserted between the upper and lower flasks, and sand is filled in; the plate is then withdrawn by simply lifting it; the guides prevent any shaking in this operation; when the flasks are closed, the impression of the head of each rivet is exactly perpendicular to its shaft. The first expense of patterns and plates of this description is large, but the accuracy and rapidity of the process of moulding is so advantageous as to cause us to look to the applications of plate-castings becoming very extensive, since the requirements of the machine-maker demand every year better castings at lower prices.

990



A, sand. B B, flask. R R, rivet pattern. P, plate.

When both sides of a pattern are symmetrical one-half only need be attached to the smooth plate, the other face of the plate being left blank. An impression of the pattern must be taken off both in the upper and lower flask, and when these are united the result will be the same as if both sides of the plate had been moulded from. For unsymmetrical patterns both sides of the plate must be employed. The system of using plates with apertures in them, through which patterns could be pushed and withdrawn by means of a lever, was first employed in casting brass nails. A modification of this system has been extensively employed at Woolwich for moulding shot and shells, in the following manner:—

Shell Casting.—A circular aperture is made in a horizontal planed plate of iron, two inches thick. Through this a sphere of iron, of the same diameter as the aperture, is pushed until exactly a hemisphere appears above the plate. The lower flask is put on to the plate, and sand filled in; the lever being relieved, the sphere falls by its own weight; the lower flask is removed, and the upper flask put on the plate; the sphere is pushed through the plate as before, and sand filled in, with great rapidity and accuracy.

The sand cores for filling up that part of the shell which is to be hollow are also carefully and quickly made at Woolwich. The halves of the core-mould, open and shut with a lever, so that the bad plan of striking the core-mould is avoided as completely as the bad plan of striking the pattern is in the process of moulding shot and shell.

Theory of Casting.—Before leaving the subject of the use of sand-moulds, we may remark that iron and brass castings with a perfect surface can only be produced when the mould is well dried and heated, so as to drive out any moisture from the apertures between the grains of sand. By this means channels are opened for the rapid escape of the heated air and gas expelled by the entrance of the fluid metal into the mould, and the surface of the metal is not cooled by its contact with damp or cold sand. It is also well to mix charcoal-dust, or coke-dust, with the sand; and for fine castings to cover the surface of the sand with a coating of charcoal-dust. The object of this proceeding is to reduce the oxide which may be present in the metal. This operation of reducing the oxide of a metal instantaneously is performed with the greatest certainty by this simple means, invented, probably, by the earliest metallurgists. By incorporating a quantity of charcoal- or coke-dust with the sand, or facing the sand with carbonaceous matter, any oxide of the metal which may be floating amongst the pure metal is at once reduced. Sand (being a non-conductor) does not abstract the heat from the fluid metal rapidly, and, therefore, solidification of the metal takes place comparatively regularly and equally throughout the mass; when one part of the casting solidifies before the adjoining part, flaws often occur, and to avoid these the skill of the practical founder is necessary in arranging for the entrance of the metal at the proper point, and for the exit of the air.

We next proceed to the third class of improvements in moulding, that of the extension of the application of metallic moulds.

Metal Moulds.—The practice of casting bronze weapons in moulds made of bronze (blackened over on their surface to prevent the fluid metal uniting with the mould) appears to have been a very general one among the ancients.

Some moulds of this description have been discovered amongst the prehistoric remains disinterred in different parts of Europe.

The facility for the escape of the heated air and gases from the sand-moulds into which liquid metal is poured, is so much greater than that from moulds of metal, that at the present time neither brass nor iron is poured into metallic moulds, except when a particular purpose is to be attained, viz., that of chilling the surface of the iron and making it as hard as steel. Iron cannot be chilled or hardened in a sand-mould.

Chilled Iron.—This process of casting in metal moulds was once supposed to be a modern invention; but it now appears, from the metal moulds discovered among the remains of the Celtic race throughout Europe, that the bronze weapons of the people who preceded the Romans were generally cast in metallic moulds, and not in sand. Chilled castings have been brought to great perfection by Messrs. Ransome, of Ipswich. Their chilled ploughshares and chilled railway chairs are cast in moulds of such a construction that the melted iron comes in contact with iron in those parts of the moulds where it is wanted to be chilled. A section of the casting shows the effect of chilling.

Zinc.—In casting zinc (a cheap and abundant metal), which fuses at a low temperature, metallic moulds may be most advantageously used. It is, however, necessary to heat the iron or brass mould nearly to the temperature of melting zinc, in order that the rapid abstraction of heat from the fluid metal may be prevented. The preparation of metal moulds, and the casting soft metal in them is now an extensive and important industry on the Continent, for ornamental zinc castings have suddenly come into extensive use in consequence of the discovery of the electrotyping process. When covered with a thin coating of brass or copper by a galvanic battery, zinc may be bronzed so as to present almost the exact external appearances of real bronze at a tenth of the cost.

When metal moulds are used their first cost is very great, as they must be made in numerous separate pieces so as to liberate the castings. The joints and ornaments have to be chased and accurately fitted at a great expense. Their use, however, requires no skill in the workman, and the rapidity with which the zinc is cast, the mould taken to pieces, and the casting removed, renders the operation a very rapid and economical one.

Such is a general view of the practice of founding. The details, however, which are contained in the original article in the earlier editions of this Dictionary appear so valuable that that article is retained in addition to the above.

The essential parts of a well-mounted iron foundry, are,

1. Magazines for pig irons of different qualities, which are to be mixed in certain

proportions, for producing castings of peculiar qualities; as also for coal, coke, sands, clay, powdered charcoal, and cow-hair for giving tenacity to the loam mouldings.

2. One or more coke ovens.

3. A workshop for preparing the patterns and materials of the moulds. It should contain small edge millstones for grinding and mixing the loam, and another mill for grinding coal and charcoal.

4. A vast area, called properly the foundry, in which the moulds are made and filled with the melted metal. These moulds are in general very heavy, consisting of two parts at least, which must be separated, turned upside down several times, and replaced very exactly upon one another. The casting is generally effected by means of large ladles or pots, in which the melted iron is transported from the cupola where it is fused. Hence the foundry ought to be provided with cranes, having jibs moveable in every direction.

5. A stove in which such moulds may be readily introduced, as require to be entirely deprived of humidity, and where a strong heat may be uniformly maintained.

6. Both blast and air furnaces, capable of melting speedily the quantity of cast-iron to be employed each day.

7. A blowing machine to urge the fusion in the furnaces.

Fig. 991, represents the general plan of a well-mounted foundry.

a, is a cupola furnace; it is capable of containing 5 tons of cast iron.

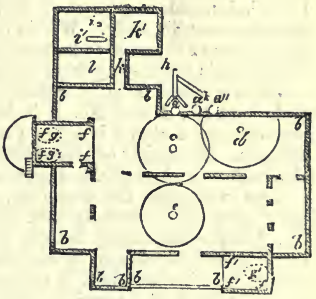
a′, is a similar furnace, but of smaller dimensions, for bringing down $1\frac{3}{4}$ ton.

a″, is a furnace like the first, in reserve for great castings.

b b b b, a vast foundry apartment, whose floor to a yard in depth, is formed of sand and charcoal powder, which have already been used for castings, and are ready for heaping up into a substratum, or to be scooped out when depth is wanted for the moulds. There are besides several cylindrical pits, from 5 to 7 yards in depth, placed near the furnaces. They are lined with brick-work, and are usually left full of moulding sand. They are emptied in order to receive large moulds, care being had that their top is always below the orifice from which the melted metal is tapped.

These moulds, and the ladles full of melted metal are lifted and transported by the arms of one or more men, when their weight is moderate; but if it be considerable, they are moved about by cranes, whose vertical shafts are placed at *c*, *d*, *e*, in correspondence, so that they may upon occasion transfer the load from one to another. Each crane is composed principally of an upright shaft, embraced at top by a collet, and turning below upon a pivot in a step; next of a horizontal beam, stretched out from nearly the top of the former, with an oblique stay running downwards, like that of a gallows. The horizontal beam supports a moveable carriage, to which the tackle is suspended for raising the weights. This carriage is made to glide backwards or forwards along the beam by means of a simple rack-and-pinion mechanism, whose long handle descends within reach of the workman's hand.

991



By these arrangements in the play of the three cranes, masses weighing 5 tons may be transported and laid down with the greatest precision upon any point whatever in the interior of the three circles traced upon *fig.* 991, with the points *c*, *d*, *e*, as centres.

c, *d*, *e*, are the steps, upon which the upright shafts of the three cranes rest and turn. Each shaft is 16 feet high.

f f, is the drying stove, having its floor upon a level with that of the foundry.

f′ f′, is a supplementary stove for small articles.

g g g′, are the coking ovens.

h is the blowing machine or fan.

i, is the steam-engine, for driving the fan, the loam-edge stones,

k, and the charcoal mill.

i′, are the boiler and the furnace of the engine.

k′, workshop for preparing the loam and other materials of moulding.

l, is the apartment for the patterns.

The pig-iron, coals, &c., are placed either under sheds or in the open air, round the above buildings; where are also a smith's forge, a carpenter's shop, and an apartment mounted with vices for chipping and rough cleaning the castings by chisels and files.

Such a foundry may be erected upon a square surface of about 80 yards on each side, and will be capable, by casting in the afternoon and evening of each day, partly in large and partly in small pieces, of turning out from 700 to 800 tons per annum, with an establishment of 100 operatives, including some moulding boys.

Of making the Moulds.—1. Each mould ought to present the exact form of its object.

2. It should have such solidity that the melted metal may be poured into it, and fill it entirely without altering its shape in any point.

3. The air which occupies the vacant spaces in it, as well as the carburetted gases generated by the heat, must have a ready vent; for if they are but partially confined, they expand by the heat, and may crack, even blow up the moulds, or at any rate become dispersed through the metal, making it vesicular and unsound.

There are three distinct methods of making the moulds:—

1. In green sand; 2. In baked sand; 3. In loam.

To enumerate the different means employed to make every sort of mould exceeds the limits prescribed to this work. We shall merely indicate for each species of moulding, what is common to all the operations; and then describe the fabrication of a few such moulds as appear most proper to give general views of this peculiar art.

Moulding in green sand.—The name green is given to a mixture of the sand as it comes from its native bed, with about one twelfth its bulk of coal reduced to powder, and damped in such a manner as to form a porous compound, capable of preserving the forms of the objects impressed upon it. This sand ought to be slightly argillaceous, with particles not exceeding a pin's head in size. When this mixture has once served for a mould, and been filled with metal, it cannot be employed again except for the coarsest castings, and is generally used for filling up the bottoms of fresh moulds.

For moulding any piece in green sand, an exact pattern of the object must be prepared in wood or metal; the latter being preferable, as not liable to warping, swelling, or shrinkage.

A couple of iron frames form a case or box, which serves as an envelope to the mould. Such boxes constitute an essential and very expensive part of the furniture of a foundry. It is a rectangular frame, without bottom or lid, whose two largest sides are united by a series of cross bars, parallel to each other, and placed from 6 to 8 inches apart.

The two halves of the box carry ears corresponding exactly with one another; of which one set is pierced with holes, but the other has points which enter truly into these holes, and may be made fast in them by cross pins or wedges, so that the pair becomes one solid body. Within this frame there is abundance of room for containing the pattern of the piece to be moulded with its encasing sand, which being rammed into the frame, is retained by friction against the lateral faces and cross bars of the mould.

When a mould is to be formed, a box of suitable dimensions is taken asunder, and each half, No. 1 and No. 2, is laid upon the floor of the foundry. Green sand is thrown with a shovel into No. 1 so as to fill it; when it is gently pressed in with a rammer. The object of this operation is to form a plane surface upon which to lay in the pattern with a slight degree of pressure, varying with its shape. No. 1 being covered with sand, the frame No. 2 is laid upon it, so as to form the box. No. 2 being now filled carefully with the green sand, the box is inverted, so as to place No. 1 uppermost, which is then detached and lifted off in a truly vertical position; carrying with it the body of sand formed at the commencement of the operation. The pattern remains imbedded in the sand of No. 2, which has been exactly moulded upon a great portion of its surface. The moulder condenses the sand in the parts nearest to the pattern, by sprinkling a little water upon it, and trimming the ill-shaped parts with small iron trowels of different kinds. He then dusts a little well-dried finely-sifted sand over all the visible surface of the pattern, and of the sand surrounding it; this is done to prevent adhesion when he replaces the frame No. 1.

He next destroys the preparatory smooth bed or area formed in this frame, covers the pattern with green sand, replaces the frame 1 upon 2 to reproduce the box, and proceeds to fill and ram No. 1, as he had previously done No. 2. The object of this operation is to obtain very exactly a concavity in the frame No. 1, having the shape of the part of the model impressed coarsely upon the surface formed at the beginning, and which was meant merely to support the pattern and the sand sprinkled over it, till it got imbedded in No. 2.

The two frames in their last position, along with their sand, may be compared to a box of which No. 1 is the lid, and whose interior is adjusted exactly upon the enclosed pattern.

If we open this box, and after taking out the pattern, close its two halves again, then pour in melted metal till it fill every void space, and become solid, we shall obviously attain the wished-for end, and produce a piece of cast iron similar to the pattern. But many precautions must still be taken before we can hit this point. We must first lead through the mass of sand in the frame No. 1, one or more channels for the introduction of the melted metal; and though one may suffice for this purpose, another must be made for letting the air escape. The metal is run in by several orifices at once, when the piece has considerable surface, but little thickness, so that it may reach the remotest points sufficiently hot and liquid.

The parts of the mould near the pattern must likewise be pierced with small holes. by means of wires traversing the whole body of the sand, in order to render the mould more porous, and to facilitate the escape of the air and the gases. Then, before lifting off the frame No. 1, we must tap the pattern slightly, otherwise the sand enclosing it would stick to it in several points, and the operation would not succeed. These gentle jolts are given by means of one or more pieces of iron wire which have been screwed vertically into the pattern before finally ramming the sand into the frame No. 1, or which enter merely into holes in the pattern. These pieces are sufficiently long to pass out through the sand when the box is filled; and it is upon their upper ends that the horizontal blows of the hammer are given; their force being regulated by the weight and magnitude of the pattern. These rods are then removed by drawing them straight out; after which the frame No. 1 may be lifted off smoothly from the pattern.

The pattern itself is taken out, by lifting it in all its parts at once, by means of screw pins adjusted at the moment. This manœuvre is executed, for large pieces, almost always by several men, who while they lift the pattern with one hand, strike it with the other with small repeated blows to detach the sand entirely, in which it is generally more engaged than it was in that of the frame No. 1. But in spite of all these precautions, there are always some degradations in one or other of the two parts of the mould: which are immediately repaired by the workman with damp sand, which he applies and presses gently with his trowel, so as to restore the injured forms.

Hitherto it has been supposed that all the sand rammed into the box is of one kind, but from economy, the green sand is used only to form the portion of the mould next the pattern, in a stratum of about an inch thick; the rest of the surrounding space is filled with the sand of the floor which has been used in former castings. The interior layer round the pattern is called in this case, *new sand.*

It may happen that the pattern is too complex to be taken out without damaging the mould, by two frames alone; then three or more are mutually adjusted to form the box.

When the mould, taken asunder into two or more parts, has been properly repaired. its interior surface must be dusted over with wood charcoal reduced to a very fine powder, and tied up in a small linen bag, which is shaken by hand. The charcoal is thus sifted at the moment of application, and sticks to the whole surface which has been previously damped a little. It is afterwards polished with a fine trowel. Sometimes, in order to avoid using too much charcoal, the surfaces are finally dusted over with sand, very finely pulverised, from a bag like the charcoal. The two frames are now replaced with great exactness, made fast together by the ears, with wedged bolts laid truly level, or at the requisite slope, and loaded with considerable weights. When the casting is large, the charcoal dusting, as well as that of fine sand, is suppressed. Everything is now ready for the introduction of the fused metal.

Moulding in baked or used sand.—The mechanical part of this process is the same as that of the preceding. But when the castings are large, and especially if they are tall, hydrostatic pressure of the melted metal upon the sides of the mould cannot be counteracted by the force of cohesion which the sand acquires by ramming. We must in that case adapt to each of these frames a solid side, pierced with numerous small holes to give issue to the gases. This does not form one body with the rest of the frame, but is attached extemporaneously to it by bars and wedged bolts. In general no ground coal is mixed with this sand. Whenever the mould is finished, it is transferred to the drying stove, where it may remain from twelve to twenty-four hours, at most, till it be deprived of all its humidity. The sand is then said to be baked, or annealed. The experienced moulder knows how to mix the different sands placed at his disposal, so that the mass of the mould as it comes out of the stove, may preserve its form, and be sufficiently porous. Such moulds allow the gases to pass through them much more readily than those made of *green* sand; and in general the cattings they turn out are less vesicular, and smoother upon the surface. Sometimes in a large piece, the three kinds of moulding, that in green sand, in baked sand, and in loam, are combined to produce the best result.

Moulding in loam.—This kind of work is executed from drawings of the pieces to be moulded, without being at the expense of making patterns. The mould is formed of a pasty mixture of clay, water, sand, and cows'-hair, or other cheap filamentous matter, kneaded together in what is called the loam mill. The proportions of the ingredients are varied to suit the nature of the casting. When the paste requires to be made very light, horse-dung or chopped straw is added to it.
