weeded, top-dressed, and pegged out shoots of frame Cucumbers, also of Vegetable Marrows and Ridge Cucumbers. Cut off large foliage that shaded the fruit of Tomatoes and thinned out the fruit, the deformed and smallest fruit being selected for removal. The trees in early and second Peach houses having had all their wood thinned out and secured to trellis, the hose was applied with the double intent of washing off spider, of which there is a little, and of watering the inside borders, which we have now mulched with clean straw, partly for appearance' sake, but more especially with the intent to keep the borders moist and prevent cracking open of the soil, which occurs as soon as it gets dry on the surface, and of course destroys many of the most valuable roots. Laterals on Vines in late houses we pinch or stop back once a week—black Grapes not quite so severely as white varieties, which require plenty of sunlight to colour them up well. Put in cuttings of variegated Panicum, a plant we find most useful for basket and vase decoration to droop over the edges, as well as for use as a setting for large flowering plants, Isolepis gracilis and the common Lycopodium being valuable for the like uses. Tuberous Begonias, Gloxinias, Celosias, and Fuchsias being now at their best we keep cool, and shade them thickly to preserve their beauty as long as possible. Put in first cuttings of Pelargoniums on open borders, Abutilons and Fuchsias in frames. Re-arranged fruiting Pine stove, the plants having fruit approaching the ripening stage being stood under the shade of Vines to retard it, and the pit is again filled up with fruiters that are just out of flower. Potted a few suckers, and plunged them after renewal of leaves, which we use for bottom heat, in a well heated pit, which will be kept close and moist till the roots have formed in the new soil. Flower garden work has been much the same as that of last week—pinching, tying, clipping edges, mowing, in fact, whatever tends to neatness of appearance, a thing which we do so far as means allow. As to variety of flowers and styles of flower gardening, our ideas are progressive, for, besides having a goodly assortment of what are termed old-fashioned flowers, herbaceous plants, Lilies, &c., we have annuals and biennials—such as Stocks, Scabious, Candytufts, Sweet Peas, and Roses in abundance—sub-tropicals, and what is termed carpet bedding—a term we repudiate, simply because we have none of it, as not one of our designs is flat, which necessarily must be the case for the term carpet to be applicable. Picking off bad flowers and seed vessels to keep the various plants in good flower, and tying tall plants securely to stakes are matters of daily occurrence. Single Dahlias are now in splendid flower, and perhaps there is no flower that more quickly shows signs of exhaustion, or rather stops flowering, if allowed to seed; hence it is of the utmost importance that as soon as the flowers fall the seed-pods should be picked off. Violas, Calceolarias, and Verbenas are very nearly allied to Dahlias in this particular and continuous flowering can only be assured by picking them over as frequently as Dahlias. Sowed Brompton, East Lothian, and Queen Stocks at the foot of a south wall, in which position they are intended to winter. Hants.

FRUITS UNDER GLASS.

Pines.

The forward batch of Queens intended for early fruiting, having filled their pots with roots, will now require more light and air to mature their growth before the short days set in. Where space is limited these plants are not unfrequently plunged too close through the early part of the summer, and require a general turn over about this time, when a selection of the most promising is made, but this is the only advantage gained, as the best growers agree that the most satisfactory results follow plunging newly-potted plants where they can remain until the fruit is ripe. It sometimes happens that the beds heat themselves dry or sink too low, when the roots receive a premature check or the foliage becomes drawn. To steer clear of these evils it becomes necessary to renovate the beds and re-plunge rather loosely in a bottom heat, which should not exceed 80° to 85° about the crock roots and rather less near the surface, or, better still, the old beds may be levelled and well watered to revive the heat, when the plants can be re-arranged on the surface and loosely packed with fresh leaves to keep them steady and draw the heat upwards. Treated in this way danger of over-heating is avoided, and yet the gentle increase will favour, giving moderate supplies of diluted liquid or guano water when the roots require it. As autumn draws on and a steady bottom heat becomes absolutely necessary more dry leaves or tan, as the case may be, must be added and made firm to reduce the necessity for giving water, and to prevent the temperature from falling much below 80°. These remarks apply specially to Queens, whose tender roots are often injured by being rested in too low a medium, when the plants throw up deformed fruits, but Rothschilds and Cayennes, which are hardier, will bear a matter of 5° to 10° less, provided they are kept steady and not overdone with water. Where Pines in various stages are swelling and ripening it is a good plan to lift the most forward out bodily and place them in a dry vinery or warm Grape room to ripen. Those left behind can then receive their proper treatment, and the house can be shut up with the full complement of solar heat and atmospheric moisture.

Successions.—By this time all potting should be brought to a close, and the plants placed where they are to remain for the winter. The nearer the glass and the less fire-heat for the present, the better; shading likewise, unless to newly potted plants in light airy pits, should also be discontinued. There is, of course, no rule without an exception; but shading and crowding should always be the exception, as succulent plants like Pines, no matter what their age, always winter best when the foliage is broad, flat, and firm, and the roots are kept steadily progressing in a mild tropical bottom-heat. If stock of any particular variety is likely to run short, a few suckers may still be taken off and potted; but unless they are very strong and a snug pit with a sharp bottom-heat is at command, little, if any, time will be lost by allowing them to remain on the old stools through the winter.

Figs.

The second crop having been gathered from early forced trees, a season of rest must now be secured to them, either by running off the roof lights to their fullest extremities, or placing pot trees, which do not require potting, in the open air. The Fig being so thoroughly at home in a high temperature, exposure through the month of September will be quite sufficient, when the lights, having been painted, may be returned to the roof to protect the points from autumn frosts. Thorough cleansing, it is hardly necessary to say, should be the first consideration after the fruit is gathered, the *modus operandi* depending entirely upon the kind or kinds of insects with which the trees are infested. Spider, scale, and bug, one or all, make rapid progress in the high and dry temperature of the Fig house, and the best time to dislodge them is during the season of rest. Spider can be destroyed by pure water or soapsuds applied with great force through the syringe or garden engine. Brown scale melts away under hot water plied at a temperature of 100° to 120°, and the trees take no harm, always provided they are well syringed immediately with water some 30° to 40° lower. Bug, on the other hand, although it may be checked, cannot be entirely destroyed with water, hot or cold, but by adding a wineglassful of paraffin to four gallons of water, and keeping the latter well agitated with a second syringe to prevent the oil from floating, an occasional syringing will keep the trees clean until the time arrives for applying the tar dressing.

Pruning.—Forced Figs, like forced Peaches, hould be pruned and thinned as soon as the crop is off, as there is then less danger of bleeding, and the shoots retained have full exposure to the influence of light and air. Moreover, old shoots pruned back at this season push forward latent buds which break into growth when the trees are started, and produce a second crop of fruit in the autumn. The principal point in pruning is the removal of all weak, straggling, and blind shoots, and the retention of short spur-like points well furnished with leaves, from the base of which the first crop of fruit, as yet barely perceptible, will spring. If half swelled fruits were rubbed off as soon as it became evident they could not ripen, embryo Figs will have formed in the axils of many of the leaves, and the removal of the remainder, everything in fact larger than a small pea, will enable the trees to expend their declining force upon them. It often happens that we see trees carrying a quantity of green Figs through the autumn and winter, but this is bad culture, as they never stand to ripen, while their retention robs the trees and prevents useful fruits from forming.

Succession houses in which the second crop is ripening will require more air and drier treatment, aided by gentle fire-heat to ensure high flavour and to prevent the fruit from spotting. The finer and better the fruit the more is it liable to suffer in a damp, stagnant atmosphere, and as moisture in the form of diluted liquid must be supplied to the roots, the only preventives are plenty of dry mulching, liberal ventilation, and fire-heat to keep the air in motion. To have a steady supply of good Figs, three houses should be at command; the first, which ripens its fruit in April and May, will then ripen its second crop immediately after the first is gathered from the second, and as these trees should be perpetual bearers they will keep up the supply until the autumn house comes in. Late houses and cases, it should be borne in mind, do not produce more than one flush of fruit. These, therefore, should be kept thin of wood, and all half-grown Figs which cannot ripen should be broken off, as they are worse than useless. When late Figs begin to ripen in cold houses, and the trees, as they should be, are clean, syringing must be discontinued, but root moisture being necessary, a copious supply of liquid given on a fine morning and well mulched in with dry litter, will keep them safe over a long period.

Peaches.

I stated some time ago that the best time to commence cultivating the next crop is immediately after the last fruit of the current year has been picked from the tree. The remarks upon the management of the early house which then followed also apply to the second and third in almost every particular, the only difference, as the season advances, being more dry heat with a brisk circulation of air through the day, followed by early closing with solar heat on fine evenings. If the trees in early houses are quite satisfactory and can be depended upon another year, the removal of old mulching and sour surface soil is a light, but important, operation which cannot be undertaken too soon, as every day gained after the buds are well formed means a stronger roothold on the new top-dressing. Having worked off the inert soil quite down to the roots and thoroughly watered the trees, I give them a liberal sprinkling of bone dust and apply fresh compost, consisting of any calcareous loam and old lime rubble, minus animal manure. This is rammed or beaten as firm as the backs of steel forks can make it, and a thin covering of fresh stable litter completes the operation. Trees, on the other hand, which show the slightest tendency to grossness are kept in condition by annual root-lifting and slight shortening when the points are relaid in fresh compost. Although fruit trees of all kinds so readily respond to root-pruning and relaying in pure loam, a great number of would-be fruit growers look upon the slightest disturbance as sacrilege, and defer the operation until their trees become gross or unhealthy; they then lift or root-prune with a vengeance, when they require at least one year to recuperate and make fresh fruit-bearing shoots. Once bitten, twice shy; they condemn the system instead of

themselves, gather one or two good crops, and again drift into an unsatisfactory condition. To this class of spasmodic cultivators I say keep the roots entirely under control by checking them every year, and do it in this way: If the tree has not been root-pruned for several years, throw out a semi-circular trench 6 feet to 9 feet from the bole, more or less, according to its size; clear it out down to the drainage, save all the roots, and work steadily inwards until the deepest show signs of rising to the surface. Keep the roots as well as the foliage moist, as the work must be performed while they are in full leaf; make good the drainage, put in a good stratum of new compost, and having cut away all cankered roots and shortened the strongest, commence relaying. Cover each set of roots with a thin layer of soil, make it firm, and proceed in this way until the last set rests just beneath the surface, a firm resisting bed as solid as the undisturbed ball, which may be from 3 feet to 6 feet in diameter, being imperative. Flood the trench with tepid water —the best of all rammers—and leave it for twenty-four hours to settle. When the water has passed downwards, put in the rest of the compost, prick over the undisturbed part of the ball with a steel fork, top-dress and mulch with stable litter. Keep the house rather close, syringe two or three times a day, and shade from bright sun if the foliage shows signs of suffering. If early-forced trees are treated in this way, say in August, they will commence making new roots and pushing laterals within a fortnight, when a gradual return to ordinary treatment will become necessary. The leaves, it is just possible, will fall earlier than usual, but the wood being ripe, every flower-bud will stand and set, when the weight of the crop can be regulated at discretion. This, the first and most trying ordeal, having been got over, the work the second and succeeding years will be safer, lighter, and easier. A trench 1 foot in width must be taken out quite close to the first year's new compost, when all the strongest roots, considerably increased in number, must be shortened to within 12 in. of the first year's pruning, re-laid, and watered home as before. I lately heard a gentleman say, "Take no notice of gardeners; they preach what they do not practise." This is my practice; and I now have trees which have occupied the same stations for twenty-five years carrying full crops of fruit averaging 10 ounces each, and I attribute their longevity to slight, but annual, root-pruning.

Late houses, which have been brought on steadily, are unusually backward this season, and with us require a little assistance to get the fruit ripe before we commence gathering from the open walls. The fine rains we have recently had having thoroughly penetrated the external borders, proper attention to the mulching will keep the roots in a satisfactory condition for a long time to come, most likely until all the fruit is ripe. It will not, however, do to depend on summer rain, as large trees growing close to the glass and carrying heavy crops of fruit carry off immense quantities of water. If all available fruits have not been raised to the influence of sun and light, no time should be lost in getting this work finished, as colour adds greatly to the quality and value of Peaches. Some do not endorse this opinion; whilst others assert that a Peach capable of laying on deep crimson or purple is wanting in one great essential to perfection where exposure is neglected. The old Alexandra Noblesse, Early Silver, that delicious Peach the Malta, now so rarely met with, and a few others are naturally pale, but full exposure to sun and light streaks and mottles them, and adds a blush which all admirers of beauty appreciate. Let every Peach, then, which can be turned have full exposure, and increase its size to the fullest extent by pinching the points of all shoots which will be cut out after the crop is gathered. Trees on reserve walls should now be looked to and checked if the heavy rains have started them into vigorous growth. Checks of all kinds, it is generally admitted, are bad; but when trees growing against open walls are intended for forcing, and ripe wood is of more importance than ripe fruit, there are ways and means which may be brought to bear without hurting either. A fine tree, say, of Bellegarde or Royal George, which was carefully root-pruned last autumn and well mulched in the spring, may now be relieved of manure to let in warmth and air. Further, a trench may be thrown out quite clear of the roots, and glass-lights, at this season plentiful, can be placed in a slanting position against it to increase the air temperature and throw off drenching rain. These aids tell more or less in the right direction, but trees intended for early forcing should always be prepared under glass.

The Blue Winter Windflower (Anemone blanda). Engraved for "The English Flower Garden" from a photograph.

The preparatory house need not be large, but it should always be fitted with a flow and return pipe. The border should be narrow and elevated, and the entrance sufficiently large to admit of the removal of a good-sized tree when the time arrives for removal. W. Coleman.

Flower Garden.

ANEMONE BLANDA.

One of the earliest and loveliest of spring flowers is this good Greek plant, its blossoms of a rich deep blue beginning to open in the end of February, a full six weeks in advance of its paler Italian cousin, A. apennina. It thrives in a rather sunny, open, but sheltered place in poor soil. It is strange how rare in gardens this fine plant is still; it is raised from seed with the greatest ease, so that anyone beginning with a single plant could raise a large stock in two or three years.

Intermediate Stocks.—These are so commonly grown for spring decoration only, that they are not encouraged for summer use to the extent they merit. I put out from a spring sowing some 300 plants of a white intermediate, and all are now grandly in bloom. They are about 12 inches in height, branching, and of the purest white. Quite 80 per cent. are double, and a better Stock for summer culture I have not seen anywhere. If Stocks be needed to furnish cut flowers, this is a first-rate variety for the purpose. We have such a wealth of beautiful summer Stocks, that we miss the Bromptons less than was the case some years ago.—A. D.

HOLLYHOCK CULTURE.

The Hollyhock blooms shown lately at South Kensington, and alluded to in The Garden (p. 157) formed an interesting feature of the exhibition. Hollyhock cultivation has been discontinued to a very considerable extent in the south during the last few years, owing to the disease with which the plant has been attacked, but it has been grown, and grown well, in the north, and it is perhaps not more difficult to fight the disease in the south than in the north. In 1884 some magnificent varieties were exhibited at the Crystal Palace from growers in the north, the single flowers of which were the largest I had ever seen. Our plants have been growing in one position for two years, and no plants have been propagated from them. This has been done in the hope that the disease would die out, but it does not do so. As far as I am able to judge, I do not think it likely that it will be stamped out, but in most seasons it does not materially injure the bloom. It was certainly very virulent when it first made its appearance, and cultivators were for the time nonplussed. I have just now carefully examined our plants, and find only one leaf with a slight trace of disease upon it. The whole of the plants are in full bloom, and even although the disease should spread (although I do not think it will), the bloom for this season will not be affected.

Now is a good time to propagate Hollyhocks, and if the cuttings or eyes are free from disease when taken off, it is possible that the old plants might be attacked out of doors, while those in frames in other parts of the garden might be free from it. Those who are not accustomed to propagate Hollyhocks would do well to act on the following advice: The leaves will most likely have red spider on them, even if not discernible; therefore dip the cuttings in a pail of soft soapy water tinctured with tobacco water: this will destroy this pest. There are usually some cuttings to spare round the base of the stems; these ought to be removed with a heel attached to them, and be planted separately in 2½-inch pots, or 3-inch ones; use fine sandy soil, pot them firmly, and place the pots in a close frame. The side growths may also be cut off now, although it is better to do so in July. Each leaf that has a leaf-bud and not a flower-bud at its base may be cut out and planted much in the way in which Vine eyes are done. The plants produced therefrom will flower earliest next year. They may be potted into 3-inch pots, and may stand the winter in cold frames or in a cool greenhouse. In order to make sure of the old stools passing safely through the winter, they also should be carefully dug up in October, and be potted in 7-inch or 8-inch pots. It is best to get the roots into as small pots as possible, although it may be necessary to use 8½-inch ones for the largest. After re-potting the frame in

which they are placed should be kept rather close for a week, and no water should be given to the roots until the end of that time, as a too liberal supply will cause them to decay. Such growths as cluster round the crowns of these plants will continue to grow from the time when the plants are potted until February; then all but one should be taken off and propagated either as cuttings or by root-grafting. They will strike freely in a gentle bottom heat, and better in a heated propagating house than in a frame. The temperature of the house should be about 55°. In a frame there is a greater tendency for the root-grafted plants or cuttings to damp off. They form roots more quickly if covered over in the house with a square of glass laid flat over them and resting just above the leaves. As soon as rooted let them be lifted out of the bottom heat and placed near the glass, to be subsequently moved to a cold frame. From this they should be re-potted and planted out in May. Spring-struck cuttings succeed those propagated the previous autumn, and thus form a succession. The Hollyhock is one of the grossest feeding of plants, and requires a deep rich soil in order to produce large healthy leaves, the usual precursor of the best flowers, on long stout spikes. Spring-struck plants make, as a rule, more vigorous growth than those struck in autumn, although some autumn-struck varieties are also very vigorous. In ordinary seasons it is not difficult to save seeds of the very best varieties, but in that case the decayed or decaying flowers must be removed before they cause any injury to the seed-pods. If not quickly removed the seed-pods sometimes get destroyed by the decaying petals.

Rearing of seedling plants is most interesting, 50 per cent. being really good varieties. Some of the best sorts produce seedlings neither better nor worse than their parents, and it must also be observed in reference to this point that seedlings are always much more vigorous than the parents, and can be grown up to the flowering stage without the aid of either glass houses or frames; herein, therefore, lies the value of seedlings for those who have no glass houses, or who are unable to use them for such a purpose. The seeds may be sown on a border of fine sandy soil in the open ground. As a rule it is unwise to trust them to the ordinary soil of the garden. Mix up, therefore, a compost of loam, leaf mould, and sand. Rake it over to remove stones and the rougher portions. Draw shallow drills 6 inches apart, and sow the seeds thinly in them about the 1st of May. If frames or a hotbed are available, the seeds may be sown in boxes and be placed under glass to vegetate. In any case the young plants should be pricked out in the open ground as soon as it is possible to do so, after the first leaf or two are formed beyond the seed leaves. The plants may be planted on the ground where they are to flower in July or August, in order that they may be well established before winter sets in. When they have a good hold of the ground, they pass through the winter without being injured by frost. The ground for seedlings ought to be well drained, and if deeply trenched water will pass rapidly through it; water hanging about the roots is as injurious to Hollyhocks as frost. The disease will often attack the plants when they are in cold frames in spring, or even when they are being propagated. I had to fight a stubborn attack of this kind some four or five years ago; we cut off every leaf that had fungus spots upon it and burned them at once. The entire stock of plants was then dipped in a strong solution of soft soapy water and flowers of sulphur. Treated in this way, the disease had disappeared by the time the plants were put out in the open ground. It, however, re-appeared in autumn after they had flowered. This attack I attributed to the evil influence of some Mallows that were growing in the neighbourhood, that were almost destroyed by an attack of the same fungus. J. Douglas.

Primula floribunda from seed.—This is well named, for it is a singularly free bloomer, and, still further, comes into bloom at an exceedingly early stage. Most of the hardy Primulas, if seed be sown in the spring, will bloom only in the following spring. P. floribunda, from seed sown in spring, is in bloom already, the plants being so small that a score go into a 12-inch pan, and yet every one, even the tiniest of the batch, is either in bloom or throwing up buds. The foliage bears some resemblance to that of P. verticillata. The blooms are bright yellow and borne most freely in whorls or trusses. This species is admirable either for rockwork or pot culture, and merits wide appreciation.—A. D.

SPRING FLOWERS IN THE PYRENEES.

No. III.

If the garden of the Pyrenees at Esquierry proved a failure in June, we found such a beautiful natural spring garden a day or two afterwards above the Luchon Hospice, as quite made up for any disappointment. This place is about 6 miles south-east from Luchon, and the road to it, though flowery in parts, is not without drawbacks. It is very different in construction from the Routes Thermales, which I have mentioned before. The avalanches and slips of the winter are seldom repaired by June, and it is not till then that communication by wheels is open. The road runs along the side of an almost precipitous slope covered with Silver Firs wherever they can find standing room. There is just space for two carriages to pass and no protection on the lower side. As soon as the road is clear an extensive cartage of wood to the town takes place, and the bullock-carts downwards get the inside. So that the road, bad in itself and, at the time we used it, puddled by heavy rain, is not a pleasant one for a four-in-hand, such as is always used to take tourists about in those parts. But we had walked on, and two ladies were left in the carriage, when in passing a line of descending bullock-carts the overworked horses began to jib and the carriage to slip back; so they got out and walked the rest of the way with anything but a pleasant recollection of the drive to the Hospice. But this is not all that is dangerous in the road. There are, on the upper side of it, certain open slopes called "timber shoots," down which trunks of trees are sent, butt first. A man is stationed to warn any passengers, showing a written authority to close the road for two, four, or six hours, as the case may be. To pass with a carriage is impossible, as the trees block up the way. I was coming down with a guide when we were stopped, and the guide told me we might make a rush if we did not like to wait two hours. Trees can be dodged, but they loosen large stones in their descent, which are more erratic in their movements. Such are the unpleasant incidents of going to the Hospice. On the other hand, the scenery is grand, and the flowers along the more open parts of the road are beautiful. Huge spikes of Marsh Orchis, Thistles with such heads as I never saw before, but of which I do not know the name, and a large Vetch, or Everlasting Pea, with orange-coloured flowers, called Lathyrus montanus in Grenier and Godron's "French Flora," but being, I believe, Orobus luteus of Linnæus. I saw it in several parts of the Pyrenees, and it struck me as a novelty, though I doubt whether it would be an acquisition in gardens. The carriage road ends at the Hospice, but a mule road goes on into Spain. An hour's steep walking along this, through open slopes covered with a forest of white Asphodels in flower and large yellow Gentians not near flowering, brings us to a mountain pasture with a stream running down the middle. This is from 5000 feet to 6000 feet above the sea level, Luchon being about 2000 feet. The higher slopes of that pasture are filled with what we may call garden flowers more thickly than I ever imagined possible in Nature. I was reminded of Ovid's description of the Vale of Henna, in Sicily, when, after filling several verses with the names of all the beautiful flowers he knew, he said there were besides these a multitude of kinds of flowers without a name. Four months of the flowers of an English garden were all here in their prime at once. Besides nearly all the flowers I have mentioned as growing about Gavarnie, there were Daffodils and Poet's Narcissi, Fritillaries (Pyrenean) and Orchises, Dog's-tooth Violets, and Hepaticas, both in great abundance; Soldanella alpina and Gentians, both verna and acaulis; besides the rocks which bounded the slopes being covered with the usual rock alpines, such as Primula viscosa and integrifolia, and many Saxifrages and Sempervivums. This was the only place in which I saw Ranunculus amplexicaulis, but it was everywhere here, with larger flowers than I can make it produce in my garden. Once before I thought I had found it, covering a high mountain pasture near Eaux Bonnes, but the flowers there were much smaller, and it proved to be an inferior kind of more slender growth—R. pyrenæus—no acquisition where the other can be obtained. But to return to my Hospice garden. Yellow Oxlips were plentiful; Anemone narcissiflora grew here and there in patches with large bunches of flower, the outside stained with bright rose. Geum montanum was there too; also low beds of Daphne Cneorum, a mass of fragrant pink umbels. I had before recognised this abundant on the racecourse at Biarritz, where it grows very dwarf, flowering in March. Another remarkable plant which was common on this mountain, and which I saw in several parts of the Pyrenees, is Eryngium Bourgati. It has prettily variegated leaves, and it is easily cultivated in gardens. An Orchis with yellow flowers (O. sambucina) I had not seen before. The flowers I have here mentioned, with many others, were all growing together within a short distance on one mountain side. I was there twice; on one occasion it poured with rain, which afterwards turned to snow. On the other I started so late in the day that I had hardly two hours on the mountain, or I might have seen much more. On the whole, I came away from Luchon with the conviction that the whole neighbourhood at the right season affords excellent lessons in the treatment of garden plants.

Edge Hall, Malpas. C. Wolley Dod.

SHORT NOTES.—FLOWER.

Zinnias.—Amongst these there are some superbly-coloured double flowers that vie with bouquet Dahlias in dimensions and density, and excel them in beauty. Plants put out singly in good soil and with ample space produce wondrous flowers and exceedingly rich in colour. It is a wonder florists have not adopted Zinnias for exhibition as they have done Asters?—A. D.

Bartonia aurea.—Were I asked to give the names of a dozen annuals for a mixed border this must be one of them. The flowers, which close up at night, are golden yellow, and borne in terminal clusters. The foliage is rough and of a greyish green colour, but, unlike that of some of the other members of the family, it does not possess the power of stinging. Seeds of it should be sown in a cool frame in early spring, and planted out along with other annuals.—W. H.

Iris susiana.—This is one of the most distinct and striking of all Irises, and one which when seen in perfection is not easily forgotten. Some time back a good clump of it might have been seen in the Botanic Gardens, Cambridge, bearing a number of beautiful flowers large in size and rich in colour. It is planted on a south border against the Cactus house, where it thrives with very little attention; the only care taken with it is to place a garden light above it as soon as it has finished flowering, and left until the Iris commences to grow, when it is removed.—W. H.

White Spiræa palmata.—Spiræa palmata itself is now beginning to be popular, and I should say that the white variety, when better known, will meet with an equally favourable reception. It is, except in colour, a counterpart of the older kind. The situation in which we grow it is hot and dry, conditions scarcely suitable to this Spiræa when planted out of doors, but in pots slightly shaded and well watered it produces a magnificent display. The white variety has this year given universal satisfaction.—H. P.

NOTES ON HARDY PLANTS.

Epilobium obcordatum is in several respects a trying plant, and, pretty as it is, I fear it is not destined to be often seen in our rock gardens. In winter it is liable to be killed if left out of doors. I am inclined to believe, however, that it would succeed if kept dry, for where no more protection than that of a bit of glass has been given plants of it have survived the winter, and, moreover, proved stronger when growing time arrived than roots kept under warmer conditions, viz., on the top shelf in a cool greenhouse. I have, however, another fault to find with it, and that is when the flower-stems have well developed their flower-buds, they turn brown as if blighted and dry up, but the plant remains all right at the crown. Later on—about September—a few perfect flowers may, however, be seen, suggesting that the sunny and somewhat dry places thought to be essential for it in winter are too hot in summer; it enjoys plenty of moisture during the growing period. Whether in the open or in pots young plants of it should be well rooted before the cold season sets in. Either slips or divisions may be chosen; if slips, no time should now be lost in getting them rooted.

Asarum caudatum. — Poking among the acute leaves of this plant with a bit of stick to loosen the surface soil, I was delighted with the fragrant smell of the ripening herbage, and if it proved as sweet in the scent jar, that alone would be a good reason for growing this plant, which may be otherwise considered more curious than beautiful. This American species makes itself quite happy with us in almost any situation if the soil is loose and not dry; it spreads moderately—just enough to make one feel that it is fairly well accommodated.

Sibthorpia europæa.—It is astonishing in how many ways this native trailer may be used with happy effect. Indeed, it may be said that there is more in the manner in which such graceful plants are made to do duty than in the plants themselves. Many imagine that this Sibthorpia cannot be grown except they can give it a constant moist bed. True, it is found wild under such conditions, but if one can give it shelter from wind, it will succeed without more root moisture than that afforded other plants. Do not, however, deprive it of dews and light showers by sheltering it under trees, the drip from which is injurious. Set it in a little depression that will catch the rain, between stones that will guard its brittle stems and leaf-stalks from wind, and it will thrive in full sunshine. Some fine sand or old cocoa fibre laid around it will form capital material for it to root into.

Linaria hepaticæfolia.—This is also a small creeper, but one which quickly covers a good space and flowers freely. It may be said to be adapted for situations just the opposite of those which suit Sibthorpia. It will flourish on the drier parts of rockwork, provided its roots have been placed in a seam of good rich loam. In less critical places it will need no care beyond stopping as may be required. Small as its purple Snapdragon-like flowers are, they beset the flat herbage in such myriads as to render the plant quite a favourite.

Silene Schafta.—This is such a lasting and brilliant Catchfly, that, common as it is, few of us can dispense with it. Perhaps the greatest objection that can be raised against it is the fact that it seeds freely. About this dwarf, rosy-red flowered Catchfly there is none of that miffiness which characterises some of the section to which it belongs. In short, it is a plant which brightens up our gardens for many weeks in summer.

Campanula hirsuta.—This is one of the best of dwarf Bellflowers. Its blossoms, which are clustered on spreading prostrate stems, last in succession for many weeks. They are also of a darker blue than those of most of the dwarf varieties. This Campanula is very hardy, and never fails to be effective. It should be set on a sloping bank, or be allowed to droop over stones. It is suitable for either beds, rockwork, or pots, and its grey-green foliage and violet-purple blossoms render it capable of association with the best of alpines.

Catananche cærulea and its variety bicolor are magnificent flowers, but, unfortunately, bright only during sunshine. There is, too, another drawback, and that is, the outer florets rarely expand into the horizontal form. Moreover, the plants being tall, suffer greatly from wind. To obviate this, when the main stems are well developed and, say, just about the time when the first flowers open, draw down the stems and peg down the long flower-stalks, the shorter ones from which in a few days will all become erect. Thus situated, the heads seem to open fresher and fairer than when left aloft exposed to wind. The idea regarding bending down the stems occurred through an accident. Several plants had their tall stems in our way, and they were pressed down, but being rather ripe they did not break near the root: the tops came down among some plants of Saxifraga Fortunei, where they could do no harm, and there they were left. The charming effect produced by the big sky-blue heads of the Catananche among the deep green fleshy leaves of the Saxifrago may be readily imagined. A more lovely blend of leaf and flower could scarcely be conceived.

Hypericum olympicum.—This has a princely flower, large and beset with a brilliant array of dazzling stamens. The species is suitable for borders, rockwork, and even for pot culture. I fear, however, that it is not quite hardy—in the north, at least. It should have a warm situation and a somewhat light soil. The herbaceous tender kinds are more easily dealt with in winter than the shrubby species; in many instances where well established, one or two shovelfuls of coal or wood ashes put over the crowns are all that is required. A good way of growing it is as follows: Take slips or young shoots in spring, say, 3 inches long, place one each in 2½-inch pots, and set them in a Cucumber frame. As soon as rooted, which will not be longer than from ten to twenty days, pot them in 3-inch pots, keep them close for a day or two; then move them into airy quarters, and as soon as all danger from late frosts is over, plunge them out of doors. Sturdy little plants about a foot high will be the result, each one in August being topped with a cluster of flower-buds, which will expand one by one in a very pleasing way. These little pots may be employed in or out of doors for any special purpose, and if garnished with Moss may be even used for table decoration.

Calliprora flava.—This if grown in good clumps in borders is very effective; or it may be placed on rockwork to stop the gaps caused by the dying down of spring flowering bulbs. The flowers, which appear in July and August, are three quarters of an inch across, and are of a somewhat tawny-yellow colour lined with brown. They are of good substance, and are set on stalks seldom more than 6 inches or 8 inches high. It is a free bloomer, and increases moderately well. It should set at least 4 inches deep, and may be mixed with such plants as Chionodoxas, Scillas, Ornithogalums, &c., at the planting season in September, for, though it may have been in flower but a month previously, its leaves will have ripened.

Sisyrinchium convolutum.—This is a pretty summer bloomer, which, from its ample tuft of pale green Grass-like foliage, continues for four or five months in succession to send up sheathed scapes furnished with bright yellow flowers more than an inch across. The plant, which is about 9 inches or 12 inches high, is therefore very useful either in warm borders or on rockwork. The colour, size, and shape of the flowers remind one somewhat of those of the single Jonquil. Its hardiness is doubtful, but I have proved it to be capable of enduring repeatedly 16° of frost, *i.e.*, when under dryish conditions. Glass or wire shelters might therefore prove sufficient to keep it alive in even other than light warm soils. As a matter of fact, I have lost it more than once in the open, but I kept it last winter by means of the shelter just named. J. W.

Outdoor Balsams.—Permit me to mention that the double Balsam flowers sent lately, and of which you wrote favourably, were the produce of plants growing in the open ground. It was chiefly to show what fine blooms could thus be produced that I sent them to you. I have not a plant in a pot or under glass, but large numbers are growing in the open ground as ordinary annuals, having been dibbled out in rows at the end of May. They are all blooming superbly, and are greatly admired by all who see them. Balsams should be more grown for outdoor decoration than they are. Here, simply lifted from the seed-bed and dibbled out in rows after they have become stout and some 8 inches high, they become all that can be desired as decorative plants.—A. D.

China Asters. I observe in the report of the Royal Horticultural Society's exhibition of the 10th inst. that it is stated "Asters were indifferent." That such was the case I can readily understand, because Asters generally are late this season, and the classes were arranged for a date too early to secure good blooms. It is also notorious that the first or main-stem blooms of Asters are seldom the best, the strong side shoots usually yielding the best flowers. Though late, therefore, we shall probably have finer blooms this year than have been seen for several seasons, for everywhere the plants are clean and robust. I saw a grand lot of the Victoria and Paeony-flowered kinds the other day in the gardens at Maiden Erleigh.—A. D.

White-leaved edging plants.—Two of the very best light-coloured edging plants for beds are Santolina incana and Euonymus radicans variegatus, and this is the best season for rooting cuttings of them. Little bits dibbled into firm soil in a cold frame will form roots during the winter, and make good plants for setting out in spring. Place 2 inches of coal ashes in the bottom of the frame, and when trodden and beaten down cover them with 4 inches of light sandy soil, which must also be made firm. If ashes are not used, worms may become troublesome during the winter, and although they might be dislodged by the aid of lime water, it is best to keep them out when possible. Dibble the cuttings 2 inches apart, and keep the soil moist by watering when necessary, which will not be often. The frame should face the north.—E. Hobday.

Dianthuses.—Two fine selected double forms of Dianthus chinensis, pure white and deep crimson, are well worthy of notice. Some blooms of the white kind fairly rival in size and bulk those of Mrs. Sinkins Pink; the crimson may be described as a fine double form of Crimson Belle. A very charming pure white single kind is Snowflake, but it seems to be a little taller than the usual height. With a little more selection that, too, will make a very handsome and distinct variety. One of the most striking and richly coloured of the annual Chinese Pinks is the fiery red kind called Brilliant. This reaches an average height of 8 inches, and produces large richly coloured flowers that glow brilliantly in the sunlight. These are beautifully fringed. It makes a grand bedding plant, and its colour can hardly be excelled. By merely sowing seed in spring and dibbling the plants out some 9 inches apart a rich mass of colour can be readily obtained. Mixed kinds sown in rows beside paths in kitchen gardens or on Vine borders yield a profusion of flowers for cutting, a purpose for which the doubles are specially useful, but all the forms are more or less serviceable in this respect.—A. D.

Giant Mulleins.—I have never grown Mullein as garden plants, but now and then one has come up in my garden, and because of its fine leafage and noble appearance I have let it stand and bloom. This year one solitary plant has shown itself, and now when it is some 5 feet in height and has begun to bloom, it will probably reach 7 feet ere it has done. But my attention has been specially attracted to it, because the flowers are so much larger than usual; indeed all preceding ones have had flowers comparatively inconspicuous. The plant now blooming, however, has very fine bright yellow blossoms quite an inch and a half across; the spike of bloom is therefore very striking and handsome, almost resembling that of a Foxglove bearing Œnothera-like flowers. So this must be a finer form than usual.—A. D.

Portulacas, single and double, make good edgings. I saw some the other day 14 inches in width and perfect throughout, but varied so far, that in some cases there were lengths of distinct colours, and in other cases they were mixed. Amongst Portulacas may be seen whites, apricots, yellows, orange and rose tints, reds, creams, and other hues, all beautiful when distinct, and all also beautiful when in combination. Portulacas grow to a height of about 3 inches at the most, and spread and intermix admirably, forming dense lines, margins, or masses. The soil for them, after being dug and levelled, should, early in May, be trodden to the width to be sown. This hardening is needful in order to prevent heavy rains from washing the seed in too deeply. A very shallow drill 6 inches broad should then be drawn, the seed thinly and evenly sown, and then very thinly covered; under this treatment growths soon result.—A. D.

5506.—**The Stocks** referred to by "R." belong to the intermediate class. The seeds should be sown thinly in boxes or pans in September or October, and the seedlings should be pricked off in 2-inch pots as soon as large enough to handle and placed in a frame. They should be shifted in February into 3-inch pots, using plenty of manure in the compost. Air should be given to the frame in all but frosty or wet weather. Do not let the pots get too full of roots before they are shifted into their flowering pots, which should be about the end of March, using half manure and half loam. I may add that no artificial heat should be given them from first to last; the frames should be covered with mats on frosty nights. Very little water should be given in the winter, except it is really necessary.—C. E. F.

Dwarf Nasturtiums.—No bedding plants can possibly excel in the production of gay colours and plenty of bloom dwarf compact-growing Tropæolums. These forms are not to be confounded with the King of Tom Thumb type, from which they materially differ. There are four diverse colours—yellow, scarlet, crimson, and maroon all of the same dwarf-spreading and marvellously free-blooming habit. These always throw their blooms well up above the foliage, and produce effects throughout a long season such as no other annuals can produce. I grow them from seed every year, simply dibbling the plants out into rows when strong enough to be so treated. Generally they reach a height of 8 inches, and spread to a width of 12 inches to 14 inches, keeping up until frost comes one constant head of bloom.—A. D.

Clumps of Lavender and Rosemary.—A dozen plants or so of Lavender planted in a cluster on the lawn have at all times a pretty effect, but especially so when in blossom, and their scent is exceedingly pleasant. The site for them should have some preparation in the way of deepening the soil and, if necessary, adding fresh material to it. A warm, well-drained spot suits Lavender best. Slips or cuttings of it will root now under a handlight. It is always desirable to have a stock of young plants coming on, as old plants die sometimes in a cold winter. After the flowers are all gathered the plants should be clipped with the shears, cutting off all *débris* as to flower-stems and making all neat and trim. Rosemary is equally effective for grouping on the lawn; in fact, it is more so at most seasons, and in spring, when in blossom, few shrubs possess so distinct a character. The growth has a spiky appearance, and a cluster of plants, 10 feet or 12 feet in diameter, jutting out into the lawn on the margin of a group of shrubs cannot be surpassed for effectiveness; the Rosemary, too, improves with size and age, which the Lavender does not. A cluster 7 feet or 8 feet high and as much in diameter or more, when once seen, needs no recommendation.—E. Hobday.

Giant Poppies. — Both "Veronica" and "J. W." have done their best to make clear the distinctions which exist between Papaver bracteatum and orientale. It is very possible that the designation "orientale," with its association of deep and brilliant hues, has led many to believe that the intense crimson-flowered kind was of that name, and not bracteatum. However, the huge orange-red flowered sort is now shown to be the true orientale. Judging, however, by my own plants, I am inclined to think that crosses have already been made between the two kinds, as in a batch of seedlings a considerable variation in habit, foliage, size and colour of the flowers, and other divergences have been found. Whilst the very largest blooms produce rounded capsules, others have them decidedly wineglass-shaped, as described by "J. W." It is, therefore, evident that some features of both the giant Papavers are found in the strain. Grand as are the huge blooms of P. orientale, yet they are very fugitive; hence any evidence of doubling in them would be welcomed. Probably by constant seeding and selection double flowers might some day be obtained, and once we have giant double Orientals we shall have, without doubt, the largest and grandest of flowers which our gardens can produce, the biggest of Pæonies not excepted.—A. D.

PROPAGATING HARDY FLOWERS.

For cutting and decorative purposes hardy flowers are indispensable, but in order to be successful with them frequent attention as to propagation, dividing, and remaking of beds and borders has to be paid. One effect of the dry weather which we have had has been to hasten the ripening of bulbs. The foliage of Croci and Narcissi as well as of early Tulips is now withered and yellow; and when it is intended to re-make the beds or borders specially set apart for them, that kind of work may be done at once. I am aware that some prefer top-dressing Narcissi with leaf-mould later on to lifting them periodically. Many advantages attend this treatment in large collections; but in the case of my limited collection, lifting, dividing the bulbs, manuring, and adding fresh soil suit better. This applies also to Ranunculuses—Persian, Scotch, Turban and French, including that fine robust-growing variety, the Cockade Ranunculus, the Meladores of the old florists. I should add Ranunculus aconitifolius (Fair Maids of France), that no garden should be without. In the case of alpine Auriculas I like to have my beds always presentable. There is no reason why a bed containing bulbs need be a blank until next spring. There are plenty of showy, handsome, surface-rooting plants for the centre and around the edges, and as I have been at this work at intervals lately, I will name a few, commencing with the alpine Auriculas; ground where these were planted had become hard, and water would not lodge on it. Like many other things in the late hot weather, they suffered much, and as they contained many edged, shaded, and self seedlings, not procurable elsewhere, I resolved not to lose them. Of mossy Saxifrages I have many, all useful and handsome; but I shall only mention the largest and smallest, S. Wallacei and S. purpurea. The former is now becoming generally known for cutting and indoor decoration. It suffers much in dry weather, and, except propagation at this time of the year is resorted to, it is likely to die off and get lost. A moist cool shady place suits it best. As a dry-weather plant commend me to this delightful little velvety-green cushion S. purpurea. With me it has not got even a sprinkle for more than a month, and here it is quite fresh and velvety, neither foliage nor flowers ever exceeding 2 inches high. Another advantage is it does not overrun neighbouring plants like the others. These Saxifrages answer admirably to edge bulb beds. I have covered two beds of Leucojum æstivum and Colchicum autumnale with them. Veronica gentianoides variegata I regularly lift, divide, remove the flower-stems, and replant about this time every year. The foliage is exceedingly handsome—a combination of green, white, and purplish green, while the pale lilac flowers on tall stems when others are scarce render it useful. It is perfectly hardy, and decidedly the handsomest of herbaceous Speedwells. The perennial Cheiranthus is an old acquaintance, and gives masses of yellow blooms when the flower beds contain hardly another hardy yellow flower, except Alyssum saxatile, and of a deliciously rich sweetness quite different from that of the Wallflower, to which it is allied. It is readily propagated by cuttings, but an easier method is to move up the soil around the young stems in spring into which they readily root, and can be removed with the soil attached without check. To Pansies and Violas much sun heat is injurious. Of the latter, Countess of Kintore, Mrs. Gray, and a very dark purple withstood the late drought and heat best; at least a dozen other varieties degenerated or died. I have cut off all the seed-pods, long stems, and blooms, and given them a new heavily manured bed. If I had not propagated my show and fancy Pansies from side shoots in April and May, many would have been lost. Of choice double white hardy flowers the following are useful and easily grown, viz., Campanula persicifolia (the true variety is as double as a white Camellia, and much superior to the double blue Campanula), Achillea Ptarmica, Hesperis matronalis (the pure white double old Rocket, hard to find now), Spiræa Filipendula, very useful for cutting, and, best of all, Matricaria inodora, very double.

Clonmel. W. J. Murphy.

Primroses and Polyanthuses from seeds.—Whether due to season or to some other cause I know not, but certainly I have never found thrips or spider so non-prevalent amongst Primroses and Polyanthuses as this summer. It is a most hopeful sign for next spring's bloom that the foliage has remained so green and vigorous, whilst the new leafage is breaking up fast, and I anticipate as a result a gay show of bloom all the winter. Northern readers who find these spring flowers to thrive with luxuriance always can hardly realise the miserable appearance of ours here in the hot south during some seasons. When thrips eat up every leaf, naturally such defoliation seriously affects further growth, and summer drought often proves far more injurious than winter cold. Primrose and Polyanthus plants, raised from seed sown just after having been saved last summer and planted out in spring, are so robust and fine as to afford the fullest proof, if proof were wanted, of the value of summer sowing. A big patch consisting of about 1000 fancy Polyanthuses will next spring make a show that must be seen to be appreciated. Seed of both Primroses and Polyanthuses of the present year's saving sown three weeks since in frames is now coming through rapidly, a good watering daily during dry weather being alone needful to ensure free germination. Considering how readily a grand show of these charming spring flowers may be obtained from seed, it is remarkable that they are not more plentiful in gardens than they are.—A. D.

Sweet Williams.—These are now a striking feature in the public park at Wolverhampton, where they are largely used as edgings to large clumps of shrubbery. Here one realises what dense flowering subjects they are. Strong plants have thrown up many spikes of bloom, and, whether looked at near or at a distance, the effect is very fine. The plants stand about two seasons, and then they are replaced by young ones. The strain is good, but capable of improvement by means of careful selection. Where, however, hundreds are required, the cultivator cannot select as rigidly as in the case of an amateur who wants but a small quantity. The Auricula-eyed Sweet William is one of the best decorative strains. The original of this was a rich dark crimson flower, having a bold white centre and smooth edges to the petals. In course of time this type gave various shades of colour and marking, and that known as Barlow's Giant is one having large, stout, smooth-edged flowers in great variety, It will be observed that a great many of the Sweet Williams grown at the present day have fimbriated edges to the petals. Hunt's Sweet Williams were popular years ago, but they had fimbriated edges to the flowers. There are, however, many who like flowers of this character when associated with large and stout florets. Fine as are our Sweet Williams of the present day, they are yet capable of improvement by careful selection. It is not too late to sow seed. Good seed soon germinates if sown in the open ground, provided the situation be a shaded one for a portion of the day and the soil kept moist. As soon as the plants are large enough to handle, they should be pricked out into a nursery

bed, so that they may grow on into size; and then some of the strongest at least, if not all, will flower next season; but by the second year they will make plants that will produce huge heads of bloom of a showy character. Any particular variety of unusual excellence can be propagated by dividing the plants in autumn, or by cuttings of the young growth made during the present month.—R. D.

ORNAMENTAL GRASSES.

Members of the Grass family belonging to this country do not, as a rule, reach a great height, but in tropical climes they assume gigantic proportions, some of them attaining to 50 feet, 60 feet, and even 100 feet in height, rivalling the Palms in stature and resembling them in structure. For the decoration of the lawn and wild garden the material in the way of Grasses from which to select is ample; the difficulty is what to choose and what to avoid. The following enumeration contains species calculated to add grace and beauty to our gardens:—

The Arundo, or Reed Grass as now understood, does not include any species indigenous to this country. All of them are tall, handsome Grasses, attaining a height of from 6 feet to 10 feet, and should be introduced into every garden where there is the slightest possibility of their thriving. A. conspicua resembles a small form of Pampas Grass. It commences to flower in July, and is therefore a desirable acquisition; it is hardier than the Pampas, which should have its crowns protected in winter. Besides A. conspicua, there are A. Donax and Donax versicolor.

Arundinaria.—This genus is nearly allied to Bambusa. A. falcata has been planted somewhat extensively in Ireland, where it thrives admirably and attains a height of 20 feet. It has also been found to grow well in the south and south-west of England. Its graceful growth should lead to its being planted very largely everywhere. There is another very fine species, A. Schomburghi, a native of the Upper Amazon, which grows some 50 feet or more in height. This should be a grand ornament, planted in isolated groups upon the lawn, if we could only get it introduced. In 1862 I received specimens from Nagasaki of a very fine feathery Grass, supposed to be a species of Arundinaria. It grows 10 feet in height and is said to prove good for planting in tufts like the Pampas Grass. In Japan it has a fine effect on the hillsides in November and December. Let us hope this may soon be introduced.

Agrostis, or Bent Grass (A. vulgaris), is a troublesome weed upon light lands, but useful for covering dry sandy banks where but little else will grow. There are in this genus some extremely beautiful species varying in height from 1 foot to 3 feet. Some of the smaller kinds are suitable for pot culture, and are well adapted for working into button-holes and shoulder sprays. The best are A. capillaris, diffusa, dulcis, nebulosa, pulchella, verticillata, vulgaris vivipara, and vulgaris variegata.

Aira, or Hair Grass, is a widely distributed family. A. cæspitosa is one of the tallest of our English Grasses, often attaining a height of 6 feet. It is not only very ornamental in isolated groups, but useful as a cover for game. It is, however, troublesome in pasture land. The best are A. cæspitosa, cæspitosa vivipara, lutescens, and pulchella.

The genus Andropogon contains many fine ornamental species. A. schœnanthus, the Lemon Grass, deserves a passing notice, although too tender to be used in the open air. An infusion of its leaves is said to be useful in cases of fever, whilst from its fibrous roots and from those of another species (A. muricatus) mats and fans are made in India, which impart an agreeable fragrance to the atmosphere where used. Although none of the species can be said to be thoroughly hardy, they amply repay any attention bestowed upon them. The best are A. bombycinus, formosus, and squarrosus.

Bamboos in their native habitats often attain a height of 100 feet. Their economic properties are well nigh inexhaustible, and in a decorative point of view they cannot be over-estimated, their elegant, feathery spray giving a distinct and tropical appearance to any garden in which they are grown. The kinds enumerated below vary from 6 feet to 20 feet in height, and form grand groups upon the lawn, or indeed in any sheltered position. They enjoy a free, rich, open soil. The best are B. aurea, nigra, edulis, Metake, Simoni, Fortunei, striata, violacea, viridis, and viridis glaucescens.

The Broom Grass, a very large genus widely distributed, contains some seven or eight species indigenous to this country, and amongst them one or two make beautiful garden ornaments, especially when grown in good rich soil. The best are Bromus brizopyroides, diandrus, hirsutus, jubatus, lanuginosus, macrostachys, Schraderi, scoparius, and vestitus.

Of Briza, or Quaking-Grass, some of the species are handsome, and well deserve attention. Two are British, viz., media, which is widely distributed and much sought after for winter decoration, and minor, which is local. They are useful either in pots or in the border. B. gracilis, maxima, media, and virescens are the best.

Brizopyrum.—This is a small genus of handsome and singular Grasses, none of which are indigenous. They range from 1 foot to 4 feet in height, and are mostly from the Southern Hemisphere. The best are B. siculum and scirpoides.

Coix (Job's Tears).—This genus has obtained its popular name from the supposed resemblance of its pendent hanging seeds to dropping tears. C. Lachryma is a broad-leaved handsome plant which thrives well in the open air, in a warm sheltered spot. It is also very ornamental when grown as a pot plant. It requires an abundant supply of water, otherwise the leaves are apt to become brown or rusty looking.

Dactyloctenium.—This genus contains a few distinct and ornamental plants which grow from 1 foot to 2 feet high, most of them annuals; they produce dense finger-like spikes of flowers, all pointing one way. As pot plants, they are very elegant, but rather tender for the open air. D. ægyptiacum and radulans are the best of them.

Digitaria (Finger Grass) is a genus containing handsome plants, mostly natives of the south of Europe, the inflorescence of which is produced on long finger-like spikes; they grow from 1 foot to 2 feet or more in height, and are very suitable for the fronts of mixed borders. They thrive best on a light sandy soil. The best are D. ciliaris, sanguinalis, and villosa.

Dichelachne.—Under this name I have grown a very handsome Grass, which makes dense tufts some 2 feet or more in height, and is furnished with a beautiful feathery inflorescence. It is a native of New Zealand, and is perfectly hardy. It is named D. crinita.

Elymus is a genus containing about half a hundred species, two of which are natives, viz., E. arenarius, the Sea Lyme Grass, which grows about 3 feet high, and is useful for planting by the sea-side; and E. geniculatus, the Jointed Lyme Grass, a kind of great service for planting on dry gravelly inland warrens and game preserves. Some of the exotic kinds are very effective, although somewhat coarse. Amongst them E. crinitus, condensatus, Caput-Medusæ, and giganteus are the best.

Erianthus.—As a genus this is nearly allied to Saccharum. E. Ravennæ forms large, dense tufts, similar to those of Arundo conspicua, and should be grown if only for its foliage, but it produces in addition large handsome panicles of bloom, which rise to upwards of 6 feet in height. This plant requires a light loamy soil and a southern aspect.

The Pampas Grass is too well known to need description. It forms a bold, isolated mass, the flower-spikes from which rise some 10 feet or 12 feet in height. Unfortunately, its handsome plumes often get damaged by wet. I am under the impression that when first introduced it bloomed earlier than now. The West Indian G. saccharoides is a grand species, producing noble silvery plumes, but as far I know it has not yet been introduced.

The Lagurus, or Hare's-tail, is a useful Grass, found somewhat sparingly in Guernsey. L. ovatus, which is an annual, grows from 8 inches to 18 inches high, and produces roundish, soft white, spike-like panicles of flowers, ornamented with long beards. It is useful either in pots or in borders.

Melica.—The species belonging to this genus are widely distributed; two are natives of Britain, but very few of them are worth cultivating. M. nutans, however, is worthy of note, being one of the few Grasses that thrive under the shade of trees. M. altissima makes a good garden ornament. It grows from 2 feet to 4 feet in height, and produces dense racemes of flowers, with large shining glumes.

The Blue Moor Grass (Molinia) is an indigenous plant, and very effective in the front row of a mixed border. It also makes a good bog plant. Its leaves are about 8 inches high, and its branching panicles often extend a foot above them. The best are M. cærulea and cærulea variegata.

Panicum.—In this genus are large, bold, and, in some instances, gigantic Grasses. They are widely distributed throughout the tropical and sub-tropical portions of the globe, but many of them are sufficiently robust in constitution to withstand our climate in summer. Dotted upon the lawn or grouped in masses in the sub-tropical garden, they form grand ornaments. They enjoy good rich loamy soil. The best are P. altissimum, aurantiacum, bulbosum, clandestinum, capillare, miliaceum, and virgatum.

Pennisetum longistylum and setosum are handsome plants either for indoor decoration or for the mixed border. Their bearded heads of flower somewhat resemble those of Hordeum jubatum, but more dense and soft in texture. The species are widely distributed through sub-tropical countries, growing usually from 1 foot to about 3 feet high.

Paspalum scrobiculatum and stoloniferum are highly decorative and beautiful Grasses. They grow some 2 feet in height, and bear their inflorescence in long dense spikes; in some species it is digitate, in others alternate.

Phalaris, or Canary Grass.—The species of this genus are mostly annuals, and very elegant. They are natives of Central Asia. Some fifteen or twenty are recorded, but amongst them there is great sameness; they form beautiful masses either in the wild garden or mixed border. P. arundinacea is perennial, its variegated form being known as Gardener's Garter. The best known are P. aquatica, arundinacea variegata, brachystachys, canariensis, and cærulescens.

Phragmites, known also as Arundo Phragmites, is the largest of our British Grasses. It is very ornamental placed beside rivers or lakes, where it grows upwards of 6 feet in height, whilst its creeping roots afford material protection to the banks by binding the earth together.

The Sorghums are bold and effective plants for isolating on lawns, or for massing in the sub-tropical garden; their broad handsome leaves and large dense panicled inflorescence make them conspicuous. S. halepense is perennial and hardy, but the majority of the species are annuals. Their seed, under the name of millet, is largely used for poultry feeding, but it does not appear to ripen in this country, so as to be profitable. The best are, in addition to halepense, bicolor, rubens, and vulgare.

Stipa, or Feather Grass.—A large genus, in which, however, few species possess any beauty when out of flower, and their feathery panicles are but short-lived. Plants of this Grass are usually grown in quantity, in order that the panicles may be cut and preserved for winter decoration. S. pennata is the species mostly employed for this purpose; but S. juncea and tortilis are also attractive Grasses.

Maize (Zea).—This is an effective plant, but we have heard objections raised by some to its introduction into the flower garden. To me it matters little what the plants used there are provided the desired effect is produced, and the tropical appearance of this plant ought to secure it a place there. It should be planted in a warm sheltered position and in rich soil. The variegated form is a charming addition to the garden. It is not quite so robust as the type, but it grows freely in the open air, even close to the sea. It comes true from seed, from which it is easily raised in spring. It should not, however, be planted out until properly hardened off. W. H. G.

Drummond's Everlasting Pea.—This has been exceptionally effective this year; whether owing to deeper root-hold or to some other cause I cannot say, but certainly

the flowers have been not only finer and more abundantly produced, but deeper in colour than usual, and two huge bushes 5 feet in height and as much through have been very beautiful. I am glad to find that this year the plants are seeding fairly well. In previous years it was most unusual to obtain seed, and it is not at all an easy plant to propagate otherwise. It is a capital plant with which to clothe an old tree stump.—A. D.

Garden Destroyers.

INSECTS INJURIOUS TO FRUIT CROPS.

The report on insects injurious to fruit crops prepared for the Agricultural Department by Mr. C. Whitehead has just been issued. The introduction states that the report relates entirely to insects injurious to fruit crops, and to those among them which cause the most serious losses to fruit cultivators. There are others whose injurious effects are comparatively inconsiderable, so that it has not been deemed necessary to describe them here. For the most part the insects which have been described are formidable enemies, and in many cases more formidable because their work of mischief either is attributed to other causes, or is not discovered until it is too late to adopt means of prevention or to apply remedies. Some of these insects cause the failure of an entire crop, as, for example, the Hyponomeuta padella, or ermine moth, by whose action the Apple crop has in some seasons been destroyed throughout large areas of orchard land; while others, like the Carpocapsa pomonella, or codlin moth, materially damage the appearance and quality of the fruit. Fruit growing is a most important branch of agricultural industry, and, taking the average of seasons and of the various fruit-producing districts, has proved profitable when other crops have not answered. The acreage of fruit land in England, according to the statistics given in the "Agricultural Returns," was 197,539 acres in 1885, and probably at this present time amounts to over 200,000 acres, as there has been a gradual increase in the acreage during the last ten years at the rate of about 3500 acres per annum. Besides this acreage, properly termed "arable or grass lands used for fruit trees of any kind" in the "Agricultural Returns," which is *bonâ fide* farm fruit land, there is a large aggregate acreage of garden ground appertaining to all houses in the country, from the nobleman's mansion to the labourer's cottage, upon which much fruit is produced, and whose full yield is most important to the owners and to the consumers of fruit, which in its natural state, or preserved, forms an important and most wholesome part of the diet of the people. Information as to the history and habits of the chief insect spoilers of the fruit crop may, it is hoped, tend to their discomfiture and to the larger production of the fruit lands of this country.

The following insects are mentioned in the report:—The raspberry beetle (Byturus tomentosus), the green chafer (Cetonia aurata), the strawberry weevil (Otiorhynchus sulcatus), the red-legged garden weevil (Otiorhynchus tenebricosus), the raspberry weevil (Otiorhynchus picipes), the apple-blossom weevil (Anthonomus pomorum), the nut weevil (Balaninus nucum), the pear saw-fly (Selandria cerasi), the gooseberry and currant saw fly (Nematus grossulariæ), the currant clearwing (Ægeria tipuliformis), the goat moth (Cossus ligniperda), the wood leopard moth (Zeuzera æsculi), the lackey moth (Clisiocampa Neustria), the common vapourer moth (Orgyia antiqua), the magpie moth (Abraxas grossulariata), the winter moth (Cheimatobia brumata), the codlin moth (Carpocapsa pomonella), the small ermine moth (Hyponomeuta padella), the strawberry moth (Peronea comariana), the currant borer (Lampronia capitella), the raspberry shoot borer (Lampronia rubella), the cherry aphis (Myzus cerasi), the apple aphis (Aphis mali), the plum aphis (Aphis pruni), the currant aphis (Rhopalosiphum ribis), the woolly aphis (Schizoneura lanigera), the mussel scale (Mytilaspis pomorum), the red spider (Tetranychus telarius), the black currant mite (Phytoptus ribis), and the natural enemies of injurious insects.

Sulphide of potassium.—This remedy for mildew has now been extensively used by a large number of our leading gardeners, and as I have been mainly instrumental in getting its merits tested, I am glad to be able to report that the anticipations of the discoverer of its value as a remedy for mildew have been fully realised. As mildew is very prevalent this season I hope every one who is troubled with this pest will test the sulphide, and report whether it proves successful or not.—Edward W. Badger, *Mosley, near Birmingham.*

MR. WILLIAM INGRAM.

The spring garden at Belvoir the Rev. Canon Hole has on more than one occasion styled "the most beautiful garden in all England." Writing in his own genial style, he says: "It has been my happy privilege to visit many a fair ground and goodly heritage between the Border and Land's End; I have admired in many a pleasant spot those tasteful and skilful combinations of Nature and Art which are not to be found in other lands, even where climate and scenery are far more favourable than ours; but Belvoir in its vernal loveliness excels them all!" Then he goes on to tell how the position of this garden is perfect—sunny slopes, "green and of mild declivity," or steep and stony, suggesting alpine plants and pathways, with grand old trees, evergreen and deciduous, over which, as you walk on the higher ranges of the gardens, you see the lake beyond, and through which, as you wander below, the picturesque towers of the castle above. The arrangement of the beds, banks, and groups is perfect; colour just where it is most effective, of every hue, but always in congruity; no sensational contrasts, but an exquisite freshness, brightness, unity, and repose. Mr. Ingram, it may not be generally known, was the originator of the system of spring gardening, which is here carried on to such a state of perfection; and for the last twenty-five years he has been following it up and developing it. When he first went to Belvoir, the pleasure gardens were comparatively small; but year after year he has gradually matured and worked out his plans for their improvement. After the summer flowers are over, the spring plants, which are all perfectly hardy and able to resist the most rigorous weather, are allotted their respective positions, and begin to bloom, some as early as February in a fine season, continuing throughout March, April, and May, and making the garden very beautiful at a season of the year when formerly gardens were without a flower. Countries very wide apart contribute to the charms of Belvoir. Himalayan Saxifrages, Siberian Squills, plants from the Pyrenees, hardy Primulas from the Alps, Rhododendrons from the Caucasus, and one of the loveliest of the bulb family, Glory of the Snow, from the mountains near Smyrna—all these not only exist, but flourish at Belvoir. More than this—we had almost said, better still—many of our English wild flowers are utilised, and, under Mr. Ingram's careful tending, are brought into vigorous and stately growth. We are glad to be able to record, therefore, that Mr. Ingram's labours and skill in originating and developing spring gardening have, during the past week, received a very generous recognition. No one who has ever visited Belvoir could fail to accord him the fullest meed of praise; but this appreciation has now taken a tangible form, the result of a movement which was set on foot some twelve months ago, and of which Lieut. Emmerson, of the Belvoir Company of Volunteers, has acted as the efficient and courteous secretary. A committee was formed, and subscriptions have come in so liberally, that the committee were able the other day to present Mr. Ingram with a cheque for £90 15s. 6d., and several pieces of plate, on which was the following inscription: "Presented, with a purse of money, to Mr. W. Ingram, by his friends and neighbours, in appreciation of the manner in which he originated and developed the spring gardens at Belvoir Castle."

Canon Twells, in making the presentation, which was done in the garden, said: "Most of us know that Latin inscription in St. Paul's Cathedral, which tells us that if we ask for the monument of Sir Christopher Wren, we have only to look around us. In the same way, if anyone asks for a justification of this testimonial, he has only to lift up his eyes and survey the lovely scene by which at this moment we are confronted."

We may add that Mr. Ingram also received the gift of a framed photograph of the garden, which had been very successfully taken by Mr. Broadhead, of Leicester.

Orchids.

ORCHIDS AT SOUTHAMPTON.

For upwards of twenty years Mr. N. J. Buchan, of Wilton House, Southampton, has been a consistent lover and grower of Orchids, of which he has an extensive and well grown collection. Seedlings are springing up here in all directions—Cypripediums, Selenipediums, Dendrobes, and various other seedlings—the result of crossing distinct genera. Seedling Odontoglossums, too, come up everywhere. They have a very peculiar mode of vegetating; the seed appears to swell up beneath the Sphagnum until it attains the size of a Pea, after which it produces leaves from the upper portion and roots from below. Here Orchid seeds not only vegetate in the Sphagnum in which the old plants are growing, but even upon bare boards; some actually grow between the latticework of the footpaths, a proof surely that temperature and atmosphere are properly balanced. Cypripediums and Selenipediums, the gardener, Mr. Osborne, has not succeeded in crossing. There is a very promising hybrid here, the result of a cross between Colax jugosus and Zygopetalum Mackayi; the plants are strong, and may probably flower in the autumn. Coelogyne Lemoniana here exhibited a distinct character, inasmuch as it produces flowers twice in the season; these are now showing, and the next batch from the same pseudo-bulbs will come up after Christmas. On a fine plant of Oncidium macranthum I counted sixty flowers, all expanded; and there was a beautiful variety of O. Lanceanum with upwards of fifty flowers, and the leaves were not disfigured with the black cankerous scars so common to this plant. Cattleya crispa superba had forty open flowers on it. Dendrobium Dearei was growing as freely as the old nobile, and flowering most profusely. There were also large plants, well furnished with numerous flowers, of Odontoglossum Uro-Skinneri and various grand varieties of O. Alexandræ. Oncidium Jonesianum is a grand plant. Its leaves are terete, somewhat like those of O. Cebolleti, and the flowers are large and pure white, spotted and barred with brownish crimson. Cattleya Schofieldi is another fine plant in this collection. Its flowers are olive-green spotted and barred with brown, and the lip is white dotted and spotted with violet. W. H. G.

White Lælia anceps of 1885.—Can anyone yet tell the best way to succeed in growing this refractory Orchid? We have tried plants in various houses and ways. Plants of it in pots in the Cattleya house on the north side stage with shingle under the pots have proved the best, but we cannot get a spike of flowers. Certainly our plants are not large, but ample in size to bloom in quantity were they typical L. anceps or L. Hilliana, &c., which are blooming alongside the new comer. Mr. Douglas says he finds his plants to be equally unsatisfactory. Can others record any success? if so, I would be obliged if they would do so.—De B. Crawshay, *Rosefield, Sevenoaks.*

SHORT NOTES.—ORCHIDS.

Shading cool Orchid houses.—At Wilton House, Southampton, the canvas shade of the cool Orchid house does not touch the glass, but is supported upon false rafters about a foot above the roof. This allows a current of cool air to circulate between the shade and the glass, and doubtless contributes to the geniality of the atmosphere within the house.—W. H. G.

Certificated Hollyhocks.—In our report of the last meeting of the Royal Horticultural Society at South Kensington we erroneously stated that Mr. Blundell, of Dulwich, was awarded two certificates instead of three. The sorts for which he received certificates were Princess of Wales, Primrose Gem, and Shirley Hibberd.

Names of plants.—*Mrs. M. A.*—1, Buphthalmum cordifolium: 2, Bocconia cordata; 3, Saponaria officinalis.—*L. P. and Co.*—Pyrethrum Parthenium fl.-pl., Sedum oppositifolium.—*R. Linter.*—1, Oncidium ornithorhynchum; 2, O. incurvum.—*Inca.*—1, Cut-leaved Beech (Fagus sylvatica laciniata); 2, Diplacus glutinosus.

WOODS & FORESTS.

LARCH SEED, NATIVE V. FOREIGN.

It has recently been stated that the oldest and best Larch forests in this country are those that have been acclimatised, while the younger plantations from home-raised seed are the most diseased. There is some truth in the first part of that statement, viz., that the oldest and best Larches are those that were first introduced, but for the rest of the statement there is no foundation, because the younger plantations are not from home-raised seed, but chiefly from foreign seed. And even if the younger Larch plantations were from home-raised seed, this does not prove that that is the cause of disease, or that they are the most diseased; no, it only proves negligence, and that there is a want of judgment on the part of those employed to gather seed to discern between that which is fit and that which is not. Last season, for instance, I found the gatherers picking cones from the very young and most unhealthy Larch trees of our woods. And it is well known that diseased trees often bear seeds most abundantly. A year ago the seed of the Larch was destroyed in our woods by summer frosts, and I do not believe there was above one per cent. of vital seed. Nevertheless, these cone-gatherers bore away great burdens of these bad cones, until I stopped their work and turned them from our plantations. What do these men care how much they deceive their employers and the public. They have no interest in the future success and prosperity of the trees that are to ensue from the seed they have been entrusted to gather; no, their interest in the matter ends when they get their bags filled.

For some years I have been testing the quality of the vitality of both foreign and home Larch seed, and the result of the test is not favourable to the progeny of the foreign Larch. In the seed-bed during the growing season the progress of both Larches are nearly the same, the foreign, if anything, having the best of it; but the foreign does not ripen its wood in proper season; it is cut down with frost, and is ever afterwards permanently injured. On the other hand, the home Larch does not at first show such rapid growth, but manifests throughout a stronger constitution and vitality, and when once consigned to the forest ground, the produce from the foreign Larch cannot be compared with the home trees; in a word, the home Larch lives on, and the foreign Larch dies away. I am aware that there are districts both in England and Ireland in which the climate is quite conducive to the growth of foreign Larch. Still, I am of the opinion that the most propitious climate and conditions conducive to its success would be yet more so to the home-raised Larch.

Since the Larch was first introduced into this country the climate must have undergone a vast transformation. For example, the Larch refuses to grow in soil which formerly it delighted to luxuriate in. What is the cause of that? The soil being the same, the climate, a co-equal factor in plant life, must have changed. Moreover, I again repeat with all the small force of urgency at command that there is not sufficient care used in the gathering of tree seed. Perfection of parts in the parent plant is indispensable to perfection in the offspring. Perhaps it is not generally known that from a bushel of Larch cones there is not more than from 2 ounces to 3 ounces of good seed; from a bushel of Scotch Fir there is only from 6 ounces to 8 ounces; and from a bushel of Spruce from 7 ounces to 9 ounces. But these weights are liable to modification, depending on the age, &c., of the individual trees they are gathered from. J. F.

USES FOR WASTE WOOD.

It is not altogether easy to define what should be classed as waste wood, but in the ordinary meaning of the term it is understood to be the lops and tops of timber trees and the off-cuts from the boles in the process of sawing up. The proportion of waste in manufacturing will naturally vary greatly, according to the dimensions and quality of the article it is primarily the purpose to obtain from a given tree, and the conformation of the body of the tree will of itself be an important factor. It is not, however, to this side of the question I wish to look, except so far as it concerns the production of waste. To take the subject in the order in which the waste or unmarketable wood is produced, it is obvious that the lop and top of the trees will have to be dealt with first, as, when a felling occurs, the greater proportion of the woodman's work is at once directed to the disposal of this waste wood. There is one way in which it may readily enough be got rid of, viz., for fuel, and when it is not valuable enough to be carted away for ordinary domestic use it can be burnt upon the spot for charcoal or otherwise. There are, however, purposes beyond this to which waste wood may be put, and it is to these I wish to allude.

Firewood.—In lopping trees for removal, between what is usually denominated the brushwood and the bole there is always more or less, according to the size and the habit of the tree, of limbs or branches. This in many parts of the country is called cordwood, but it is a term very loosely applied, as in one district it means round logs, whilst in another it may mean short blocks of less than a foot in length and cleft ready for, say, a register grate. When the limbs or branches have been reduced to the last-named form, it is clear that the chance of any usefulness beyond that of making a fire is at an end, but when they are merely lopped from the bole of the tree in lengths as long as can be conveniently handled, they may often be turned to much more useful purposes, inasmuch as fuel can be obtained from other material. To utilise these logs to the best advantage, however, it is necessary that some cheap cutting power be available, as, although it is not often that any great skill is necessary in working up, cheapness is all-essential, otherwise the cost of labour would make it more profitable to use something else. In short, to make the most of this class of waste wood a saw-mill in some shape must be at hand. The usefulness, and, in fact, the almost indispensability, of such an appliance has often been urged in this paper. For working up small wood of the class under notice a single bench would answer every purpose, and now there are very few districts where such a thing is not to be had, if the owner of the wood does not himself possess one.

Generally when a fall of timber takes place it will be found most convenient as soon as the brushwood has been disposed of by being made into fagots, or in some other way, to cart the branches and limbs to which reference has been made to some central spot where an engine and bench can readily be set to work upon them. In doing this there is the advantage of selecting from the bulk of wood such as is suitable for the especial purpose in view and of cutting up what has no better worth for the firewood stack. It will, however, be generally found that a lot of useful material may be found among the waste before this becomes necessary. To take Oak logs, for instance; one of the handiest things upon a place is a supply of mound posts. These, as they are generally wanted from 6½ feet to 7 feet long, should be one of the first selections made. From the branches of ordinary trees it will be difficult to find round pieces which run straight to the length, but in most cases there are many logs which are approximately straight one way. In this straight direction they have to be sawn into two sections by means of a centre cut, and a couple of useful mound posts are at once available.

Fencewood.—Amongst this waste wood it is seldom that material suitable for rails is found, but it is almost in all cases capable of affording a large quantity of rough palings, so that the rails, in erecting a fence, would be the only thing left to be provided. A height of 4 feet or 4½ feet very often makes a serviceable fence, and for such as these logs of wood which are not long enough for posts may be turned to account. Dividing fences of this class may not be required to be absolutely close, and yet close enough to make them quite secure. Small and rough logs properly cut up may be made to answer this end. The size of the round wood itself and the purpose to which it is to be put will to a great extent control the way in which it is prepared. If a rough and heavy erection is wanted, then it will be enough to merely cut the logs into sections in the same way as the posts and use them in the same way, with the difference that they merely reach the surface of the ground and are fastened to the rails instead of being let into the ground for support. For this portion of the work Elm or Oak may be used indiscriminately. When a lighter style of erection is wanted, it will be necessary to employ a little more labour in the preparation of the wood, but the same kind of logs will do duty. Instead of merely cutting them into half round sections they must be reduced to a greater number of pieces of lesser thickness. To make the most of the material, the straightest pieces should be chosen and two parallel cuts be taken, so that a thin slab may be taken off each of the two opposite sides and a plank of some inches in thickness, according to the size of the log, be left to be reduced to pales of the required thickness by making cuts at right angles to the original ones. The slabs taken off in the first instance may then be edged down and will make two additional pales. It is obvious that such wood as this can be employed for many other uses beyond that of pales for low fences. Turned in a horizontal instead of a vertical direction, it would be useful for the pales for tree guards, and in many instances it could be used for rough floorings for sheds and outhouses, where the nature of the use would not allow of the employment of material of appreciable value, but where wood of this class would be greatly to be preferred above an ordinary soil floor. So far, I have spoken of waste wood in its raw state, *i.e.*, as it is always to be found in quantity wherever any trees are felled, but there are other kinds of waste wood which may often be bought from the merchant's yard and used in conjunction with what is manufactured at home.

It will be seen that the materials which have been referred to hitherto have been of short lengths and narrow widths, conditions which are unavoidable when only small logs or branches are cut up. Merchants, of course, saw up trees of all lengths and size, and in consequence of the uneven way in which British hardwood trees generally grow, it is seldom they are not well supplied with waste. This takes all shapes and sizes, according to the form of the trees which have been sawn and the class of scantling into which they have been worked. There is, however, generally a good proportion of slabbing of good lengths and widths, *i.e.*, the rough outsides which are always cut off to make at least two

square sides to the tree. Besides this, there are often right-angled pieces coming off, which make useful light posts. I have spoken of these things as being procurable from the merchant's yard, as it will sometimes be found that work of the kind we have been dwelling upon could not be carried through entirely with the material at command upon the place. It of course requires discretion as to how far it will be economical to use up "waste wood," as it is quite possible that it may be made to cost more than using really good and marketable timber. D. J. Y.

NOTES ON THE PARLIAMENTARY REPORT ON FORESTRY.

By "Yorkshireman."

The report from the Select Committee on Forestry, or the chief part of it, has been circulated, and contains some evidence that may interest foresters, but not so much as might have been expected.

The committee.—This body deserves notice from the fact that it is composed of men who may be said to be practically unacquainted with the subject they had to investigate, but that was probably unavoidable in a parliamentary committee. That some of its members did not always feel sure what questions they should put to the witnesses, and did not grasp the answer when they got it, will appear in a rather amusing aspect here and there to those who read the report and who understand forestry themselves; as, for example, when Mr. Seely asks Mr. Thistleton Dyer what planting Oak "pure" meant—a forester's expression borrowed from one of the horticultural papers—and on another occasion when another member asked the same witness to give him the English name of a certain Indian tree, &c. This unacquaintance with the subject on the part of the examiners is quite apparent in the report, and hence, no doubt, its diffuseness and length, considering that the sole object of the enquiry, as set forth in the report in three lines, was "to consider whether by the establishment of a forest school, or otherwise, our woodlands could be rendered more remunerative." Not knowing exactly what questions to put in examining the "witnesses," the latter were encouraged, by leading questions and otherwise, to say what they had a mind to, and some of them have, of course, availed themselves of the opportunity to ventilate their hobbies pretty freely.

The witnesses.—"The committee had power to send for persons, papers, and records," and they availed themselves of this power to the extent of summoning six witnesses, and under the head of "Profession or Condition," three of the six are described as "Civil Service Ingineers" (if "C. S. I." indicates that), "M. D.," and "Colonel" respectively; the other three are Mr. W. G. Pedder, Mr. W. T. Thistleton Dyer, and Mr. Julian C. Rogers. It might be regarded as a phenomenal circumstance by some that of the twenty-six committee-men and witnesses nominated to investigate the subject of forestry, there is not a single practical forester amongst them. It might have occurred to a jury of common-sense people with "power to summon" whom they liked before them that the examination of woodmen or foresters was desirable, if for no other purpose than to show whether our British foresters were as stupid or as clever as they were reputed to be, but such an idea does not appear to have occurred to the commission in question that did sit. Numbers of questions were put and answered on this point to witnesses who did not, and could not, give any reliable information on the subject. The evidence of Mr. Thistleton Dyer on the subject is amusing, but honest. Asked by the committee: "You are assistant director of Kew?" the reply is, "Of the Royal Gardens, Kew." To the second question, "And you have paid great attention to the management of forests and woodlands?" the conscientious answer is, "My attention has been drawn to the general subject of forestry from the fact that Kew performs to a large extent the part of a botanical authority to the government, and numbers of questions affecting botanical work are referred to Kew, which it is my special business to attend to. Amongst these, of course, from time to time are questions relating to forestry, and although I have not myself any practical knowledge of the management of forests, I have been compelled, of course, to look into the subject," &c. This is a good example of some of the questions and answers. The assumption on the part of the chairman of the committee, Sir John Lubbock (who put these questions), that an officer of Kew must necessarily have paid "great attention to the management of forests and woodlands," shows the crude notion our legislators have concerning the functions of a botanical garden, and Kew in particular. Mr. Dyer, pressed to say if it was "his opinion that if a general education in forest matters were available, it would have an advantageous effect upon our English and Scotch forests and woodlands," "imagined there could be no doubt about that," and he quoted from "a file of a contemporary in which some of the superior members of foresters in this country occasionally write" to show "that the woodland practice in this country is in a very unsatisfactory state when you find two competent authorities on the same subject in a prominent newspaper diametrically in opposition to each other on the same point." This one cannot but regard as rather second-hand evidence on such an important subject, but it is an example of the kind of evidence sought and given.

Testimony of the witnesses.—It seems to have been assumed by the committee that our Indian forests are better managed than the forests at home, and that this better management is due to the better training of the forest officials there; hence, much of the evidence was directed to the elucidation of this point, the purpose of the committee, be it remembered, being to prove the need of educating British foresters also. Mr. William G. Pedder, of the Revenue Department of the India Office, was the first witness on this point. Sir John Lubbock surmised that the increase in the net revenue from Indian forests was due "to a considerable extent to the improved education of the forest officials," but the witness "did not lay much stress upon the increase of revenue, because, as a matter of fact, the financial results had hardly yet become apparent at all," and the general purport of his evidence was to the effect that "the principal duty of the forest department of India" had been rather to arrest the destruction of Indian forests and take care of what was left. This witness said he "knew but little about English woodlands," but gave some evidence on the subject of schools and about our Indian forests and their extent. Here is a specimen of the questions addressed to this witness by one of the committee, and which should be quoted as put with the answers:—

138. I suppose forests have existed in India for a great number of years?—Yes, from the creation of the world.

139. Then who planted them originally?—No one; I suppose they planted themselves; they are primæval forests.

140. They have not been planted within history?—No.

141. Then the process of managing these forests in ancient times must have been better than it is now; because if the process of destruction that you say is going on so rapidly had gone on before they would have disappeared from the face of the earth long ago?—Yes; but there are reasons why they could not be interfered with. Forests through which there are no roads it was impossible to cut and take away.

To ask a witness who planted forests "originally" that had been there from the creation of the world showed a laudable desire to "bottom the matter," that should be commended to all future Parliamentary committees.

Dr. Farquharson, the committeeman who wanted to know who originally planted the forests at the creation, and who was unfortunately not referred to the twelfth verse of the first chapter of Genesis, volunteered some information himself to the witness, Mr. Pedder, on the grazing of woodlands, a subject discussed in *Woods and Forests* before. Dr. Farquharson said they were in the habit of grazing woods in Scotland with highland cattle and held that they did not eat the young shoots of the trees; but the witness contradicted him, pointing out that forests could not be safely pastured by cattle, according to the best authorities, until they had grown up, and that sheep and goats were particularly destructive.

Dr. Cleghorn was of opinion that "we are in England very good arboriculturists, but not very good sylviculturists," a rather vague description, which he explained to mean that in the production of fine specimens of trees we stood higher than any other country, but were not skilled in the management of woodlands or in the production of timber—an opinion with which we agree, speaking generally. In this witness's opinion "the selection of species, the choice of soils, the situation, the mode of planting, the mode and degree of thinning, and the determining the time of felling the timber so as to obtain the best results" are all matters of first importance "requiring skilled training and much observation," an opinion that receives corroboration in *Woods and Forests* almost every week. He also thought Great Britain and Ireland in a very backward condition as regards "systematic forestry," while at the same time he was aware there was no country relatively where the consumption of timber was larger than in our own—a somewhat paradoxical condition of things, though the description is true enough. Dr. Cleghorn also believes, as all foresters have also declared who have written on the subject, that there is still vast scope for planting waste and other lands in this country, but whether by doing so we should be anticipating future demand caused by the present rapid destruction of natural forests abroad, or whether it might be worth while to plant any but readily accessible positions in this country under any circumstances, was open to question. The west coast, it is also stated, is more favourable to the production of timber than the east coast. Another fact elicited was that "with a steadily increasing annual demand for timber, which is constantly rising all over the country, the amount of timber in England, Wales, and Ireland is steadily, and even rapidly, diminishing"—in some parts "without any attempt at reproduction of timber." If true, this may be said to be the most important fact brought before the committee, and one showing the necessity of State interference of some kind.

As to foresters, the same witness said there were some exceedingly shrewd and valuable men in Scotland, but they would have been better if they had had "more theoretical knowledge . . . They have read what books they have been able to get in their cottages, but having no school to go to, lacked the opportunity of improvement." We fear the experience of publishers of papers and periodicals on forestry does not quite bear this out either in England or Scotland. Colonel Pearson, the next witness, did not think the young foresters in Scotland were practically very well instructed in the management of timber for commercial purposes, but thought there "were many of them exceedingly intelligent men who, by rule-of-thumb and by experience which had been handed down to them, had learned the system of planting and growing trees exceedingly well." These were points on which knowledge was required, and an example of want of knowledge which the colonel quoted was a case "in which a great number of trees (Scotch Firs) were blown down that might have been saved by a fringe of Birch, which would have grown perfectly well above the Scotch Fir, and which ought to have been planted to keep the wind out of the ravines," but which was instead planted by Scotch Fir right up to the top of the ravines, and "the wind got amongst them and knocked them down like a field of corn." What do Scotch foresters say to this hint? We confess to not seeing the advantage of a fringe of low Birch at the top of a ravine to protect Scotch Firs further down that had overtopped the Birch a long way. The rather extraordinary character of Colonel Pearson's evidence has been commented on before. To this report I may again allude.

No. 771. SATURDAY, Aug. 28, 1886. Vol. XXX.

"This is an Art
Which does mend Nature; change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

ROSE GARDEN.

ROSES OF THE FUTURE.

WHAT rosarian can fail to welcome with glowing enthusiasm "T. W. G.'s" "coming race of Roses (see p. 138), which shall keep all gardens gay throughout the summer with blooms of every conceivable shade of colour, in which blue is an unknown factor." This, indeed, is a grand idea, and it is well to aim high, as Sam Slick said to his father, when surprised up the parental Apple tree, though we may never reach it. Roses in perpetual bloom and many-coloured beauty, with fragrance thrown in without stint or measure, would lift the floral treasures of our gardens out of the miry clay at once. A Rose without fragrance is hardly more than half a Rose at best, and hardly deserves its name. Other qualities, too—such as constitution, continuity of blossoming, form, substance, staying power—are needed in popular Roses. Constitution is a comprehensive phrase, and includes all that pertains to vigour, health, and fairly long life. Not a few of our popular Roses are the creatures of a season, if not of a day. They come, they go; we can hardly say they are with us in health when already they droop, become diseased, and die, and are seldom seen more. The ratio of the durability of Rose life has decreased more rapidly than the quality of our Roses has improved, and, with a few notable exceptions, it may be affirmed that, as the quality of the blooms has waxed, the health and length of life of the plants have waned. Worse than this, the highest qualities have not seldom been wedded to milliness of constitution. It is time all this had become matter of long past experience. As one means of getting rid of milly Roses, a juror of experts should sit upon the Rose itself as well as its produce before the latter was certificated.

Semi-disease-proof Roses ought to become possibilities of the near future were more attention paid to constitution in the selection and propagation of Roses new and old. At present it is hardly too much to say that constitutional stamina and vigour are wholly ignored in such matters. The great aim is to produce perfect blooms. No sooner are these produced than they are exhibited, certificated, forced into unnatural growth to form plants quickly, until any natural vigour the seedlings possess is rushed out of them in the feverish race to convert each bud into a half-sovereign or a guinea. Thus by the time the plants are distributed most of their natural strength has been further overstrained and attenuated to the lowest living point by the feverish forcing to which they have been subjected. Bearing all this in mind, we marvel the less to find miffy Roses disfiguring many gardens, while Roses, like giants, are becoming more and more rare. As to continuity of blooming, never was the force of a word or a phrase more misleading or more abused than the words Perpetual or Hybrid Perpetual. I accuse no one, no class, of fraud. The phrase was chosen at first more to define a class than describe a quality. Gradually, and especially among amateurs, it has come to be understood as twice or more times blooming Roses in one season. In this sense the phrase is certainly a fraud as applied to the majority of the Roses in these classes; and as for true continuity of blooming, that is, crop succeeding crop of bloom at very short intervals where can we look for it? I fear we shall still have to search for it among the old China monthly Roses, or their lineal descendants, the Teas. So far as quality in its full and free development is concerned, we may almost be said to have advanced backwards. The nearest approach we have to this quality among the many so-called Hybrid Perpetuals may be found in the exquisitely fragrant, clustered, white Rose Boule de Neige. This crossed with Chinas, Teas, or Bourbons ought to yield a rich harvest of fragrant continuous-blooming Roses. Good form is another quality that is far from being perfected in many of our popular Roses. The National Rose Society has done useful work in publishing its semi-perfect types of Roses of several forms. Whether some of these should be admitted to the honour of a place at all in such estimates may be an open question. But my one point here is that each Rose accepted as of good form should be so and continue so from earliest budhood to perfect expansion. The latter phrase is not used here as synonymous with full blown. This last has a *passé* flavour or ring about it, suggesting the possibility of falling to pieces, or of one or more petals having already fallen. But perfect expansion should excite no suspicion of decay, nor exhibit any symptoms of deformity. Roses, such for example as Souvenir de la Malmaison, however beautiful in bud and useful in the garden, could hardly come up to our standard of good form, viz., fine buds and finish.

Substance or thickness of petal should be a prominent quality in the Roses of the future. Camellia-petalled Roses take on more colour and hold it longer than the flimsy petalled that fade or curl up at the first touch of sunshine. The burning out of the colour of Roses is such a common expression and such a growing evil, that whatever of constitutional vigour or substance of petal would hold it longer with a firmer and more unchangeable grip is to be eagerly welcomed in the Roses of the future. This is closely allied with what is here termed the staying property of the flowers, alike on the plants and after the blooms are cut. Some Roses, as it were, fade and fall to pieces, or lose colour or fragrance almost as soon as they are severed from the plants, while others keep fresh and sweet perhaps a week or more after opening or gathering. There are also curious differences between the staying powers of Rose blooms of the sorts that flower in summer and in autumn, and these are not by any means always explicable by any mere differences of temperature between the two seasons. Neither is it always true that the fuller the Rose the greater the staying properties of its individual blooms. Niphetos is by no means a full Rose, and yet few, if any, equal it in staying properties, and the same remark holds good of others; and perhaps few contributions could prove more interesting than the experience of Rose growers and exhibitors on this most practically useful point of Rose growing and use. The journeyings to and fro of some individual blooms and perfect dozens of such varieties as Niphetos, La France, Maréchal Niel, &c., would astonish not a few non-exhibitors, and greatly raise the general reader's estimate of the staying powers and travelling abilities of individual Rose blooms.

D. T. F.

Passiflora laurifolia.—Mr. Morris, of Kew, in his paper on tropical fruits, read at a conference in connection with the Colonial and Indian Exhibition, referred to the fruits of this Passiflora as among the choicest and most refreshing of the tropical Poma. They are called Water Lemon, or Pomme d'Or, in Jamaica, where they are highly prized as a dessert fruit. The species, which is now flowering in the Palm house at Kew, is distinguished from all other cultivated Passion-flowers by its dark green Laurel-like leaves, and, when in flower, by the russet-red colour of the short reflexed petals, and the double series of erect filiform corona rays, which are coloured a rich violet with white bands. The fruit is egg-shaped, 3 inches long, and purplish brown when ripe, so that it resembles the fruit of the well-known P. edulis, the Sweet Cup of Jamaica, and cultivated in a few gardens in England for the sweet, watery juice of its berries. English-grown fruits of these Passifloras, as well as of the Granadilla (P. quadrangularis) are usually mawkish, and relished only when well sugared or in other ways rendered palatable, and no doubt this inferiority, as compared with the delicious lusciousness of the fruits of Passifloras produced in the tropics, is partly explained by the absence of intense and continual sunlight. In tropical countries the parched palate, too, must often find refreshment and delight in what would not be though much of in this country.

GARDEN IN THE HOUSE.

FLOWERS FOR HARVEST FESTIVALS.

HARVEST festivals having become general all over the country, and flowers forming as they do such an important feature in connection with them, reference to some of the most suitable for the decoration of churches and other buildings may be useful. Anyone who has been much engaged in this kind of work will, I think, agree with me that where large quantities of flowers are wanted a certain space of ground should be set apart specially for their production as cutting them from beds or borders causes sad disfigurement. It will be readily understood that in order to make conspicuous decorations rather large flowers are necessary. The Dahlia is perhaps as valuable as any for such purposes, especially the large show and double Pompon varieties. Single ones also come in admirably for positions more immediately under the eye. The large double sorts are indispensable for the decoration of lofty buildings, as the blossoms are bold in character and embrace many striking colours. Of the latter the most useful perhaps are yellows, whites, and scarlets, large numbers of which should be provided. Tasteful arrangements may be made with the flowers of Pompons, especially in the case of crowns or monograms. Some good lilacs and fiery reds work in well with a judicious mixture of greenery. The annual Asters are also indispensable for this class of decorations, as they last in good condition for a long time. The most showy, on account of their large size, is the Chrysanthemum section. These produce very large flowers, which are most useful where masses of colour are required. They may be pulled up intact out of the ground, or cut off just above the soil, and the whole plant may be used with good effect if desired, or the individual blooms may be used in any way where wanted. The Victoria is another grand class for forming masses of colour, as are also the quilled varieties, but the latter are generally preferred for mottoes or devices, as they possess better form and outline than the others. Asters for this purpose need not be raised in heat. If the seed is sown on a warm border in the middle of April, and the plants are brought on under hand-lights, they will be well in flower by the middle of August, which is as soon as they are generally wanted. They require to be grown in an open position where the ground is thoroughly rich, and in order to obtain large flowers the plants must stand 15 inches apart each way, and receive an abundance of water in dry weather.

HOLLYHOCKS are also valuable for decorative purposes; few other flowers, indeed, are so stately in their bearing, and the larger the building to be decorated the more will they be appreciated, as whole stems may, if desired, be used, or the stems may be cut into lengths. The individual flowers may also be removed from the stem, and used for devices or other purposes. The flowering portion of the stem I, however, look upon as being the most valuable, as, if the plants have been well grown, there will be ample foliage associated with the blooms to set them off to advantage. There is, too, such a wide range of colour amongst the flowers, and they are so thickly set on the stem, that no list of blooms for indoor decoration would be complete which did not include them. The best way in which to grow Hollyhocks is to sow seed of them in the open ground in July or early in August, and, if the plants are well attended to, they will be strong enough to plant out early the following spring, and will flower grandly at the end of the summer, but they require to be planted in rich, well-prepared ground, and to be well watered in dry weather.

GLADIOLI of the gandavensis section are undoubtedly amongst the most brilliant of all flowers for

church decoration that blossom late in the year. The colours are not only bright, but they are also varied, and there is no other plant with which I am acquainted that lasts so long after it is cut. The flower-spikes are admirably suited for suspending in bunches if desired, and also for mixing with other subjects. The most reliable way in which to get and maintain a stock of these flowers is to raise one's own corms, which may be readily done from seed. Plants thus raised will flower strongly the third year, and a little seed sown every year will keep up the stock. The next best plan is to buy seedling bulbs of a flowering size, as these invariably do better than named sorts, which are reproduced by offsets. Gladioli must be planted in deep well manured soil, and they should have a change of ground every year. Hyacinthus candicans, although not a striking plant, has tall flower-spikes, towards the tops of which hang numbers of white bell-shaped flowers, admirably suited for mixing with other things, and, owing to the length of the stems, the operator, with the aid of these, will be able to break up what might have been a flat or monotonous surface. Being a hardy plant, and indifferent about soil, anybody can grow it. Three or four-year-old bulbs, if planted in good soil, will push up flower-stems 4 feet in height.

Harpalium rigidum, when used in sufficient quantities, is a very showy plant for indoor decoration. Its bright orange-coloured florets and black disc render its flowers very conspicuous, and as its stems reach a height of 4 feet, they may be used with striking effect in large or small quantities. With plenty of greenery as a background, and a large handful of the stems tied together at the bottom, and the ends encircled with damp green Moss to keep the flowers fresh, a bright bit of colour can be produced for filling up recesses or angles in rooms. No plant is more easy to grow than this, and it will thrive in almost any kind of soil; its only fault is that its roots cannot well be confined to any particular spot; they have an awkward way of running beneath the surface, and sending up shoots next season some distance away from the old stool. The best way in which to grow it for indoor decoration is to plant a mass of it in some position where its spreading proclivities do not interfere with other subjects. Hydrangeas are hardy flowering shrubs, the blossoms of which come just in time to be useful, and where good-sized plants exist they afford large quantities of them. The common Hydrangea is perhaps the freest flowerer, but H. paniculata and Thomas Hogg are both desirable sorts, the last-named producing white flowers. These plants, when well grown, bear large heads of flowers, which are conspicuous in decorative arrangements when used in sufficient quantities. They are not quite hardy in all parts of the country, but in all doubtful situations they should be planted pretty close to a wall facing the south or west, and be allowed to grow away from it in their own way. Chrysanthemum Leucanthemum thrives anywhere, and its flowers last long in good condition, *i.e.*, if the stems are tied up in damp Moss. Large armfuls of this may be cut from a few strong plants, which, if they get plenty of sun and air, will grow in any odd corner. Its florets are pure white and the disc yellow.

Michaelmas Daisies are not, as a whole, particularly showy, but they produce flowers so freely on long stems, that they will be found useful where decorations are carried out on an extensive scale. Amellus has violet-purple coloured flowers that are large and showy. Sunflowers are indispensable in decorations for large buildings, and they are so easily grown that I need not say more about them. Zinnias, too, are useful where there are tables to decorate, as both in form and colour the flowers are good. In neat devices I have always found Sweet Peas to be much valued; but in order to have them in quantities so late in the summer they require special treatment. The seed should be sown about the middle of May in a trench prepared for it as for Celery. During summer they must be well watered, if the weather is dry, and be supported by sticks in the usual way. The seed-pods that succeed the first flowers must in all cases be cut off as soon as they appear, as their production exhausts the plants and stops their flowering.—*Field.*

Yuccas and Ivy for balcony culture.—One of the balconies in Portman Square is now a picture of freshness and leaf beauty, even amid dust and smoke; the baleony railings are covered with gracefully drooping Ivies; three or four plants of Yucca recurvata, too, in ornamental vases, break the formal line of the trellis below and give a finishing touch to the whole arrangement—one of the best of the kind, by-the-by, that I have seen for some time. —H. B.

PLANTS IN ROOMS.

We have many plants that are well adapted for use as permanent ornaments for apartments, although there are but few in general employed for that purpose at present. Among the plants best adapted for the permanent decoration of apartments we may mention Ivy, Palms, hard-leaved Ferns, such as Cyrtomium or Niphobolus, and many of the more vigorous-growing American Aloes or Agaves. The common India-rubber, Ficus elastica, is also invaluable for indoor decoration, as are also many of the Yuccas. For the temporary decoration of saloons, drawing-rooms, or reception-rooms, we have a much larger variety of plants at our disposal. Many of the Palms and Ferns generally cultivated in stoves may be gradually inured to a cooler temperature before removal, and can then be used during mild weather without much injury. Flowering or foliage plants, judiciously arranged, are always attractive as indoor ornaments. Hard-leaved plants, as Palms, Ficus, Cycads, and Aralias, are specially adapted for indoor culture or for temporary groups, and can easily be cleaned and refreshed by occasional spongings with clean tepid water. Dust and gas, and excessive aridity in the atmosphere are always, more or less, injurious to all plants, but those we have named will stand better than most others under these unfavourable conditions. We have still much to learn with regard to the indoor uses of plants, and, in this respect, might do worse than imitate the Parisians, or inhabitants of North Germany, many of whom make room and window gardening contribute much towards the comforts and attractions of home. B.

NOTES OF THE WEEK.

Alocasia Sanderiana.—Not only is this plant one of the most distinct and effective of the genus, but it has the additional recommendation of doing well in a lower temperature than that required by most of the family. It is very effective even in a young state.

Griffinia hyacinthina.—On this very beautiful old-fashioned plant the variety splendens, now flowering in Mr. Bull's nursery, is a great advance, both in size of flower and in the intense richness of its amethystine petals. It is a plant well deserving more extended cultivation than it generally receives, blooming, as it does, at a season when flowers are somewhat scarce.

Lilium auratum at the National Art Treasures Exhibition, Folkestone.—We have here a fine specimen of Lilium auratum, kindly lent by Mr. J. Lonsdale, of Sandgate. It is the produce of one bulb, bought nineteen years ago, and never since disturbed. It is in a tub, and is bearing 45 spikes, on which in a few days there will be 315 fully-developed flowers. Last year it bore 275 flowers.—Henry King.

Crotons at Holloway.—Crotons are often too heavily shaded; as seen in the Victoria Nursery, they are most brilliant—fountains and pillars of gold and fire. Here they are staged close to the glass, and therefore fully exposed to the sun. They are never shaded, and those whose Crotons are without colour should adopt this system. It will soon produce a marked difference in their appearance.

Lilium tigrinum Leopoldi.—This form is so much better than the ordinary Tiger Lily, that when placed side by side, the latter suffers greatly by the comparison. Its flowers are larger, and the spots are more conspicuous and richer in colour; the plants, too, retain their leaves better, a matter of importance when grown in pots. Large masses of this variety form at present quite a prominent feature in Mr. Bull's nursery at Chelsea.

A graceful basket Grass.—Ophiopogon intermedius is one of the most graceful plants with which we are acquainted for decorating hanging baskets, or for edgings to borders or stages in stoves; its soft, green, crispate leaves render it very effective. It is not readily crushed or broken, and it affords a pleasing contrast to plants having brightly coloured flowers. For such purposes Mr. Bull uses it with excellent effect.

Eucharis Mastersi.—This elegant species, placed in commerce this season by Mr. Bull, undoubtedly rivals in beauty the older and well known E. amazonica, not on account of its size, for its flowers are smaller than those of amazonica, but from its greater adaptability for button-hole bouquets and shoulder sprays. The flowers, which are of the purest white, are delicately fragrant, and have a refined appearance, just suiting them for the purpose indicated.

Haplocarpa Leichtlini.—Some flowers of this plant have reached us from Mr. Ware, of Tottenham, and we think them extremely pretty. The plant is a Composite, with flowers as large as those of a Doronicum, bright yellow inside and stained with purple outside. They are produced singly on stalks nearly a foot high. The leaves are deeply cut, and their under surfaces are quite white. We have no experience of its hardiness, but we imagine that it is quite hardy, judging by the specimens before us.

Exhibition at Dresden.—A great international horticultural exhibition, of which the King of Saxony is a patron, is announced to take place at Dresden during the second week of May next year. It will be held in one of the fine old royal parks close to the city. The schedule embraces 392 classes, and about £1000 are offered in prizes, which number about 1000. Special invitations are given to foreign exhibitors, so as to make the show as international as possible.

Passiflora vitifolia is a beautiful climber for a warm greenhouse, surpassing all other Passion-flowers in the brilliant scarlet of its large graceful blooms. In a cool house, where, for instance, P. cærulea would be at home, this species would not thrive, nor yet would it in a stove; but on the roof of a Cattleya house, in a warm conservatory, or on the end of a vinery it grows and flowers well. It must have plenty of sunlight too, and, of course, a rich soil with liberal allowances of water in summer. It may now be seen in flower at Kew.

Chrysanthemum atratum.—Mr. E. G. Loder has sent us a photograph of this plant growing in his garden at Floore, Weedon. The specimen is 3 feet 8 inches high and as much across, and bears 670 flowers, each 4 inches in diameter. They are white with yellow centres; in fact, very similar to those of Leucanthemum maximum, to which the species is nearly allied. It is a native of Central Europe, and is also known as C. ceratophylloides. We intend to have an engraving made from the photograph.

Crimson Cactus Dahlia.—Mr. Hartland, of Cork, sends us flowers of a very fine double Dahlia, which, as regards shape, is only comparable with the Cactus Dahlia (Juarezi), though in reality quite different. The flowers, which measure about 5 inches across, are of a glowing crimson, and the florets shine with a satiny lustre. It must be an extremely effective sort in the border. Mr. Hartland sends for comparison one called Cochineal, which is not only much smaller and inferior in shape, but duller in colour. He believes that his large crimson Dahlia has existed in Ireland for many years.

Gloxinias at Heatherset.—This collection when we saw it a few days ago was very fine. Imagine a thousand plants, each bearing from seven to fourteen flowers, and some idea of the effect produced by them may be formed. They are only in 3-inch pots, but the blooms in some instances measured upwards of 2 inches in diameter. The kinds included erect French spotted kinds, English erect forms of every variety and shade of colour, and selfs rich and, in some instances, new in colour. A badly shaped flower amongst them was an exception.

Aristolochia elegans.—This lovely climbing plant, to which allusion was made last week, is not so robust as to require much curtailment in order to keep it within bounds; on the contrary, it thrives admirably even as a pot plant. Its shoots are slender, its leaves medium sized, green above and slightly glaucous beneath, and from their bases hang in profusion flowers of singular beauty. They are deep velvety purple—in short, nearly black, and mottled with creamy white, the throat being golden coloured. Owing to its neat habit, this is a plant which can be grown by everybody, whilst the fact of its blooms being destitute of any evil odours which most of the species possess renders it all the more welcome.

Begonia gracilis is a beautiful cool house plant, and should be grown even in gardens where the large-flowered tuberous-rooted kinds are in favour, for, although like these it has a tuberous rootstock, annual stems, fleshy green leaves and large flowers, it differs in several particulars, whilst in habit it is, as its name

denotes, graceful. From the rootstock several erect, unbranched stems are developed, and these when about 2 feet high bear from the axils of the leaves two-flowered racemes, a male and female flower springing from each cup-like pair of green bracts at the top of the peduncle; their colour is a beautiful crystal rose, and they are 1½ inches across. Along with the flowers, and produced in the subtending bracts, are clusters of tiny bulbils, which may be taken off and preserved as seed till spring, or they may be sown at once and the pots kept in a cool place till winter is over. Easily grown, for it thrives only when kept in a cool house or frame, easily wintered, and propagated without any trouble, this Mexican Begonia should become a popular garden plant. It is sometimes known as B. Martiana, B. diversifolia and B. annulata. The soil it thrives best in is sandy peat and leaf-mould.

Pancratium speciosum is a magnificent plant, and is almost as easy to grow as an Aspidistra. Its large heads of pure white flowers are not equalled by any other stove bulb, even Eucharis being its inferior in this respect. Either planted out in a rich border or in large pots it grows well and never fails to flower. It likes shade, that is, it may be grown under Palms and such like tall plants without suffering in any way. In addition to the size and beauty of the flowers they have a most fragrant odour. Altogether, this plant deserves to be placed in the very first position among useful stove-flowering bulbs.

Spiræa callosa alba.—If this is a white form of Spiræa callosa, it differs from the type in many other particulars besides the colour of the bloom, but, whether the above is its proper classification or not, it is a most beautiful flowering shrub at this season of the year, and under anything like favourable conditions it will continue to bloom till frosts set in. I had last year some not very large plants here in bloom from July till October—surely a long enough period. This Spiræa forms a low dense-growing bush, with flattened clusters of pure white flowers, that are produced so freely as to almost cover the upper portion of the plant. The delicate character of the flowers fits them for employment in a cut state if gathered just before they expand.

Shropshire Horticultural Society.—The annual summer show of this society was held in the Quarry Grounds, Shrewsbury, on August 18 and 19. The exhibits were more numerous than at any previous show, there being no fewer than 900 different subjects staged in the cottagers' tent alone. Fruit, too, was very extensively shown, and formed, perhaps, the most striking feature of the exhibition. The receipts at the gate were very satisfactory; on the second day, when the charges of admission were the popular ones of 1s. and 6d., no less than £115 was taken. The very handsome prizes of £25, £20, and £15 for plants, as well as £10 for Grapes, and £10 for a collection of fruit, provoked keen competition. During the last half-dozen years the society has given upwards of £1430 to Shrewsbury institutions out of its surplus funds.—Cambrian.

Aristolochia tricaudata and **A. ornithocephala** are now flowering freely at Kew, and are remarkable in structure as well as in odour. The former has flowers singularly like those of a Chimæroid Masdevallia; the saucer-shaped limb with three drooping tails, each 6 inches long, the tawny brown-red colour, and the position of the flowers being not unlike what one sees in Masdevallias. The Kew specimen, which stands in the Victoria house, is a shrub 4 feet high, with arching branches from which the flowers hang singly from the leaf axils. A. ornithocephala, now called brasiliensis, is a very large-flowered kind and climbs half way up the roof of the Palm house, where its blooms would be passed by unobserved were it not for their disagreeable smell.

A long-winded name.—Most of us think it sufficient to have to master two long and unfamiliar Latin words as the name for each kind of plant that we grow, but what is to be thought of this string of words fastened on to such a pale-faced innocent little plant as the white-flowered Anthurium, viz., Anthurium Scherzerianum album maximum flavescens? One wants to take breath in the middle of such a sentence. Possibly some of our nurserymen imagine that a new plant with an imposing name like this will surely attract attention. One of the good works of the great Linnæus was to abolish names of the above kind for binomial ones, that is, a generic and a specific name, but it would appear that we are being led back to the pre-Linnean period, or why should such a name be catalogued as the above? We will not mention the title of the periodical in which this name appears, but it is a respectable Continental one.

Aster Townshendi.—To many, and even those who grow collections of hardy plants, this Aster is a stranger, yet it has been known in botanic gardens for years. It is only lately that nurserymen seem to have discovered it, as being something worth their notice. It is really a beautiful plant, and we are glad to see that Mr. Ware, of Tottenham, thinks highly of it. Judging by the specimens he has sent to us, it succeeds admirably at Tottenham, and we presume it has proved itself perfectly hardy there. It may be best described as being in the way of A. Amellus, but its colour is a bright purple, and the florets are narrower and more numerous. It may be at once recognised by the bristly involucre. It grows a foot or more high, and is floriferous.

Montbretia crocosmæflora.—The New Plant and Bulb Company send us from Colchester a series of so-called varieties of this plant, all with different names, but we fail to find any difference amongst them in a cut state, though perhaps they may be distinct in growth. There are six named sorts, all with flowers of a bright orange-red, except one called Etoile de Feu, which has much darker flowers than the others. It seems a pity to multiply names in this way. The Continental raisers, however, are responsible for it. The names of the sorts sent are Etoile de Feu, aurea, elegans, Bouquet Parfait, pyramidalis, and Grebe d'Or. From the same nursery also come spikes of Watsonia Meriana, a showy Cape bulb with bright orange-scarlet flowers; likewise Antholyza Cunonia, with curiously shaped scarlet flowers.

The Butterfly Flower (Asclepias tuberosa).—This is one of the prettiest and most interesting of August hardy flowers, though it is not often that one sees it grown or flowered well. It is a hardy perennial, growing about a foot high in tufts, each stem carrying three or more dense clusters of orange-scarlet flowers of curious shape. The flowers are intermixed with the foliage, and as the clusters expand from below upwards, the plant remains some weeks in bloom. It is reputedly a difficult plant to manage, but in rich and moderately stiff soil it succeeds famously, particularly after warm and dry summers, which suit it admirably. In Mr. Ware's nursery at Tottenham it thrives to perfection, and is now covered with blooms, some specimens of which he sends us for our table.

Aquilegia Skinneri.—We have received flowers of this rarely seen Columbine from Mr. Hartland, of Cork, who states that he has a bed of it in full flower for the second time this season. To those who do not know the plant it may be best described as being similar to A. californica (truncata), and may probably be only a southern form of that species. The flowers measure 2½ inches long, including the stamens, which protrude half an inch or more. The sepals are greenish yellow, and the petals bright orange-red tipped with greenish yellow. They are spurred in the usual way. The flower-stems grow from 1½ feet to 2 feet high, and produce an abundance of flowers on slender stalks. It is a most elegant and pretty plant, and if it could be kept pure, *i.e.*, not hybridised, it would find many admirers. It comes from Guatemala, where Mr. Skinner found it in the mountain districts; hence it is almost, if not quite, hardy in England, and it seems perfectly so in Ireland.

National Chrysanthemum Society's catalogue.—About six months ago we intimated that a sub-committee had been appointed to revise the official catalogue published by this society. That work has now been done, and the result is a handy book of 36 pages—a considerable improvement upon the former edition. The varieties enumerated and described are divided into ten sections in the following manner: 1, Incurved varieties; 2, other incurved varieties not so generally cultivated as the preceding; 3, Japanese varieties; 4, other Japanese varieties not so generally cultivated as the preceding; 5, reflexed varieties; 6, large Anemone varieties; 7, large hybrid Anemone varieties; 8, Pompon Anemones; 9, Pompons; 10, summer and early autumn varieties. The type used for the varietal names is clear and distinct, and the descriptions of all the leading kinds are more fully set forth than hitherto. Considerable pains seem to have also been taken to ensure orthographical accuracy. A noticeable feature of this catalogue is the addition of the raisers' names in the leading sections; while the synonyms have been so treated that the grower will be sure to find a flower under any name which it may happen to bear.

Disa grandiflora.—From Straffan House, Kildare, Mr. Bedford has sent us some fine specimens of three distinct forms of this grand plant. Of these the finest is that named superba, which has sepals of the most vivid scarlet imaginable and the shell-like labellum of a yellowish-white ground veined and pencilled with crimson. The second variety is named violascens, so called on account of the distinctly violet tinge with which the whole flower is suffused. The sepals are more crimson than those of superba and the lips are tinted with rose. The third variety has broader sepals than usual, and these are tipped with pale yellow. Lovelier or more distinct varieties of Disa than these we have not seen, and as their stems are over 2 feet high, they have a fine appearance. Mr. Bedford states that this year there is at Straffan a group of Disa carrying no fewer than 156 spikes! Such a striking display as this is rarely seen, even among Orchids. The fact shows that Disa culture is well understood at Straffan.

Trees and Shrubs.

THE WHITE ALDER.

(Clethra alnifolia.)

What is known as the White Alder of the United States is a valuable shrub, as it flowers at this season. The Clethras resemble each other so closely, that C. alnifolia may be taken as the type of them all. It forms a rather loose-growing deciduous shrub, with neat foliage of a pleasing shade of green and spikes of pure white blossoms. The individual blooms are about one-third of an inch in diameter, and being borne in densely packed spikes from 3 inches to 5 inches long, they form a goodly display when at their best, and where favourably situated will last in bloom a long time. There are several varieties or species to be met with in different lists, the most distinct of which is, perhaps, C. acuminata, but that only differs in the leaves being more pointed than in the other form. Another feature is the pleasing fragrance of the blossoms. The Clethras are natives of the swampy districts of North America, and consequently succeed best in a cool, moist, and rather shaded position—indeed, conditions such as the hardy Azaleas and many other Ericaceæ delight in. The White Alder is rather an uncommon shrub in gardens, yet it was introduced as long ago as the early years of the last century, and in many places there are spots where it might be successfully grown. It is quite hardy, and another point to bear in mind regarding it is that the Clethras, differing widely from many of their allies, do not form a dense mass of roots (indeed, they are rather sparing in this respect), and consequently need considerable care in removal. Though the North American kinds are all closely allied, there is a species very widely removed from any of these, and that is the evergreen C. arborea, a native of Madeira, which consequently needs the protection of a greenhouse in this country. It forms a low-growing tree, suggesting an affinity to the Arbutus, and bears spikes of deliciously scented Lily of the Valley-like flowers. For large conservatories it is well suited, the dark green foliage being attractive at all seasons, while the floral display occurs about July and August. H. P.

Clematis coccinea.—There seems to be a diversity of opinion as regards the merits of this plant.

After a considerable experience of it, I am convinced that individual plants vary greatly as to the attractiveness of their blossoms, some being not worthy of comparison with others. Among the finest forms that have come under my observation is the large plant at the Coombe Wood Nursery, and a specimen that flowered a season or two ago in the temperate house at Kew. Such as these would commend the scarlet Clematis to all, but the washed-out flowers that I have occasionally seen would as surely condemn it. A lesson to be learnt from this is, in buying a plant, purchase it if possible when in flower, or at all events go where a good strain exists.—Alpha.

VERONICA ANDERSONI.

This shrubby Speedwell is one of the most useful plants in cultivation, either for window, conservatory, or outdoor decoration. It requires no special care, is evergreen, ornamental in leaf, and beautiful when in flower. It is perhaps best described as a hardy greenhouse or cool conservatory plant, though it is not by any means so tender as most others grown in these structures, and it will stand with impunity several degrees of frost. In the warmer parts of England it is treated as an outdoor plant or shrub, and it will survive a mild winter in many favourable parts of Scotland. I have seen some specimens of it from 10 feet to 20 feet in diameter and 8 feet high, grown in exposed positions in the Isle of Wight, where they are also extensively used in shrubbery borders and for centres to large flower-beds. In Ireland, many fine specimens of V. Andersoni are grown out of doors, but there the climate is more favourable for such plants than it is with us. When allowed to grow too vigorously out of doors they soon assume a straggling habit, but when judiciously thinned in spring, and otherwise treated so as to produce moderate growth, they flower and stand vicissitudes of weather better than plants that receive more liberal treatment. Should any doubt, however, exist as to their wintering safely, they may be covered with a mat, or protected by means of a thin thatch of Broom interwoven in a network of rope-yarn, dried Fern, Asparagus straw, Pea or Bean haulm, or other material of that kind during frosty weather, and uncovered throughout the day, and altogether in mild weather. A mulching of leaves, Cocoa-nut fibre, or litter ought also to be placed over their roots, for by this precaution their roots are often saved when their shoots are entirely destroyed, and they break again in spring and form good fresh plants. Out-of-door plants, if left uncut, bloom from July onwards, but if pruned hard in spring, they form a large quantity of young wood that flowers late, and is often too soft to safely withstand our ordinary winters. Wherever plants of this Speedwell are grown, the sub-soil should be open and porous, permitting a ready escape of all moisture; for, if otherwise, a sickly constitution and soft watery unripe growths will inevitably be the result.

Pot culture.—This Veronica forms one of our most accommodating pot plants, and thrives well in a good sandy loam enriched with decayed manure. Pots about 6 inches or 8 inches in diameter are quite large enough for it, and it enjoys abundance of water from the time it starts into growth until it ceases flowering, when the supply should be gradually lessened, though never entirely withheld. In this stage the plants are available for conservatory decoration, or for parlour or window ornaments. For windows, indeed, it is one of the best of plants, for its glossy green leaves, if sponged now and then, always look fresh and green, and its longevity and floriferous character, under such circumstances, are also recommendations not to be overlooked.

It is seen to best advantage when planted out in some good soil in a cool conservatory or winter garden. Thus circumstanced, it grows so quickly that annual thinning and pruning of the shoots are essential. Here they continue to flower very late in the year, and, being under protection, their blooms always perfect themselves, and are extremely serviceable where cut flowers are in demand. In cutting, remove the flower-spikes only; for if the points of the shoots are sacrificed, the plants are checked; if left undisturbed, they will bloom, grow, and flower almost incessantly.

For bedding-out.—Young plants of this Speedwell make good bedding plants, especially the variegated-leaved sort, which has precisely the same kind of habit as the green-leaved kind, and which is more effective than that sort in the flower garden, in which it makes a good substitute for variegated Pelargoniums. As a vase plant the variegated variety is also most effective, especially when associated with Creeping Jenny, Tropæolums, or Ivy-leaved Pelargoniums, and the plants of it used, both for bedding purposes and for vase decoration, should be lifted and potted in October, and placed in a pit or greenhouse during winter.

This Speedwell may be increased readily by means of cuttings of the young shoots slipped off in spring with, if possible, a heel attached to them. Remove the two base leaves and cut the heel cleanly with a sharp knife, then insert them in silver sand or half sand and half sifted leaf soil, in a brisk heat. Here they must remain for a few weeks till rooted, when they should be lifted and potted into 3-inch pots, and, as they advance in size, they should be shifted as required, until they occupy 6-inch pots. Those who have no artificial heat, such as is afforded by hot-water pipes or a manure bed, should not attempt to propagate this Veronica till July, when the young stubby growths may be selected and treated like those of Verbenas, that is, struck in a cold frame. Care ought to be exercised in choosing the shoots; the points of the strongest young growths have rudimentary flower-trusses visible at every joint; consequently, such growths as do not possess these are the most serviceable for producing young plants.

W.

CLADRASTIS AMURENSIS.

The Yellow Wood of the United States (C. tinctoria) has been long known in this country, but the C. amurensis is of comparatively recent introduction, and can be still classed with the more rare trees and shrubs. It forms a low-growing, much-branched tree or large shrub, with stout leathery pinnate leaves of a dull green colour. The flowers are borne about the latter half of July or beginning of August in erect, densely-packed spikes. The individual blooms are small and of a whitish hue, their most prominent feature being the profusion in which they are borne, for even a small specimen not more than 6 feet high will, during the blooming season, be quite studded over with its erect spikes of bloom. It appears to hold its own, and flowers well even in hot, dry soils; indeed, a specimen I recently saw under such conditions was so covered with bloom, as to suggest the idea that perhaps such treatment had induced extra floriferousness. It is a native of North-eastern Asia, from which district many plants have been introduced by the Russian botanists, the Cladrastis among the number. This latter is also known as Maakia amurensis. The better-known kind, C. tinctoria, is a native of North America, and, according to Loudon, was introduced in 1812. It was at that time regarded as a Virgilia, under the name of V. lutea, another of its synonyms being V. tinctoria. It forms a much-branched tree 20 feet or 30 feet high, and bears a profusion of pure white blossoms about the same time as the first-mentioned species. The flowers are more showy than those of C. amurensis, from which they differ in being larger, of a purer white, and borne in drooping instead of erect racemes. The rich yellow of its decaying leaves forms a very attractive feature in autumn. The North American Yellow Wood is best suited in a rather warm and dry soil, as the wood is then well ripened and a good display of flowers is the result. T.

The Guelder Rose (Viburnum Opulus).—The sterile form of this Viburnum is well known as one of the finest of all flowering shrubs, while the typical species that produces but a few barren blossoms towards the outside of the cluster of small fertile blooms, and is consequently far less showy than its variety, compensates for this by an autumnal display of fruits, which are bright red in colour, and borne in such profusion as to render a plant of it a very attractive object at the present time. The fact of its berries being now ripe would, indeed, point out that towards the latter part of the summer their brightness would claim recognition. The glowing red colour of the decaying leaves forms a prominent feature of this shrub in autumn. The Guelder Rose (especially the sterile form) is, like the Lilac and Flowering Currant, everybody's shrub, for it will thrive under widely different treatment, though the conditions most favourable to its full development are a fairly good holding soil in not too dry a situation. It possesses the great merit of being thoroughly hardy.—H. P.

Elæagnus hortensis.—This South European shrub forms a conspicuous feature in the landscape from the bright silvery hue of its foliage, which is still more noticeable when the long slender shoots are stirred by the summer's breeze. The under surfaces of the leaves are by far the brightest, so that when moved by the wind an everchanging effect is produced. It will grow well even in light sandy soils; indeed, the foliage is then brighter than when in a damper spot. Many of the Japanese species of Elæagnus are evergreen, but this is deciduous, though the leaves are retained well into the autumn. The fruits are not freely produced, and even when borne their brownish colour does not render them so conspicuous as those of a nearly allied genus, viz., Hippophæ rhamnoides, whose bright orange-coloured berries are borne in the greatest profusion; indeed, when in a thriving condition the twigs are often densely packed for about a foot with these berries, and being terminated by the current year's shoots, that retain their silvery leaves well on into the winter, have a very pleasing effect. Though it will thrive well inland, the Sea Buckthorn, as this Hippophae is called, forms a good seaside plant.—T.

The Mountain Ash.—This popular tree already makes a goodly show with its berries, not only under the most favourable conditions, but also when in wild and exposed spots, and as a direct contrast to that, even in the smoke of towns, where in many cases the coral-red berries serve to lighten up some otherwise dull and sombre spot. The Mountain Ash, indeed, is well worthy the attention of planters for ornament, as it is perfectly hardy, by no means particular as to soil or situation, and is very handsome in foliage, flower, and fruit, as well as in the general contour of the specimen. In spring just as the young foliage is developed, and the tree studded with clusters of white blossoms, it arrests attention as a most ornamental object, while, as above mentioned, this is surpassed in autumn when the fruit is ripe. There is also a variety with yellow berries, which is somewhat uncommon, but none the less valuable from an ornamental point of view. Besides the above noted qualities the wood of the Mountain Ash or Rowan is fine-grained, hard, and may be used for a variety of purposes.—Alpha.

The Oak in the landscape.—The colour of the Oak in the landscape, says an artist, admits of a great variety of tints induced by change of season, from the tender and emerald hues of spring to the deeper bloom of summer, and the rich and glowing tints of autumn. An astonishing diversity of colour is effected by accidental circumstances, dependent on the different aspects of morning, noon, and evening; on sun and on shade; on the colours of the sky and the clouds; on the clearness or haziness of the atmosphere, and its consequent powers of refraction; on opposition of colour; on the situation of the spectator; and on many other contingencies, all independent of the local colour of the object, yet all strongly affecting it. It is quite impossible, therefore, to give in any written description, with tolerable conciseness, sufficient instruction for selecting the colours necessary to depict objects so constantly varying in their hues. A few simple tints on the palette and an hour's study in the forest will be more instructive than a volume of remarks.

THE MONTEREY CYPRESS AT HOME.

Few of us who take any interest in trees have not seen beautiful specimens of this tree in British gardens. It grows freely throughout our country generally, but is especially good in seashore and mild districts both in England and Ireland. Nevertheless, though so free, it is not a really hardy subject. In some districts we have seen it killed in very severe winters, though plants are always worth planting for their youthful grace. Mr. Faunce de Laune, of Sparsted Court, Kent, who has lately visited California, showed us some fine photographs of this Cypress in its native home, and we selected for engraving one of the most characteristic of them, which we now produce. One of the most picturesque scenes on the beautiful Pacific shore of North America is that where these trees grow wild at Monterey. The moist, but genial, climate of that shore affords conditions that only certain parts of our own country fulfil in some degree, and therefore, though this is a beautiful garden tree, we never look forward to it as being one of great value for our country. Still, few trees present in their native homes a more beautiful aspect.

The Monterey Cypress (Cupressus macrocarpa) at home on the Pacific coast. Engraved for The Garden from a photograph sent by Mr. Faunce de Laune.

Abelia rupestris.—This extremely pretty shrub continues in bloom for three or four months in succession, and that, too, at a time when flowering shrubs are by no means plentiful, viz., from July onwards. It forms a low, much-branched bush, furnished with deep green glossy leaves and slender, drooping shoots, towards the points of which the flowers are produced in clusters. Its blooms, which are tubular, are about an inch long, and white tinged with pink. They are also agreeably scented. Besides forming an effective little bush in the open ground, this Abelia is a desirable rockwork plant; its somewhat drooping shoots are seen to advantage overhanging a rocky ledge, or in some similar position; while as a plant for covering low walls it is well suited, sufficient protection being thus afforded for it even in the severest of winters. Cuttings made of the half-ripened shoots strike root readily if kept close and shaded till they become established. This Abelia was introduced by Fortune many years ago, but it has never become popular. Besides it there are other species, amongst which the best known are uniflora, triflora, and floribunda.—H. P.

THE HIMALAYAN FIR.

(ABIES SMITHIANA.)

This handsome Spruce, introduced to us about the beginning of the present century, is one of the most distinct, constant, and beautiful of the genus, inasmuch as its gracefully pyramidal habit is rendered strikingly beautiful by the slender terminal and lateral branchlets being pendulous to, perhaps, a greater extent than those of any other Conifer, not even excepting its near rival, the Deodar. It is freely distributed throughout the mountains of Northern India, China, and Japan at elevations ranging from 6000 feet to 12,000 feet, and where it attains heights varying from 100 feet to fully 150 feet, and 15 feet or 20 feet in circumference of stem. The branches spread horizontally, the laterals being very numerous, slender, and drooping, and densely clothed with rigid, incurved, sharply mucronate, deep green leaves from 1½ inches to 2 inches in length. The cones are nearly cylindrical, 5½ inches long, 1¾ inches in diameter at the thickest part, with broad, entire, rather thick, shining brown scales. The seeds are brownish-black, small and light, nearly 25,000 being contained in a pound weight.

Since its introduction this Spruce has been widely spread over the country as an ornamental tree, proving itself thoroughly hardy in most districts, although, in common with many other Conifers, it commences to grow before spring frosts are past, and forms a remarkably handsome lawn or park specimen of neat, conical habit, and well furnished with bright green pendulous branchlets. A rather moist, sandy loam and not too exposed situation are the chief requirements of this Himalayan Fir—at least under these conditions by far the finest specimens have been produced in this country. For wind-swept districts it does not seem at all adapted, unless, indeed, good shelter obtained by other large masses of trees is provided. Near the base of the Snowdon range of mountains, at an altitude of 600 feet, I have seen this Spruce thriving luxuriantly where planted in sheltered woodland glades, as well as when placed singly for ornament on the lawn and grounds, but in all these cases it was particularly noticeable how well the prevailing winds were guarded against by well-arranged woods and screens. Several fine trees of this Spruce are to be seen in the grounds adjacent to Penrhyn Castle, notably one on either side of the front approach leading from the principal entrance, and in which the fine drooping habit is well shown off. Both these trees exceed 50 feet in height, that on the northern side having a trunk-diameter of 2 feet 3 inches at a yard from the ground, and with a spread of branches 25 feet in diameter, the lower ones of which almost rest on the ground. These trees are in excellent health, as the well-furnished stems and abundance of dark green foliage amply testify, and, judging from their present rate of growth, will in years to come, should no accident befall them, be amongst the finest specimens of their kind on the estate. The soil is rather damp, fibry loam with a porous subsoil, and the aspect north-eastern. Cones have been borne in quantity, usually every second season, for the past ten years, but owing to the absence of male flowers the seeds are of no value for reproductive purposes. They ripen in February of the following year after being produced and then fall to the ground, so that in the case of this Spruce it is not necessary to pull the cones from off the trees, as, owing to the compactly arranged scales, the seeds do not come out when the cones are shed.

Another fine tree that also bears cones in abundance stands on the lawn near the entrance to the kitchen garden and within a few yards of the drive. As in the trees just described, the fine drooping spray is, in the one in question, shown off to perfection, and being backed up with tall shrubs on the gently rising ground, the peculiar habit of growth is distinctly observable. As a woodland tree we have also some experience with this Himalayan Fir, for in the formation of a plantation twenty-eight years ago alongside the London and North-Western Railway, between Bangor and Aber Stations, numbers of these trees were planted out experimentally, more, however, as contrast trees than for their ultimate value as timber-producers. As plenty of room was at all times allowed, these have grown into fine clean specimens of about 40 feet in height, and well branched for about three-fourths their length. When thinning the wood in which they occur some eight years ago, I must own that I was as agreeably surprised with the quality of the wood of this Spruce as I was disappointed with that of the Weymouth Pine (Pinus Strobus), for the former was sound, clean, and heavy, while that of the latter was core-rotten in almost every case; indeed, it was with difficulty that I procured sufficient as a sample of the wood grown on this estate.

In its native country the timber is but little thought of, being extremely soft, though clean and easily worked, but very perishable. Sir J. D. Hooker, in his "Himalayan Journals," says that this Spruce "has white wood employed for posts and beams."

I suppose it can hardly be that the quality of wood grown in Britain is superior to that in its native country, yet my observations and notes on that produced at Penrhyn certainly lead me to believe that, as far as appearance goes, it seems quite equal to wood of the common Spruce, but weightier in trees of equal age. The soil in the above woodland where this tree was planted experimentally is gravelly loam, of by no means the best quality, but such as retains moisture even during prolonged drought.

When planted in dry, sandy soil, in too exposed situations or too confined positions, I have always noticed that the growth is slow, the foliage thin, and the whole tree wanting in that distinct and beautiful appearance which is so characteristic of it when suitably placed both as regards soil and site. It is readily propagated by seed, by cuttings or by grafting, but as seed is now readily obtained and at a cheap rate, this method of raising young stock should alone be resorted to, as cuttings or even grafted plants are never so satisfactory, the disinclination to form a permanent leading shoot being always observable. A. D. Webster.

Large Eastern Plane.—Sir John Ogilvy, of Kempshott Park, Basingstoke, writes to us as follows regarding a fine specimen of this Plane: "I think I once mentioned to you that the largest Oriental Plane I had ever seen was at Charlton Park, Malmesbury, the seat of the Earl of Suffolk. I have since seen the tree again, and it may interest you to hear that at 3 feet from the ground it measures 17 feet in circumference, that it has a beautiful clean stem of many feet, and a splendid head. I mention all this, as I do not think I am wrong in the belief that, like myself, you are a lover of fine trees."

SHORT NOTES.—TREES AND SHRUBS.

Dracæna australis.—This seems to thrive in the grounds at Netley Fort, and we understand that some of the Australian Tree Ferns are to have a fair trial in the wooded glades there. Good specimens of these have a charming appearance in a garden.—W. H. G.

Hardiness of Japanese Maples.—Of this I have had further proof. The effect of frost-bite is often not visible till summer, but none of my plants has suffered; on the contrary, they are growing vigorously on stiff loam.—Otto Forster, *Lochenhof*.

White Beam Tree (Pyrus Aria).—Some fine examples of this tree may be seen in the grounds of Netley Fort, Southampton; the snowy whiteness of the under surfaces of the leaves contrasts strikingly with the dark green of the upper portions, especially when rippled by the wind.—H. G.

AUTUMN-FLOWERING SHRUBS.

A few additions may with advantage be made to the list of autumn-flowering shrubs given in The Garden (p. 141), the most important of which I take to be the following: Aralia spinosa—this is a stout-growing shrub, which quickly reaches a height of a dozen feet and produces suckers so freely as to soon form a large mass. Its huge triangular leaves are much divided, and the whole plant has a stately and subtropical aspect. It is, however, on account of its flowering properties that I have noted it here. The blooms are terminal and borne in large pyramidal much-branching panicles. Though the flowers are individually but small and greenish white in colour, yet they are borne in such huge clusters as to have a most imposing appearance, especially when the foliage is in good condition. This Aralia possesses the merit of being readily increased by means of suckers, that may often be detached with a few fibres adhering to them, while cuttings made of the roots quickly form plants; indeed, having occasion last year to remove a specimen of this Aralia, I was astonished at the number of young plants that sprang up from pieces of the severed roots that had been left in the ground. Desmodium penduliflorum must also be included amongst autumn-flowering plants, as it will often flower till cut off by frost. The stems die nearly to the ground after flowering, but a number of stout buds at the base break away freely in spring, and quickly develop into long slender wand-like shoots, the upper part of which is terminated by great numbers of closely packed Pea-shaped rosy purple blossoms. A single specimen of this Desmodium forms, when in bloom, a most beautiful object; it is, however, sometimes injured by early autumn frosts unless placed in a sheltered position. Closely allied to it is Lespedeza bicolor, which about the end of August or beginning of September becomes quite a mass of bright purplish blossoms. It forms a round bush a yard or so high, and though when in bloom very attractive, it lacks the graceful character of the Desmodium. Hydrangea paniculata grandiflora must be included in any selection of shrubs that flower during the latter part of the summer and in autumn. It is a plant that succeeds best under liberal treatment, and if, in planting a mass or clump of it, a fair amount of manure be incorporated with the soil, its effects will be visible in the size and profusion of the blooms, as well as in the deeper tint of the foliage. Its large heads of creamy white blossoms acquire a distinct reddish hue before they decay, particularly when fully exposed to sunshine. Clerodendron trichotomum is interesting as being a hardy representative of a family chiefly consisting of tender plants, and valuable from its autumn-flowering propensities. It forms a free, bold-growing bush, furnished with large rough heart-shaped leaves and panicles of white blossoms. Its most conspicuous feature, however, is its bright-coloured calyx, which in the species under notice is of a reddish hue. It is an effective shrub from a foliage point of view alone, but it should not be planted in too exposed a position, as the wind is apt not only to disfigure the leaves, but also to break off some of the weaker branches. It is a native of Japan, and may be increased to almost any extent by means of root cuttings; indeed, I had once occasion to remove an established specimen of it, and, as in the case of the Aralia, quite a crop of young plants sprang up from small pieces of the roots. Leycesteria formosa is also a pretty flowering shrub at this season, and the showy plume-like blossoms of the Tamarisk are often in good condition till quite the end of the summer. Darwin's Barberry will frequently give an autumnal crop of bloom, as, indeed, will some other shrubs at times. Spiræa ariæfolia, included in the list above alluded to of autumn or late summer-flowering shrubs, must be, I think, a misprint for S. Lindleyana, which blooms after the flowers of S. ariæfolia are all over. The latest flowering Spiræa with me, however, is the small S. callosa alba, which flowers sometimes till the end of October. The Wych Hazel, that bears its curiously shaped blossoms on leafless branches, flowers about the end of November. Many kinds of Ceanothuses, too, bloom beautifully in the autumn, one of the best of which just now is the hybrid variety called Gloire de Versailles. T.

FRUIT GARDEN.

DWARF APPLE TREES *v.* STANDARDS.

The question is continually being asked, What can I plant to induce my land to pay a fair rent? Well, I should not hesitate long. Whether I had one acre to plant or one thousand, I should plant Apples of the very best kinds grown. While we hesitate to plant a few acres from fear of not being able to dispose of them, American and colonial growers are planting thousands of acres specially for shipment to Europe. Now there can be no question as to the soil and climate of Britain being specially favourable for the production of first-class Apples. It has been proved over and over again at our autumnal fruit shows that our home growers can hold their ground against all comers as regards quality. Now, the first question that crops up when planting is proposed is, Will it pay? My own experience is that landlords could not do better than encourage the planting of Apple orchards. But for occupiers to do so without long security of tenure would be folly. No class of the community works harder than growers for market, but their energy is restricted to crops the benefits of which they can realise. I have myself seen cases of ruined fortunes through occupiers being compelled to give up possession before their trees had repaid half the cost of planting. It is to owners of land, therefore, we must look to do the planting, at least for some time.

Happily, we have some notable examples in fruit-growing counties of the possibility of landowners improving their estates by planting orchards, and if a correct return of the yearly sales of orchard crops was kept and published, I feel sure that in many counties where orchards are now but seldom met with they would soon become plentiful, for where laid down with Grass the whole of the feed is got for nothing, as well as a good percentage on outlay and expenses. Why should Kent and a few other counties monopolise the Apple growing of the kingdom? Surely there are other soils and situations quite as favourable as Kent for Apples, and if one were going to supply our large markets it matters little where we reside; the main thing would be to get land of good quality where rents were low. In Sussex there are some grand situations for orchards. In fact, all the southern parts of the kingdom are full of most eligible positions for Apple growing. It is a mistake to suppose that only deep, rich soils will produce Apples to pay. If the question was timber growing, there would be no doubt as to strength and depth of soil being required; but as to Apples, I have proved to my own satisfaction that there are a good many ways in which they may be profitably grown, and a good many forms of tree besides 6-foot-stem standards; productive though the latter may be in the fertile valleys of Kent, we have no use for them here, for the closer we keep our Apples to the ground the better. In the light warm soils of the south coast our dwarf bush Apples are most fruitful; they make short-jointed wood, which gets thoroughly ripened, and, therefore, they hardly ever fail to produce a crop, this year being no exception. The dwarfs this season are loaded, but the old and, as a rule, neglected orchard trees are very thin in the way of fruit. These dwarfs, however, belong to the popular free-bearing kinds that have gained a reputation during the past few years for freedom and certainty of cropping. The ground around their roots is well cultivated and enriched, and I feel sure that for shallow soils dwarf Apples are the ones to plant. It is useless to expect fine fruit from any kind of tree if its roots cannot find sufficient food, and that cannot be had if bush fruits, such as Currants or Gooseberries, grow

close up to their stems, the roots of both Apple trees and bush fruits struggling for the mastery. Under such circumstances small imperfectly developed fruit in both cases is the result.

If I were starting an Apple orchard that for quantity and quality per acre would beat anything yet attempted on a large scale, I would have the soil well trenched, plant dwarf bushes 10 feet apart each way, and, beyond a row or two of Potatoes for the first three years, I would take no other crop whatever from the ground. I am convinced that if first-class Apples are required, they must have no competitors; a row of Currant bushes will take more nutriment from the soil than the Apples, and the loss by the latter will be more than the gain by the Currants. I have carefully noted the returns from bush trees that have a clear run of good soil for their roots, and that get enriched with manure in the shape of mulching every year, the old dressings being forked in, and I can safely say that if Apples do not pay for undisturbed possession of the soil, they will not do so in partnership with any other fruit. The best form of tree to plant is one year-old maidens; they are now sold cheaply by the hundred or thousand, and if planted in November, can be cut down to any desired height the following March. The saving of expense in planting maidens in lieu of bushes ready formed will be considerable, and as they will occupy but little space the first year, Potatoes might be cultivated between them with success, but exhausting green crops should be avoided. I feel sure that if one requires Apples free from blemish and of full size, the trees must never suffer from lack of nutriment. After the third year the bushes will occupy all the ground profitably, and must be kept shortened in annually, so as to allow ample space to work amongst them. The produce of bush Apple trees is of the best quality, being fully exposed on all sides to sun and air. The trees, too, are easily accessible for purposes of pruning, thinning the crop, or gathering the fruit, and if our home growers would maintain their position in our markets they must be prepared to grow the very best fruit that can be produced. As to varieties, that matter must be regulated by the object in view, *i.e.*, whether it is intended to send the produce to market direct from the tree, or to store it for sale at a later period. There appears to me to be a good opening for anyone who would grow the best late sorts to compete with foreign grown Apples in the early spring months.

Gosport. JAMES GROOM.

Bush Apple trees.—Almost every year the bush trees which were planted several years ago in the kitchen garden at Maiden-Erleigh produce good crops; though full of fruit last year, nearly all seem to be bearing well again this season. Nearly all the best kinds grown are there, and their fruits bid fair to be very fine and handsome. All the trees are on the broad-leaved Paradise stock, and are annually well mulched with manure. Trees of this kind are, without doubt, very profitable. They stand at ample distances apart on the margins of the cross walks, and, therefore, do not interfere at all with the cropping. A few dozens of such trees are of great value in a garden where room for them can be found. —A. D.

SHORT NOTES.—FRUIT.

Cold district Strawberries.—In many gardens in Lancashire I have found, without exception, that the so-called Duc de Malakoff has been Vicomtesse Héricart de Thury. And I fancy that is the kind, judging by description, to which Mr. Bird alludes in THE GARDEN last week (p. 161).—JAMES SMITH, *Waterdale, St. Helens.*

Peaches.—These are abundant in the garden here this year. We are now gathering from open walls Alexander and Early Beatrice; they both ripened at the same time to the day, and both are growing within a few yards of each other. Alexander is certainly much the larger of the two and beautifully coloured. Hale's Early will soon follow; we find it, as near as possible, a fortnight later than either of the kinds just named. The next to follow will be Dr. Hogg, an excellent Peach and one which should be in every collection, and, of course, the main crop follows. We have found nothing to surpass Sea Eagle as a September Peach. It comes in well between Bellegarde and Late Admirable, and Salwey ends the season.—G. HARRIS, *Singleton, Swansea.*

VINERIES IN AUTUMN.

It must not be supposed that now when Grapes are ripe or have reached the ripening stage they may be neglected with impunity; on the contrary, much more depends upon the autumn treatment of the Vines than many are perhaps aware. A heavy crop of Grapes—and most of us rarely fail to tax the full strength of the Vines—proves most exhausting to them, and but for their capacity to recoup their strength before the foliage falls, failures would be even much more sudden and general than they are now. Those who will take the trouble to examine their Vine borders soon after the crops of Grapes are perfected will find that the roots are then most active. If they are not, then the Vines are in a poor plight, and nothing short of lifting the principal portion of the roots and relaying them in fresh compost will restore them to good health and vigour. Hundreds of Vine borders require this radical treatment, but in many cases this would have been unnecessary if they had not been neglected in the autumn. At this time of year the inside borders of early houses especially cannot well be overdone with moisture and manure. Much more, in fact, may be given with safety than would be safe or beneficial early in the season. It would really seem that a crop of Grapes is very frequently principally the result of the Vines' power of storing up food during the autumn previous, as it is very certain many Vines form very few fresh feeding fibres till after the Grapes are matured. It follows, if we neglect them in the autumn, the crops the next season will fall off in value at a corresponding rate. Sometimes it happens that roots ramble away in search of moisture and food, and finding this they do not so soon collapse. Unfortunately, it is usually outside of the house where the roots find a feeding ground which may or may not be suitable to them. The consequence is the expensive inside border is comparatively useless, and in time the roots that have rambled away get into a badly drained subsoil, shanking, imperfectly ripened wood, and other evils being the natural result. It is not a very great amount of water and liquid manure that an inside or an outside border in a dry season requires after all, and no one need be frightened or misled by growers, most successful as these may be, who give statistics of the weight of water annually applied to a border. Many thousands of gallons of water may sometimes be necessary, but not if the borders were prevented from becoming unduly dry. It may be gratifying to some cultivators to see the water running freely from the drains, but I hold that so much water passing through a border is wasteful in various ways and altogether uncalled for. At no time ought a border to become dust-dry, that being both injurious to the Vines and the reverse of economical. A hundred gallons of water applied before the borders are dry will do more good than a thousand gallons on a dry border. My plan is to anticipate dryness, and in this manner a very small quantity of water suffices. Liquid manure is simply thrown away on a dry border; if necessary, I would moisten the soil with clear water, after which it would be in a fit condition to absorb the manure. We give liquid manure any time before the Grapes are ripe, and again much stronger in this instance after they are cleared from the Vines. At one time we were able to command plenty of farmyard liquid manure, than which there is nothing better; now we have to depend upon artificials, such as sulphate of ammonia and kainit, two parts of the latter to one of sulphate, applied at the rate of 2 ozs. to 3 gallons of water. We also find an occasional surfacing of Thomson's Vine manure to be highly beneficial. A friend of mine, Mr. Gibson, of Draycot Manor, Wilts, speaks most favourably of Jensen's fish manure, this attracting the roots to the surface, and apparently greatly benefiting the Vines. Another successful cultivator, Mr. R. Phillips, practising near Gravesend, in Kent, annually gives his Vines an autumn dressing of night soil, this very powerful and excellent manure being washed in with copious supplies of rain water. The result speaks well for the efficacy of the manure, as the crops that I have seen at different times were exceptionally heavy, the bunches being above the average size and well finished. I could give several more instances of the value of good autumn attention, if more were needed, to indicate the necessity for liberal treatment at that time of year. All the time the leaves are fresh and green root-action is, or ought to be, going on briskly, and there are very few borders that are sufficiently rich to support the Vines without occasional supplies of manure of some kind. Many attach too much importance to the value of turfy loam for a border. For the first season or two this may contain all that the Vines require, but according to my experience it is soon exhausted, and is not long capable of sustaining heavy crops without extraneous assistance. Besides, it does not hold moisture nearly to such an extent as a compost more rich in humus does, and consequently a border composed principally, or, let us say, entirely, of turfy loam requires more water and manure than a richer mixture.

THE GROWTH ABOVE GROUND must also be equally well attended to if success is to be made sure. A plentiful supply of red spider or thrips is bound to impoverish the Vines, absorbing sap that ought to be expended in the formation of plump buds and the spread of the roots, and they should, therefore, be exterminated as much as possible. A coating of flowers of sulphur effectually checks red spider, and as soon as the Vines are cleared of bunches they should be attended to. We place a good handful of the sulphur in a muslin bag, and well work it through into about three gallons of soft water, in which manner it mixes well and can be readily distributed over the foliage with a syringe. If one application is insufficient, another should be given after the first has dried. Red spiders can make no progress where sulphur abounds, and are soon rendered harmless. Thrips may be destroyed by occasional fumigations, care being taken not to injure the foliage with the hot fumes, and a decoction of soft soap and tobacco water, or soft soap and Quassia chips, answers equally as well. Some growers unhesitatingly syringe their Vines in the autumn with paraffin and water, applied at the rate of 2 oz. to a gallon of water, in which a small lump of soft soap has been dissolved. This has to be kept constantly stirred to prevent the oil from collecting on the top, the usual plan being to discharge one syringeful on to the foliage and the next back into the can. Sulphur may be distributed over the Vines before the bunches are all cut, as it may be washed off them by the aid of water running strongly from a tap or pump without disturbing the bloom. In the case of thrips-infested Vines, no insecticide must be applied till the bunches are cut, or they are bound to be disfigured, but the fumigation will not long affect them, the skins of the berries not being porous or absorbent. Much may be done with the sponge if the insects are not allowed to spread all over the house before the attempt is made to destroy them. Mealy bug is not very injurious to the foliage, this most objectionable insect seemingly preferring to effect a lodgment in the centre of the bunches, which it quickly spoils. Hand-picking is a good remedy, and a good force of water will sometimes clean bunches, after they are cut, sufficiently well for the table. At the same time we should much prefer to keep unattacked, mealy bug being the nastiest pest that can get on Vines or any other plant. Mildew once established in a vinery is very difficult to eradicate, and I have known instances where a wholesale clearance of the house was necessary before it could be stamped out. The border and Vines were cleared out, the woodwork painted, and the walls whitewashed, and after that a fresh start was made with the best of results. It is a very insidious disease, and the present season is very favourable to its spread. Where it is not so badly established as to necessitate a wholesale clearance I should advise that the borders be examined, and if found very dry, as they probably are, be given a good soaking with clear

water, followed with liquid manure. A little fire-heat should also be turned on, and abundance of air given whenever the weather permits. In addition, the affected parts should be syringed frequently with a mixture prepared as follows: Take a pound of powdered quicklime and a pound of flowers of sulphur, mixing them together with sufficient water to form a paste, after which a gallon of soft water should be added, and the whole boiled in an iron saucepan or kettle for twenty minutes. When cool and settled, pour off the clear portion of it and store it in a bottle for future use. About one-quarter of a pint to three gallons of soft water is usually sufficient, but it may be used stronger if necessary. This solution was long ago recommended to me for the extinction of mildew on Roses, but it is equally valuable for mildew-infested Vines and also for Peach trees.

Ripening the wood.—It will, I think, be generally admitted that the best bunches are produced on the most perfectly ripened wood, and it should therefore be everybody's aim to ripen the growth to the best of their ability. Not only do we get the most compact bunches, as well as a greater number to select from, on the least pithy wood, but well ripened canes are the most durable, and are especially desirable for laying the foundation of serviceable rods. Overgrown sappy rods will do well for a time, but they are very liable to come to a standstill in after years, and, owing to the excessive amount of pith formed in the early stages of growth, are almost certain to contract, thus rupturing the sap-vessels, an evil very frequently followed by shanking. Anyway, whether I am right or wrong in my opinion on this point, we may safely assert that it is a decided advantage to ensure well-ripened wood. The state of the border, or rather the roots, has much to do with the perfect ripening of the young growth, as when Vines are rooting in a cold or unsuitable soil no amount of firing, sunshine, or air will have the desired effect. Very badly-ripened wood is a sure sign that the border requires to be seen to and the roots brought up into better soil. At the same time much may be done above ground. Plenty of air both at the top and bottom both night and day, and fire-heat in dull or wet weather, greatly assist in the ripening of both the crop and the wood, this being especially necessary where the vineries are situated in a valley. Here, for instance, we experience the greatest difficulty in one vinery, both as regards keeping the Grapes and also in ripening the wood, the house having been built very many years and in the lowest part of the garden, or nearly on a level with a piece of water. Our plan is to heat the flues in dull weather, giving plenty of air and the Vines plenty of room; but it is over the flues where we get the best bunches, and it is there they keep best. At no time do we encourage the growth of much superfluous foliage, and in the autumn especially all sub-laterals are kept closely pinched out. In this way plenty of light and air plays about the foliage and wood, and other conditions being also favourable, good crops are the result. It is no economy to be unduly sparing of the fire-heat, not only in the early houses, but especially in the houses where Alicantes, Lady Downes, Muscat of Alexandria, Gros Colmar, Golden Queen, Mrs. Pince, and other heat-loving sorts are being ripened off. Without plenty of fire-heat none of these will form much saccharine matter, even in our presumably favoured neighbourhood, and without this they keep badly. The black sorts colour well without fire-heat, but flavour is also wanted, and that we must have, or uncomplimentary remarks might be heard. Fire-heat without a good circulation of air is harmful. What is wanted is plenty of dry air, and if this is not ensured the wood ripens indifferently, and the Grapes also keep badly. Wasps, luckily, are very scarce indeed hereabouts—never more so perhaps at this time of year, and no steps are thought necessary to keep them out of the vineries. When they are very troublesome, we were at one time obliged to cover all the openings both at the top and bottom of the house with canvas, but this, although it keeps the wasps out of the house, also greatly interferes with the free circulation of air to such an extent as to cause "sweating," the warm moist air inside of the house condensing on the cold berries. If this is allowed to happen many times it soon damages the skins of the berries, and then it is a case of good-bye to the crop. Those muslin bags we often see enclosing bunches of Grapes are especially to be avoided. Better let the wasps have their fling than lose the crops wholesale by rotting. Not merely is it necessary to open all the ventilators as much as possible in warm weather, but the doors should also be set open, birds being kept out by nets. Wasps, what few there are, may easily be kept down by the use of Davis's Improved Wasp Destroyer. Last season we placed for trial a few drops of this mixture on berries partly eaten by wasps, and the effect was simply marvellous. It soon attracts any there are in the house and stupifies them. Their death struggles and peculiar hum would appear to scare away the rest—at any rate I have no other explanation to offer for the strange disappearance of our wasps. It reads rather like a testimonial to a quack medicine, but there are plenty beside myself who can give similar experience, as it is no new thing in the west of England.

Somerset.

APPLES AND APPLE ORCHARDS.

As the past two seasons have given us good crops of Apples, and as the trees are in many cases this year only carrying light crops, I think we ought to turn the lesson thus taught us to some useful account. Except that the trees have become exhausted through the production of two or three continuous heavy crops, there is nothing particular—at least, so far as Somerset is concerned—to which the present season's comparative failure can be attributed. The weather during the time when the trees were in bloom was not particularly unfavourable, although cold; but we have known the trees to pass through a much more critical period and yet mature good crops. It is, therefore, clear that the trees have become exhausted, and that Nature is asserting her right by giving them a rest in order to recruit their strength. Where the orchard is large and the crop heavy, it is almost impracticable to thin the fruit so as to reduce the strain upon the tree; but in gardens where the trees are but few the case is different. It is quite practicable in that case to thin the fruit on bush or pyramid trees, and also on cordons and espaliers, and where thinning is systematically done every year, there is much greater certainty of getting annually a crop. We have proved this to be so in the case of pyramid trees on which this attention has been bestowed; they have borne regularly for these past eight years, not always full crops, but they have never failed altogether, especially those that are pretty reliable bearers. As to sure bearing Apples, did anyone ever know either the old or the new form of Hawthornden to be quite destitute of fruit after the trees had reached a bearing size? I do not remember such a circumstance, although I have known both sorts for more than thirty years; almost as much may be said in favour of Lord Suffield and Cellini, both of which are well known to bear more or less every year. I do not claim for these sorts any superior merits in other respects, but for culinary purposes they are very useful in furnishing a supply of fruit from August up to Christmas. Emperor Alexander is another sort which has borne regularly with us for several years past. The trees are growing in a large bush form about 10 feet in height; the branches have all the young growth cut back to a spur every autumn, and the roots are pruned when we find that the growth is getting too strong. This is a culinary Apple in use in December, and it is very large and showy. Keswick Codlin is another autumn Apple that bears pretty regularly, as do also the Dutch and Manks Codlins. Flower of Kent is a very reliable sort for use in January. Prince Albert (Lane's) is likewise a most useful Apple and a trustworthy bearing sort. It keeps well until March. There are not many reliable bearers amongst dessert kinds. Ribston Pippin, Kirg of the Pippins, and Cox's Orange Pippin are the best; Reinette du Canada and Margil are the next best bearers. Amongst culinary kinds there are several which, although not bearing regularly full crops every year, yet bear pretty regularly, notably Cox's Pomona, Court of Wick, Jolly Beggar, and Alfriston. The last is one of the largest and best of culinary Apples.

With regard to the selection of sorts to plant in orchards, it is necessary to pay more attention than has hitherto been done to the character of the situation, *i.e.*, whether it is exposed or sheltered. Only close-growing sorts are suitable for exposed positions. Mop-headed trees, as they are commonly called, of which the Forge Apple and Tom Putt are types, are the best to choose for orchards that are much exposed to wind. They do not reach a great height, and the branches naturally grow so closely together that wind has comparatively little power over them. Many would probably be surprised at the amount of loss that a rough night's wind often causes in the end of September in some of the Apple orchards in the western counties where choice fruit is grown. I have known high wind to destroy as much fruit in a few hours as would have half-paid the rent of a 10-acre orchard. The sorts chiefly grown in this instance were the Blenheim Orange, but, unfortunately, the site is exposed on all sides but the north, and is somewhat elevated, which renders this sort of Apple wholly unsuitable for the position. Equally bad is it to plant low-growing or spreading varieties in the most sheltered places, which should be kept for large open-headed trees, that produce the largest and best fruit. Large open-headed trees are apt to start away from the stem with some half dozen main branches, which, if left unpruned, continue to increase in length and only form a few intermediate branches. The consequence is, wind has full power over every branch. This condition might have been easily altered if, after the tree had been planted two years, all the branches had been cut back to within 2 feet or 3 feet of the stem, according to their number. This would have induced the branches so dealt with to push out three or four laterals, thus giving a sufficient number of branches to form the groundwork of a well-furnished head. It is quite necessary to head some trees back about the fifth or sixth year after planting—*i.e.*, if a well-balanced head is desired, and desired it should be, for it is not encouraging to see the best fruits down under one's feet when we go out to gather them. I do not expect that losses from wind can be altogether prevented, but I am satisfied that a judicious selection of suitable forms of trees for particular sites, and careful pruning on the lines suggested, will do much to mitigate the evil.

J. C. C.

Farleigh Prolific Damson.—This remarkable Damson is producing on standard trees a grand crop here this season. Now that the fruits have coloured they are seen so densely set upon the branches as to excite wonder how they can carry them. Such a crop can hardly be looked for every year, but it is worthy of note that no other Damson fruits so freely or is so hardy. Now that real heavy cropping has set in, I think it is very probable that similar results will follow in alternate years. The trees would be helped here by receiving a thorough soaking of rain. The soil is very dry, and it is marvellous that, under such circumstances, good growth and a heavy crop should be so well sustained.—A. D.

Ripening the wood of fruit trees.—This is an important matter just now, and though it is in a great measure dependent on the sunshine we get, yet a good deal may be done to help the process. All surplus summer growth should be cut away at once, in order to give the sun a chance to reach every bud on the tree to enable it to perfect its development so that it may bear good fruit. In the case of wall trees that have been mulched, the manure may be raked off now to let the sun into the border. Warming up the roots a bit at this season has a great influence on the ripening of the wood and buds. There has been lately an abundance of rain, so that it is not likely that even late Peaches will need any moisture beyond what will come to them naturally after this date. Figs are ripening well on walls and the crop

is a full one; therefore every shoot and leaf not required should be removed. Though Apricots have not borne much fruit, the trees are healthy, and there is a good prospect for next year. There has been less branch-dying this season than usual, at least so far as I have observed. I think if cultivators could be contented with moderate progress from the first, and in good seasons thinned off more of the fruit than they do, there would be less branch-failing and less gumming. When young trees are planted in rich soil, perhaps loosely packed in the borders, they make wood more rapidly than is consistent with a long and healthy life.—E. Hobday.

Flower Garden.

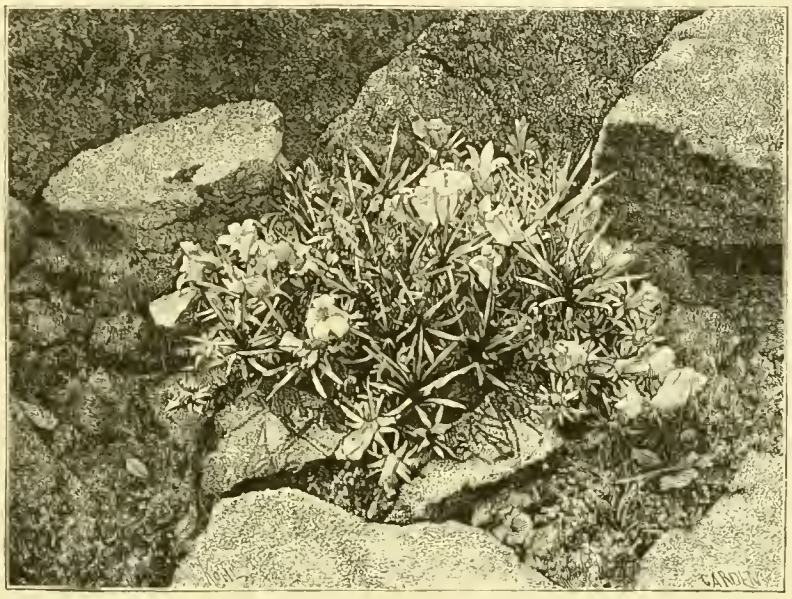
CARNATIONS AND PICOTEES IN 1886.

I do not remember a year in which these have been so fine or popular as they have been this season. Raising these plants from seed is now a very common and successful practice, and excellent varieties are obtained in that way. Seedlings grow luxuriantly and bloom most profusely, and when these qualities are combined with well formed blooms they become the most valuable of all border plants in July and August. The old crimson Clove has always been a great favourite of ours; use it as one may, it is a charming flower. I have had several white Cloves sent to me as "excellent companions to the old crimson," but not one of them developed the same sized blooms, while they were also deficient in texture and, above all, fragrance. One of the very best Carnations which I have ever grown in the open air is The Governor. It is a second Souvenir de la Malmaison in colour and size, but it grows more freely and blossoms far more profusely than that kind under any condition. I am not in favour of growing those varieties which require a great deal of coaxing to produce one or two startling blooms and no more; on the contrary, my favourites are the cut-and-come-again class, which during the season produce multitudes of serviceable blooms for every-day decoration. Probably we may be deficient of some kinds noted in this way, but apart from our collection I have had opportunities of inspecting many others this season, and the following selection will, I think, give satisfaction, viz., Magnum Bonum, bright scarlet; Celia, bright pink; The Bride, pure white; Florence, a beautiful buff; Beauty of Whitby, excellent scarlet; General Stewart, dark crimson; Masterpiece (new), rich crimson; and Countess of Ellesmere, pale pink, spotted with crimson. Amongst Picotees, Goldfinder is especially good, being a fine barred yellow. It was generally remarked the other day that Carnations and Picotees at the Shrewsbury show were of very high merit. The best stands of each were exhibited by Mr. Hans Niemand, of Birmingham, amongst whose flowers were Carnation Yum-yum, yellow, with a pink tip; W. P. Milner, pure white; Mephistopheles, scarlet; The Mikado, a very dark kind; Mrs. G. Hawtry, fine yellow; and Mary Morris, grand pink. Of Picotees, the most conspicuous were Mrs. Rayner, Lady Carington, Dr. Abercrombie, Louisa, Picturata, Dr. Epps, and Lucy. The competition for gentlemen's button-hole flowers at the same show was very keen. The first prize was awarded—rightly, in my opinion—to three beautiful Carnation blooms, backed up with a spray of their own Grass. A pretty Carnation or Picotee never fails to please as a button-hole flower, and for this purpose it is impossible to have them too good or plentiful. J. Muir.

Margam Park, Port Talbot.

COMMON HYDRANGEA.

Where this succeeds well the help it gives in making a show at this time of year is very considerable. It is essentially a wood or wild garden plant, although during summer it requires all the sun that it can possibly get. It should also be planted with the view of obtaining as large an amount of overhead shelter in winter as possible, and in places where undergrowth is plentiful this will be readily obtained. The soil in which it grows should be rich and well drained, otherwise the chances of success in our climate will be diminished. This Hydrangea in a wood is just now a perfect picture, its large trusses of pink and blue flowers making a display not soon to be forgotten. The first or second year after the cutting stage is perhaps the best as regards abundance of flower. Cuttings taken off about the end of July or August and inserted singly in pots and kept in cool frames make nice sturdy plants for the following year, when they may be planted out. A good top-dressing or mulching, or some loose material helps them during the early summer, and keeps the ground moist round their roots. K.



A silvery Harebell (Edraianthus Pumilio). Engraved for "The English Flower Garden" from a photograph.

EDRAIANTHUS PUMILIO.

A brilliant little alpine with flowers that look large in proportion to the plant. The little closely-set tufts of glaucous foliage look sharp and thorny like a Prickly Thrift, but prove of a milder nature on closer acquaintance. The flowers are of a full rich purple colour.

Allium pulchellum.—This is just now at its best, and a brave show it is making on the top of a low rockery. In large patches it makes a handsome display. Amongst the latest introductions in the way of Alliums we have a few really desirable kinds, such as A. macranthum, a species resembling pulchellum, larger, however, and much deeper in colour, with protruding style and anthers, and much broader pointed leaves. It seems to be quite hardy on a southern exposure. A. giganteum, a large Turkestan species, bearing a head of purplish flowers as large as one's hand, is a great acquisition, and will do much to make this class of plants popular. A. pedemontanum grandiflorum is the finest dwarf Allium we have yet seen. It is a great improvement on the type, and would, we think, make a charming pot plant. The flowers are much larger than those of the type, whitish streaked, and more of them in a head. A. pulchellum flavum is also a handsome yellow kind, and worth growing in company with any of the above. Most of these do well on dry banks, and flourish where other vegetation would find some difficulty in keeping alive.—K.

Monarda didyma.—This looks quite out of place in an ordinary dry exposed border, and so does Iris Kæmpferi under the same conditions. Both should have good rich soil and be placed close to water where the roots can have abundance of moisture, and where they may receive a good share of the mid-day sun. In such a position the Monarda shoots up 4 feet or 5 feet high and produces large heads of showy scarlet flowers. It requires no attention other than planting it out and then letting it alone, unless stock is required, when it may be divided to almost any extent. Another good plant for such a position as that above indicated is Lychnis chalcedonica. The single and double scarlet as well as single and double white mixed together make a fine display; all of them are increased readily by root division, which may be done in autumn after flowering is over. They prefer a peaty soil as close to the water's edge as possible without being actually in it.—D.

Echinops.—Where plenty of room, either in a bed or border, can be devoted to plants belonging to this genus, any extra labour bestowed upon them will be well repaid by a display such as we have at present. There seems to be about six or seven species of Echinops in cultivation altogether, not more than three of which, with their varieties, will be found worth troubling about. They have in the garden exactly the same effect as that produced by Eryngiums, such as E. alpinum, Oliverianum, &c., with the additional advantage of being available two rows or so farther back. Echinops ruthenicus when well grown often attains a height of 4 feet or 5 feet. Its leaves are much cut and spiny, and the stems terminate in large spherical steel-blue heads of flowers. The variety called in gardens grandis is more robust than the type, and has heads twice the size of those of that kind, but paler in colour and not so striking. E. sphærocephalus, which in good rich soil grows about 6 feet high or more in height, makes an excellent plant for placing at the back of a mixed border, or as a single specimen with a good, dark background. E. giganteus of gardens, which is probably a robust form of this species, has larger greyish white flower-heads; bannaticus, which is dwarfer, has steel-blue heads, and is useful in borders or for edging shrubberies. —K.

Transplanting white Lilies.—The beginning of September is the best season for transplanting white Lilies, *i.e.*, Lilium candidum, for the purpose of increasing one's stock of it. The bulbs can then be singled out without injury. They should be divided and sorted into sizes, giving the largest bulbs the most space. We have generally obtained the thickest stems and largest flowers from two-year transplanted bulbs. Even small bulbs will flower the second year if well treated. Two years ago I planted a number of bulblets, obtained from the stems of the double Tiger Lily, and most of them have flowered during the present summer, but their propagation and culture, as a rule, are very easy. —E. H.

Hybrid Lobelias.—Among the most showy of all autumn-flowering perennials must be included tall-growing Lobelias, the best known of which is ignea,

or Queen Victoria, for the plants usually grown under these two names differ but slightly, if at all, from each other. There are some other recognised sorts closely related to the above, but, horticulturally speaking, one of this class is sufficient, as differences amongst them are but slight. Great numbers of hybrid kinds have, however, been raised within the last few years, the result of crossing the above with L. syphilitica. Of these the following are especially worthy of mention, viz., Jason, bluish lilac; Nizza, a charming shade of crimson-purple; Amethyst, purplish blue; Queen of Whites, white; Vesuvius, deep crimson, with a violet shade; Stromboli, bright purple; Orion, cerise-scarlet; and Firefly, very bright crimson. When to these are added one of the Queen Victoria class, with its red stems and foliage, combined with intensely glowing blossoms, a selection is formed that at this season of the year will be welcome. Lobelias of this class prefer a good open soil, that is, especially during the growing season and at least fairly moist; indeed they will flourish in quite swampy spots; but, under such circumstances, are very liable to perish in winter. A little ashes, or Cocoa-nut refuse, around the crowns will ensure their safety during winter. At Mr. Bull's where we saw them the other day, they are grown in pots.—H. P.

A FEW USEFUL HERBACEOUS PLANTS.

I believe that great good would be done to the lovers of herbaceous plants if from time to time growers in different parts of the country would notice plants that have done well with them, or indicate those which seem to them unworthy of cultivation. Especially is this the case after a severe winter such as we have passed through, which has done much to test the hardiness of many plants about which doubts have been expressed; but the term "hardiness" is a comparative one, and few people take into account the many causes that tend to injure plants in winter, or how very opposed to ordinary notions are the real facts of the case. To most people's minds the very name of Torquay, for example, suggests the idea of a soft, relaxing climate, where everything must do well; but I met a friend the other day, a true horticulturist, who told me that for three weeks last winter, or rather early spring, the thermometer was down to 12° of frost at night and 3° by day without any variation, and when vast numbers of plants perished; on the other hand, when one writes about Scotland, the idea immediately presents itself of cold, dull, cheerless skies and severe frosts and snowstorms, and doubtless of many parts of Scotland this is true, but there are parts of Scotland where things will flourish which the winter would kill in the south of England, and where others grow with a luxuriance we in vain attempt to equal here. So again with S. Wales. The magnificent Himalayan Rhododendrons which adorn such places as Mrs. Vivian's at Swansea or Mr. Llewellyn's at Penllergare cannot be approached in the Surrey grounds so famous for their American plants. Then Cornwall, so early in sending its vegetables to London, and with a climate mild enough to induce invalids to try its influence, is fatal to the well-being of many plants, owing to its moisture and the consequent succulent character of the growth; while Lapagerias flourish and bloom out of doors there Roses run all to wood. It must also be borne in mind that where a climate is ordinarily mild and moist frost is far more injurious than in a climate whose temperature is generally colder and drier. Probably no part of England suffers more than the midlands, and plants which are hardy there may be pretty well relied upon in most parts of the country. My own county, Kent, is a favoured one, and although in this south-eastern part we are not as warm as some people imagine, yet our drier atmosphere, and in some districts our cretaceous soil, give us many advantages, and this must be taken into account when I mention hardy plants.

I consider an herbaceous plant useful when it is good for cutting for indoor decoration, either in vases or as bouquets, and there can be nothing, I think, more desirable for this purpose. With these and some annuals one is quite independent of a greenhouse; indeed, I feel convinced that a vase tastefully set out with these will be by the generality of people much preferred of one of exotics. There is such variety of form as well as of colour, that their value is at once recognised. I do not pretend to say that these are novelties, for many are very old plants, but they are none the worse for that, and those who have not grown them will be, I am sure, glad to have them brought under their notice.

Aquilegias.—Of these there are many very beautiful forms; probably the most striking are chrysantha and cærulea, the former a very beautiful plant with its pure bright yellow flowers and long spurs. Two hybrids raised by Mr. Douglas and sent out by Messrs. Veitch some years ago are also very beautiful. There is no flower which more readily hybridises than this, and anyone who grows a number in his garden will bear witness to the difficulty of keeping any species true. This has in another way its advantages, and as the seed germinates very freely, I am in the habit of allowing the plants to scatter their seeds, and from these seedling plants I have a number of the most varied colours, and they come in excellently for mixing with other flowers, being very light and graceful.

Achillea Ptarmica fl.-pl.—This is probably the whitest flower in growth. There is not a shade of green or flesh colour, which so often takes off from the whiteness of many flowers, to be found in it. When once established it requires to be kept in check, as it will run everywhere; it is very useful for cutting, for, although the flowers are double, they are not heavy.

Asperula odorata.—The common sweet Woodruff will grow anywhere, under shrubs or in any situation for which it may be required. In early spring it comes in very useful for cuttings; its small white flowers mix admirably with other more showy things, and its fragrance, like new-mown hay, is very agreeable.

Bocconia cordata.—A stately plant with white flowers, which succeeds anywhere. It has very striking cordate leaves, and throws up a number of flowering stems. It is well adapted for placing in large vases, or the side branches can be cut off for smaller ones.

Anemone japonica Honorine Jobert.—There is no need to dilate upon the extreme beauty and usefulness of this plant, and yet it might seem as if it were a novelty, for amongst the plants which are to be distributed to Fellows of the Royal Horticultural Society I found it mentioned. What a privilege to be a Fellow when such rare and new plants are to be had for the asking! I have heard some people find a difficulty in growing it. I think this can be only from excessive bad management. With me it is quite a weed, and has to be kept in check.

Buphthalmum salicifolium.—A very free-flowering and pretty plant; its very bright yellow blossoms are freely produced, and are very enduring when cut. There is some confusion about another species, which is coarser. I find in Mr. Paul's list it is said to be synonymous with Telekia speciosa. Is this the same as that which I find in other catalogues as T. speciosissima?

Dodecatheon Meadia.—When properly treated this becomes a very vigorous plant, and its fine spikes of quaint blooms are generally much admired. It delights in a cool, moist place, and when well established is a grand spring-flowering plant.

Doronicum austriacum.—A most useful early spring-flowering plant with yellow blossoms. It is very free and perfectly hardy. There is another member of the family sometimes called plantagineum excelsum, and sometimes Harpur-Crewe, as it originated with that ardent florist; it is more stately and has larger flowers. Austriacum is a capital plant for growing in pots to bloom early, its bright yellow flowers being very striking.

Epimedium pinnatum.—An exceedingly pretty plant, resembling somewhat a small Dendrobe. Its foliage, too, is very pretty, although this is apt to get disfigured in cold weather. It is not a showy plant in the border, as the spikes of bloom hide themselves under the foliage; but as an early spring-blooming plant it has few to rival it in quaint beauty.

Erigeron speciosus (syn., Stenactis speciosa).—A very pretty plant, with flowers of a peculiar silver-grey colour, very easy of cultivation, and most useful for cutting and mixing with flowers of gayer colours. It will grow almost anywhere in the garden.

Galega officinalis and G. alba.—Very old-fashioned and showy plants, the one with blue, the other with white pea-shaped flowers, which are very useful for cutting. Very free flowering and easily grown, it is one of the old plants that one often finds in cottage gardens.

Geum coccineum and G. montanum are both easily grown and useful plants, one with scarlet, the other with yellow flowers. Both are very easily grown in any border in the garden, and are well adapted for vases.

Gypsophila paniculata.—One of the most useful plants we have for cutting. Its flowers are very minute, but they are produced abundantly in large panicles, and when placed in vases add greatly to the lightness of the arrangement. It is very much used by the bouquetists in Paris, but not so much here; indeed, I have very rarely seen it grown in English gardens, although I cannot understand why this is, as it is very easily grown. The roots are said to get hollow and bad with age, but the plant which I have, which is some 3 feet through, has been in its present position for years. It has also, from its name, supposed to be only adapted for cretaceous soils; but I have it growing where there is not an atom of chalk or lime in the soil, and it is apparently one of those plants which accommodate themselves to various soils, no matter what may have been their natural habitat. It is a plant which all ladies rejoice to have when arranging flowers.

Hesperis matronalis fl.-pl., the old Rocket of our gardens, is a very excellent and sweet-scented plant. The true white is rather scarce. There is another plant which has an amount of flesh colour in it which is not so good. Although Rockets are of easy cultivation, they require to be divided every year, and rejoice in a bright, sunny aspect.

Inula glandulosa.—A very beautiful plant; the flowers are of a beautiful soft yellow, and hang like golden tassels on the plant. It is exceedingly hardy, and it has the advantage of blooming a second time if the flowering stems be cut down. I have it now blooming abundantly (end of August) after having given me a fine head of bloom in the spring, and no one, I am sure, can pass the plant without noticing it. I am surprised to find it absent from some catalogues where many things far inferior to it are lauded to the skies.

Lupinus polyphyllus.—Where large spikes of flowers are wanted for decoration, there can be nothing better than this fine old border plant in both the blue and white varieties, and once established there is no fear of its being lost.

Malva moschata alba.—One of our native plants, very hardy and free; the white of the flowers is very pure, and it stands very well in water after being cut, although the papery character of its petals would rather lead one to an opposite opinion; like the preceding, it is, when once established, pretty sure of holding its ground.

Papaver nudicaule (the Iceland Poppy).—There are three varieties of this—yellow, white, and orange—all perfectly hardy, and all flowering freely and distributing their seed in all directions when they are mixed together in the garden.

Platycodon grandiflorum (sometimes known as Campanula grandiflora).—A very beautiful plant, flowering in August; its large lovely blue flowers are produced on the tips of the flowering stems rather sparingly, but they make up in size and depth of colour for this, and there is not one of the family I think more attractive.

Statice latifolia.—Very free, being covered entirely with small lavender, lilac and white flowers; it is one of the most useful plants for late blooming, as it mixes so well, on account of its lightness and elegance, with other flowers.

Of course there is an abundance of other flowers which I have not noticed—Asters, Delphiniums, Campanulas, &c., but these have seemed to me worthy of special notice in the one aspect, viz., plants valuable for cutting, and if other growers of herbaceous plants would follow it up, I for one should be very grateful, and I think others would be also. Delta.

Symphyandra pendula.—This is one of the finest plants in the way of a Campanula that we have seen for a long time. It is quite distinct from the better-known S. Wanneri, the latter having mauve flowers, very slightly lobed, and rarely opening in a perfect way; S. pendula is a much more floriferous species, being literally laden with large pure white bellflowers, sufficient, indeed, to weigh down the branches, and suggesting a position on a projecting ledge on a level with the eye. This species appears to be more perennial than the other, forming woody stems likely to stand. It is, however, easily raised from seeds, which ripen freely in ordinary summers. Campanula Rosani is just now at its best, but seems to lose much of its character when growing in the ordinary border. In sunny Italy, of which we believe it is a native, it hangs from the rocks, forming great patches of pretty blue white-eyed flowers. It wants good soil, otherwise it commences flowering when very dwarf, and thus its gracefulness of form becomes quite lost.—K.

Plants for permanent beds.—Would you kindly suggest any arrangement of plants suitable for permanent beds in a flower garden? The exposure is good and the soil deep; it suits Rhododendrons and Azaleas specially well. The place is high—a little over 500 feet above the sea.—Carlotta.

*** The fact that your soil suits Rhododendrons and Azaleas shows it to be a suitable one for Lilies of every description, and what a wealth of permanent flowers there is in these alone! Pæonies, too, would do better in a deep peaty soil, well enriched with manure, than in any other; and the same is true of Christmas Roses, Delphiniums, Japanese Anemones, and Tritomas, not to mention what I may term the hardy evergreen section of flowering plants, such as Heaths, Menziesias, Veronicas, and as carpeting plants the evergreen Sedums and Saxifrages. Then, again, we get beauty of form, which should always be associated with flowering plants, in such things as Yucca recurva, the variegated Retinosporas, Phormiums, and Euonymuses, every one of which is at home in your description of soil. As tall flowers for the centres of beds, there are the varied forms of Spiræas, from the common white Meadow-sweet to the rich purple-flowered S. palmata. Helianthuses (Sunflowers), too, might be planted in variety, and Asters (Michaelmas Daisies) the same; Hyacinthus candicans and Gladioli, if your soil is well drained, will also prove permanent flowering plants, *i.e.*, they will winter in the beds without injury. With regard to arrangement, local conditions, surroundings, and size of bed are the most important points to be considered, and obviously size must decide the numbers or variety of plants to be used. Perhaps the greatest difficulty will be to restrict the species or variety of plants within appropriate limits. Be it remembered that numbers alone do not constitute beauty nor effectiveness; they lie in selection, combined with artistic arrangement.—W. W.

Gentiana asclepiadea.—This still retains its character of queen of the autumn Gentians. Just now it is flowering in the greatest profusion, and on the rockery at Kew, where it has been planted pretty extensively, it forms one of its chief attractions. The largest clump is planted in a dampish, shady position, which seems to suit it perfectly. The plants in this clump are much more robust than any planted in exposed places. Seed is by far the best way of increasing it, as when the old stools are disturbed they take some time to recover; while seeds sown in a sheltered spot in the open air as soon as gathered begin flowering the second year, and in three or four years, such a rapid grower is it, large clumps are formed. The white variety planted by itself makes a charming mass, but when seen mixed with the blue the effect is still better. G. affinis, though inferior to asclepiadea, is also a desirable plant, and owing to its dwarf habit suitable for places for which the other would not be suitable. Seed appears to be the only means of increasing this species; it forms large succulent roots resembling those of G. lutea and others.—H.

NOTES ON HARDY PLANTS.

Saxifraga aromatica.—The beauty of some plants is only revealed to us on the closest acquaintance with them, and this is one of them—not that it is otherwise undesirable, for it is much above the average of its class as regards neatness and distinct form and good white flowers. But it is when you begin to handle this Saxifrage and remember its pleasant name that its good properties become known. Its herbage, both dead and living, gives off a fragrant odour when pressed, and one cannot but feel a sort of satisfaction that this or that descriptive name is in harmony with the plant's character. This Saxifrage may be introduced into the most select collections of alpines. It is a neat and steady grower; it has a clean and attractive appearance all the year round; the flowers are few, but clear white, and the leaves form themselves into little rosettes of a pale green-yellowish tint. The present is a good time to divide it; though two-year-old pieces are not more than 6 inches or 8 inches across, they may be made into four. The persistent old herbage which thickly besets the stems under the green leaves should not be taken off on any account, for in doing so the stems would be pretty sure to have their skins removed, and this kind is not like many that will grow if they touch the ground; indeed, a small mistake may kill it when being divided.

Acantholimon venustum is a rock garden gem. The bristling grey-green tufts of short Grass-like foliage are compacted together much in the same manner as in the better-known species glumaceum, but I question if it ever grows into such large masses. The pretty arched spikes are notable for the way in which they bend and touch the ground with their points, and also for their sered appearance just before the bright flowers push forth. Many who have not had experience with this plant would not expect such large and brilliant blossoms, or indeed any, perhaps, from the chaffy-looking stalks, but would be more likely to suppose that the flowering stage was over. I find this plant to do admirably in a fine loam with plenty of leaf mould. It is also partial to the moister parts of rockwork, say on the sunny side of a big stone and close to it, the stone acting as a miniature water-shed. Some have tried it in dryish positions, but under such conditions I have found it to starve. Slips taken in early summer make nice plants, which, however, are as well or better if kept in a cold frame for the first winter and set in the open in spring. The slips are certain, but slow rooters if set firmly round the sides of small pots and kept just moist; they need not be set in a frame, for the plant hates heat.

Dianthus Seguieri is a glorious Pink when seen in the form of good-sized specimens in full bloom. Its lateness also gives it an extra value, its blooming period taking us well into that of the Carnations, with the brightest of which it vies successfully as regards effect. Though the flowers are comparatively small, they are borne on tall stems 1 foot or 15 inches high, and in large quantities. The well expanded character and bright crimson colour of the flowers are the chief features of this Pink, but there is something about the flowers which induces one to closely examine and admire them. The stems hold them perfectly erect, the petals neatly overlap and form a flower nearly an inch across and as flat as a shilling. Their brightness of colour is a little subdued by their soft, hairy surroundings. This plant may be increased by means of underground shoots. It differs from many Pinks in being best when left alone for several years together. From the fact that it makes its grass late and in the heyday of slug ravages, great care should be taken to dress the surface freely and frequently all around the plant with wood ashes in a white and dry state. This is all the more needful, seeing that the plant has to remain in the same position for several years.

Stipa pennata.—At present the fleecy masses of awns on a number of very strong plants of this Grass constitute quite a feature in the garden. I have mentioned it before in these columns in connection with Carnations, and I would again urge that the two be planted as near neighbours, for, seen either closely or a little distance off, the animated Feather Grass lends a charm to the Carnations which hang heavily on their supports. This Grass, like many others, is better for being divided and replanted in fresh soil after a few years, and the time to do it is as soon as the awns have dropped off or in spring, when new growth is just pushing. I should prefer to do it in August, as then one secures an established plant with plenty of good long roots before the cold sets in.

Gillenia stipulacea.—This is hardly less elegant than G. trifoliata. It may not have so many, or quite so large flowers, but they are much in the same way, and charmingly set off by the handsome foliage, which assumes its ripened hues very early. The red tints of the growing parts are of themselves attractive, and almost before the flower-buds open, the lower leaves, quaintly shaped, with large stipules, begin to turn a rich brown-red. The plants grow from 18 inches to 3 feet high, according to the quality of the soil. It has a slender habit and should be sheltered from wind. It is also the better for a little side shade from the midday sun, and under such conditions it will not fail to colour its foliage in summer; but the shading should not be overdone. Longish shoots cut make good material for decoration indoors.

Saxifraga odontophylla.—This is so delicately beautiful, as to suggest that it should be taken indoors and made secure from rains and mud splashes. It may not be much known yet, but seekers after hardy gems should make a note of it. It belongs to the same section as the well-known rotundifolia, if you class the Saxifrages by their leaves, but it is without the coarseness and luxuriance of that kind, and otherwise totally different from it. Its flowers rather remind one of those of the Megasea section as regards form; they are large, erect, and somewhat bell-shaped, but instead of a thick fleshy scape they are borne on leafy stems and in spare panicles. Each flower is nearly an inch across and of waxy whiteness. Their erect cups are half filled with dumpy stamens, and the large red anthers are so compacted as to form a dotty ring against the ivory-white wall, so to speak. The leaves are from 1 inch to 2 inches across, nearly round, with longish stalks, a hairy coat, stout substance, and a boldly toothed margin. This kind, too, comes into flower when the crowd of Saxifrages has gone by; therefore it richly deserves appreciation. My plant of it I have not long had, so I have not fully tested its hardiness, but I have proved it to be capable of enduring 16° of frost under somewhat dry conditions.

Sidalcea candida.—This is one of the more recent introductions, and the shortest description I can give of it is, that it is practically a miniature Hollyhock. Its erect flower-stems are in rich land about 3 feet high. The flowers, which are satiny-white, are perhaps a little flimsy, and certainly short-lived, and I fear the plant has been over-praised. Many would not care to grow it, and others would eradicate it after two years' trial, owing to the manner in which the roots run under the surface. But why not take advantage of its vigour and set it in positions where other things will not thrive? I find that it does well in shade, and it might be made to do duty among dwarf shrubs and in similar places. It is perfectly hardy, and would make a capital woodland plant.

Myrsiphyllum asparagoides.—This, I have heard, has lived out of doors all winter in the border districts. The leaves are stated to have kept fresh and good in colour without protection. This proves that the stems of this pretty evergreen twiner are possessed of some hardiness, but we could not be sure that the roots had been so severely tried, for a thick covering of leaves where they cannot be blown out of position may keep out more frost than glass or mats. I have, however, examined some 3-inch pots full of

young tubers and roots that stood unplunged in a cold frame all last winter where they were frozen through and some of the pots split. The roots were partially frost-bitten, and I should think some will die; the tops were bright and fresh on all of them, a fact which clearly showed that they were hardier than the roots. How much frost the plant would really endure out of doors we may not yet know, but these facts indicate that if the roots were deeply planted they would be as safe as many other things left out. A half sunny corner sheltered from winds might suit both its slender stems and tender tubers, and as for its beauty, especially when furnished with its highly coloured berries, praise is needless.

Chamæbatia foliosa.—From its dwarf, evergreen, and free-flowering habit this may well be used among single alpine Roses, shrubby Cinquefoils, and similar plants. It is a remarkable species in many ways; the little clusters of white Rose-like blossoms, with the calices furnished to their tips with glandular pubescence, are at once curious and pretty, and out of doors this plant is, perhaps, hardier than it has been taken to be. Lovers of the interesting might well try a plant or two of this Chamæbatia. Its beautifully cut foliage is a study; the myriads of nut-brown glands give just a slight ferrugineous effect to the olive-green leaves; a mere touch imparts a stickiness, and without a touch even the peculiar resin and petroleum-like scent is strongly smelt, whilst to handle the leaves makes one feel as if a tar brush had been handled. We sometimes speak of the inflammableness of Dictamnus Fraxinella, but this is much more so; a leaf puffs and frizzles like a chop on a gridiron. Some cuttings are making roots under a small glass, and as the fresh leaves develop the effect is charming. Never could Filmy Fern be more beautiful; indeed, it is worth while to put in cuttings of it, and to treat them under a bell-glass in a cool house for the sake of watching their development, either by the aid of a lens or with the naked eye. Besides, cuttings put well down very much resemble young Filmy Ferns in appearance. Has anyone tested its hardiness? Its habitat being the Sierra Nevada rather favours the possibility that it may prove hardy with us.

Mitchellia repens.—On the first glance at a tuft of this evergreen creeper in flower one could almost fancy somebody had been scattering twin flowers of the Myrtle or Hoya among the little veined Box-like leaves. Examined more closely, of course the similarity disappears, but the effect may be imagined; then there is the charming berry state. A more beautiful and interesting creeper than this could hardly be named for adorning rockwork. To have it with uncurled foliage and freely-grown shoots, it not only needs a moist place, but such material on the surface as will encourage new roots from the stems. Half-decayed leaves and a little loam or even sand to solidify them will do, but the main point is to fix on a little spot where moisture will naturally collect, and unless there can be found such positions the rockery can hardly be said to have been formed to meet the requirements of moisture-loving plants.

J. W.

Wigandia caracasana.—Well grown specimens of Wigandias are very effective planted out on sheltered portions of the lawn or pleasure ground during the hottest of the summer months. They are easily propagated in the spring by means of cuttings, and if the thick roots are cut off in the autumn, when the plants are taken up for removal indoors, a large proportion of them will form young plants if planted in light sandy earth, on a genial bottom heat. This species of Wigandia is a very quick grower on warm rich soils, often attaining a height of 6 feet or 7 feet in a single season. Where it does well, it is a noble sub-tropical plant, its broad foliage being of a fresh green colour, and forming a charming relief to the brilliant scarlet and yellow which are the prevailing colours of ordinary bedding plants. During the winter months, the old plants may be stored under the stage in a warm greenhouse or vinery, and these old stumps will furnish an abundant supply of cuttings in the spring. The Wigandia rarely flowers in our climate. When it does it produces a large scorpioid inflorescence at the top of a thick fleshy stem. It may be seen growing vigorously at Battersea and in the other London parks during the summer months, and there its large foliage is seen to the best advantage. A little well-rotted manure, added to the compost in which it is grown, will be found to be beneficial to it, and it requires a liberal supply of water when growing.—B.

FLORISTS' CARNATIONS OUT OF DOORS.

For the past thirty-five years, and I have no doubt for years previously, the old school florists never ceased to recommend the Carnation and Picotee as border flowers, and especially their beautiful run, self, and fancy flowers, as the latter are termed in these days. Because our old florists grew plants for exhibition and cultivated them in pots, they did not thereby mean to indicate that bizarre and flake Carnations cannot be grown on the open border. Between thirty and forty years ago many bizarre and flaked Carnations were sold and grown for border decoration, but many of them were much neglected, and in consequence their flowers became inferior in quality; layers were not made every year in order to keep up a succession of vigorous young plants as they are by the florist who grows for exhibition, and thus it came to be said that named Carnations and Picotees were not suitable for cultivation in the open air, but the inference was not a just one. Many Carnations and Picotees grown in borders thirty years ago were raised from seeds, and as good in the main as they are at the present day, but few cut flowers then for indoor decoration, and there was not that desire to possess hardy plants that there is now. Border Carnations of those days neither lacked size, symmetry, nor refinement. The fact is, bedding-out in flower gardens caused the Carnation and Picotee, and many other things equally valuable, to decline in popular estimation; and there not being much demand for seeds of them, but little good seed could be obtained. That the Carnation is deservedly popular now I admit. Talk of border Carnations and Picotees, why Mr. Dodwell blooms all his seedlings in the open ground. Let anyone pay him a visit at Oxford just now, and they will see his borders and seedling beds gay with hundreds of flowers of varied colours. Anything specially good is marked and proved in pots the following year. I called on a well-known Carnation grower at Clapham a few days ago, and, in addition to some 250 pots of choice Carnations and Picotees, he had many fine varieties in the open border flowering freely, and they had stood there all the winter. What is done at Clapham, therefore, can be done elsewhere. I have now blooming in my own garden some of Mr. Dodwell's seedlings—robust growing plants, some with self-coloured flowers, some flaked, some bizarre. Amongst these one or two varieties are marked for trial another year. Since I received them in October last they have never had the slightest protection. Therefore, it will be seen that the named Carnations and Picotees grown by florists are as thoroughly hardy and fit for border culture as any others. R. D.

Hardy Clematises as bedding plants.—Notwithstanding the success which has attended the hybridisation of this magnificent group of flowering plants, I have failed to obtain a variety possessing that remarkable floriferous continuity of bloom which we get in C. Jackmanni when used for bedding purposes. Its richness of colour, when grown in masses, imparts to the parterre a hue of purple, which is altogether captivating and lovely. My object, however, is not to eulogise the well-known merits of C. Jackmanni, but to endeavour to ascertain if there really exists amongst the mauve or light coloured varieties a suitable companion to it for bedding purposes. I was at one time inclined to believe that in Lady Bovil we had found this desirable desideratum, but lovely as the individual blooms of that kind are, I do not find it to possess continuity in the way of bloom to warrant its being successfully admitted into parterre arrangements, where it is important that uniformity in the flowering period of the various subjects should be maintained to the longest possible period, as a single failure produces an unsightly blemish. While fully admitting the marked advance that has taken place amongst Clematises owing to hybridisation, I think it important that perfect hardiness and freedom of growth should not be lost sight of in any attempt at cross-breeding, for without this the flowering period cannot be sufficiently prolonged, so as to warrant their use in flower-garden arrangements, where most assuredly, owing to the brilliance and richness of their colouring and grand proportions as regards size, they are destined to play a most desirable part. I shall, therefore, be glad for any information from any of your correspondents who may have practically tested the merits of the various sorts as to their continuity of blooming and adaptability for flower-garden embellishment.—G. W.

Garden Flora.

PLATE 559.

CHOICE HAIRBELLS.

(WITH A PLATE OF CAMPANULA TURBINATA.*)

The Hairbells, generally speaking, are such a popular class of plants both for rockwork and ordinary borders, that a few words on the merits of the choicer kinds may not be out of place in connection with the annexed plate of C. turbinata. Numerous as the Campanulas in our gardens now are, considerable numbers have not yet been introduced; many are lost to cultivation, and a few which are not quite hardy require the protection of a greenhouse during winter. Choice

Campanula Waldsteiniana.

kinds so dwarf as to be suitable only for growing on rockwork are both many and varied in habit—some, such as abietina, increase rapidly into large patches, while others, like Waldsteiniana, Lœfflingi, &c., take a long time to acquire any considerable size. The range of colour, too, amongst them is rather restricted, but they flower at such widely different periods as to make them all acceptable where space can be afforded them. A. Allioni is a plant but rarely seen, even in choice collections, although frequent importations of it are brought to this country. It is a charming Hairbell, dwarf and large-flowered, with hardly any stalk, the blooms sitting apparently on the ground. It requires plenty of room, as it runs often a long distance underground in a year. It likes a sunny position in gritty, well-

* The Campanula was drawn in Messrs. Backhouse's nursery, York, by the late Mr. Noel Humphreys. The Haberlea is from a drawing sent to us by M. Max Leichtlin, Baden-Baden.

HABERLEA RHODOPENSIS

drained soil. C. barbata, the bearded Campanula of which there are many forms, grows well on rockwork in full sunshine. C. cenisia is one of those rare kinds that require special treatment, such as that usually given to Androsace glacialis.

Campanula fragilis var.

It does well in gritty soil, mixed with a little peat and Sphagnum Moss, and the roots should be kept always moist. C. fragilis, of which we believe there is also a hairy form, is quite hardy with us, and grows freely on an old stump in a

Campanula garganica.

heap of lime rubbish. Its branches hang down and make a fine show through the summer months. It is nearly allied to isophylla—the old floribunda of gardens—which requires a similar position. C. garganica and the variety hirsuta

Campanula Raineri.

are also useful for hanging over ledges in the rock garden, as well as for pots for the decoration of the greenhouse. It is very floriferous and handsome. C. haylodgensis, said to be between pusilla and Lœflingi, is a very free-flowering sort, and a good companion to G. F. Wilson, another charming hybrid. Portenschlagiana and pulla are also very desirable, the latter a veritable gem and worthy of a place in every collection. Others, such as Tommasinii and a few varieties of rotundifolia, &c., are all good rock garden plants.

C. TURBINATA, of which the accompanying coloured plate gives an excellent idea, is considered by many to be a distinct species, but after cultivating both this and C. carpathica for several years, and seeing the intermediate forms that exist between the two extremes, we are convinced that C. turbinata is only one end of C. carpathica, the type being the other. For horticultural purposes, so far as floriferousness and compactness of habit are concerned, C. turbinata is a preferable plant to the others; for rockwork decoration it can hardly be surpassed even by C. Raineri, nestling as it does close to the rocks, and bearing in abundance very large turban-shaped flowers. It sheds its seeds freely, and there need be no lack of plants if these are allowed to germinate undisturbed. The seedlings come up in all sorts of out-of-the-way nooks, flourishing where there is hardly a vestige of soil to support growth.

HABERLEA RHODOPENSIS.—Of this we also give a coloured illustration. In every list of choice hardy alpine plants those alluded to below always find a place both on account of the ease with which they can be grown and on account of their profuseness and beauty. No one with proper accommodation for cultivating alpines will have any difficulty with these, so far as they are procurable. Ramondia and Conandron have been included, being near allies. But another, though doubtfully hardy, is Rehmannia sinensis, with flowers similar to those of the Haberlea, but requiring a sunny instead of a shady position in which to grow well. Wulfenia carinthiaca, another restricted species, and W. Amherstiana, both of which are charming alpines, do well in company with the above, as well as other Himalayan genera, too few of which are in general cultivation. Haberlea rhodopensis, here shown in a young state, in habit and manner of flowering somewhat resembles the Pyrenean Ramondia, to which indeed it is nearly related, as is also another rare and interesting plant from Japan, viz., Conandron ramondioides. The Haberlea, of which there is only one species, is said to abound on the southern declivity of the Balkan range, growing on shaded schistose rocks near the town of Kalofer. With us it is perfectly hardy, and requires exactly the same treatment as regards shade, &c., as the Ramondia. The soil should be peaty, well drained, and of a good depth, and it will be found to succeed all the better if a few pieces of soft sandstone are placed thickly round the collar of the plant; they not only assist in keeping moisture in the soil, but help to protect the roots, which may be seen matting the ground thickly at a good distance round the plant. We prefer a sloping position on which to plant it; indeed, the more perpendicular the better, as then the chances of water stagnating about it are considerably reduced and the chances of success increased. Where it is too much cramped it rarely flowers, but produces plenty of offsets—as many as half a dozen in one year. As in the case of other cultivated plants, it shows signs of improvement, the varieties robusta and grandiflora being considerably better than the type, although the colour in neither form is so pronounced as it will probably in time become if seeds instead of offsets be the means of increase. Seeds apparently soon lose their germinating power; the best plan, therefore, is to sow them in shallow pans as soon as they are gathered, placing them in a cool frame in the shade, and covering them with a slip of glass elevated a little above the pan. Plants of it generally grow about 6 inches in height and are clothed, with the exception of the flowers, with soft white hairs; the leaves, which are all radical, form rosettes close to the ground. They are from 2 inches to 3 inches long, dark green, oval, coarsely and evenly crenate, and taper into a broad, stout stalk. The flower-stems are dark purplish-brown, and carry from two to five Gloxinia like pale lilac or bluish purple

Conandron ramondioides.

flowers with a yellow speckled throat 1 inch in diameter. A short time ago a plant of it flowered beautifully on the rockery at Kew. Its flowers are produced in May and June.

RAMONDIA PYRENAICA, though an old and well-known rock plant, is too good a companion to the above to be omitted here. It is the Blew Beare's-eares with Borage leaves of Parkinson. Unlike the Haberlea, there is not much chance of increasing it by division—at least, to any extent; it is fortunately, however, very easily raised from seeds, and although plants of it can be imported from the Pyrenees in good condition, we much prefer home-grown seedlings. They appear after a time to form much stronger plants, and are certainly more amenable to our mode of cultivation than those imported. Seedlings if kindly dealt with flower the third year, and go on increasing in size. We sow the seed

as soon as gathered, and prick off the young plants as soon as possible, putting them between two small pieces of old brick which they cover with their rough leaves in a few weeks. Shade is generally recommended for this plant, and doubtless it succeeds best under such conditions, but we have seen it grow on the top of an old wall fully exposed to the sun, which in summer quite burned up the leaves. It, however, flowered well, but the blossoms were not so large as those of plants grown in the shade. It begins to flower in May, and a few straggling blooms of it may yet be seen. A plant represented to be a new species and called R. Nataliæ is being distributed, but, so far as we can judge from the scraps of it which we have seen, it is nothing but a synonym added to pyrenaica. R. p. var. serbica, a Servian variety, is quite distinct, though as a garden plant inferior to the type. The leaves are not wrinkled, as in pyrenaica; they are lobed, not crenated, and the margins are thickly covered with long shaggy brown hairs. The flowers are lilac-blue, and not so large nor so handsome as those of the ordinary kind. R. p. var. alba, which we have never seen alive, is said to be a grand plant; its flowers are as large or larger than those of the type, pure white with black stamens. This is as yet too expensive to be a common rock plant.

R. Heldreichi, also called Haberlea Heldreichi, we have never seen growing. It is very distinct, however, from all others. The leaves are covered with a white silky pubescence, resembling those of Salvia argentea in a young state, and they are entire, not lobed or crenated. Only one or two flowers, which are purplish in colour, are produced on each stem. It is a native of Greece.

Conandron ramondioides.—This is another plant that should be associated with the above. It inhabits the higher mountains of Japan, where it is found on the north side of moist rocks. In habit it somewhat resembles Haberlea, Ramondia, and Streptocarpus, and, so far as the appearance of the leaves go, in a measure Wulfenia. It grows about 6 inches in height, has shiny, glabrous, somewhat wrinkled leaves, 6 inches long by 3 inches broad, their margins being sharply, but irregularly serrated, and the stalks, or petioles, winged and serrated their whole length. The flower-stem as well as the leaves proceed from rhizomes covered with brown, shaggy hairs, not unlike the Hare's-foot Fern. The flowers, which are pale blue and white, and about a dozen in each umbel, are about the size of those of Ramondia. It thrives well in rich soil and in a position that would suit Ramondia. It flowers in June and July. It is easily increased by taking off the rhizomes and fastening them down with pegs in gritty soil. K.

Wild flowers at Shrewsbury.—When nicely arranged and shown extensively, no display of cut flowers is more interesting than that of wild flowers. The Shrewsbury Horticultural Society patronises these and offered good prizes for them in three different classes at its recent show, which brought out about forty exhibits. The way in which they were shown was very varied; the subjects employed consisted of many kinds of flowers, Grasses, Ferns, and fruits, such as Nuts, Crabs, Sloes, Mountain Ash berries, wild Solanum fruit, and berries of various other kinds. Some of the exhibits were simple, others more elaborate. The best were those in which crowding had been avoided, and where graceful wild Grasses were introduced with flowers. Altogether they were probably as much admired as the many stands of hothouse flowers close by, and I am of opinion that societies in general do not encourage this kind of decoration so much as they should do. It allows many to compete who would not otherwise have an opportunity of showing flowers or trying their hands at artistic decoration of this kind. That decorations of this kind are popular is beyond dispute. There are some who think that these prizes induce exhibitors to destroy our wild flowers and that from this cause many of the more valuable and rare sorts have been annihilated, but I do not belong to that class. For years past I have been watching these exhibits closely, and it is in a very exceptional case indeed in which anything but the most common wild flowers and Grasses of our hedgerows and fields are to be seen in their composition.—Cambrian.

WORK DONE IN WEEK ENDING AUG. 24.

August 18 to 24.

The weather has continued dry and dull except on the 20th and 21st, which days were so hot and sunny, that we again had recourse to shading the vineries in which ripe Grapes are hanging and latest Peaches; houses containing ripe fruit we shaded by tacking tiffany over the glass. Watering is still the order of the day in respect of inside Peach and Vine borders, also of wall fruits—Peaches, Pears, and Plums—on a west wall. The few dozens of Apricots that we have this season are all ripening together, but their season of use we are endeavouring to extend by gathering them before they are quite ripe and placing them on the shelves of the fruit room till they are fully so. The flavour or quality is somewhat deteriorated thereby, but our end is gained—longer supplies, which counts more than the little loss of quality in the fruit. The wood of Peaches on walls has had the final tie and nail in for the season, extra care being taken not to shade the ripening and swelling fruit by the process. Early Albert Peach we are gathering in quantity from a south wall, and Lord Napier Nectarine is ripening up on the same aspect. Jargonelle Pears have all been gathered, and a few of Beurré de l'Assomption and Williams' Bon Chrétien. All are small by reason of the drought, and I think also partly so from over-exhaustion, owing to the heavy crops of last year. We mulch and water a few of the finer kinds as often as our limited means will allow. Kirke's, Jefferson's, and Green Gage Plums are all ripening on a west wall, and protective netting from birds and wasps has been put over them, which will also prevent scorching of fruit should the sun prove exceptionally hot. Surface hoeing in kitchen garden. Earthing up we have discontinued till rain falls in quantity, that the ground may get a soaking before this work is done. Flower-garden work has been of the usual routine description at this season, viz., picking over plants—the flowering section—to keep them free of bad flowers and seed vessels that they may continue to flower the better; and the foliage section, to ensure the outline of designs being distinctly marked. Turf edgings of flower-beds are regularly cut once a week, as also are the Grass verges and edgings of walks, and the gravel is kept smooth and free of weeds. Bedding plants are now at the height of perfection, and as we trench deeply scarcely any watering is now needed, the roots of all kinds having descended sufficiently deep as to be out of harm's way from drought. With herbaceous flowering plants it is different; many of these have not been moved for three years; consequently the ground has got so full of roots that watering has become a necessity if they are to be kept in good flowering condition, and they are worthy to be so, the Phloxes, Potentillas, Sunflowers, and many others being at the present in extra good flower. Funkias, Spiræas, Pyrethrums, Delphiniums, and Pæonies having done flowering, all traces of flower-stems and bad leaves have been cut away, and by way of making the borders still more gay, we have plunged near these kinds of plants flowering plants in pots, such as Fuchsias, Pelargoniums, Campanula pyramidalis, Tea Roses, and auratum Lilies. General work has been the keeping of every place in the neatest condition, roads and walks in this respect being as great a consideration as are flower beds. Put in cuttings of Pelargoniums, Carnations, Pinks, and Roses. The runners are kept pinched off Strawberry plants in pots; they grow so fast, that this work needs to be done twice a week, and the plants are given more space as growth progresses. Overcrowding is never permitted, nor the plants to get dry; hence it is that we are never troubled with red spider or mildew, or ever experience the least difficulty in getting the crowns well matured. Other indoor work has been of the usual routine description—watering, tying Chrysanthemums, potting Primulas, Cinerarias, Bouvardias, and Gardenias.

Hants.

FRUITS UNDER GLASS.

Vines.

The principal crop of Muscats intended for hanging until Christmas will now require a gradually increasing supply of light and air, with sufficient fire-heat at night to prevent the temperature from falling much below 70°. Although it is not advisable to expose the tops of the bunches to the direct influence of the sun, perfect finish cannot be secured where it is entirely shut out; judgment must therefore be brought to bear, not only in the removal of laterals, but also in their retention and tying in where spider has injured the main foliage. The fine rains we have recently had having penetrated the external borders, covering of some kind for throwing off cold autumn storms should be provised for use when the fruit is quite ripe. Glass lights, if at command, answer best, as they do not impede the passage of sun heat and air. Shutters or sheets of corrugated iron stand next, or, lacking these, a good covering of fresh stable litter; while feeding the surface roots will absorb a great deal of moisture, to be given off to the atmosphere when the weather is bright and fine. Well-drained internal borders, on the other hand, must be kept regularly supplied with tepid water or diluted liquid for the present, and well mulched with rather dry litter or Fern to prevent evaporation, as want of water inside is one of the most common causes of shanking and the rapid spread of spider. The roots of Lady Downes, Gros Colmar, and other bottling varieties will require similar protection when the Grapes are ripe, but the laterals must be more sparingly shortened, as black Grapes always colour and keep best through the autumn months under a good canopy of healthy foliage.

Midseason houses from which the fruit has been cut, unless the roots are to be disturbed, from this time forward may be divested of all laterals, provided the main leaves are sound and capable of feeding the buds. Strong canes which it is hardly possible to over-ripen must also be cleared of laterals from the base upwards to the bud to which it is intended to prune, while those above it may be allowed more liberty until the foliage is ripe. If spider has gained possession, the hose, garden engine, or syringe applied with some force on fine evenings will soon dislodge it, and the water which falls upon the borders will keep the roots in satisfactory condition. If root-pruning in these or early houses is contemplated, now is the time to set about putting the borders in order, but instead of cutting out laterals every bit of young growth must be allowed full play until fresh root action has set in. At one time it was thought indiscreet at least to disturb the roots of Vines while they were in full leaf, but now the best Grape growers commence as soon as the last bunch is cut from the Vines, and, aided by warmth, shade, and moisture, get them thoroughly re-established in the new compost before they fall. Assuming, then, that all laterals have been allowed to grow and the roots have the run of external and internal borders, one or other may now be taken out with impunity, not unfrequently when alternate renovation is reduced to a system, without causing the Vines to flag. Caution, however, in these matters being a virtue, I would suggest keeping the house close, moist, and shaded during the performance of the work and for some little time afterwards, as flagging means loss of vital power. Despatch being the main

factor, compost, consisting of fresh fibry turf, old lime rubble, and crushed bones, should be prepared in advance, and placed conveniently near for wheeling in immediately after the old has been disposed of. Some prefer old turf, but, provided it is dry when cut and free from wireworm, the sooner it is used the more likely will it be to ferment, no small matter where quick root action is of paramount importance.

Lifting.—Having worked out the old compost with steel forks and saved every particle of root and fibre, tie them up in bundles and sling them out of harm's way, where they can be kept moist and shaded; ascertain that the drainage is satisfactory. Cover this with large thin sods of turf, Grass-side downwards, and form the foundation of the border with the roughest of the new compost, make it quite firm, to prevent much settling, and see that it is well rammed and dovetailed into the face of the old as relaying is proceeded with. If the space originally allotted to the roots is too wide, a retaining wall of turf must be built up from the drainage, always a little in advance of the filling, otherwise the compost cannot be made firm and all the points of the shortened roots will be laid with a downward tendency. The width of the new section is a matter which must be regulated by the size of the house, the width of the undisturbed border, and the condition of the roots under treatment. If abundant and healthy and a check is all that is needed, the new border may be one-third narrower than the old one; if fibreless and bad, the narrower the better, as a moiety 3 feet to 6 feet in width and well filled with fresh healthy roots is always preferable to large masses of soil in which feeding, exciting with warmth, and protecting are more difficult. Indeed, it is a question if a superabundance of crude, cold compost is not one of the most common causes of disappointment when the Grapes are passing through all the most difficult stages of their culture. When all the roots have been re-laid, a moderate supply of warm water at a temperature of 90° while settling the soil about them will most likely aid fermentation, especially if the turf is dry and the herbage has not perished. The final covering of compost may then be placed over them, firmly beaten, and covered up with fresh stable litter.

Strawberries,

Unusually late this season, will well repay a little extra attention, as good crops of forced fruit entirely depend upon plump ripe crowns with an abundance of healthy roots beneath them. In my notes some time ago I suggested a run upon small pots, as they fill quickly, and it is of no use trying to ripen the crowns until the roots have taken full possession of the compost. To promote this growth of root and crown, the plants should have sufficient room to favour the free passage of air and warmth; the stations should be kept moist, as the constant exhalation of vapour feeds the foliage, and keeps it free from spider and mildew. Water in abundance must, of course, be given to the roots, not slapdash with the hose, as is too often the practice, but carefully with the watering-pot, without wetting the foliage in hot weather; each plant will thus receive sufficient for its healthy development, and stand without further attention for at least twenty-four hours. Plants in all stages, after they are well established, must be kept free from weeds and runners, and if the surface soil is occasionally loosened with a sharp-pointed stick, the time so spent will be a decided advantage. Stimulants need not be used the first season unless the plants are decidedly weak and require a start, but a mulch of old Mushroom manure will be of service to the earliest potted plants when they have made their growth, and the pots, being small, require slight protection in hot, dry weather. As days decrease in length and nights become damp and cold, the general stock of plants will require more room and frequent turning about to prevent them from rooting through; indeed, it may be necessary to elevate them on dwarf walls or plank stages, where they can remain until the time arrives for storing.

Storing for the winter is a matter upon which many differ; some plunge the plants in cold pits, some stack them in cones, heads outward. Others prefer plunging them out in the open air where they can have full exposure to the elements. Results in a great measure depend upon the winter; if very wet, plants intended for early forcing or for fruiting late in the spring can be kept most under control in cold shallow pits, from which the lights should be removed on fine days and well tilted when heavy rain is falling. For general forcing they do quite as well when plunged in the open air—indeed, perhaps better—as the Strawberry is perfectly hardy and always fruits best after exposure to the elements through a severe winter. If proof of this assertion is wanted we have only to go back to the past winter, one of the longest and most trying on record. Open-air beds lost all their old foliage, but where they were well mulched and watered through the preceding summer's drought they started well and every crown threw up a flower-scape. Where they failed the surface roots had perished, not by frost and snow, but through lack of moisture when completing their growth. Staking does not find general favour. If the winter is wet and mild the plants take no harm, as the constant percolation of water keeps the balls moist; if, on the other hand, keen cutting winds and dry frosts, minus snow, prevail, the balls shrink from the sides of the pots and the plants become useless.

Cucumbers.

If not already disposed of, a few plants for fruiting up to Christmas should be put out without delay. A small compartment or pit to which top and bottom heat can be applied when the days become short and nights cold will suit them well, but for the present fermenting material, aided by solar heat, will be found quite sufficient. Although Cucumbers revel in a bottom-heat of 80° they quickly resent dry fire-heat, become infested with spider, and fail just when they should be in full bearing. This collapse, it must be admitted, is disheartening; but why allow it to occur when primitive measures so well understood by the old school will prevent it? Let the bottom-heat pipes be laid in cemented gutters, which can be filled with water and emptied at leisure; cover them with rough slabs and plant out on elevated hills or ridges, resting on a good layer of fermenting material or broken brickbats. Lacking the tanks, let the pipes be laid in broken bricks, rough coke, or clinkers, but on no account omit the fermenting material, as root moisture forms the key-stone of success. Another point of importance is thin planting. Many court failure by crowding their plants too much, when they become weak and require pinching before they are strong enough to bear fruit; whereas leaders being allowed to travel to the top of the trellis, side shoots regularly tied out, every leaf carefully preserved and fully exposed to the influence of light, a robust constitution capable of withstanding November fogs will be formed before the winter months set in. When free varieties, like Telegraph or that excellent sort Masters's Prolific, are treated in this way, and 4 feet to 5 feet are allowed to each plant, the base laterals generally show at the first joint. If these first fruits are wanted, it will be necessary to pinch at the joint beyond and follow up this mode of manipulation so long as the weather favours free growth. If, on the other hand, the crop is not wanted, the first shows may be removed and the laterals pinched back to the joint nearest the main stem. The best compost for early winter plants is light, turfy loam, the rougher in reason the better, a dash of soot to stimulate the roots and check worms, and a liberal admixture of old lime rubble. Manure mixed with a compost of this kind is objectionable, as it forces a growth at the outset which the plants cannot sustain, whilst the best of all stimulants, warm diluted liquid or guano water, can be given when they require assistance. Cleanliness in the house and freedom from insects are imperative; the walls, therefore, should be frequently limewashed, the glass washed, and the atmosphere sweetened by the introduction of thin sprinklings of fresh virgin loam. Prevention being better than cure, good culture will keep down spider without the aid of direct syringing, and an occasional puff from Bloxham's handy little fumigator will secure immunity from aphides. Fruit and plant growers who have not used this blower will do well to give it a trial, for it fills up a want which has long been felt: moreover, it is neat and cheap, and cannot possibly injure the most delicate foliage.

Cucumbers from cuttings.—Where a really good strain has been tested, the end of this month is a good time to perpetuate it by putting in cuttings. The plants, it is hardly necessary to say, should be clean and healthy, and a strong bottom heat in a close, moist pit is one of the chief essentials, as the cuttings should never flag. The plan I adopt is as follows: Having secured a few very small clean pots and beaten the fine soil out of a sod of light fibry loam, the pots and fibre are laid where they can become warm. The tips with one or two leaves are then taken off the plants just below a joint, but the base leaf is not removed; they are then folded in a piece of the fibre, care being observed that they are not bruised, and forced rather tightly into the pots. A little dry silver sand sprinkled over the surface and watered in finishes the operation. The pots are then plunged in a bottom heat of 85° to 90°, covered with bell-glasses, and shaded with a sheet of paper. In eight days they are rooted, when a little air is given by tilting the glasses; this is gradually increased, and eventually the glasses are removed altogether, when the young plants are potted on and treated as ordinary seedlings. This mode of propagating Cucumbers is by no means new, as I raised all my stock of Lord Kenyon's Favourite, a shy seeder, from cuttings more than forty years ago. Plants so raised are firmer and more fibry than seedlings; hence their value for winter culture, as they are never touched by canker.

Plums and Cherries.

All portable trees from which the fruit has been gathered will now do best in the open air. If potted a fortnight or three weeks ago, they will be making new roots, which must not be checked by sudden exposure to the drying influence of the sun or want of water, neither must they be deluged, as the second extreme is perhaps more injurious than the first. Therefore in order to steer clear of extremes and still maintain a happy medium, let them be plunged to the rims, well watered and mulched with short stable manure. Syringe well on fine evenings and repeat the watering when the roots actually require it. Permanent trees trained on trellises may also have full exposure to the elements, that is, if the lights can be taken off the house, otherwise every door and ventilator must be thrown wide open and the roots heavily mulched to reduce the necessity for giving much water. If root-pruning or top-dressing is still in arrear, this work should be completed before the leaves fall, but the wood and buds being ripe, it will not be necessary to keep the lights over the trees, as has been advised in previous papers. Young trees generally require a check; old ones need stimulating. The first can be secured by careful lifting and relaying the roots in pure loam and lime rubble; the second by the removal of all inert soil and making up with compost enriched with bone dust and heavy mulching. If very weak, an occasional soaking through the autumn months with generous liquid will help the buds and tell favourably when they burst into flower.

W. Coleman.

Eastnor Castle, Ledbury.

Asparagus plumosus from seed. — The plant distributed under the name of A. plumosus nanus, although extremely beautiful, has proved anything but dwarf; on the contrary, it is strong and vigorous. There is, however, a form of this plant in the gardens at Heatherset, Streatham, which is truly dwarf. It was obtained from home-grown seeds, and has all the beautiful plume-like aspect

of its parent, but it is not scandent in habit, plants of it four and five years old not being higher than 2 feet. This form would appear to be a valuable acquisition.—W. H. G.

NOTES FROM FRANCE.

American Grapes *v.* Phylloxera.—The restoration of vineyards destroyed by the Phylloxera in the wine-making districts of France by means of American Grapes has been going on for some time, and although opinions are much divided and many good growers are doubtful as to the permanent benefit of the work, the results up to the present are of a sufficiently satisfactory nature to warrant the optimist view which some good authorities hold in this matter. In Herault about 111,200 acres were planted in 1885 with American Vines, principally the Riparia. The demand for these American Grapes is yearly increasing, and as, in addition to their Phylloxera-resisting properties, the French growers are becoming better acquainted with the means of combatting the other enemies of the Vine, the future is now looked forward to with hopefulness by them. Only time can prove whether or not in this way Phylloxera-infested vineyards may be restored to their normal fertility; suffice it for the present that plenty of good wine was made last year in districts which, through the attacks of the most formidable foe that the Vine grower has ever had to encounter, have for some time been, so far as Grape culture is concerned, quite barren. In the environs of Montpellier about as much as 3,300,000 gallons of wine were made last autumn, and a writer in a French gardening paper says that it did his heart good to see the joy with which the small growers there exhibited specimens of their produce.

New race of hardy Azaleas.—M. Rosseel, of Ghent, has had the happy idea of crossing Azalea mollis with some of the best hybrid Rhododendrons, and, judging by the specimens exhibited by him at the late flower show at that town, our gardens are likely to be endowed with a race of fine flowering shrubs. These new hybrids are likely to prove of great decorative value. In appearance they come nearer to the Azalea than to the male parents, but the leaves are stouter and the wood is of greater substance. The flowers are arranged in medium sized heads and open well. In colour they are lilac and pale rose. It is said that they force remarkably well, and can easily be brought into bloom in January. If this statement is correct, they will be in great demand for conservatory decoration early in the year. The fact that they are mules, all efforts at seeding them up to the present having been fruitless is good proof of their hybrid origin. It is, however, possible that some of the plants raised in this way may prove fertile. These new hybrids remind me of a race of Rhododendrons said to be of hybrid origin with which I was acquainted some twenty years ago. They were tall of growth, with long lanceolate leaves, and the flowers exhibited tints such as are not to be found among hardy hybrid Rhododendrons. Cream colour, rich orange, golden yellow (one kind I remember was called aureum) were the prevailing hues; but there were some bronzy yellow flowers of great beauty, and quite distinct in colour from anything I know. These were raised by a Mr. Smith, a florist, I believe, in the neighbourhood of London, and were supposed to be hybrids between the hardy Azalea and the Rhododendron. The stock came into the hands of Messrs. T. Jackson & Son, of Kingston-on-Thames, but no attempt was made to propagate them, as they were not sufficiently hardy for the open air. Although they flowered freely I never knew them to bear seeds. I have often wondered whether any of them are still in cultivation; they would be well worth looking up, their distinctness and great beauty rendering them so suitable for the decoration of large conservatories.

A giant Oak.—The trunk of an Oak is now lying on the banks of the Seine near the Pont de la Concorde at Paris which has a curious history. So long ago as 1874, at a time when prolonged drought had reduced the waters of the Rhone to an unusually low level, a boatman perceived near the village of Tenne, in the district of La Balme, the branch of a tree projecting from the surface of the river. Struck by its unusual proportions, he made an examination, which caused him to form the conclusion that a tree of giant size must be embedded in the bottom of the river. He made known the result of his observations, but the Rhone rose again to its former level, and it was not until eleven years had passed, and that unusual drought again caused the waters to sink, that the matter could be seen to by competent authorities. No time was lost, but it took five months' unremitting labour to free the trunk from some 40 feet of sand and gravel which formed the accumulation of ages. It was eventually raised on the bank of the river, and a boat being built for the express purpose of transporting it was brought to where it now lies. The most remarkable feature of this tree is the length and symmetry of the trunk, which measures about 100 feet, and of which the circumference is but little less at the topmost portion than near the base. At the junction of the roots with the soil the circumference of the trunk is about 35 feet. In girth this Oak is, I believe, exceeded by some existing trees, but so far as I am aware there is no recorded instance of one having a trunk so long and of such uniform regularity. How long this remarkable Oak laid in the bed of the Rhone can only be a matter of conjecture, but we are justified in assuming that its growth was made at a period when the climatal conditions of that region differed from those that prevail there at the present time. It is probable that we shall one day see this remnant of a remote past in this country, as it is about to make a tour of Europe in the boat used for its transport, and which is so constructed as to allow of its free passage through all navigable waters.

Chicory.—Much greater attention is paid to this salad in France than with us, large quantities of it being brought into the Paris markets through the winter and spring. In spring it is sown on gentle hotbeds, the young growths being cut much as we do Mustard and Cress, and through the winter the blanched shoots, commonly known as Barbe de Capucin, are largely consumed. Chicory is credited with many good qualities in France, and is universally considered to be one of the best blood-purifiers known. We in England prefer the milder flavour of Endive, which has also a more enticing appearance, but those who care much for salads should certainly include Chicory in their list of ingredients. It imparts a piquancy which no other salad is able to do. Chicory likes warmth when making its growth in summer, and should therefore be planted or sown in a sunny position. The better the roots are matured the more freely will they start into growth when placed in warmth. A good plan is to lift the roots in November and lay them in by the heels so that they can be easily got at when needed. The seed should not be sown in warm localities at least before May, as if sown early it is apt to run to seed, in which case the roots have no substance.

Spiræa japonica fol. purpureis.—This is a dark-leaved variety of S. japonica, which originated as a chance seedling in the nursery of the Messrs. Transon, at Orleans. The foliage, when growing in the open or in a cool house, is of a purple hue, but this, under the influence of heat, changes to a bronzy tint, which harmonises beautifully with the snowy white of the flowers. As this variety has come from seed, there is every prospect of its remaining true to character.

Genista Andreana.—This name has been given by M. Carrière to a variety of the common Broom which was discovered growing amongst the type in Normandy. It is, of course, but a seminal variation of Genista tinctoria, but is quite as distinct and far more beautiful than some of the family which rank as distinct species. Instead of the flowers being uniformly yellow, the wings are rich velvety crimson, marked with gold at the edges and base. This forms a charming contrast of colour, and the whole appearance of the plant is highly pleasing. I have no doubt that this Broom will become a favourite. J. C. B.

SCHOOL GARDENS.

The proposal to establish gardens in connection with elementary schools for the purpose of training lads in the art of gardening is not a new one, and has often been discussed. Theoretically, the proposal is admirable, but practically, most difficult to realise. Beyond needlework and cookery for girls, both of which constitute purely technical, though domestic, subjects, the educational code takes little note of anything else, except what may be termed literary subjects, the object being as far as possible to afford children whilst young opportunities to acquire knowledge which can hardly be obtained later in life. Learning to read, write, calculate, and similar work of hand and brain combined is not difficult to acquire whilst the mind is untrammelled by other considerations. Of course it may be pleaded that one object in providing instruction in practical gardening is to afford some relief to the mental labour involved in elementary learning. Girls get needlework and cookery, although the latter in a too limited degree. Boys have the variations of drawing and music. These diverse elements in both boys' and girls' ordinary school curricula are ordinarily available, because capable of being utilised at no great cost and within ordinary buildings. Gardening, on the other hand, needs something more than teachers; it needs land, and land is both costly and difficult to obtain. In towns, for instance, the price is practically prohibitory. It is, indeed, difficult enough to secure a limited area for playgrounds, which are absolutely indispensable. But it may be said that land is abundant enough in the country, and few rural schools need be without a garden for boys. That is true, and if our elementary schools were universally the property of the nation, and absolutely controlled by the Education Department, much might be done which is now, in the chaotic condition of school ownership, impossible. School Boards are so afraid of incurring expenses, that they dare not go outside the present requirements of the educational code, even if willing. Voluntary managers of schools are, as a rule, living from hand to mouth, and keeping down cost to the lowest point, that the detested School Board may be kept at bay. Thus it happens that on every hand circumstances prevent our having gardens in connection with schools. If we teach school children gardening, we shall, assuming that the prime difficulty of obtaining land has been surmounted, have to instruct their teachers in the art first, and our training colleges have neither provision nor adaptability for such work. Still further, if gardening is taught, so also must be elementary agriculture, and in localities where other vocations largely prevail, those, of course, would have to be taught also. Therefore we cannot move in the direction suggested without proceeding further, and establishing a system of technical schools in which children can be instructed in trades of all kinds after their years of elementary school probation are over. We have already in our midst such schools, but, so far, these are not available for children belonging to the better class of our poor. Industrial schools and large district pauper schools give trade training largely, the former, of course, specially so. Thus at the Middlesex industrial schools, where some 800 boys are always under control, some are trained to be agriculturists, a good knowledge of gardening being included; others are taught painting, carpentering, smith's-work, shoemaking, and tailoring. If we could give all our elementary schoolboys after they had passed the sixth standard in the normal school a further term of three years in some training school, the opportunity would then offer, with the aid of practical gardeners and ample land at their disposal, to turn out youths who would be well grounded in elementary gardening; and even though their after lives might turn in other direc-

tions, their early knowledge of garden work thus obtained would prove serviceable to them. In the course of some twenty years hence we may, perhaps, face this question in a practical way.

A. D.

GENTIANA VERNA.

The little vernal Gentian represented by the annexed engraving, and which is found so plentifully on the Pyrenees, is also a native of Britain. It is found in North-west Yorkshire, in upper Teesdale, and also in several localities in Ireland; indeed it is from the latter sources that a large percentage of the plants grown in gardens is derived. It is gathered and frequently sold for a penny a clump. Notwithstanding its cheapness, however, it is not so frequently met with in our gardens as it should be, especially in the south. Indeed, when under cultivation, it not unfrequently happens that in a few years, three or four at the most, not a vestige of it is to be seen. This is not only so in the case of G. verna, but also in that of others, such as G. brachyphylla, bavarica, and alpina. The heat experienced during summer, and the absence of a cool bottom for the roots may in a great measure be the cause of failure, but something also depends on growers not taking the trouble to raise their stock from seed. Many instances we have seen of seed shed by the parent plants growing and forming tufts on mossy limestone long after the old plants were dead. As a last resource, where failure has been frequent, a bed should be tried well filled with large pieces of limestone and soil well mixed with old lime rubbish, the whole kept thoroughly watered until the plants have had a fair start. This treatment also applies to G. acaulis, alpina, and brachyphylla. The latter is nothing more than a small form of G. verna. G. bavarica we succeed well with in a bog in gritty peaty soil, although it flowers very poorly. After planting any of the Gentians just named, they should be disturbed as little as possible. If increase is wanted it can be effected by means of stolons, which often run a good distance from the old tufts. G. verna flowers in May and June, and its glorious blue blossoms well repay the grower for any extra trouble bestowed on its cultivation.

K.

Gentiana verna.

The Wedding-flower.—This is what is known botanically as Iris or Moræa Robinsoniana, the giant Iris of Lord Howe's Island, and one of the most disappointing garden plants ever introduced into English collections. Many have tried, and perhaps a few are even yet trying, to induce it to flower, but, so far, no one in Europe has yet succeeded. We began to suspect that there was some condition peculiar to Lord Howe's Island and essential to the flowering of this Iris, till we learned that in the Hakgala experimental gardens in Ceylon plants of it had been raised and flowered in about a year from seeds produced from Australia. This is what Mr. Nock says of the Hakgala plants: "Planted round a pond are several interesting plants, among them being the Wedding-flower, a gigantic Iris. One flower-spike contains from 120 to 200 blooms, which come out a few at a time, but only last twenty-four hours; the plant is in flower for several months." Hakgala is at a high elevation in Ceylon, the temperature being perhaps somewhat similar to that of Italy. Many interesting plants are growing there, amongst them being the splendid Tree Fern found only in Ceylon, viz., Alsophila crinita, of which several fine specimens may be seen at Kew. In Ceylon, however high up, the sunlight must be much more intense than anything we get; still, the Wedding-flower may not really require all this light to make it flower. What does it want that we fail to give it here?—B.

KITCHEN GARDEN.

CUCUMBERS TO FRUIT IN FEBRUARY.

Cucumbers at Christmas are now no more a novelty than Blackberries in September, but Cucumbers for use with salmon in February, about which a correspondent desires information, test the most experienced grower's skill, as the plants have to be grown up to the fruiting stage under the most trying climatic conditions. The principal factors in successful winter culture are snug, compact span or lean-to pits, well sheltered from the north and east, light, airy, efficiently supplied with pipes for giving top and bottom heat, and fully exposed to the south. Dry fire-heat being one of the rocks on which many come to grief, the most perfect pits are those to which underground moisture can be supplied at pleasure, either through cemented tanks filled with water, or from fermenting material placed over the hot-water pipes. Tanks, however, are not absolutely necessary, as I have none, and yet I am never without a good supply of winter fruit through the first and most trying quarter of the year. As your correspondent does not say what convenience he has, I will assume that he is satisfied with his structure and describe as briefly as possible my own detailed management.

Sowing the seeds. — Continuous growth throughout the winter being imperative, the seeds should not be sown too early, and yet the plants should be forward enough for putting out and becoming thoroughly established before bad weather sets in. If at hand, a one-light frame, resting on a slight hotbed made of fermenting materials, will be found the most suitable nursery, as the young plants can be kept close to the glass where they will remain stout, and stocky, and free from insects until the fruiting house is ready for them. The proper time to put in the seeds is the first week in September, either in small pots filled with light, rich soil, and plunged to half their depth in a bottom heat of 80°, or on small squares of turf placed on the surface of the bed. In either case they must be transferred to 4-inch pots as soon as the first rough leaf is formed and kept close to the glass, where they can be slightly shaded from bright sunshine. Let the balls be quite moist at the time of shifting, and water sparingly for a day or two, but keep the sides of the frame and the surface of the bed well syringed, and take off the chink of air in time for the frame to run up to a temperature of 90°. When thoroughly rooted, give more air and less shade, place a stick to each plant, and raise the frame if more head room is required. If by this time the house is not ready for planting, a second shift into 8-inch pots will be necessary, but this, if possible, should be avoided, as frequent potting checks the plants, and, independently of loss of time, they do not always escape with perfect foliage. The loss of a leaf or two to some may appear a very small matter, and so it is in the spring, but plants intended for winter work should retain every leaf, as injury to one near the base is not unfrequently the stepping-stone to canker.

The fruiting house or pit.—Having thoroughly cleansed and lime-washed the walls, washed and repaired the glass, the next thing to be decided upon is the mode of culture. Some grow their plants in large pots, others plant them out on hills or ridges. I grow them in both ways, and find each system has its advantages and disadvantages. Of the two, planting out, unless he is a good plantsman, may be the safest and most simple mode for a new beginner. Assuming, then, that the bottom heat pipes will maintain a temperature of 80° and that tanks have not been constructed, some means must be provised for keeping their roots away from their parching influence. The simplest and cheapest way is embedding them in clean broken brickbats, coke, or other materials which will absorb and give off moisture. With these, broken rather fine at the top, the pipes should be just covered, and full heat turned on for some days before the pit is planted. Another plan is the formation of a hot-air chamber by covering, without touching the pipes, with Oak slabs, slate flags, or rough timber capable of carrying the compost. The covering complete, good fermenting material, not less than 14 inches in depth, must be placed evenly over it, and on the top of this thin sods, Grass side downwards, to prevent the roots from entering the decaying manure. The cones, or a longitudinal ridge of compost rising 18 inches, will then complete the preparations for planting.

Compost.—If light, rich, fibry turf, free from wireworm, can be obtained from an old sheep pasture, the addition of one-fifth of its bulk of old lime rubble and a dash of soot will form a sustaining staple which will not readily become sour or adhesive. The turf, chopped or broken with the hand, must be used in a rough state, and placed rather firmly in position to get thoroughly warmed through before the plants are turned out. If heavier soil is used, then the addition of a little rough peat, burnt earth, the fine sifted out, and charcoal may be added with advantage, the free passage of water being an important matter. The cones or ridges, it must be borne in mind, should not be made too near the top-heat pipes, as strong fire heat affects the foliage and fosters spider; neither should they be made wide at the base, as the plants always grow best when the roots reach the sides. If the stems cannot be kept well away from the pipes thin boards placed in front of them will throw off the dry heat and prevent the generation of steam when syringing follows sharp firing. I have not mentioned manure, as I neither use nor approve of it; better enrich poor soils with bone-dust, and feed with liquid when the plants are in bearing. Lacking bone-dust, a little very old cow manure rubbed through a sieve and mixed with a few handfuls of soot is the best substitute, but I do not press its use, as worms will follow animal manures.

Planting.—The distance which Cucumbers should be planted from each other requires careful consideration, for many fail through placing the plants too close to each other. If a single plant were placed in the centre of a pit and trained on the extension principle, the inexperienced might succeed, where under crowding he would fail. No one, however, thinks of trusting to a single plant;

the depth of trellis, therefore, must be taken into account. If less than 6 feet I would place the plants that distance apart; if 9 feet, then they might be 4 feet from each other. Closer they should not be, as they would soon interlace and require thinning, when cutting back would be disastrous. Having well watered the plants and placed a stout, neat stick in each station, with its point resting on the flooring of the chamber to prevent the possibility of sinking and strangling the shoots when they reach and are tied to the trellis, which, by the way, should be 16 inches from the glass, turn out the plants, slightly loosen the balls to set the coiling roots at liberty, and pack firmly with warm compost. Syringe the walls, floors, and dew the foliage, but defer watering for twenty-four hours; also avoid shading, unless the plants show signs of suffering. But little, if any, top ventilation will be necessary, as Cucumbers revel in an air temperature of 90°, but the front lights may have a chink on hot days, or, better still, brick ventilators on a level with the pipes may be kept constantly open. If pot culture is decided upon, the pots, 16 inches in diameter, must be clean, well crocked, and placed on solid pedestals or inverted pots to favour the renovation of the fermenting material without disturbing them, as strangling is one of the most common causes of collapse and canker.

Training.—Tie each plant loosely to its stick, pinch every side shoot at the first leaf until they reach the trellis, train the leaders upwards, and defer stopping until they reach the top of the house. Tie out the side laterals horizontally, beginning at the lowest wire, and pinch them also at the first joint unless fruit is wanted, when in every case they must be pinched at the next beyond the "show." It is, however, better to divest them of all male and female flowers until December and then allow a few fruits to set and swell. Cutting, always in a young state, will then commence about Christmas, when the plants being thoroughly established, they will keep on bearing throughout the season.

General treatment.—Syringe the house twice a day, but avoid wetting the foliage in winter, at least if it can be kept free from spider, and fumigate on the appearance of the first green fly. Let the temperature range from 68° at night to 80° by day through October, from 66° to 78° afterwards, but always run up to the maximum under gleams of sunshine. If the pit is, or can be, fitted with blinds, economise fire heat and keep in moisture by running them down at night and during snowstorms, as rapid radiation and sudden lowering of the temperature is one of the most common causes of mildew and loss of the old foliage. As the days decrease in length and growth becomes languid, pinching for a time must be suspended, the house, including the glass, kept scrupulously clean and free from all decaying matter, and the atmosphere sweet by light surfacings with pure loam and charcoal.

Top-dressing.—While keeping the plants in good growth, grossness at the outset must be avoided, as immense leaves formed during early autumn not unfrequently perish when overtaken by winter. The compost I have named will not force this undesirable growth, neither will it sustain them when they commence bearing. Steps, therefore, must be taken for keeping them regularly supplied with root food as often as the surface roots protrude, little and often. That recommended for forming the hills, with a plentiful supply of bone dust, the best and safest stimulant, thoroughly incorporated will answer well through the winter. A good supply prepared early in the autumn and placed in a dry shed where it can be covered with fresh stable litter will not only last a long time, it will also be improved by keeping, as the ammonia from the litter and the slowly decaying bones will penetrate the lumps of loam and old lime rubble. A little of this after being properly warmed should be packed firmly all over the hills as often as the white hungry roots creep through the last dressing; but, much as the Cucumber enjoys earthing up the stem in summer, its application should be performed with caution during winter.

Watering.—Successful culture cannot long be carried on where watering is neglected or imperfectly performed. Planted as it were on a suspended cradle, with hot-water pipes beneath, not only have the requirements of the plants to be supplied, but water in sufficient quantity to keep every part of the bed in a growing state and the hot-air chamber charged with vapour must be given from time to time, otherwise they will soon get wrong past recovery. Watering, then, must not only be frequent, but copious, as there is no possibility of the roots becoming too wet, whilst dribblets deceive the eye and lay the foundation for attacks of spider and mildew. Soft water, pure and simple, at the air temperature should be given once or twice a week until the plants come into bearing, when clear diluted liquid, soot water, and occasionally a dash of guano must be regularly supplied. W. Coleman.

Eastnor Castle, Ledbury.

Hackwood Park Tomato.—I have sent you a sample of this Tomato grown in a small span-roofed house on poles placed in the centre of the bed. This being my first trial with this sort, may I ask you if Tomatoes are usually grown to the size of the largest one herewith sent?—M. C. Windom, *The Lodge, Teddington.*

*** Splendid in colour and beautifully grown, but the kind is not a pretty one, the largest fruits being, like New Zealand, at present in a state of eruption. The very largest is doubled and folded back on itself, and all round its vast waist there are a series of small brown craters—the dried results of its efforts to grow far bigger than ever Nature meant a Tomato to do. It measures 15 inches in circumference; only the smallest fruits are free from these ugly imperfections. We regret much that people raise such varieties and call them "improvements." The worship of size and monstrosities is carried to an excess in our gardens, and ought to be controlled. In the case of the Tomato, excellent in its ordinary forms, gross imperfections are paraded as "valuable novelties," to say little of the eating qualities, but coarse fruits of Tomatoes have useless cores and other parts to cut away, and are as bad for the cook as they are in appearance.—Ed.

Potato disease.—The atmospheric conditions which have during the last ten days or more prevailed here in Surrey appear to have had very disastrous effects on the Potato crop. Breadths of Potatoes which a week ago looked remarkably healthy and vigorous unmistakably show the dire effects of the fungus. The early crops are of course out of danger, the drought having had the effect of ripening them off somewhat prematurely, but the yield of sound tubers in the case of late varieties will be much under the average. A proof of the virulence with which the Peronospora has attacked the haulm is afforded by the condition of the Magnum Bonum, which here for the first time is now affected, and to all appearance as badly as other kinds. In this Potato we have hitherto considered that we possessed the means of warding off a Potato famine, but if that fails us we shall be as badly off as we were a few years ago. A year or so ago I was told that it got black-hearted in many soils; but up to the present it has been excellent in quality on our light loam. As the White Elephant is coming so much into favour, it will be interesting to note its behaviour under the same conditions as the Magnum Bonum. It is evident that this latter is no longer disease-proof, and we need another to take its place.—J. C. B.

SHORT NOTES.—KITCHEN.

Prolific Potato.—I planted 1 lb. of Queen of Potatoes on May 10, and to my surprise when I dug them on August 11 the produce was 62 lbs.; they were all sound and good and nearly all large in size.—J. W. Mills, *Minterne.*

Pickling Cucumbers (*Amateur*).—Make choice of those which are small and not too old, put them in jars and pour over them a brine made of two-thirds of water and one-third of vinegar, with salt in the proportion of 1 lb. to three pints of liquid. Put the brine on the fire till the salt is melted, let it stand to settle, and before you use it pour it off clear. When you wish to use the Cucumbers, take the rind off and dress them in the same way as fresh Cucumbers.

Late Peas.—My latest Pea this season is Veitch's Perfection, the produce of a third sowing. Ne Plus Ultra has been wonderfully good in flavour and very prolific, but it is mildewed. Huntingdonian I shall not grow again here; it has turned out most miserably; the pods are small and the Peas anything but good in flavour. In the south I have seen it do remarkably well. House's Marrow, a local variety, is a good Pea, large, prolific, and rich in flavour. It is in the style of Ne Plus Ultra. It is now bearing a second crop nearly as good as the first. I am strongly in favour of mulching and watering late Peas; such treatment helps them to withstand the weather, and in a dry season prevents mildew from attacking them so quickly as it otherwise might do. As regards mid-season Peas, many came in out of place. As respects succession, I sowed Advancer, Marvel, Champion of England, Prizetaker, and Dr. M'Lean, and, with the exception of Advancer, all came in together, though sown a week to ten days apart. Marvel did not answer my expectations at all. King of the Marrows is a good Pea, and did remarkably well, as did also Telephone and Stratagem, both remarkably fine Peas.—W. A. Cook, *Holme Wood, Peterborough.*

Indoor Garden.

CYCLAMENS AND THEIR CULTURE.

Cyclamens are the most beautiful of all winter-flowering greenhouse plants. Their purity of colour and singularity of form make them universal favourites, and the early season at which they come into bloom invests them with additional interest. As a rule, I like the bloom which I obtain from plants of the first and second year best; but those of one or two years older produce flowers in greater abundance than younger plants. I have among my Cyclamens many distinct colours, such as pure white, crimson, carmine, lilac, salmon, and rose. These and other colours in good Cyclamens should always be in themselves pure and unspotted, "not beautifully spotted and striped," as some describe plants at exhibitions, such spots and stripes being entirely the result of keeping the plants in cold, damp houses. To obviate such defects, maintain a continual, though slight artificial, heat in the house in which your Cyclamens are growing, and, at the same time, allow a free current of air, regulating it as to amount according to the state of the weather. This prevents that damp and stagnant atmosphere so much dreaded by all good Cyclamen growers. About the 1st of March we begin fertilising the flowers, placing such plants as are retained for that purpose in a house apart from the others; and in furtherance of this end we select equal numbers of all the colours, omitting any possessing the least deficiency in size, form, or purity, and adopting flowers only that are perfectly uniform in shape, with broad blunt petals, each averaging about 1½ inches in length, and having a well defined base. The foliage, too, should be finely marked, and the plants should possess strong constitutions and quick-growing properties.

Some contend that Cyclamens may be successfully raised from seed, and bloomed in nine or ten months in 4½-inch pots; but this I feel certain cannot be done. To have good plants, the seed should be sown in December, in a temperature of 50°, and the young plants should be pricked off in spring into 4½-inch pots, placing ten in each pot; and when big enough, they should be potted singly in 3-inch pots. When these are well-filled with roots, which will be by the end of June, they should be potted into 4½-inch pots, in which they will flower the following spring. After this shift they should be placed in a cool, sunless house, and well watered both at root and overhead. All stimulants, in the way of manure or guano water, should be avoided, and nothing used except pure soft water, otherwise the flower-stalks become drawn and weak, and the strength of the plant

gets expended in the production of foliage. By this treatment, strong blooming plants may be obtained by March, a period of fifteen months from the time of seed-sowing; and in less time than that I find it impossible to obtain well-flowered plants. Some assert that they can grow good Cyclamens in Cucumber beds, but, judging from my own experience, such is impracticable. I always find it best to allow them some two months in which to germinate, then to keep them cool, and to bring them on gently. By this treatment they do not grow so quickly at top, but they form large bulbs underneath, and that much quicker than they otherwise would do were they subjected to a higher temperature.

Much has been written respecting the compost best adapted for Cyclamens; some recommend a little peat, others a little decomposed cow manure, mixed with the soil employed for them, and this latter I have myself recommended, but I now find that its effects are more injurious than beneficial, inasmuch as it serves to breed worms and other insects that prove hurtful to the plants. Finding such to be the case, for the last four years I have used nothing but two-year-old rotted turf and good leaf-mould in equal quantities, with a liberal admixture of silver sand. In potting, I keep the bulbs about three-fourths out of the soil, carefully avoiding the old plan of placing them under the surface, so that the flowers may come up clean, without danger of damping or rotting off. As regards two-year-old bulbs, it is customary with many to dry them off in winter in by-places, keeping them without water until every root has become dead; consequently the leaves die. When it is wished to start them, they are repotted and watered, which is all but labour lost. Some of the bulbs push freely, but others break but feebly, drag out a miserable existence, and, after a time, die. I generally find it best to keep old plants in cold frames during their period of rest, and sufficiently damp to keep the roots in a healthy condition. Most of the plants shed their foliage, and those that do not, continue to grow throughout the season, and are the earliest to bloom. Much has been said about growing Cyclamens close to the glass; but, where they form a part only of plants that are benefited by such treatment, it is impossible to supply all with such a position; therefore, amateur growers will be pleased to know that such is not absolutely necessary. The stages in our houses are from 6 feet to 8 feet from the glass, and I find no difference whatever between those grown on these and others grown nearer the glass. In the case of amateurs who generally grow Cyclamens along with miscellaneous plants, they should, however, select a stage as near the glass as possible, and in a cool or sunless part of the house.

Should the plants become infested with insects, I find it best to dip them two or three times in a mixture of soft soap and water, and when thus cleansed, they pass through their blooming season unharmed. By a free use of the syringe, I manage to keep them free from red spider and thrips. J. D.

Permanent shade for glass houses.—The best permanent shade for plant houses is linseed oil and sugar of lead, in the proportion of about a teaspoonful of the lead to a quart of oil; but the exact tint must be governed by the amount of shade required. Therefore apply the lead gradually, and prove it upon a few pieces of waste glass until you get the tint desired. The *modus operandi* is this: first wash the glass thoroughly clean, and then (having previously prepared the oil and lead), on a dry clear morning, take the oil and paint as thinly as possible over the glass with an ordinary paint-brush; then follow with what the painters call a dust-brush, loose and quite dry, and, dabbing it gently on the oiled portion, impart a frosted or ground-glass appearance to it. An ordinary garden labourer, with a little practice, will do this very nicely. This shading will stand very well for a season, and if in the autumn it is desired to remove it, that may be readily done by washing with strong pearlash water. For some plants, such as Camellias, Oranges, and other strong-foliaged things, it is questionable whether it is desirable to remove the shading. Many years ago, when there was a good deal of discussion about scorching by foreign, sheet, and other inferior kinds of glass, the late Mr. Pince, of Exeter, wrote thus to a friend: "I made short work of the scorching; I painted the glass all over with white lead paint, and I found where the paint was the thickest the plants (Camellias) did the best." There has been a good deal of misdirection about the light necessary for plants. We bring them from all parts of the world, and, without giving a thought as to whether their native habitat may be under the shade of larger vegetation or in open positions, we place them in bright full light, and then grumble because they do not grow as we could wish them to do.—A.

DOUBLE-FLOWERED GARDENIAS.

Of the many fine plants for which we are indebted to Fortune the Gardenia named after him must, I think, be pronounced to be the finest; for to size, purity, and doubleness of the white Camellia this plant adds the delicious aroma for which the whole tribe of Gardenias is so much prized. The great market growers, who cultivate Gardenias by thousands for supplying bouquet-makers at Covent Garden, grow them principally by means of the heat of fermenting materials. The general plan is to have a pit filled with spent hops from the brewers' or tan for the bottom heat, and then linings of stable manure around the sides of the pit. The plants in the growing season delight in a brisk, moist temperature—indeed, from the commencement until near the maturation of the growth they will grow in a vapour bath strongly impregnated with ammonia; but to mature the wood and set the flower-buds it is necessary that they be exposed to a drier atmosphere and a free circulation of air. Cuttings of the Gardenia strike with the utmost freedom in a close, moist temperature, with some bottom heat. Though heat from fermenting material is the most suitable for the cultivation of this tribe of plants, it must not be supposed that they will not grow in ordinary plant stoves. I have plants so treated now of G. Fortunei, G. florida, and G. florida intermedia. During the growing season they are placed in the closest part of the stove, and are well supplied with manure water. When the growth is complete and the flower-buds forming, they are exposed to full air, and for months I keep them in a cool house with Camellias. When we want bloom they will be removed to a forcing house, and there remain to make their growth. As a forcing plant, to come into bloom in March and afterwards, I know nothing so valuable as Gardenias. They are universal favourites with all who know them, and will ever remain so. The only drawback is that insect pests of every kind have a great affection for them. Mealy bug, white and brown scale, thrips, and red spider, each grow fat and multiply upon them. The best remedy for these pests is to lay the plants upon their sides, and then syringe them when in a dormant state with water heated to 120°; then follow with a dressing of some of the insecticides, of which we have now so many, and the visitation will be subdued, if not eradicated. The kind mostly grown for market purposes is G. radicans. It is a dwarf, free-blooming species, and, carefully managed, flowers most profusely. It is known by the name of Cape Jasmine. P.

Lilium auratum platyphyllum.—Some varieties of this Lily are immeasurably superior to others; for instance, weak drooping flowers with thin, poorly coloured petals are not worthy of being classed with large cup-shaped blooms richly spotted and barred with gold, and borne on good stout stalks. One of the best amongst the varieties is platyphyllum, a kind which can be readily distinguished in all stages of growth. The bulbs do not vary from those of ordinary auratum, but as soon as the shoots push above ground, it will be observed that they are much thicker than those of the type, while the leaves are much wider and larger. It also attains a greater height, and the flowers are massive and handsome in shape. They differ from each other somewhat in colour, some being almost white, while others have the golden band well defined, and are spotted to some extent, but not densely. This Lily within the last year or two has become tolerably common.—H. P.

LUCULIA GRATISSIMA.

This is one of the most beautiful winter-flowering conservatory plants in cultivation, forming, when planted out in about equal portions of turfy loam and fibrous peat, large bushes 6 or more feet in diameter, and filling the house with delicious fragrance in November and December. Some years ago I had charge of a conservatory, in which several large plants of Luculia were growing beautifully in the borders; for although it is rare to meet with a really good specimen in a pot, yet when planted out in good soil in a well-drained border, it grows as freely as a Willow. The great thing is to prune well back after flowering; if this is not done, the plant rambles up, soon gets naked at the bottom, and does not flower well. It often makes 2 feet or 3 feet of wood in one season, and the flowers are borne at the ends of the shoots; therefore it is important to facilitate the ripening of the wood as much as possible by exposure to light and by reducing the supply of water during this month and September. The Luculia also makes a grand plant for covering the back wall of a conservatory, and there is scarcely any limit to the space which it will cover. Liquid manure made from soot, and given clear during the flowering and growing period, adds to the strength and beauty of its flowers, and imparts a rich dark green tint to its foliage. The syringe should be used frequently to keep the foliage clean. About the same treatment that suits Camellias for blooming about Christmas will also suit the Luculia. A really good specimen of this Luculia in a pot is, as I have said, not often met with, and the reason probably is because the plant is usually encouraged to flower before a good foundation has been laid for the future specimen. And until it is well established in a good-sized pot, it seems rather impatient of being cut back; plants are, therefore, allowed to flower without being subjected to cutting, and it is somewhat difficult afterwards to induce the plant to become bushy. In commencing to form a specimen, begin with a young healthy plant, keep it growing in what is called an intermediate house, and persistently pinch or rub out the leading buds till a good foundation for the future specimen is formed. Do not allow it to flower till this object has been attained, and the plant will be longer lived in consequence. When potting is necessary, give a liberal shift. What is known among plant growers as "the one-shift system" is well adapted for the Luculia, but then special care is required in watering and the drainage must be perfect. Although when making its growth the Luculia delights in liberal supplies of water, anything in the shape of stagnation at the root produces ill health, from which there is little or no recovery. The best soil for pot culture is two-thirds turfy loam and one-third fibry peat, with a dash of fine charcoal. The soil should be well broken up and rubbed through a coarse sieve without extracting the fibre. Pot firmly; loose potting encourages rapid growth, but this is often inimical to the formation of a good specimen. It may be propagated by cuttings made of the young side shoots taken off with a heel, and placed under a bell-glass in a cool situation till callused, then plunged in a mild bottom heat. It may also be increased by means of layers. E. H.

Marie Louise Violet in frames.—This Violet is not a success with us in the open air; our winters are too cold for it, but it succeeds very well in frames. We usually plant it in frames from which early Melons have been cut. There is always a little heat left in the manure, which greatly encourages the Violets;

no extra preparation is required. The soil is levelled down, and the Violets which have been specially prepared for the purpose, having sturdy foliage and strong buds, are planted 9 inches apart. The soil is pressed firmly about them, a good soaking of water is given to settle the soil, and the lights are kept off till cold weather sets in, but the bed is not allowed to be deluged with cold rain at any time.—E. H.

ORCHIDS.

CULTURAL NOTES FOR SEPTEMBER.

The late Mr. Spyers was one of the best of Orchid growers, but on one point of culture, that relating to the potting of cool Orchids, I never could quite agree with him. Spyers would insist upon re-potting them in February or March, or he would leave them alone until September. I do not say that these are not the best months; probably they are; but I have re-potted cool Orchids, hundreds of them, in June, and many in all the intervening months between March and September. A very congenial temperature can be kept up during September, and those who have plants requiring re-potting would do well to have them seen to at once. Spyers used two-thirds of Sphagnum Moss to one of good fibrous peat. I mix the two in nearly equal proportions, but I always have a potful of clean washed and chopped Sphagnum at hand to add a further quantity if necessary, as I like to place the Sphagnum in more liberal proportions on the surface. The last plants of Odontoglossum vexillarium are not yet out of bloom; consequently they have not been repotted, but we will finish them by the end of the first week in September. They do not require any rest whatever after flowering; as a rule, they will be found to have made some young growth before the flowers fade, and that pushes on rapidly after the plants are repotted. If a few of the old leaves show decay-spots in places, the inexperienced cultivator need not be alarmed. It is better if they do not, but the growths are about the same in each case. As soon as cold, dull weather sets in these and the pretty, but capricious, O. Phalænopsis should be removed to the coolest part of the Cattleya house; we place the last named close to the glass at the cool end. Some of the Masdevallias should also be wintered in the Cattleya house. Those that remain in the cool house, but at the warmest end, are M. Lindeni, M. Harryana, M. Veitchiana, and M. ignea. I have never ventured to repot or break up specimens of any Masdevallias at this time of the year, but Spyers considered this a good, if not the best, time for such work. I have generally done it in February. Another good Orchid cultivator told me that a knife or any other cutting instrument never ought to be used to divide the plants. It ought to be done carefully with the fingers. If a knife is used, the plants, I am told, always die. I have never used a knife, so cannot speak from experience, but I have parted many with the fingers, and never had a single failure. We have quite a colony of plants of that most handsome of all Masdevallias, M. Harryana, that have been grown from a few little bits of the original importation. We only part the plants when it can be done easily. Nearly all the Masdevallias may be propagated in this way; some species grow much more freely than others. Some of our largest specimens, both of Masdevallias and Odontoglossums, had been grown and potted on from one pot to another for ten years or more until they showed signs of declining vigour. These plants had every particle of potting material removed, and the roots of some of them were washed. They were then placed in smaller pots. I cannot say that they improved much the first year; in fact some of them went the other way, but after the second year they did well.

In a few weeks the earliest specimens of Oncidium macranthum will be showing their spikes, and so fond of these and of the young roots formed freely outside the potting soil are slugs, that they must be constantly watched, even after we take the precaution to place the plants on inverted pots in a vessel of water. We had a fine spike in flower during the last four weeks, but the flowers have how faded, and the plant looks as if a whole season of rest would be desirable. This species becomes very much exhausted through flowering if the plants are not in a very vigorous condition. It is a good plan to give a plant a season of rest sometimes; especially if it has flowered well two or three years in succession. We give them a rest by preventing their flowering for one year. The Cattleya or Mexican house must not now be so much shaded. Cattleyas of the Trianæ section have completed their growth, and must be kept drier at the roots, as well as receive more light and air; but C. Mossiæ and Mendeli have not yet formed their bulbs, and require more heat and moisture with exposure to as much light as possible. While the nights are warm, the ventilators must be open at the top as well as at the bottom of the house. If the plants receive the right treatment as regards ventilation, atmospheric moisture, and watering, they will not be so liable to be attacked by thrips. Green fly has been troublesome in all our houses this year, and as fumigating is not quite safe, dipping and washing the plants with soapy and tobacco water have taken up much time. Cattleya Gaskelliana and C. Dowiana are now either in flower, or have passed out of bloom. C. gigas, Sanderiana, and imperialis, all varieties of the same species, have also flowered some time ago; they must be kept rather dry at the roots. If they receive an over-supply of water, or indeed if the compost is kept anything like moist, they will start into growth, which would not ripen this year and would prevent next season's growth being strong enough to flower. Calanthe veratrifolia, a well-known evergreen species, is now growing from the base, and if the plants require re-potting they should be seen to at once. We will re-pot ours, using nothing but good turfy loam, a little leaf mould, some decayed manure, and sand if necessary, just enough to keep the compost open. The thick fleshy roots of these Calanthes are easily injured by careless handling, and the plants receive a check they do not very soon get over. The compost must be kept moist all the year round. The new species C. vestita oculata gigantea has also started to grow, and must be re-potted in the same way as the others. It does not look as if it required any season of rest, as the growths have started well and the old leaves are yet green. This plant has now been introduced in quantity and may be purchased at a cheap rate. It seems to have been introduced from Borneo and requires the warmest house, while C. veratrifolia does best in the intermediate section.

The whole of the Dendrobiums are now in the warmest house we have, and they show their appreciation of the extra heat and moisture by making clean, strong, and healthy growths. It does seem that if we can get our Orchids to grow freely, by maintaining the right state of heat and moisture, they are not liable to be attacked by red spider, thrips, or any other parasites. More than any other Orchids the Dendrobiums require a decided period of rest after their rapid summer and autumn growth. We endeavour to let them go to rest by a gradual decline in the temperature after the middle of September, and some of them, such as D. nobile, D. Wardianum, D. crassinode, D. Falconeri, &c., are kept quite dry and in a warm greenhouse temperature all through the winter, a plant or two of each species being taken into the warm houses at intervals of three or four weeks. The plants ought to be marked "early, mid-season, and late," so that the early forced plants this season may also be forced earliest next season. We have some of each species flowering well into May, and plants of D. nobile in June; the first of them are in about Christmas. Probably there are no more valuable Orchids for cultivation in every garden than these Dendrobes, the best of which is D. nobile. Jas. Douglas.

Miltonia spectabilis is one of the best species of a genus peculiarly rich in good garden plants, and it is one of the easiest Orchids to cultivate, growing freely in a moist, warm greenhouse if fastened on to a raft with a few bits of peat and Sphagnum amongst its creeping rhizomes. Like many other popular species of Orchids, it is now represented in gardens by numerous varieties, which are, however, usually catalogued as distinct species. Two of the best of these are now in flower at Kew, viz., the varieties virginalis and Moreliana, the former having pure white sepals and petals and the large tongue-like labellum of two shades of purple, the darker being about the base, veins of the same dark shade running out into the paler purple of the margins. Moreliana has very large flowers with broad overlapping petals and sepals and a broad labellum, the whole being coloured a deep vinous purple, except the marginal portion of the lip, which is paler. We should call this variety, as represented at Kew, what is known in gardens as atrorubens. Give Miltonias plenty of water and a sweet atmosphere and they will grow healthily and flower annually. They cannot thrive with coddling, nor do they grow as well when planted in pots as when in baskets or on rafts.

Aerides Rohanianum is a beautiful species belonging to the same group as A. quinquevulnerum and A. odoratum, but distinct from all its allies. It is a recently introduced kind, and has only lately been flowered in English collections. There is a plant of it now bearing a stout spike of flowers in the Kew collection, the flowers extending up about a foot of the spike and forming a beautiful compact inflorescence. The sepals and petals are white with the faintest rosy tint; their texture is firm, though wax-like, and they are slightly reflexed; the labellum is horn-shaped, the point turned upwards in front, whilst the three lobes or laciniæ bend inwards at the top and form a hood over the column; the colour of the labellum is sulphur-yellow, with a few tiny dots of rose towards the tip of the horn. Inside the spur of the lip are two small horns, of which Professor Reichenbach says: "I never before saw such curious bodies in any Aerides among the hundreds and hundreds of flowers I have had under my eyes." The species is apparently a free grower, requiring intermediate treatment; it is certainly distinct and beautiful, which cannot be said of all the recently introduced and much lauded Aerides.

Dendrobium Phalænopsis was exhibited by the Kew authorities at South Kensington last Tuesday, and we are glad to see that so beautiful a species is likely to become a popular garden plant because of its good constitution, which, unfortunately, is not the case with the majority of Orchids from the Australian tropics, and especially with the Dendrobiums. D. Phalænopsis was introduced through Kew from the island of Timor, but it is also found in North Australia and New Guinea. The pseudo-bulbs are stout, about 15 inches long, narrowed to a point from whence starts the curved raceme, which is a foot long, and bears five flowers, each 2½ inches across; the sepals and petals are broad and coloured pale purple or magenta, and the lip is deep red-purple with a blotch of maroon in the throat. This Dendrobium may take rank with D. Williamsi, recently exhibited at South Kensington, as a beautiful new species, and although it is not so distinct as that kind, it is apparently a long way superior in being more amenable to garden culture than D. Williamsi has proved to be. New Guinea is the land of promise just now to Orchid growers and collectors, and if it contains many such beautiful plants as the two Dendrobes here mentioned, it will be worth exploring in the interests of the gardening world.

Masdevallia Davisi stands out distinctly amongst the hosts of Masdevallias in cultivation because of the clear bright lemon-yellow of its flowers, for, if we except the insignificant-flowered kinds, there is no other pure yellow-flowered species that could rank as a desirable garden Orchid. Apparently M. Davisi is rare, for we have not seen it lately in the collections we have visited except at Kew, where a healthy little plant is now in

flower. The leaves are thick, leathery, dark green, 8 inches long and erect, and the scapes bear each a flower about as large as that of M. Lindeni. We have an approach to yellow in some of the forms of M. ignea, but these are never nearer than orange. A beautiful quartette of Masdevallias would be the above for yellow, M. Harryana for crimson, M. Veitchiana for scarlet, and M. tovarensis for white flowers. In a small collection these four would represent the cream of the genus; whilst those remarkable in form might be represented by M. Chimæra or M. bella, M. Shuttleworthi, M. macrura, and M. Wageneriana. Here is a selection which we recommend to beginners in Orchid culture who have not yet made up their minds anent Masdevallias.

Cattleya Gaskelliana (*R. Owen*).—We consider the flower you send to be a fine form of C. Gaskelliana, which is very distinct from C. Sanderiana. The former more resembles the autumn-flowering C. labiata, but being always earlier in flowering cannot be confused with it. Your variety is remarkable for the fine broad lip, which is more highly coloured than usual. The shape of the flower, too, is good, the sepals being broad and held out firmly.

Aerides odoratum virens.—Under this name a wonderfully fine spike of an Aerides has been sent to us by Mr. Simpkins, from Mr. Measures' collection, at Cambridge Lodge, Camberwell New Road. It is by far the finest spike of A. odoratum we have seen. It measures 17 inches in length, and 13 inches of it are thickly covered with flowers, larger and finer in every way than usual. Their colour is white and wax-like, the sepals and lips being tipped with deep rose-purple. It looks more like A. Lawrenciæ or Sanderianum than any Aerides we have seen. Mr. Measures has two plants of this Aerides bearing five such spikes as that sent.

Orchids at Selborne.—This is not the time to see many Orchids in flower, but there is promise of a fine display later on. Amongst the best things which we noticed here were a richly coloured form of Cypripedium œnanthum superbum, the grand C. euryandrum, Stonei, Sedeni, and several others; also a finely marked variety of Vanda suavis, the rare Miltonia bicolor, Masdevallia Winniana and Davisi, the pure white Brassavola nodosa, a plant far too much neglected; the fine old Cattleya violacea, and a very deeply coloured form of C. Dayana. There were also a very fine marked form of the old and little-known Galeandra Baueri, and the curious Lælia xanthina; these are all late summer or autumn bloomers.

Cattleya velutina.—A twin-flowered spike of this new Cattleya has been sent to us from Mr. Measures' garden, at Camberwell. It is not showy compared with other Cattleyas, but pretty and interesting on account of its being so different from them. The flowers measure about 4 inches across the outspread sepals, which are rather narrow; they are broadest in the middle and wavy edged. Their ground colour is yellowish brown, spotted with chocolate. The lobe of the lip is 1 inch broad, white, heavily pencilled and veined with purplish violet; it is quite white on the upper part, with a dash of yellow in the throat. The flower is sweetly scented—an additional charm. In growth it so much resembles the less valuable C. bicolor, that the two plants are often confused when out of bloom.

Trichopilia suavis.—This beautiful plant is a native of Central America—a rich field from which many of our most valuable Orchids have been derived. It is one of the commonest species in cultivation, and may be purchased for a few shillings; it flowers very profusely in March and April, and is of extremely easy culture. There are several varieties of this plant in cultivation, varying in the size of the flowers and in the depth or brightness of the rosy blotches with which its snow-white lip is profusely adorned. The flowers are borne, two or three together, on a short drooping scape; and, in large well-grown specimens, their effect is very beautiful, as they frequently form a perfect wreath all round the base of the pseudo-bulbs. Good specimens often bear upwards of a hundred flowers, and as they last a considerable time (often six weeks) in perfection, they are of additional interest. The flowers are very useful for cutting, either for dinner-table decoration or for the drawing-room vase, as they sparkle very brilliantly under artificial light, and look very fresh and attractive when neatly backed by foliage or Fern fronds. This plant, together with its allies, grows well in a compost of fibrous peat and Sphagnum, care being taken to elevate it on a little hillock above the rim of the pot, or rather pan, in which it should be grown. All the Trichopilias do best in an intermediate house. They require plenty of water when growing and a decided season of rest.

SOCIETIES.

ROYAL HORTICULTURAL.

AUGUST 21.

THE large and excellent show of cottagers' and artisans' garden produce was the chief feature at South Kensington on Tuesday last, and, added to this, there was a good display of flowers, which lit up the conservatory with colour. The Gladioli from Langport were never shown finer, and the Roses from Waltham Cross and Cheshunt were almost as fine as in mid-July, while the glow of autumn hardy flowers, such as Dahlias and other composites, was seen on all sides. The new plants submitted to the committee were comparatively few, the following being those to which first-class certificates were awarded, and these, as may be observed, were all florists' flowers:—

DAHLIA MR. ROSE.—A single variety with peculiarly coloured flowers, the ground colour being rosy lilac, spotted and flaked with crimson. Exhibited by Messrs. Cannell and Sons, Swanley.

DAHLIA YELLOW CONSTANCE.—A yellow form of the white double Cactus-like Dahlia named Constance. It was certificated as a decorative variety, whatever that may mean. Shown by Mr. Ware, Hale Farm Nursery, Tottenham.

DAHLIA MISS LIMAKER.—A single variety having large and finely shaped blooms of a vivid carmine, with a yellowish centre. From Mr. Ware.

DAHLIA AMOS PERRY.—A single variety, a good deal like the original Paragon, but finer. The broad florets are of a rich plum-purple, edged with crimson. From Mr. Ware.

GLADIOLUS VOLTAIRE.—One of the Lemoine's race of hybrids, and a very fine sort. The flowers are above the usual size, finely shaped, and of a bright magenta-rose.

GLADIOLUS LADY MACFARREN, pale blush, prettily flaked on the petals. Lord Ashbourne, vivid crimson, one of the brightest of all. Prince Edward of Saxe-Weimar, salmon-pink, flaked with bright rose. Lady Salisbury, blush, flaked with crimson. Empress of India, pale purple and flaked. All these were exhibited by the raisers, Messrs. Kelway, of Langport, Somerset, and we need hardly say all were perfect examples of first rate Gladioli. All had fine, large and perfectly shaped blooms and tall massive spikes. They were selected from a large number of new seedling varieties shown in the Langport collection.

Among other exhibits shown the following were worthy of note: Mr. Crowley's gardener (Mr. King) showed from Waddon House an uncommonly fine example of Chrysanthemum Madame Desgrange, the flowers of which were pure white and nearly 5 inches across. Not less remarkable were some huge blooms of African Marigolds, lemon and orange-tinted, from Mr. R. Dean, of Ealing; the blooms were 4 inches and 5 inches across, forming dense globular heads. Mr. Eckford, of Borreatton Park, sent a series of named seedling Sweet Peas; how far they differed from older kinds could not be seen without actual comparison, but there was a brilliant carmine among them which seemed new to us, and there was also an excellent pure white. Orchids were scarce, but these included the magnificent Cattleya gigas Hardyana, which is remarkable for its large flowers and splendidly coloured lips, the tint being an indescribable shade of magenta. This variety could scarcely be surpassed among the forms of C. gigas. It was shown by Mr. Hardy, of Timperley. Another Orchid was Maxillaria setigera, shown by Mr. Buchan, Wilton House, Southampton. It has largish flowers with long and narrow petals of a pale yellow. The New Plant and Bulb Company, Colchester, showed a variety of Cattleya superba from Colombia, which, however, did not appear to differ materially from the original form, and the same exhibitors showed two Indian Balsams, one being the pretty and not uncommon Impatiens Jerdoniæ, the other a rare species somewhat like it named I. bicolor. It has two coloured flowers peculiarly curved like a horn. Mr. Bull showed flowers of the beautiful new Aristolochia elegans and the brilliant new Balsam (Impatiens Hawkeri).

Hollyhocks were again shown plentifully by two or three growers. Messrs. Webb and Brand, of Saffron Walden, had a great display of cut blooms, as well as spikes, and Mr. Blundell, of West Dulwich, again had some new sorts, among which we singled out those named Mary Anderson, straw colour: W. G. Head, crimson; Princess Victoria, blush-pink, all excellent. An elegant Maiden-hair Fern, named Adiantum cuneatum elegans, was shown by Mr. Kershaw, Shad House Nursery, Brighouse. It has finely cut fronds, and is altogether more graceful than the type.

Dahlias were plentiful, and the fine display of show kinds made by Mr. C. Turner, of Slough, included some beautiful new seedling doubles, one of which called Bendigo seemed to be the perfection of a show Dahlia. It has huge well-formed flowers of a plum-purple. Mr. Ware showed a host of new single sorts, as did also Messrs. Cannell, from whose collection we picked out those named, Our Leader, Cherry Ripe, Mr. Rose, as the finest. Messrs. Cannell also had a bright display of other flowers, including a selection of double Begonias, Carnation Pride of Penshurst, and a bunch of that rarely shown annual, Salpiglossis variabilis, in many colours.

Messrs. Carter exhibited an extensive collection of China Asters, all admirably grown and flowered specimens, representing every strain, we should say, that exists. There were Chrysanthemum-flowered, Quilled, Dwarf German, Victoria, Pæony-flowered, and others, all in various colours, so that it was not only a showy, but an instructive exhibition. A silver Banksian medal was worthily awarded to the exhibitors. Messrs. Veitch showed a collection of hybrid Gladioli of the Lemoinei race, which included a large number of varieties, some being quite new seedlings. The names of the finest were Enfant de Nancy, Emile Lemoine, Alsace, C. Colomb, La France, and Lemoinei. The rather uncommon, yet brilliant, G. Saundersi was also shown by Messrs. Veitch.

A silver-gilt medal was awarded to Messrs. Kelway for their large and magnificent collection of Gladioli, which numbered no fewer than 250 spikes, representing the finest Gladioli in existence. The collection was the great feature of the meeting, and was the centre of attraction. Among the finest new sorts, besides those certificated, were those named Lord Wolseley, brilliant scarlet; Sir F. Leighton, yellow flaked with crimson; Lady R. Churchill, blush-pink; Dr. Dresser, magenta; John Ruskin, delicate salmon; and Lady Lethbridge, blush-pink. All these are supposed to be improvements on older kinds of a similar colour. Messrs. Kelway also had a large display of Phloxes, Delphiniums, and Gaillardias, which, like the Gladioli, seem to thrive to perfection at Langport. The New Plant and Bulb Company took a silver medal for a fine gathering of Lilium auratum spikes and hybrid Gladioli; and Messrs. W. Paul and Son also took a silver medal for their large and fine display of Roses. Messrs. Paul, of Cheshunt, who likewise took a silver medal, varied their exhibits on this occasion with cut branches of ornamental trees and shrubs, such as Prunus Pissardi, the Golden Elm, Catalpa, Rhus typhina, and others, which harmonised well with the Roses and large masses of hardy plants. Mr. Ware again took a silver medal for a wonderful display of

hardy flowers which he has continually exhibited every week throughout the season. On this occasion the group indicated the near approach of autumn, by the comparative scarcity of Lilies and other summer flowers, and the prevalence of Composites, such as Dahlias, Sunflowers, Asters, Kniphofias, and the like.

Fruit.—Beyond one or two seedling Melons, which were passed by the committee, the chief exhibit among fruit was a collection of early Apples from Messrs. W. Paul's nurseries, Waltham Cross, which was both large and represented numerous sorts. Among them were the following: Lord Suffield, Devonshire Quarrenden, Stirling Castle, Cellini Pippin, Red Astrachan, New Hawthornden, Keswick Codlin, Yellow Ingestrie, Small's Admirable, Yorkshire Beauty, Echlinville, Golden Spire, and Kerry Pippin.

The Cottagers' Show.—Those who imagine that only inferior garden produce would mark the Cottagers' Show at South Kensington, must have found ample reason to admit that they were in error. Indeed, as compared with the exhibits of the co-operative association members and their gardeners at the other end of the conservatory, the cottagers' exhibits were very superior, and generally were first-rate, not a few classes being exceptionally good. The competition throughout was also remarkable, as will be seen from the details given, the judging presenting unusually arduous work, especially when from thirty to forty entries were staged. *Potatoes* were finely shown, no less than thirty-six lots, ninety-three dishes being presented, generally excellent samples. Amongst those were of white kinds, International, Fillbasket, Woodstock Kidney, Cosmopolitan, Prime Minister, Ashleaf Kidney, Chancellor, and Schoolmaster; and of coloured kinds, Edgcote Purple, Vicar of Laleham, The Dean, Adirondack, Reading Russet, Queen of the Valley, Cardinal, &c. The selected first three dishes included Essex Challenge (Bresee's Prolific), Vicar of Laleham, and Woodstock Kidney; the second three comprising Radstock Beauty, Adirondack, and The Vicar. There were no less than forty-two dishes in the single class, Fillbasket, a fine sample, coming first, Reading Russet being second, and Vicar of Laleham third. Eleven lots of two dishes of *Peas* were staged, and the best included Duke of Albany, Telephone, Ne Plus Ultra, and Stratagem. The same kinds were to the fore in the single dish class, of which there were twenty-one entries, John Bull being included. Though none were showy pods, they were mostly well filled and fresh. *Onions* included some twenty dishes, mostly autumn sown. Giant Rocca was the best, coming from Coleshill, Wilts; and some fine white Spanish took a second prize. Of *Cabbages* there were eighteen trebles, mostly large samples, the finest evidently Enfield Market, coming from Enfield; Daniels' Defiance being second. *Lettuces* were represented by Paris White Cos chiefly, in eighteen lots of three heads. The samples were only of moderate quality. *Scarlet Runners* proved to be a remarkable success, thirty-five dishes being staged, the best being a superb sample of Ne Plus Ultra, apparently a distinct kind, from Bletchington, Oxon, long, straight, and of good colour; Girtford Giant, also very fine, was second; and the handsome Ne Plus Ultra third. *Broad Beans* were moderate, the season being too late for them. The best were from Ealing—the Old Broad Windsor; Leviathan coming next in order. *Turnips* were again a remarkably good class, Snowball, Six-weeks, Jersey Lily, and White Stone all very like, but mostly very handsome and clean. The best of these were from Tring and Kent. An even more admirable class were the *Carrots*, many of the samples being most beautiful and perfect. There were no less than thirty-five lots, the best, some capital Long Surrey, coming from Mr. North, of Buckingham; whilst the second and third lots were the New Intermediate, and almost perfect in form. The Nantes were also good. *Beet* was represented by twenty-five lots and were of moderate quality. Carter's Perfection, Pragnell's Exhibition, Dell's Crimson, and the Turnip-rooted were the best. Eleven lots of three heads of Cauliflowers were shown, and included Walcheren and Autumn Giant chiefly, and were fairly good samples, especially for the time of the year. Some fifteen *Cucumbers* were staged, but few were named, and the samples were not specially good. On the other hand, *Vegetable Marrows* were in great force, being shown in some thirty couples. These included samples, white and green, long and round, ranging from a few inches to 15 inches in length. The selected lots were chiefly white and of fair even dimensions. Only eight dishes of *Tomatoes* were shown, most of these having been grown under glass. The best, which was Perfection, came from Bucks. Hathaway's Excelsior and Dedham Favourite were also very good.

Fruits.—*Apples* were very fair indeed, the best in the single-dish class being Lord Suffield, which took all the prizes; whilst in the class for three dishes Mr. Jacob, of Petworth, a rather formidable competitor, was a good first with Lord Suffield, New Hawthornden, and Gloria Mundi. The best of eating kinds was Red Astrachan. There were nineteen dishes of *Gooseberries*, both red and white kinds. The first dish was Lancashire Lad, as also was the third, whilst the second was the Old Whitesmith, all very good samples. Out of fourteen dishes of *Currants* the selected best were fine red from Amersham and Petworth, and blacks took third place. Finally, Cherries, all Morellos, and very good samples were represented by fourteen dishes. There was a well-named miscellaneous class, which included collections of vegetables, Celery, Globe Artichokes, dwarf Beans, &c., and of fruit, Plums, Pears, Apricots, and Mulberries, some twenty-two entries in all. Throughout these classes four prizes were in each offered, and, of course, all were awarded.

The National Co-operative Flower Show.—Such was the title given to the display made under the auspices of the Agricultural and Horticultural Association, of which Mr. E. O. Greening is the managing director. A large number of classes was provided, but in no case was there specially good competition, which was, with one half the classes, limited to members of co-operative societies, and the other half to members or the gardeners of their particular association. In the latter class the chief exhibitor seemed to be Mr. Dean, of Tilsey Park, Sussex, who took first place in the two collections of nine kinds of vegetables; a very fair lot, the best being Potatoes, dwarf Beans, Carrots, Celery, and Turnips. This exhibitor also had the best Cauliflowers; only two lots of three dishes of Peas were staged, and but one dish of Tomatoes—a very corrugated sample. Of Broad Beans two dishes were staged, but six dishes of Runner Beans, and of moderate quality; three lots of Cabbages, two of which were of great size. The best Carrots were Long Surrey, Nantes, and Intermediate. Beet, on the whole, was poor and ungainly. Onions were represented by nine dishes, Giant Rocca being the best; and there were ten bunches of Turnips, Snowball being placed first, though most were of indifferent quality. There were six dishes of White Kidney Potatoes, the best being International and Magnum Bonum, and thirteen dishes of coloured kinds, which included Vicar of Laleham and Reading Russet. Cucumbers were moderate; Marrows were more plentiful, but very uneven. The best lot of six dishes of vegetables came from Mr. Sexton, Northampton. A very nice feature was found in the bunches of annuals shown in six kinds, the first coming from Mr. Goldsmith, of Polesden, Herts, included Zinnias in variety, Lobelias, French Marigolds, Asters, Calliopsis, and Centaureas. Mr. J. Gow, of Hastings, was second with a large double Sunflower, Phlox Drummondi, Sweet Peas, Marigold, &c. Some spikes of Stocks were pretty, and nosegays, Asters, Dahlias, and other cut flowers interesting.

QUESTIONS.

5515.—**Mountain Ash berries.**—How can I preserve these in bunches? They are so handsome for Christmas decorations, that I should like to keep them for that purpose. The birds will soon eat them if not removed. Perhaps some of your correspondents will instruct me how to proceed.—T.

5516.—**Clematis montana.**—We fail to bloom this Clematis either out of doors or in a cool greenhouse; it grows luxuriantly, but never flowers, and I am told others in the neighbourhood likewise fail with it. Can any of your readers help us in the matter? We live at the bottom of a valley 300 feet above the sea. Is Clematis indivisa lobata likely to bloom out of doors with us?—E. L. R., *Halifax.*

FERNS.

TASSELLED AND CRESTED FERNS.

Mr. Syme names (p. 164) several collectors from whom I should seek information respecting Ferns of this class. I have done this in the case of the late Mr. Wilson, of Jamaica, who for years was a keen searcher for Ferns belonging to that island, and who contributed largely to our knowledge of them, both in a living and dead state. Dr. Thwaites, too, of Ceylon, did not allow many forms to pass unnoticed, and contributed largely, not only herbarium specimens, but many living plants, some of which were introduced by him for the first time. Krüger and Prestoe have also contributed largely to our knowledge of the Ferns of Trinidad. Krüger and Prestoe have also been searchers for these plants in Trinidad, and have enriched our collections of them to a great extent, whilst Belanger and Imray have contributed their quota from Martinique and Dominica; so also have Duncan and Horne from the Mauritius, Barter and Mann from Western Africa, Seeman from Panama and the Fijis, Milne from the South Sea Islands, Hooker from New Zealand, Spruce from the Amazon, and others. From these men I have from time to time obtained much information regarding exotic Ferns, but amongst all their contributions but few crested or tasselled Ferns have been brought to our notice. To our trade collectors we are mainly indebted for the introduction of most of these varieties of exotic Ferns, and from these I also have obtained much information.

Tænitis and Platycerium I do not consider to be abnormal forms. Antrophyums, I must confess, I have never seen forked or crested, although numbers have passed through my hands. I say again that it is my belief that English Ferns are more subject to abnormal variations than tropical ones, seeing that we have in commerce something like six hundred named kinds, mostly sports from about six species, whilst the forms hitherto introduced of exotics would not exceed a hundred. Mr. Fraser says the conclusion at which he has arrived as to the cause of our non-acquaintance with greater numbers of abnormal exotic Ferns is the want of interest shown by people abroad in that class of plants. But if botanical collectors do not care to gather abnormal forms, trade collectors do, and make it their aim to send home everything they find in that way of commercial value. Mr. Fraser seems to attach but little importance to climatic changes, but my botanical instructors have always contended that they were great factors in producing variations in plants. G.

Adiantum cuneatum var. elegantulum.—This is a fine-foliaged variety of the common wedge-leaved Maidenhair Fern, and, owing to its extreme grace and elegance, it promises to become a favourite with all bouquetists and floral decorators. If used for a bouquet or for grouping along with flowers in a vase, it can be spread entirely over the flowers without hiding them, as it then presents the appearance of a thin film of soft green colouring, through which each blossom is plainly visible. The fronds are as large as those of A. cuneatum, the only difference being the much smaller divisions. I lately saw it in Mr. Williams' nursery at Holloway, where it grows very freely and is much admired.—H.

Holly berries (p. 170).—I noted last year, on the 2nd of October, that there were still berries of the previous year on a Holly on my lawn.—William Wickham, *Binsted-Wyck, Alton, Hants.*

Double Begonias (*G. Stow ll*).—A very fine gathering of two-year-old seedlings; some are as fine as we have seen both for size and colour, and the pure white double will be valuable to you.—Ed.

Names of plants.—*H. K.*—Stanhopea radiosa.—*P. B.* (*Pamfield*).—1, Campanula (Platycodon) grandiflora; 2, Campanula isophylla alba.—*W. E.*—Bravoa geminiflora.—*Mrs. Maxwell.*—Spiræa callosa alba, Liatris spicata.—*W. P. F.*—Santolina incana, Rosa lucida.—*Walton Lodge.*—Rhus Cotinus.—*J. Z. B.*—Bignonia grandiflora.—*Secretary.*—You probably mean the Savin (Juniperus Sabina).—*E. M. G.*—Sollya heterophylla (blue), Quamoclit coccinea, allied to Convolvulus.—*W. Tottie.*—Shrubby Mallow (Althæa frutex).—*B. A. T.*—1, Eriobotrya japonica (Loquat); 2, Leycesteria formosa; 3, Liquidambar styraciflua; 4, Dodder on Furze (Cuscuta Epithymum).—*W. and H. S.*—Next week.

Names of fruits.—*J. A.*—1, White Astrachan; 2, Red Astrachan; 3, Kerry Pippin.

WOODS & FORESTS.

TREE PLANTING FOR PROFIT.

In considering this subject it is well at the outset that the planter should understand that whatever the quality of the soil is in which it is intended to plant trees that that soil will sustain and mature only a definite amount of timber. Hence, if trees are numerous on a given area, they will be proportionally small, and their money value, and also their value in the manufactured state, will be small, because they are adapted only for the most unimportant purposes. But if, instead of having, say, 1500 trees on an acre of ground at the time of cutting, there were only 500 trees, these 500 trees on the acre would be much more valuable to the owner than the 1500 poles would be at the end of the same time. Therefore, when thinning is rightly carried out, it is a most beneficial and an essential operation. The idea of planting trees at a distance sufficient from each other, that during the entire cycle of their existence they will require no thinning, is too ridiculous to be thought of. For even although planted under the best conditions, they would not yield the greatest amount nor the best quality of timber thus planted. The experienced and observant forester, who has opportunities of seeing the state of arboriculture in all parts of these islands, knows that hundreds of the plantations which he sees on all sides will never produce more than coarse-stunted scrub, fit for no better purpose than fire-wood, all owing to a want of knowledge in the planter.

Timber trees to be valuable should be tall, straight, clean grown, and large; and to obtain these qualities they should be planted thickly, that is, approximating to Nature in her method of planting, and thinned sparingly during the first decades of existence. The best soils and climate ought not to induce thin planting; inasmuch as if the soil and climate be the very best, the trees grow more rapidly and require thinning considerably earlier than they would in less congenial conditions. Should the soil, &c., on the other hand, be poor, the reverse would be the case. The more uniform the temperature of plantations, the more equal and rapid will be the annual growth, for light is not less a vital agent of healthy tree-growth than heat. A low canopy is almost certain to manifest a sickly and meagre evergreen undergrowth, for it is evident that the invigorating rays of the sun will hardly ever penetrate to the undergrowth through a dense shade of trees clad with branches and foliage from top to bottom. Nor is it incompatible or detrimental to the highest development of timber to thin trees to the widest distance, so as to encourage and create the greatest abundance of undergrowth.

J. F.

THE ASH.

No one questions that the Ash is one of the most useful of our British trees, and more especially on account of the excellence of its hard, tough wood and its rapid growth. Its value chiefly depends upon its white, dark, or pale colour, and as there are no objectionable qualities in the white sapwood, it is generally preferred. It is introduced into the field of commerce at a very early age. At four or five years' growth it is eagerly sought after by the walking-stick and whip-handle manufacturers, &c., and a year or two later it is ready for the use of Hop poles, the turner, cooper, cabinet, chair-maker, and the small wares manufacturer. It is also used for hurdle purposes, hoops, crates, and basket-making.

The second growth of Ash (that is, the growth after the first time of felling, and what is more commonly called stooled Ash) is much tougher than that on the original roots, or that of the first growth. Large Ash has many uses and is an important factor in the hands of the agricultural engineer, coach-builder, carriage-maker, and wheelwright. It is also the best wood for butchers' chopping-blocks and shop boards, as it will not readily splinter or wear away, and it is also largely used for bobbins and tools.

The Ash is peculiar in having a large amount of sapwood, and in the perfect wood taking up little or no colour in the process of hearting. The heartwood when it inclines to a black hue is frequently called black-hearted, sometimes black Ash, in which state some contend it shows signs of decay, but this is not the case, as it all depends upon the nature of the soil and climate.

Although the Ash occupies a place only second to the Oak, it cannot be planted profitably as a forest tree. The principal objection to the Ash is the injury it does to the underwood and plants that grow in its neighbourhood, by rapidly exhausting the soil. In consequence of this, few plants will thrive, or even grow, in close proximity to it, hence the very common practice of planting Ash in hedgerows. Its roots are of quick growth and extend a considerable distance, and may be easily traced by the weakness of the plants that grow near it.

FORESTER.

THE FORESTRY COMMITTEE.

So far as I have seen, nothing has been brought out in the report which was not well known before, and the only good it is likely to accomplish is the notoriety it has gained for the subject. In this indirect way the effort may prove to be of some service, as we now get articles on forestry from all sections of the press, and however ignorant of the matter the writers may be, it helps to make the question a popular one. This is a great necessity, as there is more to be hoped for in ordinary individuals becoming interested than in the production of a few skilled men. Notwithstanding what is said about exhausting supplies and no attempt being made to replenish them, it cannot be denied that the same agency is still at work as planted them at the creation of the world. It is a branch of the enquiry, a little, perhaps, beyond the points under immediate notice, but the mention of the circumstance that the primæval forests of India were preserved simply because they could not be got at, leads to it, viz., if a partially wooded country, say like Great Britain is at present, was entirely deserted by man and beast for a century or two, what would be the outcome? Would not the supply of timber naturally very largely increase? If so, and the principle can be universally applied, does it not give the key to the problem, why forests are always within a measurable distance of vanishing, but as time goes on they continually afford larger quantities of produce? Perhaps this aspect of the subject was outside the scope of the committee, as it would argue against scientific management, yet it is a thing when an impartial enquiry is made which deserves to be weighed. To take a simple instance of the way in which timber will increase by being simply let alone, we have only to take a glance at the estate of a regular tree-lover, one who does not plant to any extent, but who from a love of having trees about him allows them to grow on uninterruptedly. There are many such to be found, and it is simply marvellous to note the difference between such properties and adjoining ones where felling has been carried on at a normal rate. I am not referring to this to prove that it is the right thing to do in a country like this to allow trees to grow on for a whole lifetime without cutting such as have come to maturity, but merely to show the effect of simply leaving a district of country alone for a comparatively short number of years. A little while ago I had occasion to be upon some hills overlooking a wide valley. Over, perhaps, nine-tenths of the area, which could be distinctly seen, trees were scattered here and there in the way the bulk of the land is wooded in this part of the country, but in one particular spot, which was clearly defined, the landscape presented a totally different appearance. The same trees were there—indigenous to the soil—but they had been left alone to grow on, whilst the others had been thinned from time to time. On enquiry I found that the thickly wooded spot belonged to a gentleman who had all his life preserved his timber. An occurrence of this kind, though of no effect in itself if the principle holds good, serves to show that it is to natural reproduction rather than to planting we have to look for a continued timber supply.—D. J. YEO.

—— It seems not to be generally known that instruction in forestry is given to Civil Service candidates for India at Cooper's Hill, where there is adjoining what remains of Windsor Forest, and no doubt the best is made of such conditions of teaching as the locality affords. Still, it is evident that of practical knowledge of Indian forestry little or none can be obtained before India is reached, and then, with the grounding given at home, much good might result. One wonders, however, why natives are not trained to become Government servants, especially in having supervision of the vast forests of India. With respect to the comparative incompetence of the members of the committee, it should be remembered that, whilst not practical foresters, all had the interests of forestry at heart. If they were practical foresters, they would hardly need the evidence of those who may be, or at least profess to be, learned in woods and forests. Still, such amateurs may be enabled, having practical men before them, to extract from such witnesses all needful or possible information, although at times questions seem a little unpractical or far-fetched. Just now everything in relation to forestry seems to be regardful only of utility, but it will be a misfortune if the picturesque and beautiful gets no consideration; hence it is well, in devising any scheme for the development of forestry in this or in any other country that some persons of taste in the conjunction of trees and of foliage should be associated with any committee or authority appointed for that purpose. "Yorkshireman" throws doubt upon the value of the Birch as a shelter for Scotch Fir. Curiously enough, another correspondent at page 170 strongly advocates the employment of Birch as a shelter tree, although not specifically for the purpose first named. Now, apart from the value of the Birch for shelter purposes, it is not possible to ignore the singular beauty found in using the Birch as a fringe to masses of dark-foliaged trees, especially Scotch Firs. Some of the loveliest effects in foliage massing has been found in these combinations, and if Birch is, further, so valuable for shelter purposes, then a double reason is given for its employment. There seems to be very much room for the extension of forest planting in this country, but it is very probable that poverty on the part of landowners is one of the chief obstacles, just as that poverty more than anything else is helping to depopulate woods, parks, and hedgerows of much fine timber. Literally, vast areas of what is called poor land, chiefly producing Heather now, simply needs some rough cultivation and drainage, and then planted with Fir and some other suitable trees, would in time become valuable. Poverty on the part of landowners and disregard for the interests of posterity stop the way, and tens of thousands of acres remain as wild as at the time of the Conquest; whilst converted into plantations they would give employment to myriads of people.—A. D.

Raising woods from seed.—There has been a good deal of discussion in our pages with regard to the practice of raising plantations from seed, as against transplanting from nurseries. The system is not by any means a new one, as may be seen from the following remarks from Evelyn's "Sylva," written in the first year of the present century. The extract runs thus: "Plough the land in October or November, and

in the spring plough and harrow so as effectually to destroy the turf. Sow with Turnips to be eaten off by sheep. Another crop of Turnips should be taken in the succeeding year, after which the land will be in excellent condition for receiving the seeds of forest trees. Early in the spring on one ploughing sow one bushel or three pecks of Oats, and at the same time the necessary quantity of Acorns, Chestnuts, Ash keys, Beech Mast, Fir seed, &c. The Turnip and Oat crops will pay the expense of ploughing, seed, rent, and incidental charges. The tender plants, being nourished, warmed, and protected by the Oat stalks, will make vigorous shoots, and, having no weeds to struggle with, the first summer will push forward with amazing vigour. As the land sown in this manner will be fully stocked with plants, the feet of the reapers employed in cutting down the Oats will not materially affect the seedling Oaks, which, before the autumn, will have made considerable progress. The Firs, from the slowness of their growth, will be secured from injury, and the Ash cannot be hurt, as it does not vegetate till the second year. A wood raised in this natural manner will not only make the best timber, but will arrive at maturity many years sooner than one of the same age raised from plants drawn from the nursery."

FORESTRY SCHOOLS.

In reference to the subject of forestry instruction in this country, a writer in a contemporary observes that the art of forestry is taught in Germany in no less than nine special schools, and France and Italy have many such institutions. It is true, he says, that the latter have not been able to save the woods of Ravenna, but they may urge that they were called in too late, or that they have no pretensions to deal with the larger forces of Nature. At any rate, the Englishmen who want to learn anything of the art have to go abroad for the teaching, and that the knowledge so obtained is not without value may be seen by the work done by the Forest Department of the Indian Government, the best officials in which have been trained on the Continent. The Department was organised just before the mutiny, and has done much to arrest the blind destruction which was going on there, and which, doubtless, caused many occasional famines in the land. But it is not in India alone that the knowledge of high woodcraft is required.

The French Government is ahead of us in so far as it has an Inspector of Forests, who has not, perhaps, very many forests to inspect, but who goes very much more systematically to work than our Department of Woods and Forests. This inspector has paid an official visit to this country, and expresses his astonishment at the apathy he found on the subject. He found something to praise in the way in which Scotch proprietors were planting Larches and Firs, but he found that, beyond this sound but primitive notion, no knowledge of the capacities of the soil existed. Deer and cattle were allowed to roam at will, Beeches were planted where they would not grow, and no one seemed to know what trees to plant in the peat mosses; while no provision had been made to secure the growth of trees of varying age and size. Forests planted, as they appear to have been planted in Scotland, mature simultaneously, and have to be cut down at one time. This must be a disadvantage to land, to labour, and to the investor, as well as to natural beauty. A storm, or a supposed marketable period, thus leads to the wholesale disappearance of the forest, leaving ugliness and desolation behind, for there are no younger growths to keep up the tradition. The theory which obtains abroad is that a forest should yield a stable annual income, by judicious thinning, felling, and planting. In the German schools they maintain that the most profitable time to fell a tree is when it is two-thirds grown. This seems a sound theory, but how many wood reeves know when a tree has arrived at that age, or who knows whether Oak is best planted alone or with Beech, or with Fir? As a matter of foreign experience, Oak goes best with both Beech and Fir. Then, again, are questions of soil and exposure, of which sylviculturists know nothing, chiefly because there is no one to teach them anything. The same thing will apply to our colonies, where the sylvan wealth is far greater than ours, but where no more is known about the most economical and profitable way of managing woods. The committee obtained by Sir John Lubbock has already acquired much valuable information, and although the matter in these days of small profits and quick returns is one which must largely rest upon the good faith of one generation to another, yet we shall in future, if we sin in this direction, sin against light.

CARE IN MARKING TREES.

The present is rather an off season in matters relating to forestry, but we are within a measurable distance of the time when attention must be directed to the question of felling. There are gentlemen I know—men of taste and with a knowledge of the subject—who, if possible, personally decide upon all trees to be felled during the season. In many cases such a personal attention would, of course, be a physical impossibility, but I mention the circumstance to show that those who really appreciate a well-timbered place do not mind expending time in satisfying themselves that the right trees are felled and the right ones left. There is another class of owners who seem positively indifferent as to the way in which the work is carried out so long as a respectable sum results annually from sales. Amongst the last-named class there are, I presume, very few readers of *Woods and Forests*. Between these extremes there is probably a larger number to be found who, in a general sort of way, would like to see their timber as well managed as that of their neighbours, but who cannot bring themselves to take a sufficiently active interest in the subject to attain this desirable end. In the face of this, I believe that the stir which has during the last few years been made about tree planting and tree management, if it fails in its chief object, will cause a greater interest to be taken in the existing timber supply. The lack of an intelligent appreciation of the fact that there is such a thing as tree management seems to be at the root of the evil. Care in marking for exploitation seems to be the exception rather than the rule. Taken in masses in the landscape, there is much to be proud of in the way many of our English counties are wooded, but when we come to the detail the lack of thought or foresight is too often painfully apparent. The general impression is that of a Potato patch which has been run over indiscriminately, and a bunch of tubers lifted here and there without any idea to the general crop, but merely to supply the wants of the moment in the quickest way and with the least trouble. The comparison does not represent the case fully, but it will serve to show the absurdity of conducting operations in such a way. The one thing necessary seems to be to get the attention of those interested directed to both sides of the question. I have frequently known *carte blanche* given to a man—who, perfectly competent in his particular line, knew nothing, or, at any rate, thought nothing, of the future of the timber on the place—to go and make up a given quantity of timber in the readiest way that presented itself to him. Such a system, or want of system, cannot fail to be disastrous. The importance of carefully selecting the trees to be felled cannot be over-estimated, as it is the end and aim of the whole business. In harvesting any other crop, the neglect of common-sense rules would make a man an object of ridicule; but be a timber crop as badly managed as it well can be, it seems to excite little comment. There is, of course, the obvious difference that most crops ripen at one time, and that the production of food is a matter of necessary interest to everybody. Still, there seems no good reason why so little care should be taken of the first article essential in civilisation. There need be no great difficulty in the matter, as the issues are simple, viz., to make as good a return as possible for the present, but always with a view to the future, both with regard to profit and appearance. These two things will sometimes clash, but the accustomed eye will soon decide which must be sacrificed. If an entire group has occasionally to be taken out of the landscape, it may be better to do it than leave one or two trees which may grow into timber, but which would always be an offence to good taste. D. J. Y.

"HOW I MANAGED MY ESTATE."

This little book seems to have been pretty well received by the critics, who, as far as I have seen in several papers, appear to know even less about forestry than the author, and consequently have been careful not to commit themselves on that head. I shall, however, confine myself chiefly to the extracts from the book given in The Garden of July 24. In one of these it is asserted that an acre of land under the best of circumstances ought to carry at least "eighty Oaks worth £10 each at the end of about fifty or sixty years—that is to say, the crop would be worth £800 per acre." If this is an example of the kind of material to be found in the book, I should say the sooner those who buy it for a guide put it aside the better for all concerned. The assertion that Ivy-bound trees "lose about one-third of their natural power of expansion" must be a conclusion jumped to at first sight, and not verified by him at all, nor true. So long as the branches have scope the trunk will take care of itself, and burst the bonds of any Ivy that ever clasped it. The thickening of the trunk depends on the leafage of the branches and not upon the exposure of the trunk.

Then the author having to take the measuring of the timber "into his own hands" is good. Clearly the merchants have humoured him to the top of his bent, and made a good thing of it for themselves, I have no doubt. Finally, he gave up the tape and string, "and resolved to dispense alike with the merchant and bailiff. He went through the woods with someone to hold his measuring rod" and a ready reckoner, in the shape of the sliding rule so often used, "and set his own price on the trees" standing, and found that "he never had any difficulty in getting it," which I can quite believe, because if there be one thing a novice is apt to do in valuing standing timber in the manner just alluded to, it is to under-estimate the contents and ask too little, and that our author accomplished this remarkable feat the ready willingness of the merchants to give him his price "without any difficulty" is sufficient proof; they, at least, know how much timber is in a lot before buying, and never give more than it is worth. In short, the innocence of the author of "How I Managed my Estate" is simply charming to a practical man. "Somehow or other he found timber buyers would always give him some twenty-five per cent. more than they gave to big proprietors in the neighbourhood who left the transaction in the hands of their reeves." How delightful and how likely! Our author doubtless got this interesting information from the timber-buyers themselves, and not from the reeves. It is one of the commonest tricks of the trade for buyers to carry about with them lists of the marvellously low prices they have paid elsewhere, and to tell novices how much more they were asking and getting, and all this appears to have been swallowed by the author as profound gospel. In all probability it was himself who was victimised, and not his neighbours. Why, his writings show that any wood-reeve would confound him in about five minutes in valuing timber anywhere. The author's skill in practical forestry comes out in the confession that "he had quite ruined a two-acre plantation" of Spruce, Scotch Fir, and Larch by attempting to thin it after the trees had grown up rather thickly to a good height. He contemplated thinning other plantations of the same kind in the same way, but "found it best after this to leave them alone." What said the reeve about this management, I wonder? In the next edition, if ever there is to be one, I expect to hear similar confessions about his valuing and selling, &c. I observe from a critique of the book in a contemporary that the author, "unlike some preachers, does not venture beyond the limits of his knowledge," and tells only what has "come within the range of his own experience," which one can believe, for no experienced forester would append his name to the picked extracts of the book which I have seen. Yorkshireman.

No. 772. SATURDAY, Sept. 4, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

GARDEN IN THE HOUSE.

HARDY FLOWERS FOR CUTTING.

As "Delta" appeals to other lovers of hardy plants to record their experience of those kinds that ought to be generally grown, I venture to supplement his excellent list with the names of sundry species that have proved themselves thoroughly reliable for the particular purpose of supplying cut flowers. I will follow "Delta's" example by premising that the garden from which these notes are made is on the sandiest and most arid of soils where the rainfall is abnormally small, so that, owing to dryness during the winter, some plants survive which elsewhere might damp off, or which, from beginning to grow too soon through a damp, warm winter, get caught by a spring frost; for there is no doubt that it is the recurrence of cold after the plants have started into growth rather than the severity of our winters that is fatal to so many hardy plants, which at home are probably accustomed to be deeply buried under the snow-blanket until the sun comes out for good; whereas here they are treated Turkish-bath fashion—alternate hot and cold—until they hardly know whether they are alive or dead, and then those starving, interminable east winds settle the question. This year numbers of plants survived the hard winter, only to be killed or crippled, when they should have been coming into flower, by frosts in April and May, even such hardy shrubs as Pontic Rhododendrons and Azaleas were much disfigured.

A propos of the Himalayan Rhododendrons, is not the question of their hardiness in Surrey what Paley would call a case of absence of experience rather than contrary to experience? I do not know all the Surrey Rhododendron grounds, but I know some famous ones where, I believe, no attempt has been made until the last few years to grow the Himalayan species out of doors; but this is no proof that they are not hardy there, nor would it be if these young plants should sometimes die, for many plants are tender in the young state, although quite hardy after having attained a certain age. Now, discoverers sometimes have friends at home to whom they send their good things, and if the discoverer of the Himalayan Rhododendrons, about the year 1848, sent seeds to friends in South Wales, they would have got a long start with plants that require some patience to raise from seed, and might well have fine examples by this time. But that is no reason why the inferiority of the five-year-old Surrey plants (!) to thirty-eight-year-old Welshmen should be thrown in the teeth of the Surrey climate, as "Delta's" remarks seem to indicate. Perhaps in thirty years—but this is anticipating. To return to cut flowers. I will only make one deviation from "Delta's" convenient mode of enumeration, by placing the plants, more or less, in their order of flowering instead of in alphabetical order.

ANEMONE SULPHUREA.—This is one of the most beautiful of all early summer flowers, and has the additional advantage of being a perfectly hardy and robust herbaceous plant. Established plants throw up several stems about 2 feet high, each bearing a large single upright flower with silky petals of a pure sulphur colour. The flowers last well either on the plant or in water; but if not cut the seed-heads are afterwards extremely ornamental, owing to the great length of their silky awns. A. sylvestris is another good species which makes a pretty companion to the foregoing, being of approximately similar height and size, but having pure white flowers.

ANTHERICUM LILIASTRUM.—St. Bruno's Lily is a charming flower for vases, for its glistening whiteness is equally effective when contrasted with other flowers, or when relieved only by the foliage of the plant. The smaller-flowered A. Liliago is also light and graceful in tall vase bouquets, and the plant seeds itself about all over the borders so freely, that there is no difficulty in obtaining a good supply.

FRITILLARIA MELEAGRIS.—This native bulb and its white form (alba) should be extensively grown for cut flowers, as the blooms last well, and an old blue bowlful of them looks exceedingly rich. If the bulbs can be planted in large groups on the Grass, the flowers are especially effective.

TROLLIUS EUROPÆUS.—Although the pretty Globe flowers should be grown beside streams or in damp places to ensure the display of their greatest beauty, nevertheless even on dry soil they supply innumerable flowers admirably adapted for cutting, being produced on long slender, but stiff stems. As a companion to the pale yellow-flowered T. europæus, T. asiaticus, with less globular, but deep orange-coloured flowers, may well be grown.

CHRYSOGONUM VIRGINICUM.—A pretty, but apparently not often grown plant, of sturdy branching habit, producing abundance of stellate flowers, which retain the brilliancy of their deep yellow colour for a considerable time in the cut state.

HEUCHERA SANGUINEA has proved a great acquisition for the supply of light, graceful spikes of a bright rosy crimson colour, admirably adapted for decorating the top of an epergne or other vase where heavy flowers are not desirable. The plant is a good grower, becoming readily established, and then throwing up flower-stems in abundance. There are several other species of some interest, among which H. Menziesi, from the Rocky Mountains, has quaint brown flowers.

LUPINUS ARBOREUS.—This is the best of all Lupines for cutting. One might have thought the dear old blue and white Lupines, indispensable as they are in the garden, would have been almost too "vegetable" in the cut state to have satisfied "Delta," whose judgment in such matters is generally considered as final. But this objection cannot be urged against the yellow Tree Lupine, whose flowers supply a pure soft shade of yellow much wanted, and have the additional attraction of a pleasant fragrance; while the deep foliage is far better adapted than that of the polyphyllus varieties for use in the cut state. The plant is not very easily controlled in the border, it is true, but it is well worthy of some secluded corner just to cut from.

POTENTILLA FORMOSA.—The prettiest and best border plant of all the numerous species, with its clear cerise flowers and compact habit. Another species that is less weedy than most, and looks well associated with the above, is the pale yellow P. hirta.

DIANTHUS PUNGENS is excellently named, for its single white flowers, though no bigger than a sixpence, have a most powerful and delicious fragrance, while they are produced in the greatest profusion, and the plant will grow anywhere. Half a dozen of these little blossoms artfully introduced into a bouquet of white Camellias might induce an unsuspecting person to believe that the ordinary Camellia is only slightly less fragrant than the Gardenia.

ERYNGIUM BOURGATI (AMETHYSTINUM).—This is the only one of the Sea Hollies that is of much value in the cut state, as most of them are too coarse to be available. But the one under notice throws up numerous stems on which the leaves occur only at considerable intervals, so that they may be gathered without inconvenience and of almost any size; while the peculiar metallic or amethyst-blue which suffuses the heads and stem is a rare colour among flowers, and renders the species valuable.

CATANANCHE CÆRULEA is an old-fashioned plant by no means to be despised for cut flowers where blue is wanted.

COREOPSIS AURICULATA is an old favourite that is still "bad to beat" for cutting, in spite of its tendency to lop over in the border.

SCABIOSA CAUCASICA.—This plant supplies us with delicate porcelain-blue flowers, whose long, straight stalks render them particularly useful for bouquets.

CEPHALARIA TATARICA is another not very common plant of the Scabious family, having flowers of a pleasing pale yellow colour. Although very useful for cutting, this is a plant not very desirable in the border, unless it can have an isolated position as a specimen. It is likewise a capital wild garden plant, as it is able to hold its own against the strongest.

ALSTRŒMERIA AURANTIACA.—This plant sometimes seems rather capricious about settling itself in a new locality, but when once established nothing can exceed the wealth of blossom which it provides, so that a good clump of it constitutes a supply that may be drawn upon for a considerable time. The flowers last well in water, and do not suffer much in wet or windy weather. There are several colours besides the orange type, all more or less decorative; and there are also other good species which, however, seem to be mostly lacking in robustness.

GAILLARDIA GRANDIFLORA.—This is quite a model cut-flower plant. Of dwarf, compact habit, taking very little room, it throws up, on long stalks, gorgeous flowers of various shades of crimson and yellow; it blooms profusely throughout the summer until cut off by frost, and the flowers are very enduring; while the more they are cut the more freely are others again produced.

GAURA LINDHEIMERI.—This plant is sometimes said not to be very hardy, but, at any rate, it is hardy enough on a dry soil, and makes a very pretty vase flower with its long slender spikes of white flowers with their pink sepals.

MONTBRETIA POTTSI.—The brilliant orange flower-spikes of this beautiful Cape bulb, as well as those of the larger flowered hybrid M. crocosmæflora, are very striking in the cut state, and both deserve to be extensively grown for the purpose.

HELENIUM PUMILUM.—One of the best of the North American composites. Dwarf in habit, its light green foliage is half hidden during most of the summer by its golden blossoms about the size of a half crown. It increases readily and grows freely without ever becoming weedy, and the flowers remain fresh and bright for a long time when put in water. It is not (like some of its tribe) at all coarse in growth or flower, nor has it any rank smell.

RUDBECKIA NEWMANNI and R. HIRTA are also useful yellow Composites, while R. californica, growing 6 feet high, is effective in the garden or in great jars in the corner of a room.

HARPALIUM RIGIDUM, handsomest of its race, is another good border plant in the matter of not encroaching overmuch, and its bold straight-stemmed flowers, with their dark centres and rich gold rays, are unrivalled among Composites for the combination of strength with elegance.

HELIANTHUS DECAPETALUS.—This is a tall-growing plant, 5 feet or 6 feet high, but the pale sulphur-coloured star-shaped flowers are not at all coarse, being freely produced as laterals on stiff wiry stems.

POLYGONUM POLYSTACHYUM.—This is a pretty plant to cut from, of a class not very generally met with. There are several species which make very handsome specimens where they can have plenty of room, but the one under notice is of dwarf branching habit about 2 feet high, and having a spike of pure white flowers issuing from

the axil of every leaf, so that a branch with its slender spikes displayed against its deep green foliage makes a very fresh and pleasing effect when used in the cut state.

Zauschneria californica.—There seems to be no situation too hot or too parched for this sun-loving Californian, for it succeeds admirably on a sandy, stony bank, facing south, where it leans over a great flat stone that gets as hot as possible in the sun. In this position it produces numerous spikes of small, bright scarlet tubular flowers, which are very effective.

Schizostylis coccinea.—This useful plant flowers so late in the season, that it is liable to be disfigured by weather in some localities, although it is quite hardy. But it is quite worth the protection of a bit of canvas put over it at night if rough weather sets in before the flowers are expanded, as flowers in October and November are of importance in gardens where there is little or no glass. It flowers equally well in pots, and makes a capital foreground for a large group of white Chrysanthemums.

Tussilago fragrans.—No garden that lacks glass should be without a few plants of the winter Heliotrope to counteract the sometimes aggressively strong Christmas decoration by the delightful fragrance of its pale flowers. The plants may be thrown down in any out-of-the-way corner, or behind a hedge, and be forgotten till January, when their flowers are sure to be welcome.

Among plants to avoid for cut flowers, note should be made of the Pentstemons, which, gorgeous and persistent as they are in the garden, fade almost immediately in water. The strong, brown-sugary smell of the Phloxes again is very disagreeable to some people; while it is impossible to sit in the room with the otherwise attractive flowers of the double perennial Sunflower (Helianthus multiflorus fl.-pl.). The same remark applies to the superbum Lilies, which are very unpleasant company in the house, and L. auratum, though not disagreeable, is too strongly scented for many persons' liking; but without these there are plenty of Lilies that are among the finest subjects for cut flowers, especially the Tigers, single and double, lancifolium, testaceum, and colchicum. The brilliant umbrosum Poppies have been sometimes objected to on the ground of smelling rank, but as this is only from the broken stalks, if the vases are arranged elsewhere and not taken into the room until the ends of the stalks are safely immersed in the water, no unpleasant smell will be noticeable.

T. W. G.

BALCONY GARDENING.

It may interest your correspondent of last week ("H. B.," p. 186) to know that the balcony garden of Yuccas and Ivy in Portman Square to which he refers was in good condition at least ten or twelve years ago, when I made a sketch of it for *Domestic Floriculture* (*vide* p. 97). Its permanent state of freshness and beauty, summer and winter, is a great advantage in the town. There is a corner house in the Fulham Road which is also noteworthy, the strip of front garden being planted with Yuccas, and a Wistaria has been trained very prettily up to the balcony above. These two examples show us something of the possibilities of town gardening. It is only a very few years ago since several fine old Mulberry trees used to fruit freely in the old Drapers' Gardens, within a stone's throw of the Bank of England; and the white Water Lily used to flower in a little pond there as freely as in Kent or Surrey. It is not as yet ten years since a pair of rooks used to build in the Plane tree in Wood Street, Cheapside, and the Plane is still there as healthy as ever, I believe. The garden around St. Paul's is another example of what can be done with green turf and Ivy; while old Sam Broome's Chrysanthemums at the Temple Gardens quite supplanted the white and red Roses which formerly grew there, and led to one of the most remarkable of all our civil wars.

F. W. B.

NOTES OF THE WEEK.

Spiræa palmata alba.—This variety is likely to become as popular as the species, especially as it has now proved to be amenable to forcing in pots; in foliage and habit it is undistinguishable from palmata, but the flowers are of the purest white. It is now very fine in Messrs. Backhouse's nursery at York.

Montbretias at York.—The following varieties of Montbretia and Tritoma are also flowering now in the York Nursery: Montbretia crocosmæflora, Golden Sheaf, sulphurea, Fiery Star, elegans, Bouquet Parfait, Pottsi, Tritoma Uvaria, nobilis, glaucescens, Saundersi and Macowani.

Citrons at Waddon House.—A very fine plant of Citrus medica is now bearing a heavy crop of fruit in the gardens of Waddon House. The plant is in a border, the head being trained over half the roof, and is about 24 feet long, bearing upwards of a hundred of its large ovate fruits. These are cut before they are ripe and used for preserving.

Rosa foliolosa.—This tiny Rose seems to promise to be a gem among Roses for the rock garden. Its pale green, very small, and finely cut foliage distinguishes it from all others; while its flowers, faintest blush colour when opening, but white when fully blown, are rather large in proportion to the plant, being nearly the size of the Dog Rose. The tiny buds, tipped with faintest pink, are especially delicate and pretty.—G. J.

Fuchsia Riccartoni.—This fine old Fuchsia, now in full beauty, appears to enjoy the sea breezes, for the gardens hereabouts are full of large bushes of it now laden with countless numbers of crimson blooms. In Fuchsias, as in other plants, hybridisers have aimed to get large blooms, but to many a crowd of delicate little hanging sprays of Fuchsia blooms are prettier than a small number of large ones.—J. G. H., *Gosport*.

Passiflora Constance Elliott.—This pretty sweet-scented white-flowered Passiflora is said to be perfectly hardy; it is now in great beauty upon the roof of a glass corridor at Beddington House, where its flowers are highly appreciated. The corridor can be heated, and the extra protection it gets here will probably prolong its blooming into the winter months, when flowers of all descriptions are highly appreciated, and white ones doubly so.

Solanum jasminoides.—This old plant covers a large space on the back wall of one of the greenhouses at Beddington House, and is invaluable for cutting, a profusion of its blooms being now open; and, indeed, the same might be said of it nearly every month of the year. As a pot plant it is seldom satisfactory, but planted in the border it cannot be overrated; and we have found that in delights in frequent applications of liquid manure.

Anthurium Andreanum.—In the stove at Waddon House there is a distinct, dwarf, compact form of this plant. Its leaves are comparatively small, and are produced upon shorter foot-stalks than usual, and it is now bearing fourteen large flowers, which are very highly coloured. When seen in this condition it is really a grand and imposing plant, and the less robust habit of this form will enable amateurs with small houses only to add it to their collections. It may be called the Waddon House variety for convenience, as we are convinced of its distinctiveness.

Begonias at Forest Hill.—The display of tuberous Begonias at Messrs. Laing's nursery at Forest Hill must be seen to be appreciated; their effect cannot be adequately described. In the open air there are about a hundred thousand Begonias, all profusely laden with flower, raised from seed this season, whilst a conservatory, upwards of 100 feet long, is devoted to the culture of specimens both in pots and baskets. Amongst these are both doubles and singles, bearing flowers of all shades and variety in colour to be found in Begonias, and measuring, in some instances, upwards of 7 inches in diameter. Among the finest novelties of this season are those named Queen Victoria, deep rose; Prince of Wales, vivid crimson scarlet; Princess of Wales, deep rosy pink; Prince Albert Victor, bright scarlet, shaded with orange; Princess Louise, purest white; Princess Victoria, rosy carmine margin, pale centre; Duke of Edinburgh, dark maroon shaded chestnut; Duchess of Edinburgh, deep yellow shaded orange.

Floriferous Eucharises.—I have half a dozen pots of Eucharis amazonica now finely in bloom. One plant in a pot 12-inches across bears 18 spikes—10 spikes with 7 blooms, and 8 spikes with 6 blooms, making a total of 118 blooms. On another plant the same size there are 17 spikes with 110 blooms. The other pots (10-inch) average about 11 spikes and about 70 blooms each. This is the second time they have flowered this year, and I hope to have another batch a few months later.—W. A. Cook, *Holme Wood, Peterborough*.

Lilium auratum platyphyllum.—This is a new and most distinct type of the auratum group, an improvement on the ordinary auratum. It is dwarf in habit, has broad and massive leaves, and its flowers measure some 9 inches in diameter. The ground colour, which is white, is profusely spotted. The variety giganteum is a more vigorous grower; its flowers are pure white with a broad central stripe of deep lemon. L. platyphyllum luteum differs from it in having the lemon colour spread over the petals. All three forms are now in bloom in Mr. Bull's nursery at Chelsea. They are grown in quite small pots, which are found to be better than large ones for Lily cultivation.

Eucryphia pinnatifida.—Our tree of this, which is 5 feet 6 inches high and 6 feet across in the widest part, is now finely in bloom. Each blossom, which is of the purest white, measures 3 inches across, and consists of four, and in a few cases five, and even seven petals. Of such blossoms there were some 500 on the tree last week, but they are now beginning to fade. To my mind it is the most beautiful hardy shrub or small tree in cultivation. Antholyza paniculata, Montbretia Pottsi and crocosmæflora are in bloom side by side. I am convinced that all three bloom better if taken up and kept nearly dry for a short time. Montbretia Pottsi can hardly be kept within bounds without drying it off and replanting. The Eucryphia, I should add, is quite hardy.—C. O. Miles, *Sunny Hill, Shirehampton*.

*** The Eucryphia certainly merits all that is here said in its favour. A coloured plate of it will be found in The Garden, Vol. XII., p. 544.—Ed.

Tecoma radicans.—This beautiful hardy wall climber is just now attracting attention by its large showy flowers. Should the wall on which it is trained be rather rough, it will attach itself firmly thereto in the way that Ivy does, and grow very freely when once established. The flowers, borne in good sized clusters, are of rather a distinct shade of bright red. Besides forming a good strong-growing wall climber, both this Tecoma and the allied T. grandiflora may with advantage be used in festooning neighbouring trees or shrubs, where that practice finds favour. This shrub is a native of North America, and was introduced more than a century ago. It can be increased to an almost unlimited extent by means of root cuttings, for if roughly chopped up nearly every bit will grow if favourably situated.—T.

The flower beds in Hyde Park are in excellent condition just now. We noticed Herniaria glabra and Mentha gibraltarica as being amongst the best plants for groundwork, the vivid green of their foliage affording a better and more pleasing contrast to the bright colours of the Alternantheras than other plants used in these beds. Spergula pilifera aurea has a telling effect used in proximity to the darker colours, but should be kept away from the lighter foliage of its surroundings. A very effective groundwork for Alternantheras in one of the beds is Mesembryanthemum cordifolium variegatum. Sedum glaucum, used as groundwork for beds of Alternantheras, has not grown much and does not look well, but as

setting for smaller plants it is good. Another striking bed is planted with variegated Pelargoniums mixed with Iresine Lindeni, encircled with Festuca glauca, and edged with Alternanthera. A group of Ricinus sanguineus is also a fine feature, and the same may be said of Solanum Balbisi and Polymnia grandis. The two best dark Pelargoniums are Henri Jacoby and Miss Stubbs, and the best pink is Sybilla. Begonia Lady Stanhope is a fine pyramidal variety and good in a bed, but the other kinds of tuberous Begonias used here are very poor, and do little credit to this beautiful race of plants. The fine old Gazania rigens, used here as an edging, is one of the very best plants where orange is desired, and has the recommendation of lasting well into the autumn. The Dell is this year peculiarly attractive, the combination of giant Tree Ferns, Australian Dracænas, Musas, Palms, Bamboos, Phormium, &c., being charming; all these plants have a very noble appearance. Phœnix, Chamærops, and Seaforthia amongst the Palms are more effective than any other Palm used here. Seen from above or below, the view is equally beautiful, yet presenting a totally different appearance.

Night-flowering Cacti.—It is, perhaps, somewhat tantalising to our readers to be told that during the last month there has been an unusually fine display of the flowers of these plants at Kew, such magnificent kinds as Cereus Lemoinei, C. nycticalus, and C. Macdonaldiæ having borne numerous fine flowers, all, however, at night when only the moths and perhaps the fire stokers could enjoy them. Cultivators should, however, grow these plants for themselves, and they are so easily managed that every warm conservatory should contain at least one of the kinds. It is impossible to describe the sensational beauty of the enormous, but short-lived, blooms of those named above.

Indian Lilacs (Lagerstrœmia) are just now represented at Kew by two distinct kinds, viz., the pale rose-flowered one, which is now so common as a garden plant in Southern Europe, but which is a comparative rarity in English collections, although as easy to grow and flower as an Almond if treated in a similar way with the addition of a few more degrees of heat. The other kind referred to is the deep coloured variety called elegans, and which is one of the many choice plants that find a genial home at Pendell Court. Kept in a moist, warm house all the year round, these Lagerstrœmias will not flower, but if rested in a cool, dry house during winter they flower freely about this time of year. There is also a white-flowered variety of L. indica, but we have never seen it in flower.

White Agapanthus.—The blue Agapanthus is a grand old plant, but being so common it is rather slighted. The white variety of it is as choice as the other is common. A good sized specimen of the white variety affords a charming companion to the blue, especially if the old sort be of a good dark colour, for in this respect there exists a good deal of difference. As white flowers are always in demand the blooms can be picked singly and be used for cut bouquets and other small floral arrangements. Though there are several other kinds of Agapanthus, I take the above two, the old blue and the white, to be by far the best, for of others that I have seen one named excelsus differs principally in the unusually long flower-stem, which does not add to its ornamental appearance, and Mooreanus and minor are less showy than umbellatus, while flore-plena is worthless.—T.

Cyrtanthus McKeni.—This is one of the easiest to manage of the dozen or so kinds of Cyrtanthus which have been in cultivation in English gardens, but are now almost unknown, having gone out of favour probably because of their being difficult to keep healthy. That the majority of the species are beautiful flowering plants may be seen by the figures of them in the *Botanical Magazine* and elsewhere, and notwithstanding their bad character as garden plants they are certainly worth reintroducing and trying again. They are closely related to the old garden favourite Vallota, but in some of the kinds the flowers, instead of being erect, are pendulous, as in the Australian Blandfordias. They are found principally in the eastern districts of the Cape and about Natal. C. McKeni is found in the latter place, and therefore requires warm greenhouse treatment, under which it keeps healthy and flowers freely annually. Some pans of it are now flowering at Kew, where it has been cultivated for years amongst the plants of tropical Africa in the Palm house. It has narrow, strap-shaped leaves, erect scapes one foot long, and flowers in an umbel; these are narrow tubed, 3 inches long, white, and sweet-scented. Specifically, this kind must be considered only a form of C. lutescens.

Desfontainea spinosa.—Just now when this singular-looking, Holly-like shrub bursts out into a profusion of crimson and golden blooms, it stands out conspicuous from everything near it. Unfortunately, it is not often met with in a flourishing condition, and is frequently injured during severe winters, though when at its best it is just now among the most attractive of all shrubs. It needs planting in a somewhat sheltered spot, and in a situation where it does not get too dry during the summer. Cuttings of the half-ripened shoots strike root fairly well in a close frame, and this is the method usually employed for its propagation. The Desfontainea was introduced from South America to this country about 1845 by William Lobb, to whom we are indebted for such high-class plants as Berberis Darwini, Lapageria rosea, Embothrium coccineum, Escallonia macrantha, and Philesia buxifolia. Of these, the Lapageria and Darwin's Barberry are certainly two of the finest plants in cultivation.—T.

Ipomæa velutina is a beautiful climber which has been introduced from Queensland to Kew, where it is now flowering in the Water Lily house. Close to it is that grand old tropical Bindweed, I. paniculata, figured in The Garden a year or two ago as Batatas paniculata, and we couple these two because they have some points of resemblance in robustness of growth and in size and shape of flower. But whilst the Batatas has palmate leaves and large lilac-rose flowers, I. velutina has entire cordate foliage and flowers coloured pale pink, with a deep maroon blotch in the throat. These perennial Ipomæas are of the finest of stove-climbers, but they want plenty of room to be seen at their best. If I. velutina proves as accommodating under cultivation as I. paniculata is known to be, it will be a valuable addition to stove-climbers; indeed, it may not require the heat of a stove, judging by the plant at Kew, which has a great amount of leafage, but comparatively few flowers. Admirers of I. paniculata will be able to form some idea of this new introduction when we say that whilst it is at least as beautiful as the finest forms of that plant, it is quite distinct from it and all other garden Ipomæas.

Varieties of Montbretia.—I notice that, at page 187 of The Garden, a note stating that you had received from the New Plant and Bulb Co., Colchester, a set of six so-called varieties of Montbretia crocosmæflora, adding that they were nearly all the same, and leaving the responsibility of the fact to the Continental raisers. It is well known that all the varieties of M. crocosmæflora in the trade were sent out by me. I have pleasure in claiming to be the raiser of these varieties of M. crocosmæflora, and I consider that they form a magnificent series of varieties, differing both in shape and in colour. The New Plant and Bulb Company received the most part of the novelties as soon as sent out, and purchased them in quantities the second year after having seen them in flower.—V. Lemoine, *Nancy*.

*** We do not doubt but that the named varieties raised and sent out by M. Lemoine were distinct. We can only repeat our previous remark, that we failed to see any difference between the half-dozen named sorts sent to us, except one, which was decidedly darker in colour.—Ed.

Battersea Park.—The flower beds in this park are probably now at their very best. Especially attractive are the white Phloxes and the various Pentstemons; a very effective group is made up with a groundwork of Vitis heterophylla variegata relieved by taller plants of Acacia lophantha. The groups of Cannas are admirable, but where arranged in stiff and sharply defined lines their effect is impaired. The groups of succulents are bold, attractive, and quaint; arranged in this manner their beauties are far better developed than placed in patches round the edges of the beds. The Fern dell is very charming; so also are the bold groups of Blue Gums (Eucalyptus globulus), Wigandias, Phormiums, and Palms. Here we noticed that the various groups of Phœnix were the most useful Palms, and next to these the Chamærops and Seaforthias. Musas have a majestic appearance, and standing in quiet, secluded spots are most enchanting. Polygonum cuspidatum is a very fine plant for isolated groups, and so is Amorphophallus Rivieri, a large Aroid which is very effective in character in the sub-tropical garden, but as used here is not large enough; probably it wants age. Arundo conspicua is in great beauty; so also are Bamboos, various species of Cycads, Wigandias, and other large and well-known ornamental-leaved plants. The white variegated Maple is beautiful in irregular groups or associated with others, but it loses much of its effectiveness when planted in straight lines, as is the case in several parts. Tobacco, again, is very ornamental both in foliage and flower, but its grace and elegance are quite spoiled planted in this manner; more especially is this the case when they have to be supported with stout and tall stakes. On the whole, however, the sub-tropical garden in this park is instructive both to the gardener and the general public, and most enjoyable to all.

A beautiful new Anemone (A. Fannini).—This plant is already represented in several gardens in England, seeds having been distributed by Mr. Adlam, who collected them in Natal, where this really wonderful Windflower is a native. It is described as having flower-stems 5 feet high, Vine-like leaves 2 feet in diameter, and pure white flowers like single Dahlias, measuring between 2 inches and 3 inches across. It flowers in the last quarter of the year in open grassy places at an elevation of about 4000 feet. It is to this last statement that we would particularly call attention, as we may from it conclude that A. Fannini will be almost, if not quite, hardy in England. Mr. Adlam states that it is as hardy as A. japonica. There is always the danger of giving a plant tropical treatment if we know nothing more about it than that it is a native of a tropical country; as, for instance, when Orchid cultivation was in its infancy all the kinds were treated as tropical plants, because they came from countries within the tropical circle. Those who have duplicates of this new Anemone should try one or two of them out of doors.

Hæmanthus coccineus is now flowering freely in the Cape house at Kew, where two very large pans crammed with stout bulbs have been for years most attractive specimens, both when in flower and when bearing their large tongue-shaped bright green foliage. A single bulb of this Hæmanthus makes a poor show by the side of these large panfuls, so that it is best to put about half a dozen bulbs in a pot to begin with, and then shift them on about every two years. The species of Hæmanthus belonging to the same group as H. natalensis, H. Catherinæ, and H. cinnabarinus flower more satisfactorily when allowed plenty of root room and a rich soil; but H. coccineus, H. albiflos, and others of the large-bulbed distichous-leaved section seem to prefer cramping treatment at the roots and a long dry rest after growth is finished. The above-named kinds thrive in a warm, sunny greenhouse, but there are also several which require a stove temperature, such as H. Kalbreyeri, which is a beautiful plant, though rather difficult to keep in health.

Phlox Drummondi is as well known as any annual in cultivation, but its magnificence is never seen unless when grown in large masses or beds, as, for instance, at Kew, where an enormous bed of it is now a perfect flame of colour, giving life and beauty to the wide expanse of lawn and other greenery in its neighbourhood. Phlox means flame, and certainly the aptness of the name is seen best in the bright crimson, scarlet, lilac, and rose-coloured flowers of P. Drummondi. Annuals such as this, and there are scores, make a grand display when grown in large masses, and we can imagine a garden of the greatest brilliancy and full of attraction if planted with a selection of them. There is one drawback to be considered in relation to annuals, and that is their being, as a rule, of short duration, and also easily injured by a spell of bad weather. Still, we know of few gardens where a good deal of space is devoted to handsome flowered annuals, and these when in full bloom

are worth a long journey to see. Sown or planted over collections of hardy bulbous plants, the smaller kinds of summer flowering annuals might be enjoyed without doing harm to the resting bulbs, and they would serve the purpose of covering soil which is often left bare during summer.

European plants (*F. W.*).—There is no book so small as you require which contains descriptions of all European plants. Hooker's "Flora of the British Islands" (Macmillan & Co.) does not contain an unnecessary word, and it treats only on British plants, but it is a good pocketful. Hooker's "Botany for Beginners" is a useful little elementary work, which any bookseller will procure for you for three or four shillings. A flora of Europe would be a large and costly work.

Elymus glaucifolius (*W. M. H.*).—This is a glaucous-leaved variety of the common North American E. canadensis, and both of them are perfectly hardy in England. They frequent river sides and swampy ground, and therefore thrive best in this country in moist situations. We have seen fine tufts of the glaucous-leaved variety at Kew, where they are grown for the ornamental character of their foliage. The flower-spikes are nodding with long awns, but they are not borne freely in this country. E. arenarius is a British species, and is common along seashores, where, owing to its long creeping rhizomes, it is sometimes planted as a sand-binder. There are about two dozen species of Elymus, but none of them are of any value economically.

Gloxinia culture.—A correspondent asks how these plants should be treated from the seedling state till they have flowered and are ready for resting. Seeds should be sown in spring on light sandy soil in pans; they do not require any soil over them, but a pane of glass may be placed over the pan. The soil to be moistened from below, not watered overhead. When large enough to be handled with safety, the seedlings should be pricked into pans of sandy peat and leaf-mould and kept well watered. After this they may be transferred when ready into 2½-inch pots, using for them the same soils, but coarser than for seeds, and from these they may be removed into 5-inch pots, in which they will form nice plants and flower freely. To grow large specimens, it is best to begin early in the year with healthy young tubers of the previous season's growth. The soil should be rich, porous and light; plenty of water may be given whilst growth is vigorous, and the temperature should always be tropical, but never close and stuffy, the rust disease, so frequently seen on these plants, being the result of a close atmosphere combined with heavy syringing. A shelf near the glass in a stove is a good position for Gloxinias.—B.

Moths caught by Physianthus flowers.—On looking at a flowering plant of Physianthus albens growing in my glass porch, I find a number of moths caught in the blossoms, and there are at present two fluttering ineffectually to get free. How are they caught? It seems to be by the proboscis.—R. H. Wake, *Ballyhooly, Co. Cork.*

*** The moths which you sent caught in the Physianthus blossoms were undoubtedly caught by their probosces, which, apparently in trying to obtain the nectar from the flowers, were pinched and held by the base of the anthers, which are of a very peculiar formation. I have known instances before of moths being trapped in this manner by flowers, but being from home, I cannot refer to my books. I will reply more fully later on.—G. S. S.

Earwigs and Chrysanthemums.—Would some Chrysanthemum grower inform me of the best remedy for earwigs on Chrysanthemums, as I am much bothered with them this year? They eat all the young buds, and we have done everything to get rid of them, but without success.—Reader.

*** The best way to trap earwigs is by putting some dry Moss in 2½-inch pots, and invert the pots on the end of the sticks. Place at the same time some hollow Bean-stalks amongst the branches. The insects feed at night, and retreat towards morning into the hollow stalks and the flower-pots. Examine the traps every morning, and shake the insects into a vessel of hot water.—J. D.

Rose Garden.

PROPERTIES OF GOOD ROSES.

It is not always the so-called fullest Roses, as "D. T. F." observes, that are the best stayers. In order that Roses should last well in the cut state, depth rather than multiplicity of petals is the great essential. Perhaps it would not be too much to say that, granted a certain amount of fulness, a Rose is enduring in water in proportion to the depth of its petals—that is to say, the fewer short petals it possesses the longer it will continue in its state of greatest beauty. When the centre of a Rose is surrounded by innumerable very short petals, the base is made so wide that the outside petals are hardly able to meet over the flower, so that if the covering outside petals part ever so little, the hollow centre, and probably the green eye, are at once displayed, and, in spite of being exceedingly full, the Rose quickly becomes unsightly. Instances will readily occur, and a typical case is afforded by the Hybrid Perpetual Duchess of Connaught. A more generally known variety, however, is Merveille de Lyon, which can certainly not be called a thin Rose. As long as the outer petals overlap, it is a perfect white Rose; but in about ninety-nine out of every hundred flowers these petals fail to meet, and then—jealousy herself is not more green-eyed. There seems, unfortunately, reason to fear that the new Eclair, as well as the beautiful Heinrich Schultheis, are failures in this respect, as are frequently Emilie Hausburg and Duc de Montpensier, among other varieties. These Roses are built very wide at the base, and it is generally more than the outer petals can do to make both ends meet across the top. Time after time I have been tempted to take a beautiful bloom of Duc de Montpensier to a show, and invariably on arrival he has got himself "chucked out" for his ill-mannered staring. On the other hand, when Roses have petals deep enough not only to meet, but also to fold or twist together over the centre, as in Innocente Pirola, Jean Ducher, Maréchal Niel, Rosieriste Jacobs, &c., those Roses are pretty certain to remain in perfection for a considerable time. The Teas are among the deepest petalled Roses, and they nearly all last well in the cut state; while the most enduring of the Hybrid Perpetuals are also the deepest petalled Horace Vernet, Alfred Colomb, Marie Baumann, Madame Gabriel Luizet, &c. Again, Roses with few, but stout petals will often stand better than Roses with many thin ones. Thus, Madame Welch, whose petals are often few, but broad and thick, will generally last longer than Francisca Krüger, with its numberless flimsies; and stout-petalled Cannes la Coquette will almost invariably outlast its thinner-petalled parent, La France.

The most certain way, however, to ensure Roses lasting well when cut is to afford the plants the best and most liberal culture. Fine substantial blooms will long outlast smaller, even if equally bright and fresh, flowers when placed in water, and will retain the colour better as well. For though all the reds that have much blue in them, such as Antoine Ducher, Cheshunt Hybrid, Comtesse d'Oxford, Madame C. Joigneaux, Maurice Bernardin, Nardy Frères, Pierre Notting, &c., will begin to look dingy anyway soon after being cut, yet when they are exceptionally well grown, there is just a chance tha they may for a time be lighted up by a brigh flush.

Not that good cultivation alone is a guarantee for the satisfactory endurance of Roses in water, for the time of day and the state of the atmosphere when the operation of cutting is performed may be points of vital importance. If in hot, bright, sunny weather Roses are cut about midday, there is small chance of their being in good condition by the next morning; while, if in addition to the hot sun, there be also a drying wind, it will be impossible to get blooms (albeit of first-rate quality) into the house before they will have begun to "flop," a process of collapse which not even the instant seclusion of a cool cellar seems able to check. In damp or cool weather Roses will last if gathered at any time; but in hot, and especially in hot windy weather the only safe times to cut Roses are the very early morning and late evening.

Is it possible that the law of compensation is to prove so rigid as to admit only of altering the distribution of qualities without augmenting the sum? We must hope not. But yet it looks as if there was considerable resistance to be overcome. As "D. T. F." points out, there seems a tendency that the development of some quality on the one hand be counterbalanced by the loss or reduction of another quality elsewhere, as though there were a fixed sum of excellences in a plant which could not be exceeded—so much form, so much colour, vigour, size, profusion, &c., the elaboration of any one of which must be effected at the expense of the others. At any rate, one of our most mildew-proof Roses is certainly not particularly attractive; several of our grandest flowers seldom appear in the autumn, and some of the most perfect in form are the weakest in constitution. Mary Bennett, for instance, is a very lovely Rose, but I sincerely hope someone is getting on with it better than I am, or it will very soon be extinct.

The suggestion to defer the award of a certificate to a new Rose until the judges have seen the plants growing is good, but impracticable. The judges are generally exhibitors, and exhibitors have little spare time during the showing season to go up and down the country to inspect seedlings in various gardens. The National Rose Society go as near as they can by demanding that a ground plant shall be shown with the cut blooms, and, with careful judges, this should be found sufficient to answer the purpose.

"D. T. F." comments on the inclusion, in the National Rose Society's illustrations of form, of Souvenir de la Malmaison. Was not the perfection of guidance, philosophy, and friendship supposed to lie in the pointing out of what to eat, drink, and avoid? I always thought this last was the vitally important office of the fifth plate in the "Illustrated Rose Catalogue."

A propos of Roses that bloom better in autumn than in summer, this seems especially to be a characteristic of Bourbon blood. Frequently Souvenir de la Malmaison, Sombreuil, &c., produce wretched summer flowers, and then in autumn are among the finest in the garden. Boule de Neige often flowers better in autumn than in July; and all the Gloire de Dijon family are better and purer in colour, at any rate, during the autumn than in early summer.

I hope "D. T. F." will maintain his crusade against the distributors of consumptive varieties, and that we may soon find our new Roses demanding some of those glowing French superlatives accurately to describe their constitutions and continuity of blooming as well as their flowers. T. W. G.

Flower Garden.

VERBASCUM OLYMPICUM.

Some of the more important biennials, Foxgloves, and, still more notably, the larger Mulleins, have in their short lives two distinct seasons of beauty. The first when the young plant, within its first year of life, has thrown all its strength into the great rosette of foliage; the second, when the garnered vigour has been expended in building up the stately flower-spike. The engraving shows the Olympian Mullein in the first state, when its leaves, of palest grey-green velvet, are in their young prime. A plant that has passed midsummer in this state will probably so remain till next spring, the grand circle of leaves, 3 feet to 4 feet in diameter, growing a little more, but retaining its perfect appearance till well into the winter. Frost will destroy the outer leaves, but they will be renewed when the warmer days come, to be followed by the great branching stem, laden with sulphur-coloured flowers.

Foliage of Olympian Mullein (Verbascum olympicum). Engraved for The Garden from a photograph.

Ranunculus Marigolds.—By this term I mean our common double Marigolds—pot Marigolds as they are termed in the seed lists. When walking through the Botanic Gardens at Chelsea a few days ago I noticed that Mr. Moore has this year a very fine strain of these Marigolds of the type of the well known Meteor, but smaller in size, more compact, and of various hues of colour, from delicate primrose and creamy white to a rich deep orange. It might have been that the nature of the soil affected the size of the flowers, but their exquisite form and compactness made them perfect models. All these Ranunculus Marigolds are very showy and most useful in the garden, but they should not be planted in too rich soil, or they are in danger of becoming coarse, and the plants should not be allowed to seed. As soon as the flowers decay they should be picked off; this leads to the production of other flowers, and a good succession of bloom is thus obtained. There are some pretty single varieties also. A few years ago one of the Italian seed firms sent out a collection, a few of them at least being very pretty. They are found by gardeners to be very useful for cutting from. Self-sown seedlings will sometimes come with marked distinctness of character, and it is a good plan to save a few seeds from the very best, rooting up and casting the others away.—R. D.

Dietes tricolor.—I never saw this plant in blossom till last week. It is one of the most striking flowers in my garden, and I was quite surprised with its beauty. No other Dietes that I know anything about can be compared to it for a moment. It does not seem to blossom so freely as its congeners. What an odd thing it is that flowers are often scanty bloomers if they are excessively beautiful; it is as though they felt they had some right to be shy. I will send you the next specimen I have, so that you may see it. It might well have a place in your picture gallery.—H. Ewbank, *Ryde*.

Sweet Sultan (Centaurea moschata).—Amongst the varieties of Sweet Sultan, the yellow form is of so pleasing a colour as to deserve far greater attention than it receives. It is rarely seen in gardens of good repute, though occasionally met with amidst collections of cut flowers at floral exhibitions. Some object to yellow flowers in any great quantity, but the particular shade of colour in this plant does not make it too obtrusive. Sown under shelter and properly transplanted into the open ground it succeeds easily and well, being a reputed hardy biennial. As it is a Persian plant, a favourable sunny site should at all times be selected. The purple, white, and yellow forms make together a fine contrast.—W. Earley.

THE BEST CARNATIONS AND PICOTEES.

Of these we have a few blooms still on outdoor plants, and very bright in colour they are, though somewhat small in size. Our earliest blooms were open on July 1, and it is now the last week in August; therefore, we have had eight weeks of flake and bizarre Carnations; also edged Picotees in abundance, and scattered blooms of the perpetual flowering Carnations all the year round. As regards raising new varieties during the past season, but little progress has been made. The northern growers have a keen eye to anything new and good, but they will not part with good old sorts until new ones have established their claim to pre-eminence. Beginning with scarlet bizarres, we still place Admiral Curzon first. It was raised forty-two years ago, and we have plants of it now quite healthy and vigorous. It is always shown well by Mr. Robert Lord at Manchester. The only new scarlet bizarre shown in the north this year was Robert Houlgrave (Barlow), a very promising variety, in which the scarlet and maroon colours are very rich and well set off by a sufficiency of clear white. Mr. Robert Lord also again brought out Mercury in his stand of twelve. I have discarded it and grow Mars by the same raiser, the late Mr. J. D. Hextall. Tom Power (Dodwell) is a good and distinct variety.

In the crimson bizarres, Master Fred, raised by Mr. Hewitt, of Chesterfield, a few years ago, has rapidly taken the lead; its flowers are large in size and of a rich crimson, but the petals are not of good form. I exhibited a very richly coloured variety, Duc d'Aumale, at the National Society's meeting at South Kensington; if it maintains its promise and is sufficiently full, it will be an acquisition. Mr. Lord exhibited J. D. Hextall (Simonite) and John Harland (Adams) in his collection, but both of them have degenerated in the south.

The pink and purple bizarres sadly need renovating. The best variety we had this year was Mrs. Gorton (Dodwell). William Skirving (Gorton) was the best two or three years ago, but it also has degenerated; from a dozen plants I could not cut a good bloom. To make up our number of blooms we had to fall back upon good old Sarah Payne (Ward), a variety raised at Woolwich forty years ago. It is quite distinct from any other. It seems more difficult to obtain a good purple flake than a variety of any other section. James Douglas (Simonite) is still by far the best in this class. I saw it in flower in the raiser's garden in 1875, and it was sent out in 1876. I have grown it every year since that time, and it is still as vigorous in constitution as ever it was. Besides this, Squire Meynell (Brabbin) and Mayor of Nottingham were the best varieties shown in the north; the first named was raised in 1832, and it still retains its vigour. I have raised some purple flakes of which I thought highly in the seedling bed, but after being propagated they have disappointed me. Squire Whitbourn (Dodwell) promised well, but that promise has not been maintained.

In scarlet flakes, Sportsman (Hedderley) must again be placed first on the list; it was exhibited in collections both by Mr. Lord and Mr. Simonite. It is really as old as Admiral Curzon, having originated as a sport from that variety in 1855. Henry Cannell (Dodwell) was well shown in the north this year. Matador (Abercrombie) was also in good colour in the south. It is, I think, a better flower than Figaro by the same raiser, and sent out from the Royal Nurseries, Slough, about the same time. John Ball (Dodwell) is also a good scarlet flake. In rose flakes it will be difficult to surpass Rob Roy (Gorton). As shown by Mr. Turner, it was simply grand in form and markings. Tim Bobbin and Robin Hood, by the same raiser, are both first rate. Sybil (Holmes) still holds a high place as the earliest, if not the best. Jessica (Turner) is also very fine in its way; it flowers late and holds a high place in its class. Good old John Keet and James Merryweather, both of which held the highest position for many years, are now fairly beaten.

Picotees.—Passing to these, we have nothing in the way of heavy red-edged flowers to equal, let alone surpass, well-known varieties such as Brunette (Kirtland), a superb sort, dwarf in habit, but having large clear white flowers with broad deep red or crimson edges. John Smith (Bower) is also a very refined flower of a paler red. This was shown well by Mr. Lord in the north, and the

first named by Mr. Helliwell. Mr. Simonite exhibited Princess of Wales (Fellowes), which I like best of all the heavy red-edged varieties. In the light-edged red class Thomas William (Flowdy) has kept well to the front, even more so this year than it has done previously. It is not such a refined flower, however, as Mrs. Gorton, which was also well shown at Manchester by Mr. Simonite. Mr. Lord had superb blooms of Thomas William. Dr. Horner, raised by the Rev. F. D. Horner, and which obtained a first-class certificate from the National Society in London last year, is a very fine flower, and may displace the other two named. Mrs. Bower and Clara have had their day. They were highly esteemed some years ago, but their glory has departed. In heavy-edged purple varieties, Catherine (Fellowes) has broad, well formed petals, with a broad edge of bright purple; the white is also very pure. Juliette, by the same raiser, has a medium purple edge and flowers of exquisite form. These will doubtless be sent out by Mr. Turner. The best of the older varieties, as proved by this year's experience, are Muriel, Mrs. Chancellor, and Zerlina; the last was raised by Mr. Robert Lord, and shown well by him at Manchester on the 14th August. Of light purple-edged Picotees, the best have sadly degenerated in our collections; it is therefore with pleasure I have to note a good variety, viz., Mrs. Nicholay (Fellowes), the flowers of which are large, well formed, and quite distinct. Clara Penson (Wilmer) was such a grand flower when first exhibited, that it was a disappointment to find that it did not maintain its character the second year. Her Majesty (Addis) improved after the first year. Ann Lord and Nymph are the best of Mr. Lord's flowers, and Jessie (Turner) is large and fine; we have shown it on our winning stands for years.

Heavy rose and scarlet edges have received a startling addition in Duchess (Fellowes), a very large flower, exhibited in fine form on the 10th August by Mr. Turner, of Slough. The white in this variety is very pure and the edge well defined, heavily edged scarlet. Mrs. Sharp (Sharp) is also a good addition to this class; it was shown well at Manchester, but not good enough to beat a lovely bloom of Fanny Helen (Niven) shown by Mr. Lord. Constance Heron is a distinct and fine variety with a scarlet edge. Royal Visit and Edith D'Ombrain are superb kinds when we can get vigour into them, but that we have failed to do for two or three seasons. In the light rose or scarlet-edged class, Maud (Fellowes) has good breadth of petals, and is altogether a promising variety. Mrs. Turner (Fellowes) is medium scarlet, that is, the edge cannot be classed with either; it has broad, well-formed petals, what the fanciers term smooth, and the white is pure. Orlando (Fellowes) makes up a good trio from that raiser in this section. It has a light edge, and the flowers are very large and distinct. Favourite (Liddington) has again held a high position; this variety went to the top of the class at a bound, and not only stands premier in its own class, but is generally the best Picotee in any exhibition in which it is shown. Ethel is generally very good, and Mrs. Alcroft has always held a high position. Evelyn (Fellowes) is also a good full flower.

Of yellow ground Picotees, no new varieties have been exhibited recently, except my own seedlings. Annie Douglas is a heavy rose edge; but the edge is not solid like Duchess or Mrs. Sharp, but a margin of bars or short lines closely placed together; the yellow is rich and clear, and the flowers are very large. It has received three first-class certificates this year—the first at the Crystal Palace, on July 3, and the last at South Kensington, on August 10. Agnes Chambers has a well defined light red edge, and neither spot nor bar defaces the clear yellow ground; this has received two first-class certificates. Almira is clear yellow, but has not a Picotee edge; the point of each petal is singularly marked with red lines. From the same batch of seedlings three varieties have been selected, with a buff or terra-cotta ground colour, edged with scarlet and crimson. Fancy Carnations and Picotees have taken, as they deserve to do, a prominent position—at least in the south. Northern growers seem to despise them, as only three competitors came forward to claim the prize for twelve, while in the south no fewer than eleven amateurs competed for that number of blooms, and a considerable number in the class for twenty-four blooms, making altogether a very fine exhibition of this type of Carnation.

Those who are saving seeds should carefully remove the decayed petals as soon as sufficiently decayed, otherwise they will sometimes cause the immature seed-pods to rot. I find the only safe way to ripen seeds is to keep the plants under glass, so as to protect them from wet—air being admitted abundantly night and day. They are apt to become infested with green fly, but that can be destroyed by fumigation. When the plants are out of doors green fly does them no harm, and layers are always best from plants out of doors, whether in pots or planted out. The best way in which to treat any choice seedlings that have flowered in the ground for the first time is to dig them up and pot them. Layers root much more freely in this prepared potting compost than in anything else. The pots containing these plants should be placed for a week or ten days in a frame kept comparatively close by day, but on a calm, dewy night I would pull the lights quite off in order that the leaves may be laden with dew in the morning. If the sun came out hot, as it does frequently in August, the lights should be placed over the plants, tilted at the back and shaded, removing them again at night. In the case of established plants in pots, when the layers are put down they are placed out of doors in an open place, but sheltered, if possible, from high winds. The last week in September or first in October is a good time to take off layers and repot them, and it is by far the best time to purchase any new varieties needed, or to repair losses that the collection may have sustained. I have named all the best of the varieties that I intend to grow next season. It is better to grow a dozen plants of a good variety than a dozen varieties which may be distinct, but which cannot be depended upon to produce good blooms. Jas. Douglas.

Double Larkspurs.—Amongst the many forms of improved garden flowers, the annual Delphiniums, or Larkspurs, are well worthy the attention of all who delight in growing good annuals. Not only have the size and form been improved, but the colours are more intensified and increased. Whenever Delphiniums are sown or seedlings transplanted in the open border, protection must be given against slugs, as they are extremely partial to them, and will otherwise eat them down close to the ground.—W. Earley.

Phlox Drummondi var. Cardinal.—This is the deepest and richest coloured of all the annual Phloxes, constituting, when in a mass, a rich glow of deep crimson such as one seldom sees equalled. It occasionally produces flowers of different hues, some of which are heavily shaded with purple. Varieties of Phlox Drummondi, to be done well, should be sown in a cool house, and, when the plants are large enough, they should be potted up singly into 3-inch pots. Thus treated they get well rooted, and when planted out soon grow into strong free-blooming plants.—A.

The Calystegias.—These are very beautiful plants during July and August, but the worst of them is that they are rather wild and rampant in their growth; and it is necessary every autumn to dig up a large quantity of their creeping Twitch-like roots, so as to keep them within bounds. They are regular "Morning Glories," and are shorn of their beauty by mid-day; but they are lovely for the decoration of a breakfast table or morning room. One of the prettiest and most rarely grown species is C. oculata, a kind which produces white flowers shaded with purple in the centre. C. incarnata, which has pale blush flowers, forms a striking object when trained up two or three tall Scarlet Runner stakes; and the same plan may be pursued with advantage with C. dahurica, which has large rosy pink blooms, streaked with white, much resembling the beautiful British seashore weed, C. Soldanella, which deserves a corner to itself in every good herbaceous collection.—H.

HARDY PLANT CUTTINGS.

A common cause of failure in striking hardy plant cuttings is excessive moisture in different forms, and especially from the soil being made too wet. It is scarcely possible to lay down a general rule, for some cuttings root more readily in very moist earth, whilst others, such as the Cruciferæ, make quicker progress if it is kept somewhat dry. The black decay which sets in on the stems and in patches, often just on a line with the surface of the soil and frequently higher up, is what many of us find most trying, for it often occurs when there are healthy calluses and roots forming. If the parts are examined before any of the leaves are disturbed, in nine cases out of ten it will be found something has been touching the part, and causing particles of water to lodge there. Many simple causes exist, such as we are apt to overlook, which quickly and effectually rot the soft material, which from its abnormal condition is very susceptible to injury. For instance, cuttings with down or hairs on the stems, if put close to the pot's sides above the surface, are pretty sure to rot at the point of contact; those of Onosma taurieum and Salvias and such like will not endure moisture so held, and black spots of decay will occur all the time a good callus is forming. I like to fix such cuttings with their heels touching the pot's sides, keeping them erect, so that at the surface they are half-an-inch or more from the side, and it is safer not to put too many in one pot. Making the soil firm in some degree is a preventive against the retention of too much moisture, but if the compost is gritty the tender skin of the cuttings is liable to be bruised, which may cause their death. It should be the aim to get cuttings rooted quickly, and those which are inserted in pots ought not by any means to have their pots plunged. Sunshine is our best friend in this matter if we utilise it. Cuttings which have stood in the sun have always the best roots on the sunny side; of course, I do not mean to say that cuttings should be inserted and placed at once in the hot sunshine, but after a day or two those of hardy and sun-loving plants may be set there, and the result will be better than if they were coddled in cool and shady places.

J. W.

Haplocarpa Leichtlini.—I thought as you did (page 186) about the hardiness of this plant on first seeing it. In fact, it came to me with a character to that effect. But I am quite sure from the way in which it behaved under the first touch of winter that it is not hardy at all. I should advise any possessors of this very pretty plant to give it some protection in winter if they do not want to lose it.—H. Ewbank, *Ryde*.

Artemisia annua.—For symmetry of growth and delicacy of foliage the annual Siberian Artemisia as a border plant has few rivals, especially where grown in rich soil. The peculiarly intense dark green of its leaves proves exceptionally refreshing to the eye during such a dry period as we have lately experienced. It may be difficult at times to secure good seed, so seldom is the plant grown; when procurable, however, it is very easily raised, and the young plants transplant readily, quickly forming handsome pyramids some 5 feet in height, clothed with foliage to the ground. Like Artemisias generally, the flowers are by no means ornamental.—W. Earley.

Pentstemons.—These make superb border plants at the present season, and deserve a greatly increased popularity. The improvement that has taken place in the quality of Pentstemons during recent years can scarcely be imagined. I have now in full flower a large bed containing some two hundred plants of Pentstemons raised from seed early in the spring of last year. They all flowered strongly last autumn, and with scarcely the loss of a plant during the winter. They have now thrown up quantities of young growths that have

been all through June, and will probably be all the autumn a mass of flowers. Their colours vary greatly; among them are scarlet, purple, pink, white, and intermediate shades of all kinds; their blooms, too, are large in size and the spikes long. —B.

VARIEGATED-LEAVED PLANTS.

We have not as yet taken half the advantage which will be eventually derived from the large numbers of fine variegated shrubs which are now at command, both deciduous and evergreen; but the knowledge of them, and with it the taste for their culture, and the true feeling of the various ways in which they may become so immensely valuable in varying the effects and imparting gradations of light and dark to our shrubberies, is becoming more fully developed. The variegated Eurya latifolia, with its long pointed leaves of mingled cream, grey, and green, is a very magnificent plant, inviting the attention of all such as wish to make a really grand addition to their conservatories. Ivies grown as shrubs or standards, especially the variegated sorts, are a treasure store in themselves, while for fine semi-tropical effect, the noble leaf-blades of the variegated New Zealand Flax (Phormium tenax variegatum) forms a grand addition to Yuccas and other stiff-leaved Aloe-like plants. With this the variegated Yucca filamentosa would group admirably. Scrophularia nodosa, with its white-bordered leaves and young sprays of golden yellow, is also very pretty; while the leaves of the variegated Hemerocallis, an old garden favourite, are so beautifully marked, that a plant of it would form a fine object anywhere. There is also the smaller double-flowered variety, the leaves of which are conspicuously streaked with clear white, which would be very attractive wherever there is room for it. Acanthopanax variegatum forms a very charming little bush of mingled creamy white and pea green. Then there is Coprosma Baueriana, an elegant shrub with golden-hued leaves of clean and regular form, marked by a spot of bright green in the centre. Euonymus latifolius and E. radicans are both of them attractive shrubs, and most useful in producing a special kind of effect; the former has leaves of pale cream colour marked very distinctly with two shades of green, some of the leaves remaining entirely cream coloured. The leaves of E. radicans are more regularly marked with cream colour. There are also several other kinds of Euonymus, all more or less beautiful as variegated shrubs. Of the variegated Hollies there is an endless variety, and no shrub or tree with variegated leaves can surpass the best gold and silver forms.

As a ground-covering foliage, where a low growth is alone desirable, what can be finer than the variegated Coltsfoot (Tussilago Farfara), so finely edged and brightly splashed with white as are some of the best variegated varieties? For spreading over rock-work in favourable positions what can be more desirable than Sedum Sieboldi, each leaf of delicate pale green blotched with a circlet of soft cream colour in the centre? And then the common old-fashioned border flower, Polemonium cæruleum (Jacob's Ladder, variegated variety), is as pretty and bright an object as can be conceived. Each of its elegant pinnate leaves is edged with a clear sparkling border of white, making the foliage even more attractive than its pretty crown of soft blue flowers. These are but a few of the many variegated-leaved hardy plants which are available to everyone disposed to make use of them. N.

Preparations for spring.—Now is the season to make preparation for spring flowers. Many seedlings, such as Myosotis dissitiflora, will need transplanting from seed-beds into rows about 6 inches apart, so that they may make nice clumps by October when transplanted to beds with bulbs for spring. Daisies, red and white, may be parted and replanted, Polyanthuses and Primroses, if they were not attended to in spring, may now be divided, and old clumps of Forget-me nots of various kinds, if pulled to pieces and dibbled in lines in shaded places, will make good plants. Several kinds of biennials, or rather annuals, sown now will flower freely next spring. The pretty Silene pendula compacta is one of the best for producing a mass of rosy pink flowers. Limnanthes Douglasi makes a good companion, with pale straw-coloured blooms; and Saponaria calabrica, a bright rosy pink, is very pretty. Many other annuals are hardy enough to stand the winter in a small state that are sure to suffer from even slight frost if sown too soon. I find it best to sow on rather poor soil, in a dry, well-drained place, such as a sloping bank or border. The Godetias, Gilias, Phlox Drummondi, and similar flowers will survive ordinary winters and make a fine display of bloom at a time when gardens are frequently destitute of much variety; and in localities where the winters are too severe to admit of open-air culture, many of these plants, if sown in a box and wintered in a cold pit, may be put out very early in spring, and make a fine display in early summer.—J. G. H.

NOTES ON STOCKS.

The summer-blooming Stocks being now on the wane, seem to remind one that the time for sowing the Brompton, Queen, and intermediate Stocks is at hand. There is always a risk about the two former, as a wet and cold winter or severe frost invariably decimates them, but those plants that stand and flower are very beautiful in the early summer. The Queen and Brompton Stocks are closely allied, and are probably only varieties of the same species; but it is curious to note that the seed of the white Brompton is pale in colour, that of the white Queen quite dark. Old growers of the Stock distinguish the foliage of the Queen and Brompton Stocks in this manner. They assert that the under portion of the leaf of the Queen Stock is rough and woolly; that of the Brompton Stock is as smooth on the under part as on the upper. Of the Queen Stock there are three colours—purple, scarlet, and white; and of the Brompton Stock the same number, with the addition of a selected crimson variety of great beauty, but somewhat difficult to perpetuate. Both of these types (if distinct enough to be regarded so) are really biennials, and the seed should be sown at the end of July in beds, and the plants, I need scarcely remark, should be transplanted to the open ground in the autumn.

The difficulty of wintering the Brompton Stocks operates to deter many from attempting their cultivation. Even in the case of an unusually mild winter many will die. A well-drained subsoil and a porous surface soil will suit them best. Shelter from biting frosts and nipping winds is of great service. A second transplantation has been tried with considerable success, the last one made about December. The intermediate Stocks are much used for cultivation in pots, to bloom in the spring and early summer, and are very useful for decorative purposes. The seed should be sown in August, and the plants, when large enough, placed in 6-inch pots, three plants in a pot, rich soil being used. They should then be placed out of doors in the shade, kept well watered in dry weather, and finally wintered in a cold frame, and drafted into the conservatory or greenhouse as they come into flower.

There is a very pretty variety of the intermediate Stock, somewhat taller in growth than the scarlet one, and forms capital pyramids of white flowers. Some of the dwarf German bouquet Stocks imported from Germany by our seedsmen make very good intermediate Stocks, being dwarf and compact in growth, and well adapted for pot culture. One, of a bright crimson hue, has a very dwarf and yet vigorous habit, and flowers in great profusion. The East Lothian intermediate Stocks, as they are termed, are in reality mainly used for late summer blooming, when they are very effective. They are sown in the usual way about the end of March, planted out at the end of May when some 3 inches or 4 inches in height, and bloom finely through August and September, and even later, as they throw out numbers of side shoots that produce spikes of flowers. Thus, by using the autumn-sown intermediate Stocks for early blooming, the ordinary large-flowering German Ten-week Stock for summer flowering, and the later East Lothian intermediate Stocks for late summer work, Stocks can be had in flower eight or nine months of the year without intermission. Q.

AMERICAN LILIES AT HOME.

Writing to the Trenton Natural History Society's journal, Mr. Ernst Volk says, respecting some of the American wild plants:—

"Among the most beautiful wild flowers growing around Trenton, N.J., are two species of the great Lily family, which, as Linnæus says, have no poor relations. These are Lilium canadense and L. superbum, the bell-shaped Canadian and the brilliant Turk's-cap Lily. L. canadense blooms about the middle of June. It has a bell-shaped, canary-yellow flower, varying to coral-red. The thick, scaly bulb is annual, and scarcely half an inch long, although it sends out runners 5 inches or 6 inches in length. In shaded places it is only about 2 inches under ground, but in sunny spots 4 inches to 5 inches. The Lily will travel slowly, as the runners produce new bulbs in every direction. I have found, in a space 18 inches square five stems, the bulbs being connected by the runners. In sunny places the stems grow to a height of 1½ feet to 2 feet; among bushes and on the borders of woods, to 6 feet. In a single instance I found a stem 9 feet 8 inches high, with fourteen flowers in full bloom. In the sun the flowers are seldom more than three on one stem, but their colour is then brilliant. In the shade the blossoms may be ten or fifteen, but the colour is usually dull. L. superbum has bulbs so closely resembling those of L. canadense, that a good judge would be needed to distinguish them, but they are perennial. The stems vary from 6 feet to 10 feet or 12 feet in height. The flower-buds are round, those of L. canadense being triangular. This Lily prefers a bushy place, so that the stem may be somewhat shaded. Four years ago I planted six bulbs of L. superbum in my garden, and the stems have each year averaged a height of 10 feet to 12 feet, with fifteen to twenty flowers in a cluster.

"Either of these Lilies may be successfully transplanted while in bloom by cutting off the stem about 2 inches above the bulb, the new stems appearing the following spring. Once planted, they need no further care. They steadily increase, and their exquisite bloom soon illuminates the whole garden."

Respecting Lobelia cardinalis, he says, "This plant needs no protection in the winter, as I accidentally proved by unintentionally omitting to cover some of my plants, which reappeared in the spring, while the protected ones all died. The wild Lobelia can be obtained and cultivated by root or seed. If the roots are taken, remove as much earth with them as possible, after cutting off all the stems. Young plants thrive best. They should not be planted deeper than found. Before the winter sets in they become established. The seeds ripen by the middle of October. Plants raised from the seed will not flower the first season."

The Comfreys.—The Symphytums, or Comfreys, are most valuable for the shrubbery and wild garden. They grow freely—in fact, rampantly, under trees and elsewhere, and are good and showy plants. S. asperrimum is the tallest, growing to 6 feet, and has red flowers changing to blue. S. caucasicum (2 feet), white flowers, and S. tauricum (3 feet), also with white flowers, are all fitted for naturalisation. S. bohemicum, with brilliant red flowers, only growing to 2 feet, is worthy of a place in the border, as is the variegated form of S. officinale (a handsome plant), and perhaps S. tuberosum, with yellow flowers, though I am not certain that the latter may not prove too rampant.—O.

Showy Mallow-worts.—The great beauty of this family has been in some of the collections of herbaceous and alpine plants around London this day season. We allude more particularly to such plants as Sida malvæflora and incarnata, Malva Alcea, and the British M. moschata with its white variety, and the Lavateras thuringiaca and unguiculata, the latter one of the finest herbaceous plants in flower at the present time, a good specimen of which may be seen at Kew. It grows about 6 feet high, and has large bright rose-coloured flowers. The flowers of these are generally

of a light clear rose colour, and are produced in dense masses, and the plants are hardy and vigorous. They are highly suited for the embellishment of borders as well as for the wild garden.—G.

THE CLAMMY COLUMBINE.

(AQUILEGIA VISCOSA.)

COLUMBINES may be found in most gardens, and where allowed to hybridise at will the result is an effective mass of well varied and striking colours; they cross so freely that it is hardly possible to keep two kinds true to name if allowed to grow in close proximity; indeed, if grown in the same garden, the chances are that in the seedlings some alteration will have taken place. Where distinct kinds are desired the better plan is to choose a few of the most marked, and grow them well apart; but if such as vulgaris, canadensis, chrysantha, and others of the robust kinds be cultivated, the progeny will be doubtful. Even if cærulea, a most distinct kind, grows along with chrysantha, the blue will be found to mix with the yellow, thus deteriorating the appearance of the flowers. In most soils Columbines appear to be short-lived plants; a renewal, therefore, every two or three years will be found to be beneficial, as well as necessary. The plant here illustrated, along with which may be included A. alpina, pyrenaica, viridiflora, &c., belongs to a dwarf growing section, very useful for cultivation on low rockwork. It seldom grows more than 1 foot high, and its flowers, which are purple, are distinct from those of any other kind. The leaves are clammy and covered with long hairs. It flowers in May and June, and is a native of Southern Europe. K.

Centaurea babylonica.—Among the Centaureas by far the most remarkable, to my mind, is the very silvery-leaved C. babylonica. It is quite hardy, and when planted in good ground, sends up strong shoots, clad with yellow flowers, to a height of 10 feet or 12 feet. The bloom, which continues from July to September, is not by any means so attractive as the leaves, but the plant is at all times picturesque. In groups, or, still better, isolated, on rough or undulating parts of pleasure-grounds, it has a very fine effect. When the leaves alone are seen, it is worthy of a place among the finest hardy variegated subjects, but when it sends up its strong stems, it is a fit associate for Hollyhocks and the very tallest herbaceous plants.—O.

SHORT NOTES.—FLOWER.

Nicotiana affinis (*G. P. Flemwell*).—There is certainly a great difference between the specimens you send, the larger flowered kind being much superior to the other. Are you satisfied that it is not the result of superior vigour of the plant induced by an extra dose of manure given to its roots?

Lasthenia glabrata.—This hardy annual composite has been flowering freely for these past two months in my garden from spring-sown seeds, and is now a perfect mass of rich orange-yellow blossoms. It grows about 15 inches in height. If sown in autumn, patches of it come in along with early Phloxes, Alyssum, Iberis, Wallflowers, &c.; it certainly far surpasses any of the Doronicums, which often find a place in such borders.—T.

Autumn-sown Cornflower.—Few persons seem to have any just idea of the value of Centaurea Cyanus as an early summer plant when sown in autumn. The variety in the colours of the pretty flowers is quite charming. The blooms are among the best for cutting. Self-sown plants, or those sown in the autumn, make a lovely display on strong soils. No garden in which flowers are valued in the early summer should be without a mass or a few tufts of it.—W.

The Rouen Violet (Viola rothomagensis).—This pretty Violet has been very beautiful with me this season. It belongs to the tricolor section, and has low-growing creeping stems, from which spring numerous small, long, narrow-petalled purple and white flowers. It much resembles another pretty species which I had some years since, under the name of V. palmensis, which is, I believe, a native of Sicily.—H.

The Sycamore-leaved Buttercup (Ranunculus platanifolius).—Few plants were more beautiful with me during early summer than this pretty Buttercup. It is a tall-growing species with large handsome dark green leaves and a stem from 1 foot to 2 feet high, bearing numerous large snow-white flowers. My plants, which lasted in bloom nearly a month, came from the Dolomite Mountains, the home of another lovely white-flowered species, which is also growing well with me, though it has not yet blooomed, viz., R. Seguieri.—H.

Ononis fruticosa.—This handsome and neatly-habited plant is now in flower. It is seldom seen about London, though no doubt it was often planted in days gone by; but being a dwarf mountain shrub, it probably often perished from being associated with coarse subjects in plantations. It is suitable for grouping with the dwarfer American plants, for banks, for rockeries, or for planting alone on turf.

Agapanthus umbellatus out of doors.—I lately saw in a Surrey garden plants of this lovely old-fashioned Lily, that had stood out in the open ground all the winter, and which are now pushing up strongly. The soil is stiff clay; aspect east. I have somewhere read that this plant ought to be allowed to have plenty of light during the winter, but here I saw a fine lot that had been wintered in an ash-pit, and I was informed that thus treated they flower profusely every season. This Lily may be wintered successfully under the stage of a greenhouse, or even in a cold pit, and never fails to bloom freely during the summer-time.—C.

FRUIT GARDEN.

THE COLOUR OF GRAPES.

IF Grapes are ripe, colour is sure to be found in conjunction with high flavour and other good qualities, for it must be borne in mind that black Grapes get black before they are fully ripe. There seems to be no doubt either that high finish is a sure sign of vigour in the Vine; for that deep black colour and purple bloom is never, as far as my experience goes, found on weakly Vines, or in conjunction with a too heavy crop of fruit. I have seen Hamburgh Grapes ripe, yet nearly green, simply through allowing the Vines to carry an excessive crop. Two or three years ago I saw a house of Grapes, Hamburghs, belonging to an amateur, in which there was not one bunch that had even got as red as a Grizzly Frontignan, and many of the bunches had scarcely a tinge of colour about them at all, but remained green almost to the last. The berries tasted sweet, but that was the highest praise that could be given them—globules of sugar and water, for they could not be called fleshy. Considering the strength of the Vines, the crop was, however, the heaviest I ever saw. Every bunch had been allowed to remain, two and three on a shoot, and every Grape grower knows what that means. The berries had been thinned to some extent, but that was all. Great stress is laid by many upon light and air as colouring agents, and I certainly do not undervalue their importance in this respect; but the most thorough ventilation and exposure just when the Grapes begin to colour, as commonly practised, is of little avail if other matters have been neglected. Plenty of light and air, acting upon the foliage, without doubt promote a vigorous constitution in the plant, and indirectly materially assist the colouring process, but the mere action of either upon the fruit itself seems to be very unimportant indeed; otherwise, in fine and bright seasons we might expect the best-finished crops, but such is not by any means the case.

Black Grapes ripened in January are often quite as highly coloured as those ripened in summer and autumn. Varieties differ in regard to their colouring power, so to speak. The Black Hamburgh is susceptible of the deepest black and the densest bloom under favourable conditions; but it is oftener seen only red, which has encouraged a belief that there is a red Hamburgh, though in all probability no such variety exists. We have at least often seen "red" Hamburghs turn black under altered circumstances. The Muscat Hamburgh is another Grape which, among other bad qualities, has that of colouring indifferently. Mrs. Pince, too, frequently gets only red. I have this Grape here on its own roots, and grafted upon the Alicante and on Lady Downes. On the first it is simply bad as a setter and in colour. On the Alicante the bunches are invariably magnificent, except in colour, though better in this respect than on its own roots; but often reddish when the Grapes on the Alicante limb of the same Vine are quite black. On the Lady Downes stock the bunches are smaller and more cylindrical; but they always finish best and keep longest. On its own roots it has a high and delicious Muscat flavour, but it is less piquant on the other stocks. Mrs. Pince is, however, most erratic in this respect, for we have tested it at other places and on other stocks, and failed to detect the slightest Muscat flavour about it. West's St. Peter's is one of the best to colour, and takes on a singularly beautiful metallic lustre when well finished that no other Grape does. The Royal Ascot would appear to be a favourite in this respect also. Barbarossa, in some soils and situations, is a Grape which finishes exceedingly well, putting on the most extraordinary bloom I ever saw.

Among white Grapes perfect finish is even more uncommon than among the blacks. Taking the Muscat of Alexandria as the type of this section, how seldom do we see it of that deep yet transparent amber colour which indicates perfection and high flavour? Buckland's Sweetwater Grape is one that, as a rule, finishes well, and has a very taking colour when quite ripe. That magnificent Grape, the Golden Champion, is certainly worthy of its name but for the constitutional speck which affects the berries when just about ripe. I have had it, however, and seen it on several occasions without blemish. My experience is that it is a Grape which requires time and a somewhat dry atmosphere to finish it properly. It is at least a month later than the Black Hamburgh, and it will not bear hurrying. By far the best stock for it is the Muscat of Alexandria. Upon the whole, we are as yet in the dark to a great extent concerning the colour of both fruits and flowers. The directly operating agents in its production are a mystery, but it is a well-ascertained fact that the general health of the subject has much to do with the intensity or brilliancy of the hue, whatever it may be; and this should be constantly kept in mind by the Grape grower who would wish to secure a good sample; while he must not forget that his prospects, however fair at the commencement, may be blighted at the last by having too heavy a crop on the Vines, or by subjecting them to a high and hurrying temperature, which alone is sure to impair both weight and colour, and, I should add, flavour. CHEF.

Leaf-shaded Grapes.—My Vines under glass, not forced and of different kinds, have this year succeeded well. They are strong and vigorous in growth, well set with Grapes, which promise to be exceptionally large and heavy. The leaves on every Vine are very large and close and form a more or less compact shade over the Grapes. May I enquire whether it is good practice to remove as many leaves as may be required to admit light and sun to the Grapes, or whether the removal of such leaves would injure the growth of the Vine and check the full development of the Grapes?—ENQUIRER.

*** Your Grapes, according to your own showing, are in a very satisfactory condition, and will

no doubt colour well. If lateral growths have been allowed to crowd up to the glass and impede the circulation of air from the bottom to the top ventilators, shorten them by degrees, but on no account interfere with the main leaves, as Black Grapes always finish and keep best under a heavy covering of good foliage. White Grapes, on the other hand, colour best, *i.e.*, lay on that rich amber which every grower covets, but does not always attain where the bunches are indirectly exposed to sun and light. These Vines, therefore, be they Muscats or less valuable varieties, should be divested of all their lateral growths, provided the main leaves are good and not too close, to prevent the refracted rays from playing upon the berries. If the large leaves of which you speak completely shut out the sun, turn or tie them aside immediately over the bunches, but do not cut them out, as such a course would most likely check the Vines when steady progress is of importance. Why do Vines which are over-cropped, badly scalded, or infested with spider fail to colour their fruit? Simply because the foliage and the roots have received a rude check and cannot properly perform their functions. Be patient, give your Vines plenty of time, cut out all the remaining pieces of laterals down to the main buds as the bunches are cut, but carefully syringe and preserve every old leaf to feed and fill up the buds.—W. Coleman, *Eastnor Castle, Ledbury.*

GOOD STRAWBERRIES.

In our district, the north east of Ireland, we had this season no room for complaint as to deficiency of crop. We grow some ten or a dozen sorts, but were I limited to one, I would certainly grow Vicomtesse Héricart de Thury (Garibaldi). This variety I find is a large and sure cropper and hardy in constitution; our next is President, which is better flavoured than the preceding, but with us has the habit of odd ones dying off, particularly if too long in one place. Keen's Seedling and Duc de Malakoff we count of equal merit. Victoria we find to be a valuable sort rather late; its fruit is somewhat soft, but the flavour is almost equal to that of President, and the plants keep long in bearing. Sir J. Paxton with us scarcely merits the high encomiums usually awarded it, but as this is only my second year with it, I should not like to speak too definitely. Duke of Edinburgh is a high-coloured, good-flavoured, free-fruiting sort of considerable merit. Many of its fruits are very large, but very rough. For late use we rely on Elton Pine, a well-known variety largely grown on north borders for lengthening the supply. Its fruit is large, ovate, of a bright shining crimson where fully exposed, and agreeably sub-acid in flavour. We grow a few rows of Victoria alongside it on a north border, which we find to be most useful in helping us to keep up the supply until late in the autumn. The above refers to kinds which we grow for general use; for pot culture we now depend on Garibaldi and President. Of sorts not generally grown we have the Alpine and Hautbois, the varieties being Galande and Royal respectively. Few would grow or would recommend them to be grown largely, yet they have their own decided characteristics. The Hautbois flavour is much esteemed by some, although to my palate it is not altogether what I like. The Alpines, on account of their firm and high-coloured fruits, are useful for bottling whole. Both sorts well repay careful and kindly cultivation, and may be increased rapidly from runners, but some prefer raising stock of the Alpine from seed.

For securing good crops of fine fruit annually I prefer and would advocate working Strawberries on the three or four years system. It is well known that young plants produce the finest fruit, although if the nature of the soil on which they are growing is suitable to them they may do well for many years. President dies suddenly with us, and more so after the third year than earlier. Last season, for example, having a spell of drought, we lost many. Necessity, therefore, compels us to study carefully the means by which the best results are obtained. Thus we every third, and sometimes fourth, autumn select all the strongest runners, and plant them thinly in nursery beds until the following spring, when we plant them permanently in a specially prepared plot. The special preparation alluded to consists in a thorough deep digging early in winter, and in incorporating a good quantity of strong farmyard manure with the soil. In digging, the surface is left as rough as possible, and by planting time it moulders down into powder. We exercise special care in lifting the plants with good balls of earth attached to them; then in replanting we work in, in the first place, a good supply of pulverised soil, and give them a thorough firming. Under such treatment they receive no check whatever. Such plants, too, would bear a fairly good crop, but this we do not allow them to do the first season; on the contrary, we rigidly nip all runners and blooms off, and by autumn they are strong plants with plump crowns, a sure indication that they will fruit well the following year. It is from such plants that the best of early runners can be got for pots; we only allow one plant to furnish one runner, so as not to tax its energy too much. As we must of necessity keep our established plants we therefore have two plots filled with Strawberries in the one season, and as soon as the old plants are past fruiting we grub them up, and immediately plant the ground with Broccoli for late use. In planting Strawberries, for strong-growing sorts we make the lines 2½ feet apart and the plants 18 inches asunder, the dwarf growers being allowed 2 feet by 18 inches. These distances we find to suit them well.—S. Kevan, *Templepatrick.*

Aquilegia viscosa. Flowers purple.

Our Strawberry Crop.

The following varieties are grown in this garden, viz., Keen's Seedling, La Grosse Sucrée, Vicomtesse Héricart de Thury, Sir J. Paxton, President, Barnes' Prolific, Unser Fritz, Sir C. Napier, British Queen, Oxonian, and Loxford Hall. The best flavoured is British Queen, but its behaviour is so indifferent in other ways, that it is not worth the space which it occupies. Keen's Seedling is superior to all the others for sweetness. Between the flavour of La Grosse Sucrée and the Vicomtesse there is not much to choose. Sir J. Paxton and President are our favourites for dessert, as the others are too small, except Unser Fritz. The latter is a large, handsome fruit, but inferior in flavour to the two just named. It, however, withstands wet better, and is a free bearer. The Vicomtesse produces the greatest number of fruit of any we grow, but it is a question if President or Sir J. Paxton would not equal it in weight. Barnes' Prolific is much grown for market in this district—more so than any other, as it travels well. Its flavour is, however, inferior, in my estimation, to that of five or six others. It is said to be a first-rate cropper; with me it stands about fifth in this respect. I cannot say much of Oxonian from its behaviour here; and Sir C. Napier has no resemblance, except in foliage, to the one I knew under that name some years ago. The above sorts ripen pretty well in the order in which they are named. I am so pleased with Loxford Hall this year, that I intend to plant more of it. Our plants of this variety are 1 foot apart in the rows, which are 2 feet asunder, but if put 8 in. by 18 in. they would not be too thick. If it succeeds as well as it has done this year, its yield from the same space of ground will equal that of any kind in the garden. Our favourite mode of culture is to layer annually as many as we can and plant 1 foot distant in the row, cutting out the second year every alternate plant. We used at one time to allow the same distances apart, and plant three plants, triangle fashion, chopping two off as soon as the fruit was gathered; but as there was some amount of crowding when pots were introduced in which to layer the runners, we gave up the practice. Plants in their third year give but a poor return compared with those in their first year.—W. P. R., *Preston, Lancashire.*

Notes on Strawberry Culture.

After years of experience I am convinced that, in order to secure fine crops of Strawberries year

after year, three or four points in their culture must be attentively observed. In the first place, early runners must be secured with the least delay possible. As soon as they are sufficiently rooted, no time must be lost in getting them on to the ground they are intended to occupy. The plants must be encouraged in their growth during the autumn by keeping the surface of the ground frequently stirred with the Dutch hoe and free of weeds, and on the approach of winter let the plants be mulched with half rotten manure. By the early part of the following May, when the flower-spikes begin to appear, the mulching given in the early part of the previous winter will all have disappeared. As soon as the flowers are fairly open another mulching must be given, either of litter from the stables or litter in a half decayed state, which will keep the fruit clean during the process of ripening. Manure in a partially decayed state I find an excellent mulching. It prevents the ground from becoming dry and parched, and also keeps the roots cool. When the fruit is beginning to swell give the beds a thorough soaking with manure water, and this should be repeated every ten days if dry weather prevails until the last fruit is gathered. A very good plan to preserve the fruit from injury I have adopted with marked success is to tie it up with sticks and matting. This entails a little extra labour, but it pays before all the crop is gathered. I have about four sticks placed round each plant, and the bunches of fruit are supported by two strings run round each plant and fastened to the stakes. If wet weather sets in the fruit does not decay by lying on the ground. It is not damaged by workmen gathering the earliest ripened fruit; it prolongs the supply, and every berry comes to perfection. I strongly recommend the tying up of the fruit in this uncertain climate, especially those beds which supply the fruit for table. The most prolific Strawberry that I have met with, and which appears to be little known, is one I have by the name of Preston Seedling. I have never seen it mentioned in any catalogue, except Mr. Lovel's, of Driffield, from whom I received the plants two years ago. It bears very large fruit; though not handsome in shape is a most heavy cropper, and the flavour is tolerably good, though not first class. Runners planted last autumn on ground previously occupied with Potatoes have given us enormous crops of fruit this season; in fact, the crop of fruit on a plantation made last autumn has been heavier than on those two and three years old. Another useful Strawberry, for late use especially, is Filbert Pine. From this and Preston Seedling we gathered fruit for table until after the middle of August. The fruit of Filbert Pine is moderately large, conical shape, dark red, and fine rich aroma—the best late variety which has come under our notice. For upwards of twenty-five years we have been experimenting with Strawberries, and we strongly recommend Preston Seedling for quantity and Filbert Pine for quality.—Q. Read, *Thornbury, Sheffield.*

I should like to add my mite to the store of information you are collecting about Strawberries. I find that Vicomtesse Héricart de Thury is known under the name of Garibaldi in many places in the north. I have grown it many years and forced it in quantity, and have never known it to fail. One kind that I grew at Cliff Hall, near Darlington, many years since, called Ruby, raised by Mr. Nicholson, of Yarm, surpassed all for cropping that I ever knew. In the East Riding of Yorkshire Keen's Seedling always did well, also British Queen and Elton Pine. The soil was a dark sandy soil on gravel. I had the ground trenched two spades deep and well manured; I then took a crop of early Potatoes or Cauliflowers before planting the Strawberries. I grew them four years on the same spot, but did not dig it, only put fresh manure from the stables every autumn, so as to make a good covering between the rows. The winter's rain and snow bleached it clean for the fruit, and if the weather was dry we gave the plants two heavy waterings before blooming and after the fruit was set, so we never failed having a good crop. In the county of Durham the British Queen has not done so well with me. At Hamsterley Hall, ten miles south-west of Newcastle, the following kinds did well with me under the same treatment as described above: President, Sir J. Paxton, Keen's Seedling, Vicomtesse Héricart de Thury, Elton Pine. Frogmore Late Pine did not do well, nor British Queen; but one other that we had did well, called Wonderful. I seldom see it mentioned in catalogues; its flavour with us was equal to British Queen, but of a much dwarfer habit, so that we could plant it a little nearer. Dr. Hogg and Sir C. Napier did not crop well. At Moorlands, Sunderland, and near three-quarters of a mile from the sea, we depend mainly on Garibaldi or Vicomtesse Héricart de Thury, also President and Sir J. Paxton; we have tried several others, but they do not succeed with us.—J. G., *Moorlands, Sunderland.*

PACKING PEACHES AND GRAPES.

Some plain directions for packing fruit, especially Grapes and Peaches, would be valuable at the present time to many who, being absent from their country homes, are in the habit of having fruit sent to them by parcel post.—H. Clements.

It should be remembered that Peaches and Nectarines require as much care in gathering as in packing, for the slightest bruise will appear an ugly blemish a few hours afterwards. Have a tray lined with a thick layer of wadding beside you when going over the trees; try only those that look ripe, and, taking the Peach gently in the palm of your hand, bring the fingers and thumb under its base, and if it does not come away with a slight effort leave it. What are ready set on the tray, and do not handle them again till they are packed. Some have their Peach boxes divided into compartments about 4 inches square; but it is not an economical plan, for only one Peach, be it large or small, can be put into a division, and they are too often bruised in getting them out again. The boxes should be of tin, and from 12 inches to 18 inches square, and 4½ inches deep. In packing lay a thick piece of wadding on the bottom, and line also the sides; then take a square piece of wadding of the requisite size, lay upon it a piece of the softest tissue paper, and on this set the Peach; fold the wadding up over it, and set it on its base in the box at one corner. Fold up the others in the same manner, pack them closely together, lay a sheet of thick wadding on the top, shut and fasten the lid securely, and they are safe from any ordinary danger.

Few fruits bear carriage better than Grapes, and yet, strange to say, they are often much damaged in their transit, for the simple reason that they are seldom packed as firmly as they ought to be, through fear of crushing them, though the Grape will stand a wonderful amount of pressure before breaking and the bunches have a certain elasticity about them which protects them. Boxes 18 inches by 1 foot and 6 inches deep are a convenient size. We use soft paper shavings or wadding for packing them, first wrapping the bunches in soft drapery or tissue paper, and twisting it at each end; they are then wedged in together with a few shavings between the bunches, and a layer below and above all, in sufficient quantity to hold them securely in their places, when the lid is put on. All our packing materials are returned in due course, and it is seldom that there is the slightest stain from a broken berry on the Grape papers. Nor does the bloom suffer to any serious extent by this mode of packing if done with ordinary care. It is friction which rubs the bloom off most, but firm packing prevents this to a great extent.

Figs are precarious things to handle in packing if perfectly ripe, as all Figs ought to be before they are sent to table. Their skin rubs off with the slightest touch. They should be detached from the tree with great care, and they should be packed like Peaches; but, instead of using tissue paper inside the wadding, use a soft vine leaf in a flaccid state and fold the fruit carefully in it, and pack tightly, using plenty of wadding.

Small fruits, such as Currants, Gooseberries, and Cherries, will travel well without packing further than a layer of leaves top and bottom. Plums will travel well in a bed of soft, clean leaves and covered with the same, but the bloom of the fruit is easily rubbed off. It is a common plan, and a good one, to pack the different boxes of fruit in one hamper when sent off. Sometimes they can be sent in the vegetable hamper. Either way, do not let the hampers be unwieldy and inconvenient to handle, and the chances are that the damage, if any, will be less than it otherwise would be.—S.

THE NAMES OF FRUITS.

The subject of fruit nomenclature was discussed at a recent meeting of the Massachusetts Horticultural Society. The Hon. Marshall P. Wilder opened the discussion, and in the course of his remarks he said:—

In naming fruits, we want to suppress all royal titles, such as emperor, king, or prince; all political titles, such as president or governor; all military titles, such as general, colonel, or captain; all indelicate names, like Hogpen, Sheepnose, and Big Bob; all ostentatious names, such as Excelsior, Ne Plus Ultra, or Stump the World; and all long names like Doyenné Gris d'Hiver, Nouveau, or Twenty-fifth Anniversary of Leopold the First; and also to strike off the hundreds of Beurrés and Doyennés from the names of our Pears where it possible to do so, and to write hereafter Anjou, Diel, and Boussoch, in place of Beurré d'Anjou, Beurré Diel, Doyenné Boussoch, &c. There are, however, some instances, such as the old Beurré Gris and Doyenné Blanc, when the Beurré and Doyenné must be retained as the original types of certain classes. There are many other terms which have become unmeaning and useless, such as Pippin, applied to Apples, and Seedling, applied to certain varieties of all fruits, for all varieties are originally from seed. The terms Favourite, Beauty, and Choice not being distinctive appellations are better dispensed with in most instances, but in some they must be retained, as in the case of the Clapp's Favourite Pear, because we have also the Frederick Clapp and Lemuel Clapp Pears. As regards Clapp's Favourite, when it was introduced the Massachusetts Agricultural Club desired to possess the control of the variety and give it its name, and authorised a committee to offer £200 for the stock; but Thaddeus Clapp, who raised it, preferred to have it dedicated as it was, and a figure of the Pear is carved on his monument in Forest Hills Cemetery.

Among Apples we have several Spitzenbergs, Russets, and similar names, which should be dispensed with as far as possible. The terms Doyenné, Bon Chrétien, and Calebasse once had some reference to the forms of Pears, but they have never been adopted in naming American varieties. In the future, we desire to use but one word for the name of a fruit, as with the Baldwin Apple, the Bartlett Pear, the Concord Grape, and other renowned fruits, which will be perpetually known by appropriate and easily remembered names. In a word, we desire to establish a system of nomenclature which shall be pure and plain in its diction, pertinent and proper in its application, and an example not only to our own, but to other countries.

A lengthy discussion ensued, most of the speakers agreeing with Mr. Wilder that some sort of reform is necessary in naming fruits. We hope the Massachusetts Society will take steps to bring about the desired revision in fruit nomenclature, but perhaps they will have to meet the same difficulties as we have here in the attempt to revise the nomenclature of varieties of garden plants.

Plum trees as cordons.—This fruit may not be extensively grown in this form, but they certainly appear to succeed admirably when so grown. I have just seen a single cordon of considerable length, form-

ing the margin to a walk in the kitchen gardens at Hardwick, consisting of some of the best varieties of this fruit, and each variety bearing a heavy crop of fine fruit, which it has been found necessary to thin out. The cordon is little more than a foot from the surface of the soil, consequently does not in any degree interfere with other crops, and occupies but little space, which is a consideration where the extent of a garden is limited. The training of fruit trees in the form of single cordons is exceedingly simple. Short strong stakes are driven into the soil, some 2 yards apart and to the desired height; while to the top of each is secured a strong galvanised wire, and to this wire the single shoot or rod intended to form the cordon is trained. The trees may be planted at a distance of 6 feet, more or less, from each other, and as soon as the wire is quite covered, which is soon accomplished, the cordon is complete, and presents a very neat and pretty appearance at all seasons of the year. At the height of a foot from the surface of the soil the fruit, when ripening, is apt to be disfigured by grit thrown up during heavy falls of rain, so this altitude may with advantage be increased to 18 inches, or even to 2 feet.—P. G.

RIPENING AND PRESERVING FRUITS.*

The principles upon which success must ever depend are now so well established, that it is only necessary to bring them to mind for our government. The preservation of Apples through the winter months is now pretty well understood, but with the Pear, Grape, and other delicate fruits more care is requisite.

The ripening of fruit depends on saccharine fermentation; this is followed by the vinous and acetous fermentations. To prevent these, and preserve fruit in all its beauty, freshness, and flavour, the temperature must be uniform, and kept below the degree at which the fermentation or ripening process commences.

Late fruits may remain on the trees until severe frosts are feared, but should be gathered with great care. Summer Pears should be picked some days before the ripening process commences. A summer Pear ripened upon the tree is generally inferior. Pears which become mealy, and rot at the core, if left on the tree to ripen, are juicy, melting, and delicious when ripened in the house.

With the increase of fruits their preservation in the most perfect condition has become a matter of great importance; various methods have been adopted, both in this and other countries, for this purpose, many of which have been failures. Nearly half a century ago the first houses of which I have any knowledge were built for the preservation of fruits by the retardation of their ripening. Most of these have been controlled by ice; others by the use of chemicals and apparatus with revolving fans to diffuse the cold air through the various rooms.

The most common method for preserving fruits in small establishments and private use is the construction of houses with walls of non-conducting materials and with well drained and thoroughly cemented cellars. Such was the house built by M. Victor Paquet, of Paris, about forty years ago—without the use of ice or chemicals—an account of which was given in the illustrated transactions of this society in 1847. The house was built with outer and inner walls, with a space of 3 feet between; in fact, a house within a house, and so arranged that he could control the temperature at will, and which he kept at a little below 40° Fahrenheit. Our climate differs so much from that of Paris, that we cannot follow all of M. Paquet's plans. Suffice it to say that by this process, without the use of ice, he kept his fruits in perfect condition until June.

On this plan, fruit houses may be constructed at a very moderate expense, in which fruits may be kept in all their beauty, freshness and flavour through the entire season. The Anjou Pear has been exhibited in our society as late as the month of May from a retarding house.

* Extracts from a paper read before the Massachusetts Horticultural Society by Hon. Marshall P. Wilder.

One great secret of success begins in the state in which the fruit goes to the cooler. It should be before any sound specimen begins to show ripeness, and no single fruit should be stored that has fallen to the ground; for, however perfect it may seem, sooner or later that dropped fruit will tell its own story, and often cause the decay of the whole package when not noticed in time, which rarely happens when hundreds of bushels are piled one above another for a month or two. The fruits intended for cold storage houses should go directly from the orchard.

The cause of so many failures in storing Pears, for instance, is that the fruit is often bought of different parties, much of it so imperfectly packed that it is never fit to go to the cooler—perhaps it has been gathered weeks previous or carried long distances and become more or less bruised and rendered every way unfit for keeping in this way. The past autumn hundreds of bushels of Bartlett Pears that were nearly ripe were stored by small fruit vendors who knew nothing about the subject.

The fruit house of Ellwanger & Barry, at Rochester, N.Y., is a building where walls and floor are lined with straw and boards, with cellars underneath for storing fruit. When the mercury goes 10° or 12° below zero, a few, 3° or 4°, of frost get in, but the boxes and barrels are all covered with straw mats and are never reached by the frost. When the late autumn and winter Pears are gathered they are put in bushel or half-bushel boxes and placed on the north side of a building outside of the fruit house and protected. They are kept there as long as the weather will permit—by that time the room has got thoroughly cooled and ready to receive the fruit. They have both Pears and Apples there now in perfection.

In an account, by Mr. S. W. Dorr, of a fruit house constructed by him on the cold-air system, without the use of ice, he lays down the principle, that in order to keep fruit for any great length of time, the store-room must be frost-proof and kept at a low, even temperature—3° or 4° above freezing, with sufficient ventilation to carry off all moisture and impurities. He was able to keep his house within 3° of freezing for five months, and when the temperature outside changed 60° in twenty-four hours, the change in the fruit room was imperceptible. Again, when the thermometer fell from 6° to 20° below zero for five days in succession, the temperature scarcely changed one degree in the fruit house. This result was effected by building a house with triple walls, 15 inches in thickness, 10 inches of which was filled with sawdust.

The conditions of success may be briefly stated as follows: The perfect control of temperature, light and moisture. All experience shows that these conditions must be complied with or success cannot be attained; hence these apartments must be cool, and constructed so as to exclude at pleasure the external atmosphere, which starts fermentation. After many years of experience, both with and without ice, I have adopted a house built in a cool, shady aspect, with the door on the north, and with a thoroughly drained and cemented cellar, with small, double windows, which may be opened or closed at pleasure. In this way I am enabled to keep my late autumn and winter Pears until February or March in good condition. Apples may be kept at a lower temperature than Pears—say 34° to 40°. In a fruit room of this kind, Mr. Thomas writes me, that by admitting air on cold nights, and closing the entrances when the air is warm, he has had sound Lawrence Pears in March, and Josephine de Malines in April, and Baldwin Apples in June.

My late autumn and winter fruits, intended for long keeping, are allowed to remain on the trees until frost is apprehended. They are then gathered with great care, into bushel boxes, and placed on the north side of my fruit house in tiers of boxes 6 feet or 7 feet high, and covered with boards, where they are kept until the ground begins to freeze. They are then removed to the cellar, piled up in the same manner, with thin strips of boards or shingles between the boxes, until wanted for use, when the boxes are looked over and the most mature are from time to time taken out. In this way I keep Pears until March or April in perfect condition.

In regard to the use of ice, I would say that where fruits are kept for some months under its influence at a low temperature, they seem to lose much of their flavour: the cellular tissue also seems to have become dry, and to have lost its vitality or power to resume the ripening process. Experience proves that, for the common varieties of the Pear, about 40° of Fahrenheit is the temperature best suited to hold this process in equilibrium. The proper maturing of fruit thus preserved demands skill and science. Different varieties require different degrees of moisture and heat, according to the firmness of the skin and the texture of the flesh. Thus some varieties of the Pear will ripen at a low temperature and in a comparatively dry atmosphere, while others are improved by a warm and humid air. Some varieties of the Pear ripening with difficulty, and formerly esteemed only second rate, are now pronounced of excellent quality because the art of maturing them is better understood. Great improvement has been made in the handling, packing, and preservation of fruits, so that they are delivered in perfect condition from distant places, every class of fruit having its suitable style of package. So well is the art of keeping Grapes now understood, that we have them in our markets in such fine order as to command from 7d. to 9d. per pound until the month of May.

Referring more particularly to Pears, some sorts of which are more delicate than others, and will not bear so low a temperature. The Bartlett Pear loses its flavour after being exposed to a low temperature for two weeks. It is very important that the temperature should be uniform. I once had a house controlled by ice and found that 40° would hold fermentation in check. My cellar sometimes gets below freezing and I then cover it with mats.

KITCHEN GARDEN.

SPINACH ALL THE YEAR ROUND.

In order to keep up an every-day supply of Spinach all the year round, the last summer crop should be sown on a well-prepared border or quarter about the middle of July, in drills 18 inches apart; this will yield a good supply of fine large leaves till October is out. For the late or winter crop prepare about the end of July a border or sheltered quarter; apply a good coating of thoroughly decayed manure, trench the ground well and cast it up into ridges, so as to expose as great a surface as possible to the influence of the atmosphere. Every dry day till August 10 or 12 east down the ridges and pulverise with a steel fork, so as to sweeten and incorporate all together. Then draw lines a foot apart and sow the Hardy Prickly variety. As the plants advance thin them out from 6 inches to 9 inches apart, and maintain a healthy and vigorous growth by constant surface stirrings in suitable weather; this, if attended to, prevents canker, and encourages the production of abundance of fine leaves for use every day throughout the winter. Timely forethought should be taken to shelter a portion with a row of short stakes about 18 inches high, interwoven with Fern, straw, evergreen branches, Furze, Heath, or other material, which should be neatly applied, and also made wind-proof. Thatched hurdles or frames, cheaply made, of battens backed together and thatched, might also be used for the purpose of protecting from frost. Make another good sowing of the same hardy Spinach on ground as well prepared as the last, about August 20 or 22, in lines a foot apart, and thin out to 4 inches or 6 inches between the plants. This will furnish a supply for use next spring, for although there is only a period of eight or ten days between this sowing and the last, this one will yield but very little before spring. To keep up a regular supply in summer,

sow the round Spinach on a warm sheltered border and between lines of early Peas, &c., once a fortnight from February to May, and for the next six weeks after that on the coldest and dampest part of the garden; and if a north aspect can be provided, so much the better.

In March, New Zealand Spinach should be sown in heat; pot off, and encourage the growth of a few plants till about the middle of April; a very few plants will produce an enormous quantity of leaves if turned out on a slight hotbed, as is done with ridge Cucumbers, and let hand-glasses be placed over them until strongly started and well established. The hotter and drier the weather, the stronger will this Spinach grow, a circumstance quite at variance with the winter and summer varieties, which "bolt" or start to seed at an early stage in hot weather and in warm situations, particularly on light or poor soils, or when under shallow culture. Another substitute for Spinach in summer is the foliage of the Silesian White Beet, a row or two of which will produce a quantity of fine clean healthy leaves in the heat of summer. In autumn the silvery clean white stalks of this famous Beet make a very good substitute for Seakale; they are served at table in the same way, and make a capital wholesome dish. W. B.

Watering and mulching.—Waterings, effectual, but not frequent, and stirring the surface or mulching immediately afterwards, form the secret of success in droughty seasons like the present. Mulching in itself has a wonderful effect on nearly all kinds of vegetable crops, and notably on Peas, all the Cabbage tribe, Celery, and Potatoes. The handiest material for such purposes is short Grass, which is always plentiful. A good mulching of this between the Potato rows, instead of earthing them up, increases the weight of the crop largely, but it is a disadvantage in wet seasons. Raspberries luxuriate under a thick mulching of Grass, which is worth a heavy dressing of manure to such moisture-loving plants. Strawberries are equally benefited by the same treatment, and the mulching should be done early in the spring in their case. On Apples, Pears, Gooseberries, and Currants, in shallow warm soils, a top-dressing of any loose material seems to work little less than a miracle. Indeed, such a practice is commendable under almost any circumstances, and at all times saves an immense amount of labour entailed by continuous watering.—J.

Earthing up Celery.—Although I know that it is the usual practice in Celery culture to repeatedly earth it up while growing, I certainly do not think it necessary to earth it up when it is growing rapidly; more than that, I think it is bad practice. A little sprinkling of earth, pushed down after a heavy watering to prevent evaporation, is all we should give during the growing season, and we know it to be a fact that some of those who grow the finest Celery in the country do not earth until full growth is attained. Indeed, some of them do not earth at all, but effect the blanching by other means. That some old professionals of fifty years' experience, and many other persons, pursue quite a different course, I am well aware; yet one would think that a single hint would suffice to point out that it is difficult to give abundant waterings to Celery, and impossible for it to benefit by the natural rains, if we pile a sharply-sloping bank of firm earth close along each line long before the plants have attained maturity or vigour. And no plant is more benefited by profuse waterings than this, naturally an inhabitant of very wet places. The repeated earthings which Celery receives in the majority of gardens are not only harmful to the Celery, but the cause of a great waste of time and labour.—R. T.

Cabbage and other vegetables.—The recent heat and drought, if so short a spell of unusually fine harvest weather merits such terms, has done much good in checking the too luxuriant growth of the Brassica family, and in so doing, assisting to render the plants firmer and more capable later of enduring hard weather. That there will be an abundant supply of all kinds of greens, inclusive of Turnips, is evident, and whilst these things will assuredly be cheap, still it would be a misfortune were hard weather to find them gross and full of soft pithy growth. Some little check, even though of but a week's duration, must be productive of good, because with rain and colder weather growth will be resumed, but now more in the direction of hearting than of producing excessive outside leafage. Rarely have extensive breadths of plants of all kinds been got out with more facility than this season, and rarely has better growth been made. Wireworm, grub, and club so far seem to have given little trouble, but any considerable spell of dry weather now might conduce to the promotion of these pests. Whilst flagging very much during the day, the foliage has found in long nights and heavy dews ample time for recovery. In spite of a late season, Autumn Giant Cauliflowers and Brussels Sprouts, of course, on early planted breadths are already turning in, thus lengthening the season, as, of course, in such case the turn in is gradual. Owing to the preceding showers and probable absence of the fly, Turnip breadths are very promising. Late sowings are receiving some check, but a gentle pressure by wooden rollers is productive of good, and if the young plants can be pulled through the drought, they will make rapid growth when the autumn rains come, and a plentiful stock of late bulbs will result. So far there is promise of plenty of marketable winter vegetables.—A. D.

Potatoes at Shrewsbury.—At the excellent show recently held at this town Potatoes were unusually plentiful, and the majority of them above average merit. Indeed, it would be difficult to find an exhibition of Potatoes to equal those shown here, and the Potato crop in Shropshire this year is evidently a fine one. The largest class was that for six dishes, and the gardener at Berwick House, Shrewsbury, showed the finest. He had Cosmopolitan, Surprise, Beauty of Hebron, Blanchard, Vicar of Laleham, and Reading Russet with splendid produce. I noticed that Sutton's Seedling was very extensively shown here in fine condition. I observed that International and one or two others of inferior table properties were not so extensively shown as usual; but the Dean, a rough, dark-coloured variety, Village Blacksmith, and Mr. Bresse, were conspicuous.—Cambrian.

Potatoes on trenched ground.—It has been said that the value of deep digging is never so apparent in the case of Potatoes as in that of other vegetables, but I am convinced that Potatoes feel the benefit of deep culture to a greater extent than is commonly supposed. A year or two ago we planted some on a piece of ground, a portion of which had been trenched 3 feet deep, the remainder having been dug in the ordinary manner. As they were planted so that the half of each row was on the trenched ground, it was easy to see the difference in the growth of the plants, and to compare the yield in tubers at digging time. During the growing period it was easy to see that the plants on the trenched ground were growing more vigorously than the others, and they gave a much greater weight of tubers. I should, however, mention that the soil is sandy loam, which quickly dries in summer, and I feel sure that in such land there is no crop that is not benefited by deep culture. In heavy moisture-holding soils, 6 inches of well-worked earth may be enough, but that is not sufficient for anything in those of a porous character.—J. C. B.

Rhubarb in summer.—Some years ago I accidentally discovered that Rhubarb may be had just as good late in the summer and in autumn as in spring. It happened that a plantation of it having been disturbed, some roots were left lying about on the top of the ground for a month or two. As everyone knows, Rhubarb has exceptional vital power, and this rough treatment did not kill the roots, which eventually were cut up into moderate-sized pieces and planted in good ground. I am not sure as to the exact time at which the planting was done, but it was early in summer. The plants grew well, and in August, as they seemed so fresh and succulent, it occurred to us to cook some of the stalks, and they were found to be fully as tender and juicy as spring-grown ones, with the difference that they had a finer flavour. This is not to be wondered at, seeing that a certain amount of maturity is necessary to develop flavour in a fruit and a vegetable, and Rhubarb is generally consumed in spring in a very immature condition. When bush fruits are over there comes a dearth of fruit, and where much of this is required in late summer, Rhubarb might be profitably used. By the ordinary system of culture, however, Rhubarb is not eatable late in the season, as the stalks produced by plants which have been growing from early spring are tough and flavourless. Some roots should be set aside expressly for a late supply, planting them in rich soil about the latter end of May. These will be in free growth by August, and will furnish good, tender stalks up to October. From the time that bush fruits are over till Apples come in, Rhubarb grown in this way would prove of great service.—J. C. B.

Garden Flora.

PLATE 560

THE ST. JOHN'S-WORTS.

(WITH A COLOURED FIGURE OF H. OBLONGIFOLIUM (HOOKERIANUM).*)

The genus Hypericum is found represented in all temperate climates, and some of the species have a very wide geographical distribution. Hooker estimates the number to be about 160, and of these eleven are to be found in the British Isles, exclusive of the large-flowered Tutsan (H. calycinum), a plant of South-eastern Europe, which is naturalised in many spots, and for considerable distances along the banks of some of the southern railways forms a beautiful dense carpet of dark green, studded in summer and autumn with numberless large handsome flowers. All the Hypericums have yellow blossoms, but, in spite of that, there is a rather large series of shades, varying from pale creamy yellow to a rich golden colour.

H. oblongifolium, the subject of the accompanying plate, was introduced to this country previous to 1856 by Messrs. Veitch through their collector, Thomas Lobb. Were it a little hardier it could certainly claim to be one of the finest of ornamental flowering shrubs. As it is, its value is somewhat discounted by the fact that—except in favoured situations—it is apt to suffer severely during bad winters. The compact habit, the evergreen foliage, the contrasts afforded by the red branches, the glossy dark green leaves, and the golden yellow flowers, however, render it a desirable plant to grow in any garden, and as cuttings strike readily it is always worth while to insert a few in a cold frame so as to guard against the emergency of losing the species. Old plants sometimes attain a height of 6 feet or 8 feet. The species is a native of the Himalayan region, and ranges in altitude from 8000 feet to to 12,000 feet above sea level in Sikkim to from 4000 feet to 6000 feet in the Khasia Mountains. The correct name is H. Hookerianum, and the plant is very nearly allied to H. triflorum already figured in the twenty-third volume of The Garden.

Among the best of the other shrubby species are H. patulum (a native of Formosa and Japan, also distributed throughout temperate Himalaya), which is a lower-growing, more rigid bush, with smaller flowers. The North American H. Kalmianum and H. prolificum are perfectly hardy and resemble each other in habit; the former has glaucous leaves and flowers about an inch in diameter. H. aureum, a somewhat rare plant, sent to this country a few years ago by Professor C. S. Sargent, of the Harvard Arboretum, is a

* Drawn by Mrs. Duffield in Mr. G. F. Wilson's garden, Oakwood, Wisley, August 20, 1886.

HYPERICUM DELONGIFOLIUM

native of the Southern United States, was first discovered by Bartram, who describes his finding it in his very interesting book of travels. H. empetrifolium and H. Coris are handsome little shrubs, well worthy of a sheltered spot in the

Hypericum patulum.

rockery; both have small Heath-like foliage and are natives of southern Europe. Cuttings of these two should be grown annually in a cold frame. The discovery of H. orientale, a pale yellow-flowered species, which, like the two last-named, is apt to disappear in the open border during inclement winters, is quaintly described by Tournefort in his "Voyage into the Levant," a perfect storehouse of valuable and original information.

H. reptans is a beautiful and graceful trailer, with small leaves and wiry prostrate-rooting branches, each of which bears a single flower at

Hypericum reptans.

its tip. In proportion to the size of the foliage the flower is very large, as it reaches 1¼ inches in diameter. This is best seen when grown between the chinks of the rockery and allowed to carpet a rapidly sloping or perpendicular surface. It is a native of temperate Sikkim Himalaya, at elevations of from 9000 feet to 11,000 feet above sea level. G.

The Cornflower.—"A. D.'s" remarks bearing on the identification of the Cornflower are interesting. There can be no doubt, however, as to which plant is intended, so much evidence being forthcoming attaching the name to Centaurea Cyanus. This species of Centaurea is, or has been, named variously Blue-blow, Blue-bottle, Hurt-sickle, &c. We find on turning to its mythology, its specific name was derived from Cyanus, a youth devoted to Corn and Cornflowers, who was so partial to this flower as to dress himself in the same blue colour he so delighted in, and amidst masses of which he

Hypericum empetrifolium

was eventually found dead, and subsequently transformed into one of them. Mythological data may not be worth much to establish a fact upon; nevertheless it seems imperative that we follow it in this instance. Old Gerard gives Cyanus as the generic name of the Order, and this species as Cyanus vulgaris. Chrysanthemum segetum has invariably been known as the Corn Marigold, having, as is well known, some resemblance to the latter class of plants. It is well to observe, however, old authorities, including Gerard, give it also the pseudonym "Cornflour;" this in itself qualifies the reasonableness of "A. D.'s" suggestion. Furthermore, both plants are to be met with in Cornfields, the Centaurea being, however, far the most generally distributed, this latter fact going far to affirm its right to the name. When it is observed how beautiful Chrysanthemum segetum really is both as regards form and colour, in its normal or weed state, it is not difficult to imagine how capable it might be of improvement, even as a garden flower.—W. Earley.

WORK DONE IN WEEK ENDING AUG. 31.

August 24 to 31.

The intense heat has quite parched up all ground that is not mulched or covered with a growing crop, and there being no signs of rain, artificial watering goes on from morn to night in somewhat the following order: Indoor, fruit borders; outside, Peach, Pear, and Apricot borders, flower-beds and turf, and, lastly, vegetables; but in respect of the latter, by deep cultivation, combined with the mulchings we give whenever practicable, the necessity to water is reduced to the lowest point; at present, however, there is plenty of it to be done, as Celery and late sowings of Peas and French Beans must have it to keep them in good growth. Of kitchen garden work, besides watering, digging Potatoes is about all we can attempt till we are favoured by rain, and these we are harvesting as fast as possible; the crops are good, and but slightly tainted with the disease. These, I need scarcely say, are every one discarded, as the tubers are collected for housing in a cool, dry cellar, on the floor of which we spread a thin layer of straw, on which the Potatoes are spread as thinly as space admits of, that they may the more readily be examined to pick out any diseased tubers, for not unfrequently the disease spreads after having been housed ever so carefully. Except Magnum Bonum, Chiswick Favourite, and Stanwell, all our kinds are fit to house, and these kinds we shall get in a week hence, as by then they will be quite ripe, unless rain falls in the meantime, in which case they will be left to take their chance, which would not be worth much, as they will either make a second growth, to the deterioration in quality of the tubers already formed, or they will get badly diseased. Wall fruits—Peaches, Nectarines, and Plums—having had good supplies of water are ripening up their crops well; on Early Albert, Early Grosse Mignonne, and Bellegarde there are many ripe fruits, and so there is on Lord Napier and Downton Nectarine, Jefferson's, Kirke's, Transparent Gage, and Pond's Seedling. Plums are all ripe, and of extra fine quality. As yet wasps trouble us very little, but they have sent out their scouts, which has put us on the alert as to preparing and fixing protective netting over all first-class fruits that are not already fit to gather. The wood of Peaches and Nectarines is being thinned out as the fruit is cleared; very little wood other than what is needed for next year's fruiting is left in the trees, a plan that gives the wood a better chance of ripening, and at the same time the winter pruning required is of the smallest description. Apricots and Plums we fruit more on the spur system, and new breaks or growths from such spurs from this time onwards we keep constantly pinched back. Of course, long shoots are occasionally left to be laid in, either to fully furnish the wall, or may be to take the place of an old branch on which the spurs may have got too long. Strawberry plots have all been cleaned and freed of runners, and now only await a favourable opportunity to give them a fresh coating of well-decayed manure. New plots in place of those destroyed are not yet finished planting, as we prefer to keep the plants in pots rather than to plant under such unfavourable weather conditions of heat and drought as prevail at present. Flower garden work can be summed up in a very few words—it is simply watering, picking off seeding and bad flowers, and keeping the edgings and lawn in neat condition. We are making progress with the propagation of Pelargoniums and other bedding plants that are usually propagated in quantity at this season, and hotbed frames are being prepared for striking cuttings of the tender kinds, such as Coleus, Iresine, and Alternanthera. Roses want a good deal of attention in the direction of keeping them free of decaying flowers, Brier suckers, mulching, and watering. We have a grand second bloom on a number of plants of that fine old variety Souvenir de la Malmaison, the au-

tumn flowers of which are always more perfect than the earlier blossoms. All the Tea varieties, having been well watered, are also unusually full of flower; we water and syringe them whenever time can be spared for the work, and well they have repaid our labour. Indoor work is now mainly prospective, such as keeping all laterals in late vineries within reasonable limits, that the sun may reach and aid ripening of fruit, wood, and buds. Late Fig and Peach houses the same; and with our first batch of Queen Pines it is the same, for, having completed their growth, a drier state of the soil and atmosphere will now be aimed at. The process, however, will be very gradual, as we have no faith in roasting plants of any description to get them to fruit. Planted out winter Cucumbers and another lot of Melons; the latter may do, though the odds are against them, the season being too late. However, we have the space, and the trial will cost nothing but our labour, and an over-high estimate is not at all times placed on that. Disbudding Chrysanthemums, tying up and watering them is at present rather a serious addition to our daily labours. Hants.

HARDY FRUITS.

Apricots.

When all the fruit has been gathered, the trees should be well washed with the hose to feed and refresh the foliage; more light, non-conducting mulching may also be laid over the roots, not so much to feed them as to prevent the escape of moisture. The fine rains we had early in August greatly assisted the fruit, but the trees now require more and must have it, not in dribblets, but thorough drenchings that will penetrate to the lowest roots and through the drainage. It is generally admitted by experienced hardy fruit growers that Apricots require and are capable of carrying off more water than any other tree, and many are of opinion that bud dropping in the spring is due to dryness at the roots through the autumn and winter months. If this theory which I endorse be correct, why not go a step further, and lay the sudden collapse of the branches of Moorpark as well as the dropping of flower buds to the same cause? But why allow the roots of any wall tree to become dry, as the best regulated fruit gardens are now well supplied with water, and in many of them thousands of gallons of this life-giving and life-saving element can be administered through the hose? If nailing in has been neglected, let all shoots be closely laid in without delay, and persistently pinch or prune back breastwood to let in light and air.

Peaches.

The crop of fruit as a rule is all that can be desired, and never in my recollection were the trees so clean and densely clothed with perfect foliage. The wood, moreover, is short-jointed, and looks promising for another year. Although at one time we were almost inclined to wish for more sun and less rain, the fruit lately has made good progress, and will be plentiful before the crop in late houses has passed away. This being the position, and having the ball in our own hands, all we have to look to is its retention by treating the roots of Peaches as we treat Apricots, and wash the foliage with pure water on fine evenings until the different varieties begin to soften for ripening. If any of the trees persist in making wood, all strong shoots, which will have performed their office when the fruit is gathered, must be pinched to increase its size and prevent crowding, but leaders must be kept closely secured to the walls. As this work is proceeded with an eye must be kept on ties and nails, as it is at this season that the main shoots thicken rapidly, and many cases of gumming when the leaves fall can be traced to tight ligatures and nails. Immunity from insects, be the cause what it may, does not affect the gluttonous wasp, for this pest, which is so small and active, is always alive to the luscious opportunity. War to the knife is the watchword; nests must be sought, no small matter in hilly and wooded districts, and late at night when the major part have reached their home the composing draught of gas tar or paraffin must be administered. A small quantity poured in and made air-tight with a piece of turf is all that is needed, but there must be no digging out or after disturbance, otherwise a remnant will rally and return. When wasps are very troublesome and attack the best fruit before it is ripe or wanted for use, the most effectual and, in the end, the cheapest course is protection with fly-proof netting. I always use Haythorn's hexagon netting, just deep enough to descend from the coping to flat pieces of timber or floor boards set up edgewise about 3 feet from the foot of the wall. A few slating laths reared perpendicularly prevent it from bagging, and entrances are provided at each end, and the whole length can be traversed at pleasure without letting in a single fly or wasp. My netting, stored away as soon as the Peaches or insects are disposed of, has paid for itself over and over again, and will still last for a number of years.

Varieties of Peaches.—Many paragraphs on extra early varieties having recently been published, the following notes from this district may be of use to growers who do not happen to have late houses to lead up to walls. Amsden Pine and Alexander, two highly coloured varieties, last year ripened on a south wall about the 20th of July, but the quality of the fruit, owing to the intense heat, was not quite up to the mark—in fact, the flesh was inclined to be adhesive. These in October were removed to a west aspect, and this season ripened finer fruit of better quality; the first on the 30th of July, the second five or six days later. Hale's Early comes next, and Condor, a highly coloured and good flavoured variety, is now (August 20) dead ripe on a south aspect. Early Grosse Mignonne and A Bec, greatly superior to the preceding, are now forward enough for gathering; not so for eating; and Dr. Hogg, an excellent Peach, follows close upon them. Amongst Nectarines, Advance is an advance on Lord Napier in point of earliness, and the quality is excellent. The last named, however, is a host in itself, and should be planted against west as well as south walls, where it will lead up to Stanwick Elruge, one of the finest and best Nectarines grown.

Apples.

Although at one time late and unpromising, all kinds have made amazing progress since the heavy rain which fell in July. The crops, too, in gardens and well managed orchards are, in many instances, heavier than they should be. We have already gathered Red Astrachan and Irish Peach; King Pippin is ready, and Worcester Pearmain must be closely watched, as wind or rain will cause many of the finest fruits to drop. Red Quarrenden is carrying immense crops in orchards, but Worcester Pearmain with us has superseded it in every respect. Our best cropped early culinary Apples are Stirling Castle, Keswick Codlin, Lord Suffield, Lord Grosvenor, Echlinville, Hawthornden, and Warner's King. These have required much thinning and the fine clear fruit will pay for it. Stone's Apple, Lady Henniker, and Peasgood's Nonsuch I have planted and trained as cordons wherever a few square feet of wall, no matter what the aspect, required filling up. Peasgood's, a strong grower of the Blenheim type, is worthy of extension, and it merits it, for the large, handsome, heavily bloomed fruits are marvels of beauty, and their quality is equal to their appearance.

Gathering fruit.—Early kinds of Pears and Apples should be gathered as soon as the first signs of changing are visible. Many varieties will ripen upon the trees, but their good qualities are so fleeting and fermentation sets in so quickly, that it becomes a question whether they should not be gathered very early, and have a place in a cool, airy fruit room where the temperature will not fluctuate. Early morning, as soon as the fruit is dry, is the best time to gather, and the greatest care should be observed in detaching and conveying it to the shelves. Peaches and Nectarines for home use may be allowed to soften on the sunny side, but not quite down to the stalk, otherwise they will lose their sprightly flavour before they are taken for use; whilst the slightest pressure with the fingers will produce bruises which will be followed by fermentation and decay. For packing and travelling they cannot be too hard to please the fruiterer, always provided they have size and colour. Whether the consumer of those fruits ever tastes a Peach at its best is not for me to determine. One thing, however, is certain; the grower must pluck early if his fruit is to find favour with the dealer.

Root-pruning.—As soon as the fruit is off, any ordinary trees which require a check to arrest and consolidate growth may be taken in hand, not upon the old system of cutting off all the roots and styling it root-pruning, but by clearing off a quantity of the mulching to let in sun heat, and perhaps by digging out a trench barely without the external radius of the roots, and leaving it open for days or weeks to dry and warm the ball. This plan, it is hardly necessary to say, does not apply to fruit trees which have never been neglected, as these can be taken in hand and finished off in a few hours at any time after the end of August. When trees of mature age get wrong, it is generally found that a few strong roots have penetrated the subsoil, and persist in forcing up crude sap quite late in the autumn. The remedy in this case requires two seasons for its completion. If the trees are espaliers, a trench may be taken out the whole length and depth of the border, when, having severed all the strongest roots, especially those which descend, and raised them where practicable, the trench may be filled in with the best of the old and a little new loam. Full leaf is the proper stage for this work, as young roots will soon form, when the other side may be treated precisely the same the following autumn. I now have in my mind six old trees of Marie Louise which were treated in this way four years ago. Previously they had not borne a dozen clean fruits each for several years; now they are loaded with handsome russetty Pears, whose very appearance betokens flavour. The same system applies also to standards and pyramids which have been neglected in their youth, the completion of the circular trench being allowed to extend over two seasons. The second or third year after planting is, however, the proper time to raise and lay the roots in a horizontal position, as we find this attention induces a fruitful condition, thus rendering further disturbance unnecessary.

Planting follows close on the heels of root-pruning, and requires equal forethought and care. If for this purpose trees have to be bought in from the nursery, now is the time while they are in full leaf to select and mark them for removal. The largest and strongest, it must be borne in mind, are not always the best, as they generally suffer after removal, when the private grower loses more than the nurseryman gains by neglected transplanting. The most valuable trees are those which, by their moderate growth of short-jointed shoots and well-formed spurs, show that root-pruning has received proper attention. Buying in for direct planting is sometimes absolutely necessary, but the cheapest and safest practice is the maintenance of a home nursery in which younger trees can be planted and grown on to one's own liking. The nurseryman's everlasting "cut-back" with a piece of dead wood buried in its centre can then be avoided, and annual lifting will fit them for transplanting before the leaves fall.

Figs

on open walls, so severely tried last winter, have made excellent growth, and promise well for another year. Although, as I predicted, the crop of fruit in ordinary situations is light, the old Brunswick is now swelling up a few fine Figs, and the young shoots are thickly set with embryo fruits, which it must be our endeavour to keep below the size of Peas by close training and full exposure to the ripening influence of dry sun-heat and fresh air. In good Fig seasons it is necessary

to mulch and water. This year, having so little to ripen, barren or partially barren trees will pay best for being kept dry throughout the autumn and winter. This withholding of water as a rule produces the desired effect on roots and shoots, but should any of the trees persist in elongating their growths, the sooner they are root-pruned the better.

Strawberries.

Young plants put out in August must be regularly attended to, both with mulching and water; the first to prevent the ground from cracking, as generally happens after ramming at the time of planting; the second, to encourage a good root-hold before winter. Newly-made beds do not require gross mulching, as the fresh loam alone will produce a vigorous growth, but they require some loose manure for keeping in moisture, than which there is nothing better than an old Mushroom bed spread rather thickly round the collars of the plants. If weeds spring up they must be kept down with the Dutch hoe, and strong runners may be taken off, but unless the crowns are likely to be strong enough to flower well next year, a few runners will do no harm, as root action is always in proportion to the rate at which runners are produced. New plantations may still be made, but unless the plants are very strong and well rooted in pots or sods and the ground is in excellent order, nothing will be gained over keeping them in nursery beds and planting out early in the spring. To this end a good quantity of runners of all the leading kinds should be pricked out in beds or along the sides of walks, not too far from the hydrants, both for transplanting in April and for giving early runners for forcing. Some growers lift and pot these young plants in June, but they are apt to lose their old leaves and become leggy and do not make such pleasing-looking stock as the next generation. Strawberries, however, unlike many other plants, submit to and produce fruit under almost all sorts of treatment, always provided their food is good, and they are not allowed to get below par through lack of stimulants. W. Coleman.

NOTES.

White Everlasting Pea.—As seen at its best, firmly established in deep rich soil, there are but few other hardy herbaceous plants that can rival this white-blossomed Pea. Of course, Anemone japonica alba stands alone—the Venus de Milo of garden flowers, as someone has said in these pages—but even that plant is not so graceful in habit as is this Lathyrus as seen climbing up a fence or other suitable support, or even as grown in a bed on the lawn without any support whatever. I saw a most lovely group of white flowers in a well planted herbaceous border the other day. Anemone japonica alba and Galtonia (Hyacinthus) candicans were boldly grouped together on a carpet of Campanula Hosti alba. All were in flower together, but even when out of flower the leafage of these plants would form a pleasing variety of tint and of form. I thought at the time that a good mass of this white Everlasting Pea towering up above everything would have been an improvement. It is a plant which requires time to become established, after which it forms a picture every year. Now and then it comes true from seed, but division in spring is a more certain method of increasing one's stock.

Flowers of autumn.—Heavily hangs the tall Sunflower, and the uprising Torch Lilies and Dahlias, Hollyhocks, and early-blooming Chrysanthemums bespeak for us the time of harvest once again, and tell us of the hot sunny days followed by the thick white night mists of September. There are white Japan Anemones and scarlet Gladioli everywhere. The Wistaria again yields us a few of its purple clusters, and its leaves are of all the varying shades between deep green and pale gold. The tall Aconite of autumn and the perennial Sunflowers wave in the warm breeze. The Tigridias, scarlet or yellow and white, flutter their petals every morning like gorgeous butterflies, and there is a golden glow over everything in the garden after the showers of yesterday. The first clean fresh Colchicum flowers opened their pink buds to-day, and displayed their daintily chequered petals as if spring were here again. Now is the time to plant bulbs of nearly all kinds for next year's blooming. The ground is so warm that Crocus, Narcissus, and Squills planted now root immediately, and gain strength to resist the cold of winter and to bear their beautiful flowers in spring. The robin has commenced its autumn song, and the fairy spider spreads out its lace veil on the hedges to dry every morning. It is the time of fruit and of ripening corn, and the bees hum among the Heather on the hillside, or they make their drowsy music among the garden flowers.

Herbaceous Phloxes.—Just at this time of the year these plants are a great ornament to the herbaceous borders, and to my mind the best varieties by far are the pure whites, or those which are white with a pink centre or eye-like spot. There are a whole host of forms of a rosy purple, lake, or magenta shade, and a few of these placed in a border along with Tritomas or other orange-red flowers are very jarring discords in our rainbow music, and one's teeth are set on edge by the sight of them. Some say they like them; but then they have no eye for colour, and persist in mixing blue-reds with orange-reds in their borders and bouquets year after year. Good pure white Phloxes are very valuable, and the drawback is that we have so few of them of really good quality. I must ask my friend Mr. Douglas to raise us a few good white kinds, of which, indeed, we can scarcely have too many, and if he would also try and raise for us a pure white Gladiolus as free and as hardy as G. brenchleyensis, it will be as heartily welcomed and far more largely grown than any hybrid Orchid yet obtained. My experience with herbaceous Phloxes is that they like being divided and replanted in spring every second year at the latest.

Autumn-flowering Cyclamens.—Here and there in the Grass and nestling under the shelter of the rockery stones, these old-fashioned garden flowers are peeping once again. I saw a broad leafy patch of them around the base of an Irish Yew yesterday, and they were lovely, forming a carpet of marbled leafage and pink, peach, or pure white flowers. They show better as seen in good breadths or masses, and seeing that they are cheap if bought by the thousand, as dug up in Austria or the Tyrol, there need be no obstacle to their becoming plentiful in all good gardens. I know of an old garden in which I am always a welcome visitor, and to which I rarely miss an enjoyable pilgrimage when the mellow Peach Apples hang ripe and rosy on every bough. It is only an old cottage garden with old crumbling walls all around, but they fortify from wind or harm many a lovely blossom. Just now the long lines of rosy lilac, and of pure white autumnal Cyclamen are a sight alike for gods and men; and no pen and ink could tell a tithe of their beauty. Here and there their corms, plump and brown and as big as tea-saucers, are quite bare of earth, but hidden now by the shelter of hundreds upon hundreds of flowers. Even if they never flowered, their marbled leafage alone would be worth the having in all good gardens.

Gladiolus brenchleyensis.—A big bed of glaucous-leaved Yuccas on a carpet of sweet white Viola was planted thickly in March last with this old scarlet Gladiolus, and the sight it now affords is an effective one. This variety is a favourite of mine, and is one of the best of all the really hardy Corn Flags in our soil and climate. What is the history of this flower? Someone told me it was a hybrid or seedling raised by the late Mr. Hooker, a nurseryman at Brenchley, in Kent, years and years ago. Be this as it may, it is effective either in the borders or as cut and arranged indoors in pots or vases. The spikes should be cut as soon as the lowermost bud expands, and as so cut dozens of spikes may be packed for post or other means of transit in a small space, and they then travel without injury. A dozen spikes in an old copper Venetian bucket are now very pretty with their own leaves, and yesterday I saw a few spikes contrasted with the soft blue tint of the Shore Grass (Elymus arenarius), and the effect was a pleasing one, heightened by the vessel which contained them being a bit of Japanese bronze quite dark in tone. Late in the season, but quite early enough to plant for autumnal flowering, the bulbs cost from 15s. to 20s. per thousand, and it is worth growing in quantity for contrasting with Lilium auratum, white Japan Anemone, or the graceful Galtonia candicans.

Grevillea Manglesi.—A very gracefully habited plant far too rarely seen, although as a pillar plant in a cool conservatory it has many charms. A friend of mine who saw the splendid specimen at Glasnevin years ago called it the Weeping Beauty, a name quite perfect in its way if considered in the same sense as the Weeping Willow of Napoleonic fame. Young plants may now and then be obtained at the nurseries, these, as a rule, being engrafted on stocks of G. robusta, and these if planted out in a conservatory or greenhouse soon grow up to the roof, their slender branchlets depending on all sides to the ground. In the springtime each shoot is tipped by a feathery little cluster of white flowers—flowers of the smallest, it is true, but the clusters have quite a pretty lace-like effect as seen amongst the soft glaucous trifoliate leaves. The slender branchlets are as useful as Ferns for cutting, and have the advantage of enduring fresh and fair for a much longer time than do Ferns when cut and placed in water indoors. Now and then it produces pods of seed from which plants are readily raised, but practically the best and quickest mode of propagation is to graft its young shoots on seedling plants of G. robusta as a stock.

Hæmanthus coccineus.—The Blood flowers have been rather neglected in our gardens of late years, although some of the species are very showy, and, unlike Cape bulbs generally, they are easy to grow. H. coccineus is very showy every spring, and at the present moment H. puniceus is bearing its vermilion brush-like clusters of flowers among the young green leaves. H. albiflos has white clusters not unlike the last named, and only the other day H. pubescens, another rather rare white-blossomed kind, came from a friend for naming. H. cinnabarinus is one of the best, and H. Kalbreyeri is another showy scarlet-flowered kind of recent introduction to our gardens. A warm greenhouse temperature suits them well, and, like most other bulbs, they are greatly strengthened by weak liquid manure during their season of growth. When the leaves die off they should be dried on a shelf in the sun until their flowers appear. Nerines do well under this treatment, for if the flower-spikes do not appear before the leaves shoot forth there is no hope for them. This year we have bloomed the rare Phædranassa chloracea by treating it on the plan as above recommended, and Urceolina pendula is most floriferous as grown in the same way.

Shrubby Hypericums.—The rare Javanese Hypericum triflorum survived the last winter in

the open air here, and is now in bloom. Its large, wax-like blooms, of a rich yellow colour, are very beautiful, and even in positions where it is not perfectly hardy it is worth being planted out in the border of a cool conservatory along with H. chinense (= H. monogynum, *Bot. Mag.*). Two of the best of all the really hardy shrubby St. John's-worts are H. oblongifolium and H. patulum. The last named was called H. Gumbletoni by the late M. Lavallée, and is just now quite covered with bright yellow flowers. A smaller form, H. nepalense, is also flowering freely; but perhaps the best, if only one kind is grown, is H. oblongifolium, which now bears its flowers so freely as to remind one of a little yellow Rose—say Rosa Harrisoni at its best. All the above are quite easily raised from cuttings slipped off now and inserted in wet sand in the open border, the whole being covered with a cap or bell-glass. So treated but few cuttings fail, and the young plants grow quite quickly after they are planted out in the spring. Cut sprays of H. oblongifolium go on opening their glossy buds for days after they are cut from the plants and placed in fresh water.

Yucca flaccida.—Now and then I meet with people who get tired of Yuccas, noble in habit as they mostly are, and they often ask me as to which is the best flowering kind. The only species known to me which can be thoroughly relied on to bloom year after year is Yucca flaccida, which is dwarf in habit, with narrow, flexible, glaucous leaves. It throws up a spire of white bells 3 feet or more in height, and is, when seen at its best, a noble plant for grouping on the Grass or for planting out permanently in either beds or borders. It is easily increased by dividing old clumps, and if the thick pieces of the fleshy root-stocks be saved and buried under a warm wall, they throw up young crowns quite freely. It is, or was, used in Battersea Park with good effect, and should become a general favourite wherever plants good in leafage as well as in blossom are appreciated at their true value. A good bold bed of this species on the Grass is now most beautiful in the Botanic Garden at Antwerp, and I saw some groups of it the other day contrasted with Clematis Jackmanni, the effect of the white spike rising from the rich purple Clematis flowers being a most beautiful one. Nearly all other kinds of Yucca are most uncertain as to their season of flowering in our climate, but this one is as beautiful as it is certain to bloom every year.

Acanthus latifolius.—All the kinds of Acanthus are noble foliaged plants, apart from their classical interest, but of all the kinds none to my mind equals this great dark-leaved kind when well and strongly grown. It always seems peculiarly happy nestling near great boulders, or at the foot of a rockery on the Grass, where its glossy leaves can spread themselves on all sides. In France, this kind and A. mollis are often grown in pots or tubs as room or balcony plants, and as so treated they succeed well and have a good effect. Once obtained, all the Acanthuses are very easily increased, since the smallest lengths of their fleshy roots produce buds and crowns if planted in warm light soils. In Holland these smooth-leaved kinds of Acanthus, along with the Japanese Aralias and that best of all room plants, the "Parlour Palm" (Aspidistra lurida), are often met with in windows and apartments in beautiful condition, their glossy green leaves hanging over the embossed brazen or copper bowls there generally used for holding pot plants in the house. Acanthus speciosus (perhaps a major form of A. spinosus) is just now throwing up its tall spikes of lilac flowers at the foot of a sunny wall where it thrives year after year. Its masses of deep green glossy leaves are just now very beautiful.

Tiny annuals.—Some of the small growing annuals are very pretty; none more so at this moment than the little tufted Violet Cress (Ionopsidium acaule), one of the most dainty little plants with which to carpet beds or borders of choice bulbs during the hot summer and autumn days. It may be sown at any time and is rarely out of bloom; often, indeed, it sows itself after it has once been introduced, and so lives on year after year without any attention. It is by no means particular as to soil or position. Another little annual eminently fitted for hot, dry soils or rockwork in full sunshine is Mesembryanthemum tricolor, which is of low and spreading habit, its star-like blossoms shining like floss silk, and varying in colour from white to deep rose. Now and then it is used in carpet bedding arrangements with good effect, but, like all its race, it is never so brilliant as in full sunshine. The brilliant little Linaria alpina grows quite freely on all soils if a little old mortar be dug in ere its seeds are sown. It is a choice little alpine with purplish blue flowers at the tip of its soft glaucous stems. A taller growing species of the richest tints of brown and golden orange is L. purpurea aurea reticulata, which may be sown anywhere over bulbs or tubers during early summer, as it is light in habit and a shallow rooting plant, not likely to do harm either by robbing the soil or by shading it too much from the sun.

Salvia patens.—Nothing in the garden just now can surpass this old-fashioned favourite as a bit of true blue of the richest and most effective kind. A good mass of it on a border amongst the uprising stems of a good white Phlox is now a sight worth seeing, and the other day I saw some well-grown plants of it in flower over a carpet of Heuchera Richardsoni, the lustrous brown leafage of which seemed to add a depth and richness to the Salvia flowers. There is a pure white form of this plant, but it is far less valuable as a garden plant, good white flowers being far more abundant than good deep blue ones. Salvia patens has long been an inmate of English gardens, its tuberous roots having been taken up every year and stored in sand or ashes in order to protect them from frost. Even now we have no deep rich blue flower that can rival it in colour, and so it is likely to remain in favour for a long time to come. The best way to plant it is to make a bold irregular group of it on the border where its flowers can be seen *en masse*, as isolated or dotted about it is too thin in habit to become really strikingly effective. Easily increased by cuttings in the spring.

Galium rubrum.—In habit this plant is not unlike a feathery kind of Asparagus, its flower-stems being purplish, covered with tiny claret-coloured flowers. It is perfectly hardy, and grows freely from seeds sown in the spring. As seen now in flower the plant looks like a soft purplish red mist on the ground. Its delicate sprays, if plucked, are almost of fairy-like tenuity, and may be associated with flowers in many pleasing ways. I first saw it, years ago, in the Cambridge Botanic Garden, and had plants of it from thence on one or two occasions, but I never succeeded with it until I reared plants in quantity from seeds sent to me with other good things by Director Regel, of St. Petersburg. Some of our native species are well worth culture, notably S. saxatile, which, if grown on a limestone rockery or on a wall-top niche in full sunshine, looks like a lace veil spread over the bricks or stones. Above all, however, I commend Galium rubrum as a pretty little species not generally known. I do not know if it has been figured in books, but it must have been a puzzle to whoever tried to show its slender habit and singular beauty if such is the case. Nothing but a most delicate etching could ever express its extreme fineness of growth. Veronica.

Trees and Shrubs.

Large Eastern Plane Trees.

It may be interesting to Sir John Ogilvy and others to know that there are at least a few examples of this beautiful tree to be seen of dimensions similar to that alluded to by Sir John at Charlton Park, Malmesbury (page 190). At Hawstead Place, near Bury St. Edmunds, at a short distance to the south-east of what must have been the front of the mansion, are three very fine old Oriental Plane trees. Nothing now remains of the mansion of Hawstead Place, which was visited by Queen Elizabeth in the year 1578, unless it be the moat which surrounded it and the proximity of these remarkable trees, which are alluded to in Cullum's "History of Hawstead," where it is stated that the largest of the three trees at 3 feet from the surface of the soil then measured 10 feet in circumference, and this is just 100 years ago. The same tree now measures 18 feet in circumference, and the three trees are now nearly upon equality as regards size.

According to Loudon, the Platanus orientalis was introduced to this country from the Levant about the year 1548, and it may be supposed that these trees, as well as that mentioned by Sir John Ogilvy, may have been planted soon after their introduction. In its native habitat this tree is said to attain to extraordinary dimensions as well as, like our English Oak, attaining to very great age, and, although perfectly hardy, grows most rapidly in somewhat sheltered situations. On account of its tolerance of smoke and other atmospheric impurities, it is admitted to be one of the best species of tree to plant in or near to populous towns. And when its great beauty as an ornamental tree is considered, it may almost be regretted that it has not been more extensively planted in parks and other suitable situations than is the case. P. Grieve.

Bury St. Edmunds.

White Jasmine.—A week or two since this old favourite was alluded to by "Veronica," who may be interested to hear of a hedge of it existing here of somewhat unusual size. It clothes a railing about 9 feet high for a distance of some 50 feet, is about a yard through, and is annually covered with myriads of starry blossoms. The main stems are very thick, some being as much as 7 inches in circumference, and are almost as rugged as the Cork Oak. This year the flowers have been exceptionally numerous and large in size. It is somewhat curious that the petals of the Jasmine vary between four and six, there being perhaps as many with five petals as those with six and four added together. — Greenwood Pim, *Monkstown, Co. Dublin.*

The Sycamore in the landscape.—There is no need to praise the common Sycamore as an ornamental tree. Everyone who pays the least attention to trees knows that there are fewer grander hardy trees than a fully developed Sycamore, and an extra fine tree is always a noticeable feature in the landscape. Its head being so massive, and its foliage of a darker green than that of most other deciduous trees, it stands out conspicuously from all others; hence it has always been a favourite ornamental tree, and that is the reason why it is common in the vicinity of mansions. One can always single out an old Sycamore in a plantation by the form of its head alone, which looks like a clouded mass of foliage arranged on branches, tier above tier, with dark recesses between them. The Sycamore produces the best effect when planted singly or in groups of three or four, placed sufficiently near each other to appear like one tree. It assumes two or three distinct

phases of beauty in the course of the year. In spring the new foliage is of a tender green colour, or tinged with red, and sometimes yellowish. In summer it is dull and heavy, while in autumn it suddenly changes to a bright golden colour. These constitute the chief points of beauty in the Sycamore. Its timber, too, is so much in demand now-a-days for a variety of uses, and fetches such a high price, that owners of fine trees cannot resist the temptation to cut them down. Being a rapid grower and not in the least fastidious as to soil or situation, no better tree could be planted in exposed places.—W. G.

THE DWARF MOUNTAIN PINE.

(PINUS PUMILIO.)

This Pine is a low, spreading, and usually stemless tree, found in alpine regions. It grows beyond the limits of trees on both the Alps and Carpathian Mountains, seldom at a lower elevation than 4000 feet, and perhaps but seldom exceeding 7500 feet. Its usual height is about 6 feet, although I have been informed that, under very favourable circumstances, it attains to two or three times that size, when it produces one or several, usually the latter, leading shoots that are hardly continuous, the bottom portion of the tree, however, still retaining its low, decumbent, semi-creeping habit of growth. The leaves, which are in pairs and thickly arranged on the branches, are fully 2 inches long, stiff and curved, and of a rather dull green. Cones ovoid or bluntly egg-shaped, produced sometimes singly, sometimes, and usually, two or three together, about 1¼ inches in length by three-fourths of an inch in diameter at the thickest part.

Pinus Pumilio: cone, scale and seed. Leaves and terminal bud all natural size.

As a covert plant for bare, rocky, high-lying districts this Pine is invaluable, and has been turned to good account in several outlandish parts of our country, and where, from the rocky character of the ground and scant supply of soil, few other plants could succeed. In ordinary mountain woodlands, where shelter for game, particularly the woodcock, is desired, nothing will succeed equal to the Pine in question, the low, spreading, evergreen branches being at all times a warm and pleasant resort for mountain life generally. When plantations are being formed at high elevations, it would be well if the owners of such could be induced to have the more rocky portions, where the ordinary run of forest trees will not succeed, or at least produce timber, planted here and there with clumps of this Pine, which would not only serve as shelter, but be valuable in preventing the naked appearance of uncovered patches in the woodlands. For this purpose small plants should always be used, as these are not only more readily placed *in situ*, but, owing to the generally scant supply of soil in such situations, these succeed much better than when larger-sized ones are used. Damp soil would seem to suit this Pine best, for its straggling nature is considerably increased when growing alongside mountain streams, or at the base of trickling rocks where an abundance of moisture is constantly supplied. This should, however, be no deterrent from planting it in drier soils, where its growth, although generally not equal to that in the damper soil, is sufficiently luxuriant to serve the purpose intended.

Penrhyn Castle, N. Wales. A. D. WEBSTER.

JAPANESE RETINOSPORAS.

I AM seeking information respecting the Retinosporas, their culture and varieties. Can you give a note respecting them in THE GARDEN?—E. PEWTRESS.

*** All the Retinosporas are natives of Japan, where some of them occur as large trees, sometimes 100 feet high. There are about half a dozen species in gardens, and these have produced several varieties. Those named R. obtusa and pisifera are the largest in growth, but of both dwarf compact specimens may be met with. The principal recognised variety of R. pisifera is that in which the foliage is golden, but of R. obtusa there are several varieties. Amongst the best are aurea and gracilis aurea, compacta, and pygmæa. R. plumosa is of rather dense habit, with delicate feathery branchlets. In colour it is a bluish shade of green. Of it there is a variety (alba picta) in which some of the shoots are marked with white, and two others, argentea and aurea, in which the young growth is suffused with white and gold respectively. R. squarrosa is a pretty low tree or bush, noteworthy on account of the beautiful silvery hue of the foliage, which makes it distinct from the rest. R. filicoides is a good deal in the way of obtusa, but the branchlets are unusually short and stout, and the colour a very deep green. R. lycopodioides is of loose, irregular growth, with branchlets curiously flattened at the tips. It seems to be more particular as to its requirements than the rest, as it frequently fails to grow satisfactorily. R. leptoclada is a densely pyramidal plant of slow growth, with cheerful greyish green foliage. It is well suited for cultivation in pots or for winter bedding, as it will not outgrow its bounds. R. filifera when 6 feet or 8 feet high forms a handsome specimen for lawns of limited extent. When larger, its growth is, as a rule, more irregular in character. When young it is a somewhat globular bushy plant, but as it increases in size it acquires a tree-like character. What makes this Retinospora different from all others is the long pendulous thread-like branchlets, often terminated by tufts of little shoots. R. ericoides is a dense, upright shrub, seldom more than a yard high, with long pointed leaves, green during the summer, but changing to a purplish brown in autumn, a colour which it retains throughout the winter. R. tetragona aurea is a little dwarf plant, with spreading branches and bright golden-coloured leaves. It is very desirable for planting on rockwork. For small gardens these Retinosporas are particularly valuable, as they are so elegant, and so neat in growth, and being slow growers, there is no fear lest they should outgrow their allotted space. They are specially adapted for rockeries, as they are all quite hardy in this country, and require no attention when once well planted in good soil in open spots. If by chance they do outgrow their bounds, they can be reduced by means of the knife without destroying their beauty, as, if cut back, they all again break freely into growth. They are among the easiest classes of Conifers to strike from cuttings, the quickest to root being R. ericoides and R. squarrosa, the two that bear only juvenile foliage; then come R. pisifera, plumosa, leptoclada, squarrosa, and filifera; while the slowest rooting, but still by no means difficult, are R. obtusa, filicoides, and lycopodioides. If you wish for further information, we will endeavour to help you.—ED.

Spiræa Lindleyana.—Lindley's Himalayan Spiræa is, during July, a most beautiful object in a shrubbery. Its large Fern-like leaves, retaining a refreshing green throughout the summer months, added to which the long, elegant spikes of small white flowers, render it exceptionally beautiful at this particular season. A specimen I have here in bloom at this date (July 12 to 29) surrounded with a dense margin of St. John's-wort (Hypericum calycinum), also in full flower, has a very pleasing effect. My partiality for it has caused me to plant it amongst wall Pyracanthas, the sombre foliage of which, now that the flowers are past and the berries green, being greatly enlivened by contrast. Spiræa Lindleyana is a deciduous shrub, and requires free culture in good soil to render it attractive.—W. EARLEY.

THE IRISH JUNIPER.

(JUNIPERUS HIBERNICA.)

As everyone is probably aware, this Juniper originated in Ireland, most probably from seed, and on account of its singular habit of growing in a slender, compact column it has proved to be a most useful evergreen tree for utilising in Italian and other geometrical gardens, where stiff and formal looking plants are needed to please the tastes of those who cultivate this style of gardening. This Juniper is not only strikingly distinct in form, but its foliage also affords a decided contrast in colour to that of most other Evergreens, being a mixture of light green and silver glaucous hues. It is effective when planted alternately, or in conjunction with the Irish and Golden Yews and standard Portugal Laurels. As a dwarf tree for planting sparingly in a cemetery or churchyard it is peculiarly suitable on account of its comparatively slow growth, as well as its slender form, occupying but little space; it is, moreover, perfectly hardy, and will grow in any common garden soil, but doubtless prefers a moist, rich, heavy soil to a dry, gravelly, poor one. J. hibernica compressa is similar to the above in habit and colour, but very much slower in growth, and smaller in all its parts. It forms a compact, slender pyramid. For parterre winter gardening on a small scale this little Juniper would be invaluable. It is not difficult to transplant; indeed, it is so dwarf a tree that it could be grown on for years in a moderate-sized flower-pot, thus insuring its safety when removed from its summer to its winter quarters, and *vice versa*; the rate of its growth I do not believe exceeds 1 inch in a year. J. excelsa stricta is an erect variety of the handsome Crimean Juniper. Its foliage is beautiful in colour, being light green and glaucous, and contrasts charmingly with dark green, wide-spreading Evergreens. It is quite hardy, having stood the test of the past few trying winters without injury. J. thurifera, the Spanish Juniper, is another hardy upright-growing tree with glaucous leaves, suitable for giving effect where formality in gardens is studied. G.

Spiræa ariæfolia.—One of the most beautiful hardy shrubs now in flower in gardens is the white S. ariæfolia. Its elegant flowers seen among our common shrubs have a beautiful effect. At present such noble shrubs are usually thrust into a shrubbery, and there allowed to take their chance. Obviously such fine subjects would look much better isolated on the turf, or associated in small irregular groups, so that each might show its character, and the whole have a picturesque effect. When we pay as much attention to tastefully arranging such noble and long-lived shrubs as we do to those which last only a few months in beauty, we shall find a rich reward.—W.

The Monterey Cypress.—The illustration given last week of Cupressus macrocarpa at home, at Monterey, California, suggests memories of pleasant hours spent in studying, among others, the identical trees therein depicted. The Monterey Cypresses planted in this country have probably been derived, directly or indirectly, from the Monterey habitat, and though differing considerably in habit, they (excepting, of course, unhealthy individuals) present a uniformly bright green colour. But I have an impression that I observed a greater variety of forms in the individuals under cultivation in California than I have noted in Britain. I observe that one of the most recently published of our popular books on Conifers limits the habitat of this Cypress to the neighbourhood of Monterey. I have myself seen a grove of this species about a hundred and sixty miles to the north

of that town, and within a few miles of the mouth of the Russian River. The trees, especially the young ones, were of a greyish-green hue, yet not quite so grey as McNab's Cypress. In habit and size they were similar to the Monterey trees, and were specifically identical. The colour of the nursery plants was decidedly a glaucous green.—Geo. Syme.

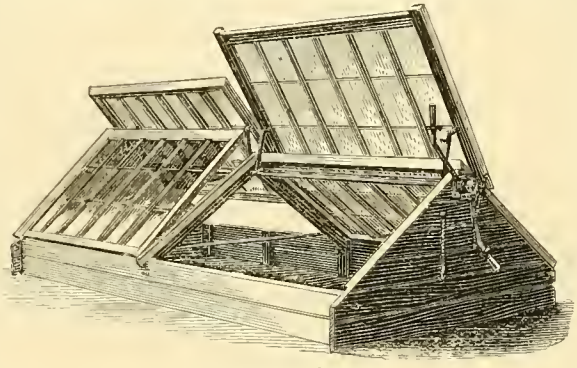
BERBERIS REPENS.

The question often arises as to a suitable permanent edging other than the common Ivy, and I can recommend this little dwarf Barberry as suitable for the purpose. Two or three-year seedlings, planted in two or more lines 6 inches apart, will, with a little attention and management, make an edging superior to Ivy and most other materials commonly employed. Although not at all particular as to soil, like everything else, it does best when well treated: therefore the ground should be trenched up and well prepared some time before planting. The plants may be planted deeper than is desirable with most hardwooded plants, as it will soon strike root from the buried portions of the stems. It will bear trimming in with the shears, but it is far better to do the necessary pruning with the knife, as the leaves that remain are left intact, and will not present a ragged appearance as when the shears are used. It may be kept for years in a dwarf compact condition by cutting well back every spring after flowering, and pinching out the point of a shoot occasionally during the summer. Of course, this close cutting back would prevent its fruiting; but, although this might in one respect be a loss, in others it would be a gain, as a heavy crop of fruit has a tendency to exhaust the plants, and might cause them ultimately to assume a ragged outline, which in the case of a verge or edging of this kind would not be desirable. Although I have only spoken of this plant as useful for verges or edgings to shrubberies, it might also, now that the advantages of introducing more variety of a less ephemeral nature into the flower garden is beginning to be recognised, be used as edgings next the Grass, in either a straight or any other outline. If this and other plants of a kindred character were more used, there would not be such a dreary blank when the frost came; and with a few additions from the reserve garden of spiral-growing plants, with bulbs and annuals, a very respectable winter display might be got together with little expense. But when nothing but tender plants are used for bedding, and these have to be entirely replaced, any attempt at winter or spring gardening becomes expensive. E. H.

Idesia polycarpa.—This handsome and most interesting Japanese tree was not known to science until 1866, when it was described by the Russian botanist Maximowicz, who met with it in cultivation at Nipon and Yedo, and ascertained that it was a native of the island Kinsiu, at the foot of a mountain called Hikosan. It is a handsome tree-like spreading shrub, with fine foliage; but, according to Professor Maximowicz, it attains in Japan the dimensions of a large tree. The leaves, which have crimson stalks, are irregularly serrate, slightly cordate at the base, the larger ones measuring about 6 inches across, bright green above, and whitish or almost glaucous beneath, with five prominent branching nerves, which are reddish towards the base. The flowers are dioecious; the males have from four to six yellowish green spreading sepals and an indefinite number of pale green filaments with orange anthers. Each blossom is about half inch across; they form long, gracefully drooping, branched racemes, springing from the axils of the upper leaves. The female flowers are similar in appearance, but are succeeded by very numerous orange berries, which appear, from dried specimens communicated by the discoverer to the British Museum Herbarium, to be about as large as a small Cherry. The flowers are deliciously fragrant, their odour resembling that of a Vanda; and although their colouring is not brilliant, their effect, combined with the red leaf-stalks, the varying green of the leaves, and their elegant drooping habit, is extremely pleasing. The tree belongs to the Order Bixineæ (or Flacourtiaceæ), to which our gardens have not hitherto been largely indebted. It was named by M. Maximowicz in commemoration of a Dutch traveller named Ides. It appears to be quite hardy about London, and a good sized specimen of it may be seen in the arboretum at Kew, in the part known as "The Dell," where it forms a fine object.—W.

A NEW PLANT FRAME.

Among the multitude of hothouses, frames, and other garden appliances shown at the Royal Horticultural Society's recent show at Liverpool, there was very few that could lay claim to originality. One of the few things that could be called novel was the opening gear of a new adjustable plant frame, invented by Messrs. Halliday, of Middleton, and of which the accompanying engraving is an illustration. Practical men may see at a glance the advantages possessed by this arrangement of the opening gear over others. The frame has provision for top and bottom ventilation which may be given at will. The lights are secured in any position and cannot be blown off; and they can also be turned right over one on to the other and securely fastened with chain and hook, and in that position easy access can be had to the plants, and there is no fear of the lights falling down, as is the case sometimes in frames with the lights held open by props. The frames are constructed in a very simple manner, and may easily be taken to pieces and stored away under cover when not in use. Such frames are invaluable for many classes of plants, and particularly for hardening off plants in spring; while for plants of doubtful hardiness and for delicate alpines liable to perish in winter they are an invaluable aid.



New garden frame.

NOTES FROM LEHENHOF.

I was particularly interested in the beautiful engravings you gave in The Garden of Mr. Otto Forster's garden at Lehenhof. Throughout my travels in various parts of Central Europe I have not met with a prettier garden or one more artistically arranged than that at Lehenhof, while it abounds with interest for plant lovers, who find there a vast collection of plants, both native and exotic, from the highest mountain peaks to the hottest jungles. As I have not before had an opportunity of publishing the few notes I made in Mr. Forster's garden when I visited it, I should like to do so now, although M. Max Leichtlin's account of it was so interesting. Lehenhof is situated in the midst of charming scenery, with long extended views on all sides, particularly to the south and south-west, where peak after peak with snow-clad summits, clothed on their lower sides with various kinds of forest trees, form one of the most charming views imaginable. The extent of the pleasure grounds and garden is about twenty acres, exclusive of the farm land. The winter garden, the fernery, the Rhododendron house, the Orchid house, and several other houses are in striking contrast to the surrounding scenery. The conservatory is about 60 feet long by 40 feet wide and 25 feet high. Here I noticed some fine examples of Tree Ferns, among them being Cyathea dealbata with a stem 8 feet high, bearing aloft a fine head of its beautiful fronds covered with a silvery whiteness beneath. Alsophila australis had a stem fully 10 feet high. There is also a fine example of Kentia Forsteriana with twenty-seven finely developed leaves; Brahea dulcis and another Brahea nearly as large.

The rockwork and waterfall in this house are most picturesque and nicely clothed with plants suitable for such positions. Another house has been specially constructed to accommodate the Sikkim and other species and varieties of Rhododendron with admirable success. It is about 60 feet long and 36 feet wide. Although it was in the winter season when I saw it, it was a great pleasure to see this house of Rhododendrons, every plant being in the rudest health, evidently enjoying the pure air from the surrounding mountains. Rhododendrons have been Mr. Forster's special study for many years, and he has been a successful hybridiser, and among them one interesting cross he effected was between R. hirsutum and R. ferrugineum, the offspring of which was pointed out to me growing on the outdoor rockery. The greatest of his successes, however, is, I think, the Rhododendron named after himself, R. Otto Forster, of which he possesses some fine specimens. The blossoms of this fine hybrid are as large (possibly larger) than R. Veitchi, creamy white on first expanding, then becoming snow-white and of wax-like texture. Of Rhododendron Aucklandi there are fine plants fully 11 feet high and nearly as much through, and of R. Nuttallianum there are several fine specimens also. R. Jenkinsi and R. argenteum are fully 8 feet high. Another remarkable specimen 10 feet high or more was R. Sesterianum. It would take me a long time to enumerate all the fine specimens and rare species of Rhododendrons brought together in this house, besides the hosts of seedlings which have yet to be flowered.

Azaleas are also a speciality, and hybrids of them are raised. Among these there is one called Hexe, which is a most beautiful variety, being raised by crossing A. amœna and A. Duc de Nassau. It is very floriferous and of an exceedingly pleasing colour. Orchids seem to revel in the mountain air at Lehenhof, and of cool Odontoglossums especially Mr. Forster can show large numbers of beautiful specimens, and besides cool Orchids there are collections of Cattleyas, Vandas, Aerides, and the like. An interesting house to me was that devoted to the raising of rare alpine plants and for wintering those which would be likely to suffer by long winters. Here I noticed amongst many rarities, such as Haberlea rhodopensis, growing luxuriantly, Saxifraga florulenta, Primula Allioni, Daphne rupestris, &c.

The rock garden is about half an acre in extent, where very many rare alpine plants have found most congenial homes, notably the rare and beautiful Ramondia pyrenaica alba. It was not in flower, but Mr. Forster kindly gave me a photograph of one of the plants taken when in full beauty, showing a dozen or more flowers open at one time on the plant. The plants of this rare gem are growing together nicely arranged on an almost perpendicular piece of rockwork in deep shade. Artemisia pedemontana was a noteworthy plant. It has silvery leaves, and is dwarf and compact. The garden is very rich in alpine Primulas; growing on the rockwork, and also in pots, amongst many others the following were noted: Primula algida, Auricula, Arctotis, Balbisi (Lehn.), ciliata (Moretti), biflora, capitata, cashmeriana, carniolica, calycina, ciliata (Schrank), Clusiana (in fine masses), Dinyana, Facchini, Göbeli, flagellicaulis, Fkerkiana, glaucescens, japonica, Kitaibeliana, longiflora, marginata, minima, pedemontana, pubescens, pumila, rosea, scotica, villosa, venusta, Venzoi, viscosa, Weldeniana, and Wulfeniana. The following, I believe, are new species: P. Kingi, reticulata, and intermedia (Portenschlag).

Besides being clothed with a variety of native trees, the garden is planted with fine specimens of Picea, Cupressus, and other rare ornamental Coniferæ and deciduous trees all arranged in tasteful harmony. No doubt many besides myself have experienced the same feeling of regret in leaving such a charming spot as Lehenhof, whose beauties cannot fail to impress one, whether a plant-lover or not. TOURIST.

INDOOR GARDEN.

CULTURE OF TUBEROUS BEGONIAS.

THE great advance made with these plants during the past few years is truly surprising, and the little care they require should lead to their universal cultivation. When the first species were introduced they were treated as stove plants; now they are treated more like hardy plants, and so numerous are the varieties, that anyone can obtain fine forms from a packet of seeds; but to succeed in this some little care and attention is required.

BEGONIA SEED should be sown about the last week in January on slight bottom-heat, the soil they prefer being a mixture of loam and leaf-mould, but carefully avoid peat. Sow the seeds upon the surface and cover with glass. In a very short time the seeds will germinate, and as soon as they are sufficiently large to handle the young plants should be pricked out, and as they increase in size place them in pots or pans; if they are intended for planting out of doors, boxes will be found most convenient.

THE SOIL should consist of turfy loam, leaf-mould, and well decomposed manure in about equal parts, carefully avoiding the use of peat, as Begonias will not succeed in this soil. The pots or pans should be well drained, as these plants are great water-lovers, and unless the drainage is good the soil soon becomes sour and the plants dwindle away. From the time of sowing the seed until they have made some few leaves these plants should have a slight bottom-heat. The atmosphere in the house should be kept cool and airy.

PLANTING OUT OF DOORS may commence about the first week in June. The seedlings will be quite small things, but still they will soon grow vigorously in their new situation. Have the beds prepared with the soil already named. Put a little Cocoa fibre refuse into the mould with them, and cover the surface of the ground with the same material when planting is finished, leaving them about a foot of space to fill. Keep them free of weeds and well supplied with water, when they will soon commence to flower and produce a magnificent show up till the frost cuts them off in autumn. When this occurs carefully lift the tubers, dry them, and store them away in a cool place, with a slight covering of dry Cocoa fibre refuse or sand, until the following spring, when the same treatment may be pursued as recommended for seedlings. As rock plants they should be freely used with other things, as they will thrive admirably in such situations and appear to better advantage than when on a flat surface like beds and borders.

FOR THE CONSERVATORY, Begonias have few, if any, rivals, their rich and varied colours making a brilliant display, and continue to keep the house gay until the flower of autumn (the Chrysanthemum) takes their place. Those who have sufficient space will probably prefer to grow the plants for this use through all their stages in pots, shifting them from time to time as occasion may require, but where space is limited they may be planted out of doors and lifted when the conservatory is getting empty and dull. The varieties of Begonias are now so numerous, that a rich display may be depended upon from seeds; there may be some, however, who require certain colours, and, therefore, would continue to propagate their stock from cuttings; we therefore give the names and colours of a few of the best: Countess of Rosslyn, bronze-orange; Distinction, crimson, white centre; Earl of Chesterfield, vivid crimson; Earl of Rosslyn, orange-scarlet; Golden Queen, golden yellow; Her Majesty, blush, centre rosy pink; Lady Brooke, dark rose shaded violet-magenta; Lord Salisbury, red shaded crimson; Magenta Queen, bright magenta; Mrs. Laing, pure white; Star of Gold, bright yellow; Thomas Bell, bright salmon.

AS BASKET PLANTS, Begonias are extremely ornamental; their large and richly coloured flowers hang as gracefully as Fuchsias, but they have the advantage of Fuchsias in the greater variety of shades of colour. For baskets the double forms are superior to the single, but the doubles are also very fine treated as pot plants and bedders. The following are a few of the very best doubles suited for baskets: Alba plena, pure white; Comtesse de Trielhart, bright apricot; Formosa, deep rosy carmine, white centre, edges maroon and fringed; Glory of Stanstead, deep rose, white centre; Goliath, soft crimson; Louise de Goussaincourt, soft rose; Marquis of Bristol, bright yellow; Madame Arnoult, salmon-rose; Marquis of Stafford, carmine-crimson; M. Brissenden, intense scarlet; Miss Amy Adcock, salmon red, white centre; Prince of Wales, rich crimson; Princess of Wales, pure white full flowers.

AS MARKET PLANTS, Begonias, I consider, are specially suitable. The great ease with which these plants can be grown in the open air and lifted when in bloom, added to their large and attractive flowers, should make them great favourites with the market growers and their customers. For this purpose seedlings would be the easiest and best. As before stated, Begonias may be grown into good specimens in one season, and they produce a crop of flowers at a time when blooming plants are few. W. H. G.

Gloxinia buds abortive (*H. L. B.*).—The Gloxinias sent are similar to those frequently observed on plants from bulbs five or more years old, which often produce abortive or partly deformed flowers, although as far as the foliage alone is concerned they appear in excellent condition. The same deformity in the flower may, however, be attributed to some other causes in case of younger bulbs, such as dry state at the roots while the surface only of the soil is kept moist, or exposure to too strong a light, or again to too much air. All these points should be carefully watched and noticed, as they are, or one of them most likely, the cause of the bad result of which you complain.—S.

Amphicome Emodi.—Of the two species of the little known genus Amphicome, A. Emodi is a more remarkable species than arguta, which was first introduced in 1837, and is indigenous to the Himalayas. A. Emodi was introduced much later; but the size of its flowers, which are of a beautiful rose colour, has enabled it to assume and hold a more prominent position in our gardens than its congener. It is tolerably hardy, and will doubtless live in the open air in most of the southern counties. It is, however, all the better for a little protection in winter.—B.

Sibthorpia europæa variegata.—This elegant little trailing plant has obtained a reputation for being delicate. I consider it, however, very free, having grown it in large quantities for some years without the slightest trouble. I grow it in a compost of half loam and peat, taking care that the pots are extra well drained. They are placed full in the sun, where very little, if any, shade is afforded them during the day, but they are always kept wet, and this, I believe, is the only secret which has led to success, for I have observed when a plant has been missed and been drier than usual it rapidly begins to dwindle. Again, although this little plant is such a water-lover, the moment the drainage becomes clogged it shows signs of distress and quickly dies. It is a veritable little gem for surfacing large pots, or for small hanging baskets.—W. H. G.

A beautiful winter plant (Holmskioldia sanguinea).—This is a bold-growing, handsome winter flowering member of the Labiatæ, which, although introduced about a hundred years, has hitherto escaped much attention. I look upon it as one of the finest ornaments for the intermediate house during December and January that can be grown. When vigorous it attains a height of from 3 feet to 4 feet, and the growths for about half the length will be laden with flowers, but it does flower well when not more than a foot high, though in this state it is not very effective. The leaves are opposite, somewhat ovate, crenate on the edges, and dark green. Its flowers are borne in terminal and axillary clusters and are scarlet, surrounded by a large cup-shaped bright red calyx. It is a plant of the easiest culture; it strikes freely from cuttings at almost any season, and does not require strong heat to grow it into a handsome shrub. Pot in about equal parts of loam, leaf-mould, and peat, making the whole sandy, and drain well.—W. H. G.

Dracæna Alexandræ.—This is one of the best kinds with white variegation. It is free in habit and the leaves are very elegant. It is peculiarly fitted for table decoration—in fact, it is a plant worthy a place in any garden. There is, however, a rival in store for it. Fancy a Dracæna with more elegance than D. gracilis, and with leaves nearly covered with silvery whiteness!

Aristolochia ornithocephala.—This is one of the strong-growing and free-flowering kinds. Its flowers, too, are very handsome seen hanging from the roof of a stove as we saw it the other day at Waddon House, where it is highly appreciated. This species, although a robust grower, has been so restricted in its roots, that it really is making almost more flowers than foliage. It should be potted in good loam.

Camellias as stove plants.—We have frequently seen these plants in the open air in various parts of the country where they grow and flower most freely, and have proved themselves sufficiently hardy to withstand unharmed a very low temperature; but, on the other hand, we saw recently at Beddington House the back wall of a stove covered with Camellias, perfectly healthy and well set with buds. Formerly this house was kept cool and used for greenhouse plants, the same Camellias being on the wall and planted in the border. When the house was converted into a stove, the Camellias were allowed to remain where they still thrive. The only effect the change of temperature has had upon these plants is it causes them to open their flowers earlier, so that, judging from the above facts, Camellias should force easily.

Clerodendrons flowering twice in one season.—I have a case under notice somewhat remarkable. Very early in the spring I had in flower Clerodendron Balfourianum, C. Thomsonæ, and C. fragrans. Some time ago, however, I thought one day they were getting rather too shabby to occupy the prominent position they held when in bloom, so I resolved to cut them back and see if they would flower again. I did so, and repotted them, the result being that I have them blooming again splendidly. I often think it a pity that plants that bloom for a very limited period should be put away for the rest of the year to remain dormant. Therefore if plants, especially short-lived ones, can be induced to flower twice a year, what a boon that would prove.—W. A. COOK, *Holme Wood*.

SHORT NOTES—INDOOR.

Saxifraga tricolor.—This beautifully variegated Japanese Saxifrage is now in fine condition at Messrs. Laing's nursery. It has hitherto proved somewhat difficult to cultivate; here it thrives in strong bright light under glass.

Vines diseased (*A. B.*).—We regret our inability to point out the cultural reason for some of the leaves prematurely bronzing, or some of the points going blind. There is no disease on the examples sent. Without seeing the house we should have attributed the affection to bad ventilation, but you say there is "plenty of air."—W. G. S.

Clematis coccinea.—Referring to the note on this in THE GARDEN (p. 163), allow me to state that some years ago I saw a plant of this in M. Max Leichtlin's garden at Baden-Baden; the impression made upon me by it I have never forgotten. Its dark green foliage and mass of interesting flowers are a sight well worth seeing.—LOUIS KROPATSCH, *Lavenburg*.

Lilium longiflorum.—We saw this week in a Surrey garden some large masses of this Lily, bearing a large crop of blooms for the second time this season; the bulbs were potted up last autumn and forced, and flowered during the month of April; after these were past the pots were removed to a cool frame, where they have remained to the present time, when a second crop will soon be in full beauty.—W. H. G.

A pretty basket plant.—I find that the alpine Strawberry is a pretty plant for house culture, and in a moderately low temperature will produce fruit continuously. I have taken up and potted a good number of plants of both the red and white alpine, and expect that their fruits and flowers will, during the winter, amply repay the little care required in their culture. I should think that those who take so much delight in window plants would try the alpine Strawberries. The varieties that produce runners are very pretty when grown in hanging baskets, for the long pendent stems produce a bunch of leaves, flowers, and fruit at every joint, and I am sure the whole appearance of the plants is equal, if not superior, to Aaron's Beard (Saxifraga sarmentosa), Tradescantia, and scores of similar plants that are generally cultivated for such purposes.—W.

Clothing plant house walls. — To turn everything to account and to make every part of the back walls of plant houses enjoyable should be attempted by everyone. That this may be done more easily and effectively than by the usual system of brackets I am confident, from the luxuriant appearance of the back wall of a plant stove in these gardens. The wall in question is covered with strong wire about 4 inches apart and the same distance from the wall; the space next the latter is filled with turfy peat, &c., and in this are large masses of fine-foliaged Begonias; the Stag's-horn Fern and other plants also luxuriate in this situation, and the groundwork is densely covered with Adiantums, Pterises, Lycopods, Panicums, &c. Fern fronds, always in request, may here be gathered in any quantity; and beyond frequent syringing these walls are scarcely any trouble; in fact, by pegging in the Lycopods and filling up any cracks in the soil with a little fresh material, they will last for a number of years.—G.

Tropical Balsams.—All the tropical species of Impatiens are plants of the highest value in the garden, and I am glad to find I. Jerdoniæ again coming into repute. Thirty years ago I grew it in large quantities, and it made such an impression upon one grower, that he bought a stock of it, intending to try it for market purposes; as I never saw it brought out, I suppose it did not succeed. The following two species belong to the same section, and both being winter bloomers are the more valuable. Their names are I. Walkeri, a free-growing plant from Ceylon, attaining a height of a foot or more, with somewhat swollen stems and alternate, ovate-lanceolate deep green leaves; the flowers are borne in large corymbose panicles, each upwards of an inch long and as red as a soldier's coat. I. bicolor, a vigorous grower, reaching 18 inches to 2 feet in height, with large, coarsely serrated, ovate, pale green leaves. The flowers are produced on single stems, but in large clusters; they are some 2 inches long, much inflated, pitcher-shaped, and rich deep plum colour, with a white throat and upper petal.—W. H. G.

Passiflora princeps (racemosa).—There are few more beautiful climbers for a warm conservatory or intermediate house than this and few more easily managed if given reasonable root room. It grows rapidly, and soon clothes the house it is in with festoons of handsome bright polished green leaves, for which it would be well worth growing, if it never flowered. The tips of these festoons, however, soon become clustered with bright red buds, in various stages of development, springing from rather conspicuous purplish bracts. These expand one or two at a time, forming large, light scarlet blossoms with a small white corona. From the older parts of the stem spring numerous leafless racemes of flowers, which blossom sometimes on the very benches. On a small plant obtained two years ago at a nursery, and only last year planted out, I have just counted more than a score of racemes in various stages, many nearly a foot long (the floriferous portion) and bearing innumerable buds and flowers. These latter are very effective in small glasses on the dinner table, as they do not close till very late, and look very bright under artificial light. The house in which the plant is growing contained a miscellaneous collection, and often falls under 50° in winter. Not the least good quality of this Passion-flower is its apparently complete immunity from insect plagues, neither thrips, scale, nor bug having seemingly any fancy for it. As it is procurable at almost any nursery for about one or two shillings, everyone who has a warm house should grow it.—Greenwood Pim.

ALPINE PLANTS ON WALLS.

In a few old gardens visited lately we have been much struck with the success in the cultivation of certain kinds of alpine plants on old walls, which in many cases were crumbling away from age. On these we saw plants clinging to them with surprising tenacity, pictures of health, and with roots often no thicker than whipcord; while the same plants growing in the ordinary border or rockery, even when well attended to, have entirely lost that characteristic growth which makes them so beautiful on walls. Much can be

learned, far more indeed than most people seem to be aware of, from a study or imitation of the old plant-clothed walls, for, if we strive to be successful cultivators, we must be always ready to take a lesson from Nature's sown plants. It is true that we cannot always find in our gardens old walls for the various selections of alpines, but in places where space can be allowed for a rockery, a little could be spared in which to imitate an old wall, and it is surprising what a large number of plants can be grown in the space of a square yard, and those, too, such as will thrive well under few other conditions. In many gardens there is plenty of waste ground that could be utilised for such a purpose, such as boundary walls, &c., instead of being built in the modern square fashion, something in the way of the old dry stone dykes, used for dividing the marches on the moors, with plenty of good soil built in, would serve the same purpose, be less expensive, and when well clothed with vegetation, be in accordance with the garden which the walls enclose. In many old places sunk walls are used to divide the flower and pleasure gardens from the park; these could be made alive with these charming little gems at a small cost, and requiring little or no attention after having been planted. The new rockery at Kew shows in a large way what may be done in miniature, even in the smallest garden; and one of the best examples of wall gardening at private gardens about London is in Mr. Latimer Clarke's garden at Sydenham, which has always been famous as a hardy plant garden. On such walls as we have alluded to Iberises, Helianthemums, Linarias, Sedums, and all the crusted Saxifrages are quite at home, making a display that repays the cultivator tenfold for his trouble at the outset. It does not necessarily require stone in building these walls, though it is best—old pieces of brick, cement, &c., being quite as useful, and, under ordinary circumstances, quite as lasting as stone. On such a structure we have seen such alpine gems as Potentilla nitida, crusted-leaved Saxifrages, Sedums, and Houseleeks. Trailing plants, however, are the subjects most suited for walls, such as Campanula garganica, isophylla, and Tenorii, Androsace sarmentosa, lanuginosa, many of the Dianthuses, Fragaria indica, Linaria alpina, &c., as well as such plants as Origanum Dictamnus and Tourneforti, Onosma taurieum, Silene acaulis and alpina, Polygonum vaccinifolium, Veronica officinalis, rupestris, &c., Cistuses, Cytisuses, Linaria Cymbalaria, white and purple, Convolvulus Cneorum, Alyssum saxatile, and many others.

K.

Ferns.

VARIATION IN BRITISH FERNS.

In my wanderings through the woods and downs of this part of Carnarvonshire I have often met with rare forms or varieties of native Ferns, and as the subject is at present exciting some comments in The Garden I have thought that a few notes on such as I have found, specimens of which are preserved in the herbarium of the University College here, may be of interest to some of your readers.

Among the Hart's-tongues (Scolopendrium) two distinct and constant forms have been found, S. crenulatum and S. multifidum. The latter occurs in considerable quantities in at least two places, but in one of these stations many of the plants have been destroyed in the course of repairing the wall and bridge on which they grew. In at least nine-tenths of the plants all the fronds are more or less multifidly divided at the apex. Crenulatum is a very desirable form, but I have only met with a couple of specimens.

Blechnums, above all others in this district, seem prone to deviate from the normal form, for I have found no less than half a dozen of the recognised varieties. B. multifidum, having not only the apex of each frond divided three or four times, but the pinnæ constantly bifid, I found some years ago. It has remained constant under cultivation, and I may add that fronds sent to Mr. Wollaston were considered by him to represent a very good form. B. imbricatum occurs plentifully in a farm hedge, and there seems to have quite ousted the typical plant; while B. strictum, also named by Mr. Wollaston, and B. anomalum I have come across on more than one occasion. B. strictum, of which there were several plants in a confined area, is a pretty form, and one of the most constant under cultivation. B. bifidum I have likewise found. In a high-lying rocky wood, where the blue Anemone and pink wood Sorrel grow, I have oft stopped to admire the multifid form of our common Bracken (Pteris

aquilina multifida), which in that guarded spot grows by the acre. This is a very distinct plant, but to transplant it successfully has puzzled more persons than myself.

The Polypodiums are, perhaps, next to the Blechnums, most liable to sport, and within a radius of one mile from Bangor, P. bifidum, P. acutum, and P. crenatum (all better in form than I have purchased under the same names) have been found, but usually in company with the original plant, P. vulgare. P. acutum, with its long acutely-pointed fronds, is very distinct, but not so attractive as acutum Stansfieldi, which occurs in a single tuft near the sea-coast at Port Penrhyn, and within a short distance of it an old Ash stump is literally covered with a very constant form of the well-known bifidum. Near Aber Waterfall I have seen a very good bifid variety of the Oak Fern (P. Dryopteris), and I am not aware that such has been before recorded.

Ceterach officinarum crenatum occurs very plentifully on an old wall I know of, where, strange to say, not a plant of the type is to be found. In another district both are found together, or at least within a short distance of each other. Under cultivation this is by far the most desirable plant, being of more robust growth and ornamental in appearance. Polystichums, although unusually plentiful, do not vary in the least, and the only departure I have noticed is P. aculeatum lobatum, but this, again, is reckoned by some botanists as a distinct species.

Three well-marked and distinct varieties of Lastrea Filix-mas I have picked up more than once. They include L. pumila, a dwarf and neat alpine form; L. fluctuosa, a very desirable plant and one that is true to character under cultivation; and L. interrupta, which occurs rather plentifully in a wood. Another form of L. Filix-mas, with irregularly divided fronds and pinnæ, almost monopolises an old Oak wood on the banks of the Menai Straits. Some of the specimens are very handsome, the dividing up of the apex of each frond being regular in a marked degree. The normal form also occurs in the same wood, but is not so plentiful as the plant under consideration.

I sent to THE GARDEN some time ago a description, with specimens, of a beautifully crested form of Hymenophyllum Wilsoni that I was fortunate enough to meet with on the top or roof of a damp, dripping cave. It was, in truth, a lovely plant, every frond being multifid or crested, and, sorry am I to say so, most of these were given to enquiring friends. I searched all the ground where it was found over and over again, but although the typical plant occurred in plenty in several places close at hand, only one small patch of the variety could be detected.

Asplenium Adiantum-nigrum acutum may be seen in plenty on a shady hedge bank not a mile from Bangor, while a variegated form of the species used to occupy, in no mean quantity, the side of an embankment close to the old Roman camp at Bethesda, or rather, I should have said, near to that place.

Some years ago a single specimen of the forked Spleenwort, A. septentrionale, which was found on the Snowdon range, was brought home, potted, and placed with other Ferns in a cold greenhouse. Gradually the young fronds developed into those of A. germanicum, and the plant, half of which is now in my possession and half in that of the finder's, would to an ordinary observer be classed as that species. Fronds intermediate between the typical A. septentrionale and A. germanicum (none of the former now exist) are not uncommon, some of which resemble very closely drawings sent to a contemporary recently from fronds collected by Dr. Lowe, of King's Lynn, near the Maloja Pass in 1882. Dr. Lowe, in a note which accompanied the drawings, says he found several specimens bearing on the same root every intermediate form between A. germanicum and A. septentrionale. It has likewise been stated that A. septentrionale and A. Ruta-muraria have never been found in company with A. germanicum, but this is wrong, for I could point out a wall on which the two former are growing almost side by side, and the latter with only the road width between them. I have picked fronds from a plant of Ruta-muraria that have on more than one occasion passed off as those of germanicum.

Can it be that two of the three plants, A. germanicum, A. septentrionale, and A. Ruta-muraria, are but forms of one species? From the above, as well as the observations of the late Professor Balfour and Mr. Boyd, it is certainly not at all unlikely. A. D. WEBSTER.

Penrhyn, Bangor.

ORCHIDS.

SEPTEMBER BLOOMING ORCHIDS.

THE following are now in flower in Mr. Bull's nursery, Chelsea, affording proof, if that were wanted, that even at this season of the year there is plenty of material among this tribe of plants to maintain a brilliant display, and when associated with Maiden-hair and other Ferns, as they are in this establishment, the effect produced by them is greatly enhanced. The secret of success in this case lies in maintaining a cool atmosphere, giving plenty of moisture and air, and in paying strict attention to cleanliness:—

Acineta densa
Aerides quinquevulnerum
Anguloa Clowesi
Brassavola nodosa
Calanthe Dominii
  mastica

W. H. G.

Oncidium Jonesianum.—This invaluable and beautiful Oncidium we lately saw in perfection at The Firs, Laurie Park, Sydenham; some two dozen plants, from an importation last February, were blooming freely. The plants generally bore from three to five spikes each; one plant with five spikes is bearing sixty flowers, two of the spikes carrying eighteen and sixteen on each spike, being the largest amount we have seen at present. Mr. White attributes his success to starting the plants gradually in the Cattleya house on the west side of the roof, removing them into a higher temperature as the roots and growths advance. The plants are fastened on teak rafts, bulbs downwards, and have received copious syringing three times a day. They are quite a mass of roots. Surely if this lovely and cheap Oncidium can be so easily grown, it must become very popular in the Orchid house, seeing that it lasts fully three weeks in perfection.—B.

Cattleya gigas Hardyana.—Mr. Hardy, of Pickering Lodge, Timperley, writes to say that the Cattleya shown at the last meeting of the Royal Horticultural Society was not the true C. gigas Hardyana, but another form of C. gigas, which he considers very good. Of the true variety named Hardyana there is but one plant, and that was exhibited by him at South Kensington in August of last year, when it obtained a first-class certificate.

Twin-flowered Cypripediums.—I send you a specimen from one of my plants of C. niveum, bearing two flowers, and a third in bud. The same plant bore twenty flower-stems, almost all of which have two flowers. I send you also a very dark form of Miltonia Regnelli, and flowers of the beautiful old Oncidium Lanceanum from a spike carrying ten flowers—a very fine variety.—J. C. PARR, *Grappenhall Heyes, Warrington.*

Cypripedium Godefroyæ.—This species appears to be almost a perpetual bloomer. It was first exhibited in this country in the month of May. We saw it again this week flowering freely in Mr. Laing's nursery, where it and its allies, C. concolor and C. niveum, are flourishing vigorously, so that it may be regarded as an autumn bloomer. The variety we saw was exceptionally fine; its large sepals and petals were broad and full, creamy white, profusely spotted and blotched with crimson-magenta, the long pouched lip being similarly marked, but in a less degree. Orchids generally are growing strong and flowering freely in this nursery. They are treated in a moist, airy atmosphere and moderate heat. We observed a total absence of stone or bricks in the pathways, these being simply clean ashes, and we believe the less stone and metal used in houses for these plants the more genial will the atmosphere be and better the health of the plants.

THE death is announced of Dr. HENRY FLETCHER HANCE, F.L.S., which took place at Amoy. He has long been well known, especially in connection with his important contributions to the study of the flora of China and Hong Kong. Dr. Hance was born in London in 1827, and entered the Civil Service of Hong Kong in 1844. His chief scientific work was in descriptive and systematic botany, to which he early devoted himself, and he has left behind him a collection numbering nearly 20,000 species of oriental plants, chiefly Chinese.

MR. SHEPPARD, the gardener at Woolverstone, writes to inform us of the death of his employer, Mr. J. BERNERS, at the ripe age of 86. Mr. Berners was an ardent lover of his garden, and has really made Woolverstone what it now is—one of the finest gardens in this country. The work of improvement has been gradual from the time that Mr. Berners came into possession up to the time of his death.

WOODS & FORESTS.

LARCH SEED, NATIVE V. FOREIGN.

There is no foundation, says "J. F." (p. 183), for the statement that "the younger plantations from home seed are the most diseased," but he admits there is some truth in the statement that the best Larch forests in this country are those that have been acclimatised and produced from foreign seed. The lack "of foundation" specified exists, he writes, in the fact that young plantations are raised "chiefly from foreign seed." I doubt this, because it implies that our nurserymen deceive their customers by selling trees from foreign seed as from home-raised seed, and there is really no occasion for them to do that, as stock from home-grown seed is plentiful and can be had by those who want it. Then "J. F." goes on to furnish some rather inexplicable information as much against as for his own argument. "Even if," he writes, "the young Larch plantations were from home-raised seed, this does not prove that that is the cause of the disease. No; it only proves negligence and a want of judgment on the part of those employed who gather seed to discern between that which is fit and that which is not." This I call a distinction without a difference, but it proves that seed that is "not fit" is found in greater abundance than any other, which speaks volumes against home-raised seed, even without "J. F.'s" testimony as to an actual case wherein he saw the "cone gatherers bearing away great burdens of these bad cones until he stopped their work." Does "J. F." expect his readers to believe that these "great burdens" of bad seed were selected because they were bad? Far more likely is it that good seed was scarce and bad was taken in its place. Very strong testimony this to the danger of using home-grown seed! It is general results we have to deal with. Truly the interest of the seed gatherers "ends when they get their bags filled," but they are not filled intentionally with bad seed, but with what is most readily procurable. Next, we are assured that Larch from foreign seed does well at first, but dies away in the end, after being transplanted to the forest, while the home-raised lives on, which is an open contradiction of "J. F.'s" admission at the outset that "the oldest and best Larches are those that are first introduced" and raised from foreign seed. If foreign seed produced good trees once, why not now? I would like to hear of, or see, a properly managed Larch plantation from foreign seed that is dying away in the manner "J. F." states. Can he refer us to one example that can be certified? The fact of the matter is, this scare about the Larch disease and its causes that has been promulgated by foresters for years back has not a leg to stand upon. There can be no doubt about there being two or three diseases affecting the Larch, but there is no reliable data as to the causes of the disease. In the evidence given before the forestry committee one of the witnesses said that the Larch was still a very good tree to plant if people would only plant it in the right situations, and he gave evidence to show that plantations of Larch, otherwise equally grown, failed and died away, while others throve amazingly, the cause being the difference in the situation, although the plantations were in the same locality.

Yorkshireman.

Preparations for planting.—The present time is the most suitable for pushing forward the preparation of ground for autumn planting, by fencing, draining, opening pits, and trenching where necessary. In opening pits, they should be formed of sufficient size to hold the roots of the trees to be planted without cramping, as this is a matter of vital importance for the welfare of the trees in after life. Pits should always be made of such a size that when the tree is placed in the centre the roots can be spread out in a regular manner from the collar of the stem to their full length, by which means they will be enabled to derive food from all quarters, and support and keep the trees in an upright proper position during a storm. In cases where notch-planting is intended, and where the soil is of a poor and hungry nature with a crust of hard till below the surface, the places where the trees are to be inserted should be broken up and pulverised with a pick, by which means the plants will get a good start at the commencement, which is always a matter of much importance in the successful formation of young plantations. On bare exposed situations where wire fencing is being used for the protection of the plants, it is a good plan to warp some branches through the fence on the most exposed points, which breaks the force of the wind and ameliorates the climate till such time as the trees take to the soil and get established, when they will then be able to bear the blast with impunity and afford sufficient shelter to protect themselves. Take advantage of dry weather to open pits and convey soil or clay to peat bog ground to be planted in spring. Leave a small portion of soil at each pit to be exposed to the ameliorating influence of the weather during winter, by which means it will be rendered more fertile and in better condition for mixing with the bog at the time of planting. In trenching ground for ornamental plantations, see that the hard subsoil is thoroughly broken up and pulverised with a pick, and that drainage has been properly executed, in order to render the soil dry and warm for the roots of the trees. In cases where the soil consists principally of poor inorganic matter, such should be improved by mixing a quantity of soft, boggy earth, in order to establish a proper ratio between the organic and inorganic constituents of such a soil, by which means it will be rendered more fertile for the healthy development of the plants.—J. B. W.

THE FORESTRY REPORT.

Owners and managers of woodlands.—It was stated by some of the witnesses examined by the committee that the woodlands in England belonged to private owners mainly, and that practically the people who have to manage them are land agents, who know little or nothing of forestry, often being factors or lawyers residing in towns who "have no practical means of getting information" on the subject. This is a subject that has been dwelt on before in *Woods and Forests*, or rather the danger of trusting matters of practical woodcraft to agents at all, for those who occupy the position of factors and agents on estates have seldom either the time or the desire to attend to such matters any more than they have to attend to the practical duties of the garden or the farm. We are, of course, speaking of large estates on which woodlands of any extent can be said to exist. The proper person to look after the woods is the woodman, and it is he who must be educated for his work.

Mature forests.—Colonel Pearson gave some evidence on this head that may be questioned. According to him, the German theory is that the most profitable time to cut down a tree is when it is two-thirds grown. Formerly matured timber took the place iron does now. When a forest is about two-thirds grown there is the greatest volume of timber on the ground, and this witness said there "was no doubt about that, because, supposing you have 1000 trees growing upon a certain piece of ground, when they are twenty years old some of them, the weaker ones, begin to disappear, and at forty years you will only have on that space 500, and at sixty years more will disappear, until at last you will only have 50 or 60 mature trees. . . . Therefore, it is more profitable to cut the crop down (when they are two-thirds grown) and to replant it, because you have to count compound interest on the value of the crop as it stands upon the ground from the moment of its removal up to the time when it would have arrived at maturity." The time or age when it is most profitable to fell a crop of timber depends, we think, altogether on the demand, the purposes for which it is intended, and other circumstances not depending upon the maturity or age of the crop. But it is an extravagant estimate that a thousand trees will dwindle down from 1000 to 50 in about as many years, even if left to themselves. We would be confidently disposed to estimate the final residue at a much greater number—say 300 at least.

Planting Oak pure.—On the subject of "scientific management," Colonel Pearson said that there was no doubt that the fault of our public forests was that they have planted Oak pure. He had no hesitation in saying that Oak is not, and cannot be, successful alone. It must be said that the Oak planted alone in the New Forest has been a failure. There was one spot in the forests of Compeigne, in France, that used to be shown as an example of the result of planting Oak alone, and Oak with Fir, and Oak with Beech. The pure Oak plantations are now fast disappearing from the ground, although only 100 years old; while in the mixed plantations the Oak is magnificent. In regard to such evidence as this, we can only say here that we believe the witness to be wrong in his conclusions regarding the cause of the failure of the Oak, because there are Oak woods in England that have been Oak woods and nothing else for centuries that have not behaved in the above manner, while there is no physiological reason for Oak refusing to grow alone that we have ever heard of.

M. Boppe's report.—The "report on a visit to the English and Scotch forests by the professors and students from Nancy Forest School" forms an appendix to the committee's report, and is by far the most interesting piece of reading connected with the inquiry. I only note a few of the most interesting items it contains. The Frenchmen, as foresters of the Continental school accustomed to live among forests regularly managed, and having for their sole object the production of timber, "had no little difficulty in understanding the widely different motives which actuate forest cultivation in this country. Everywhere they found the forests fenced in on all sides with walls and hedges, and, as a matter of fact, that the forester or agent carried the keys of the gates in his pocket. They learned that these costly enclosures were erected, not for the purpose of keeping out the cattle and deer, as in the Jura, but for the purpose of keeping them in. It appeared to them like shutting up the wolf in the sheepfold." The French foresters have been misled on this point by their English conductors, for cattle are not fenced into woods "everywhere" in this country, nor, indeed, anywhere, except in some Scotch woods and here and there a neglected wood in England.

It is curious to find these French experts condemning "the monotonous regularity in the height and age of the trees" in English plantations as "an unmistakable sign of their artificial origin and want of methodical management," seeing that the efforts of the woodman in this country is directed to that end in culture and thinning. Under such circumstances M. Boppe declares "when the time arrives for the trees to be cut down, or should they be uprooted by a hurricane, the forest disappears in its entirety, owing to the total want of young growth, which is necessary as a link between the old forest and the new one." It will not appear clear to experienced English or Scotch foresters that creating plantations of trees of all sizes from saplings up to mature trees is a desirable practice in this country. The modern German practice of growing plantations in solid blocks and felling them in the same way is preferable in the production of timber. M. Boppe, however, saw many things that Sir John Lubbock's committee failed to discover, or rather about which they put few or no questions. "Scotch foresters," he writes, "are not responsible for the present regrettable state of affairs. They are powerless to effect any improvement so long

as the landowners and the general public have not learned to appreciate the manifold advantages to be derived from a regular and methodical management. They have to struggle against many adverse interests and hindrances, such as grazing, game routine, pecuniary exigencies, and the fancies of sportsmen from all parts of the world"—things that have been dwelt on in *Woods and Forests* many a time.

Our French visitors conclude by stating that among all the forests visited by them (in England and Scotland) "there is not a single one suitable for the treating of sylviculture (forestry) on that broad basis so essential when pupils are called upon to apply it in all quarters of the globe."

Readers of the parliamentary evidence given before the committee, we may just remark in conclusion, will be struck by the fact that little or nothing has been asked or elicited on such subjects as the ravages by game, the kinds of timber planted, value of different kinds of timber, the kinds of trees that succeed best, effects of climate, and other matters closely related to the subject, and which would have thrown a flood of light on our forest management. YORKSHIREMAN.

PLANTING UNDER COVERT.*

In the planting and management of shrubs as ornaments in plantations, or as under-wood for game, it should be kept in mind—first, attention to the application of general principles on which to found proper directions for guidance in planting and culture; second, a consideration of local peculiarities as to soil, situation, or climate.

Regarding the distance that trees should be left apart where it is intended to grow shrubs as undercover, very much depends upon the size and form of trees of which the plantation consists. It is sufficient to say that the trees should be standing so far apart as to allow the under-wood to be mostly out from the drip of the overhanging branches. This is very essential, that the shrubs may have the necessary supply of light and air for their healthy development, without which we can hardly expect them to thrive luxuriantly, more especially when they are planted in a soil already occupied and partly exhausted by the roots of existing trees.

When the shrubs are planted in a healthy soil, beyond the drip of the branches and free from the action of the strongest roots of the trees, they very soon become so thoroughly established in the soil, that under proper management they can be easily made to extend underneath the shade of the trees to the very base of the stem. It is not desirable, however, to have the whole plantation thinned, but only those parts where it is intended to place groups at intervals throughout the plantation. These groups should be made of various forms, and of a size that will correspond with the situation and extent of plantation, as also with the number of plants that are available in the hands of the planter. When the primary object is to get up under-cover for game throughout a plantation, the groups of plants should be placed from 50 yards to 60 yards apart.

After having determined where the various groups are to be placed, the ground should be prepared by cutting out a sufficient number of trees, and trenching over the soil from 12 inches to 18 inches deep according to its character and quality. If the subsoil be bad it should not be turned up at all, but well stirred with the pick or fork. It is a great advantage to prepare the ground during summer, and then plant in autumn; or to prepare in winter, and plant in spring. In either case exposure to the influences of the atmosphere will tend to pulverise the soil and bring it into a suitable condition for receiving the plants. If, however, it is not intended to trench the ground for the groups, large-sized pits should be opened for them some months previous to planting; all this tends to encourage their growth, and they never fail to thrive under this treatment.

An open, properly selected piece of ground as a home nursery for the rearing of large-sized plants will be found advantageous. With a home nursery, small-sized plants can be bought at a low rate, and reared under such local circumstances as will produce the essential requisites and functions required to enable the plant to overcome the immediate effects of removal. Frequent transplanting, and at the same time a liberal dressing of turf, sandy peat, or leaf mould, encourages the formation of rootlets and spongioles. Under such a system of treatment the plants may be kept in the home nursery till they are from 3 feet to 4 feet high, and of a wide-spreading bushy habit, having large fibrous matted balls of earth. When brought to this condition, they suffer less from the attacks of hares and rabbits, and a less number of plants are required to plant a group of sufficient size.

Time for Planting.

The season of the year best suited for planting Evergreens is the latter end of August and the month of September. At this season the temperature of the earth is usually greater than that of the atmosphere, and this at once promotes the formation of spongioles, enabling the plant speedily to take root in its new situation, and secure itself against risk of injury from the evaporating winds of spring. Another good season for Evergreens is the latter end of April and early part of May. At this season the dry and frosty winds are generally past, and the temperature of the soil is such as at once to promote a growth of the rootlets.

When planting is resolved upon in early autumn or late spring, the best method to follow is to have the pits all dug and made ready for the plants, and then choose a dull, dampish day for the removal. In spring, if the weather is not dull and moist, and if the plants are rather barely rooted, to prevent flagging pour water over the roots after the finer soil has been packed, and this will form a sort of puddle about the roots, and at once promote their activity. This method of watering employed previous to filling in the whole of the soil into the pit leaves the surface soil open and pervious to the most gentle showers; whereas watering after the soil is all filled in binds the surface and tends to form a crust, which is somewhat impervious to rain.

Mode of Planting.

When planting is proposed, good large pits should be made. The size must in all cases be regulated by the nature of the soil, and in proportion to the size of the plants. On hard, stiff, poor soils the width of the pit should be increased, and the soil in the bottom well stirred with the tramp-pick. It is needless to expect that plants can grow so vigorously when their roots are crammed into a pit in the form of a bowl, with their tender extremities pressing hard on the undisturbed sides of the pit, as they will do when they are planted into square-shaped pits, so large that there will be a portion of prepared earth between the roots and the hard sides of the pit, to encourage the formation of spongioles. In sheltered plantations, under a crop of deciduous trees, where the soil is naturally good and annually enriched by the fall of leaves, shrubs may succeed very well without much previous preparation of the soil or assistance to its fertility, but in more exposed situations, where the soil is thin and poor, and not much benefited by decaying leaves, it is imperative that the soil should be thoroughly prepared—first, by being deeply trenched and exposed to the atmosphere; and second, by digging large pits, and giving them a plentiful dressing of peat or decayed vegetable matter. It is a great benefit to dig the pits deeper than is required for the plant, and then lay the turf in the bottom, where it should be chopped into small pieces and mixed with the soil, for the purpose of fostering the roots. When this is done on good soils, there is often no other assistance required; but on poor soils, such as gravel or stiff clay, a good dressing of peat, turf, or leaf-mould will immensely benefit the growth of the plants, as it will greatly assist the formation of rootlets, and enable the roots to become more fibrous, and matted into a sort of ball. This method of treatment will be found of very great advantage in the future management of the shrubs, because the plants, after several years' growth, will be found to have a fibrous ball of earth, secured by the roots of the plants forming a net-work through and round the body of leaf-mould and turf, and will thus be made suitable for safe transplanting when it is considered to be necessary to thin the clumps. The greatest possible activity should be displayed during the time of planting, and the utmost care taken to have the roots exposed as short time as possible. For want of sufficient care in this respect, many plants are very much injured and their after growth much retarded; while some of the more peculiar or fastidious, such as the Holly and Portugal Laurel, have their vitality by exposure almost completely destroyed, and instead of taking root and at once beginning to grow, often are found to die down to near the root. We have known instances where planting was conducted so carelessly, and during weather so unpropitious, that many plants died solely from exposure. One other important matter is to lift the plants from the nursery with the least possible mutilation of the rootlets, and then have them carefully "sheughed" in near to the planting ground till they are required. In this department of practical forestry there is room for considerable improvement, but all that is needed is a little more energy and expedition in handling the plants to prevent the drying of both roots and branches, so that their naturally succulent condition may as little as possible be injuriously affected.

A dressing of peat or leaf mould at the time of planting causes the plant to retain a ball suitable for transplanting for a number of years. But where this has not been attended to, the plants should be prepared for transplanting by digging a trench round the roots a year previous to removal. When filling up this trench leaf mould, or the best of the soil, should be put in next to the roots, and, if possible, the plant should be pulled a little to the one side, so that part of the mould may be put underneath the roots. In transplanting plants that have been pegged down, those branches that have taken root, and are sufficiently strong to thrive without the parent stem, may be cut off and taken away to be planted similarly to nursery-reared plants; or, in order to prevent a bare appearance when the parent plant is removed, a few of the rooted branches may be left to grow for a time and be afterwards removed.

In very old plantations, where the trees are mostly deciduous and standing far apart, as also in younger plantations composed chiefly of tall, bare, over-drawn trees, with here and there open spaces of ground, it is often desirable to keep up the ornamental appearance of the plantation, although the trees are so slender as to be past becoming any better value as timber. In these, and similar situations, some recommend the promiscuous planting of shrubs as the best method of keeping up the appearance. But from experience, I consider it far better to plant one or more specially prepared trees (from 3 feet to 4 feet high) in the larger vacancies, and then intersperse a group of shrubs here and there throughout the plantation.

One of the trees best suited for this purpose is the Silver Fir. This tree grows well, even though it is a little shaded by over-hanging branches when in its young state. The soil and situation most suitable for this tree is a rich moist loam, but not saturated with water, in deep glens or slopes of hills. But it also grows profitably on dry soils, and it is very well adapted for planting as a succession crop. Another excellent tree for being planted in the largest openings is the Abies Douglasi. If it is not overhung, or too much shaded, but planted in a healthy loamy soil, and somewhat cool situation, it becomes one of the most rapid-growing trees. It will not stand anything like the amount of shade or drip from the branches of other trees that the Silver Fir will do. But when planted, as it ought to be, in an open space entirely free, it has no equal in rapid growth and beauty, or as a timber-producing tree.

Overgrown Evergreens should not be cut down during the winter months. The latter end of April or May is the best time. The reason of this is obvious, for when they are cut over in winter, the plant being then dormant, the lengthened exposure to the weather causes the inner bark to get dry and to separate from the wood, and when spring arrives

* Extracts from an essay read before the Highland Society "On Planting and Rearing Shrubs, &c., in Plantations for Ornament, or as Under-cover for Game," by A. Gilchrist.

any shoots that do come strike out through the side of the stump, and are weakly when compared with spring-cut plants.

When the cutting is not done till spring, the inner bark never loses its naturally healthy condition, and the vital functions of the plants becoming then active, strong shoots are quickly sent right out from the top, as also from the sides of the stump and surface of the ground. Several examples have come under notice illustrative of the benefits that accrue from spring cuttings, and others have proved plainly that it was most injudicious to cut in winter.

Another point in the management of shrubs as under-cover, worthy of more attention than is usually paid to it, is to have the management of the shrubberies and groups of under-cover methodically arranged, so that a portion will fall to be done each season. It will be generally found that two years is long enough to be allowed to pass without cutting back a branch here and there, pegging down, or transplanting some of the shrubs, so that those that are adapted for standards or fine specimens may have room for greater development.

When shrubs are planted as under-cover at the time the plantation is formed, they may be placed from 8 feet to 12 feet apart, in groups of 3, 5, 7, or more plants, with Larch or Spruce as nurses that can be cut out as the shrub requires room. This saves transplanting of shrubs, and enables a tree to be left in the centre of a group if desired. Trees, such as the weeping Birch and some of the Poplars, have a fine effect in a group of shrubs, as also Cupressus Lawsoniana, C. nutkaensis, and some of the upright growing Junipers. In managing these plants, and many others of a similar habit, they should never be allowed to grow with more than one leading shoot; timely pinching of rival leaders and all strong side branches will prevent this. If this were more regularly attended to, there would be no necessity for having plants, such as the Irish Yew, Arbor-vitæ, and Juniper tied up with wires. The plants would have one stout stem that would be able to resist the wind without being destroyed or made unsightly.

Select Covert Plants.

In detailing the plants best suited for under-cover, the Azalea pontica is very hardy, and will thrive best in a peaty soil and sheltered situation. It flowers profusely in early summer, and in autumn its foliage becomes very ornamental. There are several excellent varieties of this plant well suited for low groups in ornamental grounds. Rhododendrons are well-known evergreen flowering shrubs, possessing several peculiarities that make them an excellent class of plants either for cover or ornament. They luxuriate in peat, moss, sandy loam, or in decayed vegetable soils, such as in low-lying moist situations, where the leaves of deciduous trees have accumulated. In fact, they grow well on most kinds, except cold, stiff, or thin moist soils; but even if such unfavourable soil is in a sheltered situation, and thoroughly prepared for their reception, by being trenched and exposed to the action of the weather until thoroughly pulverised, and if at the time of planting a plentiful dressing mixed together of leaf-mould and peat is employed, Rhododendrons will then thrive. They will bear transplanting very well, even after they are large. They are never injured by hares or rabbits, and their bushy habit makes them favourite plants for under-cover. As soon as they are fairly established after planting, attention should be paid to have some of the strongest branches pegged to the ground every year, and at the same time a few plants may be transplanted from the group. When treated in this way they grow very rapidly. For example, a group of hybrids containing upwards of 200 plants, from 9 inches to 12 inches high, planted in April, 1869, were in spring of 1870 reduced by transplanting to less than one-half that number, many of them having grown upwards of 12 inches that season. Most of the hybrids and fine named varieties are very attractive both in their flowers and foliage, and are all very useful where a low group is desired on a well-kept lawn.

Mahonia aquifolia is another useful low-growing shrub. It grows freely on any kind of loamy soil if not too damp. When planted in a prepared soil, if kept clear of weeds and coarse Grass, it has a fine bushy habit of growth, but otherwise it gets bare below.

The Bay Laurel (C. Laurocerasus) grows best on a light loam, with dry subsoil, but it thrives on a great variety of other soils. When properly attended to in thinning and cutting back over-strong branches, it assumes a reclining habit, and is well suited for being pegged down. This plant seems to grow the faster the more it is treated in this way; attention should every second or third year be paid to this. It is easily propagated by layers or cuttings.

The Portugal Laurel (C. lusitanica) is more particular as to soil than the former. The soil most suitable is a rich loam in a rather sheltered situation. It is of a compact bushy habit, and very well adapted for growing as large-sized specimen shrubs. They are rather difficult to transplant, unless previously prepared; but bushes from 3 feet to 6 feet high, when planted amongst turf or peat, as recommended in the former part of this paper, can be successfully transplanted after six years' growth.

Common Holly (Ilex Aquifolium) is a very hardy shrub, and the best of all the Evergreens for planting in exposed situations. It thrives well on soils of various qualities; it is also rather difficult to transplant, unless frequently moved or treated similar to the Portugal Laurel. There are several cultivated varieties of the Holly, very beautiful and fast growing, and all well worthy of a place in every shrubbery.

The English Yew (Taxus baccata) is also a very hardy shrub. It thrives best in a sandy loam, having a cool and moist situation and a northern exposure, and is well suited for being planted in a group or as a single plant. At first it seems to be of a compact habit of growth, but as it increases it sends out a number of horizonal spreading branches. The Yew is naturally fibrous-rooted; hence, with ordinary skill and treatment, it can be transplanted of a large size. It is well adapted for forming ornamental hedges in pleasure grounds. It can be clipped to almost any shape; some fine examples may be seen at Hopetoun House, Edinburgh. Being a very hardy plant, it makes an excellent boundary or screen-fence in grounds where shelter from cold and cutting winds is desirable; but owing to the poisonous nature of this shrub, it is not suited for being used as a hedge within the reach of animals. There are several variegated and other varieties of Yew that are scarcely as hardy, but are very beautiful and handsome shrubs.

The Privet (Ligustrum vulgare) is a plant that is very well adapted for forming clumps of under-cover. It is a fast grower, and not particular as to soil, and thrives in a sheltered situation. It should be regularly pegged down to the ground, and the strong branches in the centre cut back. It is easily propagated from layers or cuttings, and altogether is one of the cheapest and best plants that can be got for game cover. There is a broad-leaved variety of this plant recently sent out from nurseries, possessing all the good qualities of the old variety, and, owing to its broad foliage, is a more ornamental plant.

Cotoneaster Simonsi is well worthy of being extensively grown as an under-cover. This plant is a very rapid grower, four-year-old plants being sometimes upwards of 3 feet high. It is not very particular as to soil, if dry and not too much exposed. This Cotoneaster should be regularly cut back and pegged down every two years. If this is carried out properly, there are very few shrubs that will extend more rapidly. It is an Evergreen, and bears fruit very abundantly, which is an additional ornament during the winter. The fruit is useful as food for pheasants and other birds. Other varieties of the Cotoneaster are also useful as under-cover and ornament.

Hypericum calycinum (St. John's-wort) is an excellent plant for covering banks, where low-growing shrubs are wanted. It has few equals, and extends itself over the ground very rapidly, forming first-rate under-cover. It is easily propagated by lifting up a spadeful here and there, breaking it up, then replant it in small portions. It is an improvement to thin out masses of it in this way. It has very pretty yellow flowers, which continue in full bloom from July to November. From experience of this plant, it is well worthy of being more extensively planted.

The Aucuba japonica is another very ornamental plant, well suited for good soil in a cool situation. The same may be said of the Daphne Laureola and Berberis Darwini, the latter being a free-growing beautiful flowering shrub. Several other varieties of the Barberry are also worth attention.

The Sweet Bay, Laurustinus and Arbutus, are all beautiful plants, when grown near the sea coast, in a warm and sheltered situation. The Elder is a useful plant, suited to withstand the sea breeze and cold cutting inland winds. This forms one of the best of all plants for producing shelter.

The Sea Buckthorn (Hippophae rhamnoides) is also very suitable for maritime situations. The Snowberry and Syringas of sorts should be recommended as useful for planting, as nurses to the more valuable shrubs, to be gradually cut away as the finer sorts grow. These plants are readily raised from suckers. Ribes and Dogwood of sorts make also good under-cover; both are rapid growers, and well suited for being cut back and pegged down, the treatment previously recommended. Both are easily propagated by cuttings.

The Mountain Pine (Pinus montana) is admirably suited for under-cover. It is a low-spreading bushy tree, with long creeping branches, which generally take root in the ground, and then the extreme points, rising to the height of 3 feet or 4 feet from the surface, gradually turn down again. This hardy tree is specially suited for being planted as an under-cover on those poor moorish parts of land that are planted for the most part with Scotch Pine. It is well known that Scotch Firs soon lose their lower branches, and cause a want of under-cover. This evil would be remedied if a number of the Mountain Pine were planted at intervals throughout the whole plantation at the time of its formation, as they would make very fine cover by the time the plantation was thinned for the first time, and the oftener it was thinned the better would these plants extend. I have seen Pinus montana growing beautifully (after twenty years' growth among Scots Pine) on a light mossy soil only a few inches deep, resting on a grey freestone. Each tree had a number of stems, all a little reclining towards the ground, the lower branches spreading out on all sides, and reaching from 12 feet to 15 feet out from the centre of the plant, with numerous branchlets thickly covered with foliage, forming a regular thicket. Some of these plants are growing between Scots Pine 12 feet apart, and although their centre branches are more drawn up than those that have had more room, still their lower branches spread equally. This Pine grows on almost any soil; it thrives very well on poor, thin soils and high exposures, such as rugged shelves of rock where hardly any other plant can thrive. In fact, on the most favourable soils it has no inclination to become a tree. In its native habitat it never grows much above 20 feet, but forms a large spreading bush.

All the shrubs and trees here mentioned will grow vigorously, even when partially under the shade and drip of trees. Numerous other sorts equally deserving of attention for individual characteristics might be named, but a sufficient number of kinds has now been referred to to enable anyone with a little practical experience to select suitable plants for under cover for any district.

Before concluding, I would mention a few of the trees that are most suitable for planting in large vacant spaces in woodlands, or for planting amongst severely thinned and overdrawn or branchless trees. The Silver Fir is among the best for general purposes, especially in larger openings and most sheltered situations. Abies Douglasi, the common Spruce, Corsican and Austrian Pine are also suited for this purpose, and the latter will thrive on high exposures and poor soils. Abies nigra is also a very hardy tree, and is well adapted; so is Abies alba, though scarcely so hardy. Both these trees suit well for nurses. All these trees bear transplanting very well after they are upwards of 3 feet high.

No. 773. SATURDAY, Sept. 11, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

FRUIT GARDEN.

GOOD STRAWBERRIES.

Strawberries a Sure Crop.

MY opinion is that no one should fail in producing good crops of Strawberries every year, once they have found out the varieties that suit the soil and locality, provided a few plain rules of culture are observed. Under these conditions there is only one cause of failure to be apprehended, and that is late frosts when the plants are in flower, and that is a danger that need seldom be feared, because the Strawberry blooms, as a rule, after late frosts are over. These are facts that must be considered of great importance to market growers, seeing the Strawberry is such a remunerative crop. To have a good crop every year means profit just according to the ground laid under crop. Market gardeners wisely like to have more than one string to their bow, but if I was confined to one string, I should make it the Strawberry. It has the advantage over the Raspberry and all other small fruits that it produces a good crop the year after planting, and that it may be planted after the ground has borne its crop for that year. It is all a question of culture, and the culture is simple. I can testify, as has been testified before in THE GARDEN, that for over a score of years we have never missed a good crop of Strawberries out of doors—that is such a crop as would have paid the market gardener or anyone else well.

THE ESSENTIALS OF CULTURE are, first, the production of good runners; next, the planting of them in time; and, lastly, manuring and keeping the stools in order. To have runners early is an easy matter in the south, but in the north and in late seasons it is not so easy, but still runners can be secured early enough anywhere by a little forethought. The Strawberry produces an offset at the first or second joint of the runner. Usually the first good offset is procured at the second joint, and beyond that in succession; but if the runner is allowed to extend beyond the first offset, the latter is never so early or strong. Here, in our late district we are compelled, in the case of pot plants, to pinch the points of the runners as soon as they can be got hold of beyond the offset and before leaves appear. This causes the plants to form roots considerably earlier than they would do if the points were allowed to grow till good leaves appeared. In this way there is no difficulty in securing good, young, well-rooted plants by the beginning of August at the latest, and if they are planted in their permanent quarters then, a heavy crop of fine berries is assured the following season. Such plants never fail, and the crop will just be in proportion to the vigour of the plants. It is well to layer the runners in a ridge of good soil, to begin with, laid between the rows; from this they lift easily with good roots, and suffer no check.

AS TO THE GROUND AND PLANTING, sorts can be found to suit all ordinary soils, and they should be at least deeply dug and well manured; but, as much can be done by mulching and surface dressing, I do not attach so much importance to deep trenching as some do, and it doubles the cost of preparing the ground. Strawberries will produce good crops for several years in soil that is only deeply ploughed or dug one spit deep, a fact of some significance to small market growers who are short of labour. The ground being ready, the mode of planting and distance between the plants is the next question. I have little or no faith in planting very wide and trusting to "snatch" crops of vegetables between the rows. Devote the ground to Strawberries alone, and make the most of it. The distance between the rows depends on the sorts—kinds like the Black Prince succeeding in rows 2 feet apart and 18 inches between the plants, but for ordinarily strong-growing kinds like Vicomtesse Héricart de Thury, 2½ feet between the rows and 2 feet between the stools is not too much after the first year, as the heads get large and meet between the rows if planted closer. Nothing can be worse than thick planting, as in that case the crowns are never so productive, but the worst consequence is the loss of crop caused thereby through the depredations of slugs and beetles, and, above all, by wet, if the weather be at all moist when the crop is ripe. Every grower knows how soon a good crop spoils in wet weather, how important it is to gather the fruit dry, that when the plants have plenty of room all round a few hours will dry the crop, and that when the beds are crowded by foliage it will not dry before it rots. In a case that once came under my notice it was estimated that at least half the crop was lost one rather wet year owing to thick planting, and all the profit as a matter of course, if not more. This happened in the case of the older plantations, perhaps three years of age, with large crowns. On the autumn-planted quarter where the plants had room little or no loss happened, as the fruit dried during the intervening blinks of sunshine or dry weather, and was gathered as it ripened. My advice, therefore, to growers is have every stool standing clear. Then it ripens its crowns thoroughly, produces fruit all round, and the crop is safe.

MULCHING AND GENERAL CULTURE.—A good crop of Strawberries, safely gathered, depends a good deal on the mulching applied and the time it is put on—far more than some would imagine. I find it best invariably, for the production of good growth and crop, to mulch early in spring with stable litter, which soon gets washed clean, and serves just as well as clean straw beneath the ripe fruit, and which is usually put on later. But an early mulching of this kind has one decided drawback—it encourages black beetles greatly, and also slugs, and the amount of damage they do to the earliest and finest fruit is most serious. These pests seem to breed under the loose surfacing of litter, and when the Strawberries are ripe they literally swarm. Naturalists have declared that the common black "clock" does not eat fruit, but I know better. It is, in fact, one of the worst enemies of the Strawberry, and early mulching encourages it. When straw is put on later in the old way, beetles are not nearly so bad; but without the mulching neither the crop nor the growth is so good. If it was not for the trouble and expense, I would prefer tiles or slates under the fruit. As to general culture, once a Strawberry plantation is established the labour of culture is not great. It consists in cutting off the runners with the spade after the crop is gathered, and keeping the soil between the rows clean and free from weeds without digging or forking. If a good mulching of manure can be put on at the same time in autumn, all the better for next year's crop; for it should never be forgotten that the quantity and size of the fruit depend mainly, if not altogether, on the treatment the plants receive the year previous. The number of fruit on each scape and the number of pips to each fruit, and on which size depends, are all settled, as a rule, before growth is finally matured in autumn. S. W.

ROOT-PRUNING BEFORE LEAF-FALL.

THERE does not now appear to be so much difference of opinion respecting the advantages of root-pruning fruit trees as there was at one time. Those loudest in condemning the practice now admit that favourable results follow this method of correcting over-luxuriance. In fact, it is generally allowed that, with the exception of the little toy trees that are dwarfed by incessant shoot-pinching, there is no way of keeping fruit trees within the size it is often desirable to confine them to, and still have them in a condition to bear freely, except by taking them up and replanting or by root-pruning them. The advantages attending the latter practice in preference to taking them up wholly are so obvious, that it does not require much consideration to enable anyone to decide which course is best. The principal objections to taking up and replanting are, that if the trees have attained a considerable size, the check they receive is often too great, and is followed by a stunted condition that lasts longer than is desirable. In addition to this the labour of taking up and replanting, if the work be done as it should be, and if the necessary staking to keep them from being disturbed by the wind is carried out, is fourfold that of root-pruning. Beyond this, trees that have attained a size, say, of 12 feet or 14 feet in height, and consequently too big to remove when it can be avoided, can by root-pruning be brought into a fruitful state, and kept so without allowing them to increase further in size. It is scarcely necessary to say that, as regards the root-pruning of fruit trees, the practice is most applicable to such as are bush or pyramid shaped, and that require to be kept within a limited size, such as in kitchen gardens, where trees unrestricted in size are objectionable. In the case of standards in orchards it is only in exceptional cases, such as where there is a disposition to bring them sooner into bearing than would occur with their roots unchecked, that root-pruning is necessary.

TAKING VEGETABLE GARDENS as they exist throughout the country, large and small, in much the greater number, fruit trees, more or less, are grown by the sides of the walks, the presence of which contributes much to the effect in taking off the uninviting appearance inseparable from ground occupied by culinary vegetables only. But the advantage attending the cultivation of fruit trees in vegetable gardens is not confined to matters of appearance and the bare interest attached to their presence alone, but to something of more importance, which is, that under such conditions their roots participate in the cultivation bestowed on the vegetables to an extent that enables the trees to bear much finer fruit than that which is produced in orchards. This fact is so patent to anyone who has any acquaintance with fruit growing as not to require comment. Still, if proof was wanted, it was furnished at the Apple exhibition held at the Royal Horticultural Society's Gardens, where the Apples that took the lead in the various competitions were the produce of trees that were located in vegetable gardens. And in respect to Pears, the fruit that is forthcoming from trees in kitchen gardens, bush shaped or pyramids of medium size, is usually as large again as that which is borne by orchard trees. Yet where fruit trees are grown in kitchen gardens it is obvious that they must be restricted in size, otherwise the dimensions they attain are such that they soon not only destroy the character of the garden, but also interfere with the growth of the vegetables, which they overhang and shade in a way that does too much injury to make their presence admissible where anything like good gardening is attempted. The miniature fruit trees kept to Lilliputian size by persistent shoot-pinching may do for those who are fond of fads, but they would never be likely to find favour with the majority of people engaged in gardening who require the best return they can get for the outlay

they incur, and who find in trees kept to medium size, such as are obtainable by root-pruning, just what they want.

The work of root-pruning is so simple and generally understood and the labour involved, even where a large number of trees has to be gone over, is so little, that it seems strange to see the numbers of places where gardening in other respects is well carried out, yet where there are quantities of fine young trees that have reached a size as large as it is advisable to allow them to grow to, and which keep on year after year producing little besides wood, which, as a consequence of the constant shoot-pruning they are subjected to without a corresponding reduction of their roots, they make in such quantities as to prevent the formation of fruit buds. Hence their barrenness, a condition in which they are likely to remain for time indefinite, unless means are taken to secure a more equal balance between the roots and the tops. Fruit trees that are located in kitchen gardens owe much of their over-luxuriance whilst young to the manure which is applied to the ground for the vegetable crops, to which their roots have access, and it is the presence of this manure, coupled with their restriction in size, that enables the trees to keep on producing large fine-looking fruit after they have reached an age when the produce of ordinary orchard trees is undersized and of proportionately less value. It is only whilst the trees are in the full flush of youthful vigour that they require restriction of their roots, as after this in soils of ordinary character the crops they carry keep down any disposition in the trees to run too much to wood. It, therefore, follows that those who root-prune need not be under the impression that they have begun work which will require unceasing repetition. So much finer are most kinds of Pears and Apples, especially the best dessert varieties of the latter, when grown on trees confined in size by restriction of the roots, that if I was going to plant with the intention of marketing the fruit I should have no hesitation in adopting this form of tree in preference to standards, as, excepting the biggest varieties of Apples, the fruit from standard trees, after they have been some years in bearing, comes so much smaller that it does not fetch more than half the price of that from trees confined to medium size.

During a course of years I have carried out the work at different times, extending from the latter end of August, through the autumn and winter, up to so late in spring as when the buds had begun to move, with a view to ascertain what influence the difference in time had on the trees operated upon, with this result that when the work was carried out whilst the leaves were still green and full of life it tended to the formation of a much greater quantity of bloom-buds the following season, and to a better condition of the trees in every way. This is shown in Apples, Pears, and Plums where the trees are subjected to this treatment, but most in the two first-named fruits, in the case of which a reduction of root power to induce fertility is oftener required than with Plums. When the operation is carried out whilst yet the leaves are in a condition to act the trees at once show a disposition to form bloom-buds, which become fully developed the ensuing summer to an extent that does not occur when the pruning takes place after the fall of the leaves. When these are off the trees do not appear to be affected by the time they are operated on, provided it is not deferred until the buds begin to move, which in mild winters frequently takes place earlier in the new year than is often supposed; consequently if the pruning is not effected before the leaves fall it is well to do it before the end of the year. Some trees that I purposely left untouched until the buds were swelling were so weakened—though the roots were not shortened more than those of others operated on earlier—that they were two or three years before they recovered, although plenty of fertile buds were formed the ensuing summer, but these were thin and weak, and the fruit they produced, both Apples and Pears, was so small as to be useless for two or three years, the leaves being alike affected in size.

It is not good practice to root-prune young trees too soon or too severely, that is before they have attained enough size to produce fruit worth taking into account, as if they are thrown into premature bearing there is a loss of time in their reaching a size that will admit of their carrying sufficient crops. The right course is to regulate the root power for a few years before the trees have reached the size they are to be grown to in a way that will secure as much fruit as is consistent with the necessary top growth to admit of the gradual increase of their heads, and never to let them get into a condition that will cause the production of too much wood after root-pruning is once begun. T. B.

Magnum Bonum Plum.—This is without doubt one of the finest Plums in cultivation, though not of such a continuous bearing habit as the Victoria and some of the popular market kinds. It should, nevertheless, find a place in private gardens as a wall tree from the fact of the fruit making such a noble dish on the dessert table. I find that this variety is most fruitful after it becomes well established, or at least half a dozen years old, as it grows so vigorously in its young stage that strong wood is produced more than fruitful spurs; a rather hard soil, not much enriched, should be selected for these kinds of Plums, or they run too much to wood and leaf growth at the expense of the crop. The Magnum Bonum Plum needs to be fully ripe before it is eaten, when its flavour is very good indeed—in fact, little short of that of the Green Gage; on walls, if a little care is exercised in putting the leaves aside so as to fully expose the fruit to sunshine, a beautiful pink tinge is imparted to the fruits that makes them very attractive on the dessert table. —J. G. H.

Madresfield Court Grape.—I have never seen Madresfield Court Grape so extensively and well shown as it has been this season. Cultivators generally are surely improving in their ways of producing it, as the majority of the bunches recently exhibited have been large in size, beautiful in form, handsome in berry, and altogether attractive. The flavour, too, is excellent, and although few samples are seen without a green tinge at the footstalk of many of the berries, this is the whole that can be said against it; and if it can be grown and shown year after year in the same excellent condition as it has been this season, it will certainly take the position of the leading black summer Grape after the Black Hamburgh. It was very conspicuous in many instances at the recent Shrewsbury show. It was shown in most of the prize-winning collections, and in the class for three bunches of any black Grape it gained the first prize amongst eighteen exhibits, beating Black Hamburgh, Muscat Hamburgh, and several other black varieties; and it merited its position. It was also shown as a dish in several collections of fruit, there being upwards of two dozen exhibits of it, and there was not an inferior one amongst them. The excellent state in which it was seen here will be sure to induce many amateurs to plant it, and I feel sure they will have every reason to be satisfied with it, as in size of bunch and berry, and especially in flavour, it is capable of giving the highest satisfaction.—Cambrian.

Six good Apples.—According to The Garden fruit reports, Apples are a thin crop generally. That dwarf or pruned trees or bushes are recorded to be better cropped than tall, wide-spreading standards is an important fact. I am well aware of the grand crops that can be produced on large orchard trees, but I do not think that the merits of dwarf bush trees have yet been fully tested. Looking round my little bushes that are loaded with fine fruit, I noted half-a-dozen that may be useful for anyone requiring that number of really good, reliable sorts, viz., Lord Suffield, New Hawthornden, and Small's Admirable for kitchen; Summer Golden Pippin, Cox's Orange Pippin, and Court Pendu Plat for dessert. These seldom fail, and, taken collectively, are useful for a small garden. I may here remark that the number of times some of these kinds receive favourable mention is sufficient of itself to fix their character as the best of our excessively long list of Apples. And, happily, there is now such a wealth of really good kinds, that there is no need for growing second-rate or worthless varieties. It is not owing to the expense of the trees, for they are now obtainable at a price that only a few years ago would have been thought impossible. Now is the time to prepare the soil for planting, and be sure and select your bushes early in the season, for the best always go first.—J. G., *Gosport*.

RASPBERRY CULTURE IN AUTUMN.

Where any old rows have become useless and are to be rooted out and thrown away, this work should not be deferred until autumn or winter, but clearing should take place at once to have the ground ready for another crop. As a rule it will be found that ground which has been occupied with Raspberries for some years has become very poor, especially a little way from the surface, and it is generally necessary to trench the ground after them and manure it well. As many spent vegetables are now being cleared off, a quantity of these might very profitably be trenched into the subsoil of old Raspberry ground. If this was done now and the surface left rough during the winter, the soil would be in excellent condition to produce a fine crop of early Potatoes next spring. Where Raspberry rows have become rather blank and only consist of a good plant here and there, it would never pay to retain these in their present state, and the best way of dealing with them is to lift them during September and make up the vacancies in some of the other rows with them. In this case the worst of the rows should be cleared to make good the best ones, and it will be found to be better to have two or three rows fully furnished than half a dozen with only a plant here and there. Some of the young suckers which have been thrown up from the strongest of the stools may also be lifted to make up blanks, and wherever any planting is done the piece of ground in which the roots are to be inserted should always be manured and dug up before planting. Several of our rows will shortly be treated in this way, and the whole of them will be gone over at once with the object of cutting out the old growths which produced the fruit this year, but which are now useless and withered. These old growths are sometimes left until pruning time in winter, but this is a mistake, as September is one of the best months of all to ripen the young rods, which will produce the crop next year, and they cannot have too much light, sun, and air just now, but when the old rods are left they partially obstruct all these. Where the canes are tied to wire or fences of any kind it is an excellent plan to tie them into their places now, but where this cannot be done at present the cutting out of the old rods should on no account be neglected, as this is one of the most important points in successful Raspberry culture with which I am acquainted. Where the stools are very strong and many young growths have been emitted, some of the outer ones may be shorter and weaker than the centre or main ones, but these may be dug up further on to form new plantations or fill up blanks, and where not wanted for these purposes they should also be cut out with the old ones and allow none to remain, except those required for fruiting next year.

J. Muir.

Apricot Musch-Musch.—This is unquestionably the hardiest and most reliable sort that can be grown. Our tree of it now reaches the top of a wall 14 feet high, and has a proportionate diameter of branches. It is now carrying as many fruits as some half-dozen trees of the Moor Park variety. The form of the tree is that of almost a perfect fan, for it has never lost a branch larger than one's thumb, and very few of them; while trees of the

Moor Park are terribly disfigured through the loss of large branches. Our Musch-Musch tree has never failed to bear a good crop since it was large enough to do so. It is quite a distinct variety, the leaves of which are slightly glaucous. Its only fault is the fruit not being quite so large as that of the Moor Park; but surely a good crop of rather small fruit every year is better than larger fruits which are uncertain. I prune Apricots on what I call a rough-and-ready system. What pruning our trees get is done in the summer time. Most of the young wood is nailed or tied in, only the young shoots for which there is no room being cut away. Early in the spring all dead wood is cut out, and that is about all the attention they get, except covering them with a wide glass coping and old fish net while in bloom. The glass is taken away again as soon as all danger from frost is over. —J. C. C.

Scalded Peach leaves.—Allow me to send you some leaves from young Peach trees growing in a cool house in which they have been planted about two years. They have not as yet borne any fruit, though they appear to be in good health. Within these last few days, however, the leaves are dropping off fast, and they have a scalded appearance. They decay round the edges, and there seems to be little black spots about them. They have had abundance of air day and night, and about three weeks back they were syringed with a weak solution of sulphide of potassium (quarter of an ounce to a gallon of water). I might add that I syringed Rose and other plants with the same solution, and they show no appearance of being hurt by it.—Selly Oak.

*** Your Peaches were doubtless perfectly healthy up to the time of the mishap in question, which is simply a case of scalding. The cause without seeing the borders it is impossible to define with certainty, but, judging from the tender nature of the leaves sent, it is more than probable that the roots, insufficiently supplied with water during the intensely hot weather which has prevailed, have been wholly unable to sustain the rapid perspiration. Yet another conjecture. Your trees, which you say are never shut up, may have been syringed too early in the afternoon; a circulation of air combined with intense sun heat would speedily injure the unusually tender leaves. Sulphide of potassium, quarter of an ounce to the gallon of water, would not harm them, as we have applied it double that strength to the tender tips of young Melons. Mulch your trees, give them plenty of water, and syringe well to induce a free growth of laterals, which will prevent the main buds now destitute of leaves from bursting into wood or flower. Reduce the laterals when the trees show signs of ripening, and they will break satisfactorily next season. A word as to the use of sulphide of potassium under glass. Always apply it late in the evening, and syringe thoroughly with pure water, and give air very early the following morning.—W. Coleman, *Eastnor Castle, Ledbury.*

Cordon Apples.—These are largely grown at Beddington House, Surrey, and, as usual, this year again they are producing a large crop of fruit of good quality. The principal kinds we observed were Bedfordshire Foundling, Ribston Pippin, Keswick Codlin, Scarlet Nonpareil, Cellini Pippin, and Hawthornden. The trees are heavily mulched annually.—G.

SHORT NOTES.—FRUIT.

The Dorchester Blackberry.—This variety has proved the most desirable for exhibition purposes in America, although it is said there are others equally, if not more, desirable for general cultivation. It is claimed for the Kittatinny that it is more hardy, a good cropper, and produces good sized, saleable fruit.

Peach house (*Ellingham*).—There is no reason why you should not build a Peach house in the position you name. The heat from the house on the other side of the wall cannot possibly affect the Peach trees. Have the house constructed so that the lights may be taken entirely off the roof after the crop is gathered.

Plum Cox's Emperor.—This fine all-round Plum is far too seldom seen. It may be grown successfully either as a pyramid or trained upon the wall. It may be depended upon for a crop, and is a large handsome fruit, flavour excellent, and fit for culinary purposes or dessert.—G.

Diseased Melons.—Our late Melon plants are suffering from a disease an example of which I send, and I would be glad if you would tell me the cause of the disaster and the way to cure it. I have noticed numbers of small black specks on the part affected very much resembling those on the Potato leaf when attacked by disease. The plants previous to the attack were very strong. I first noticed a small drop of moisture which seemed to exude from the stem. Presently the bark became brown and the disease continued to spread until it reached round the stem, and also worked through it, bursting the tissues and splitting the stem, which eventually collapsed and the plant died. I have tried to check the disease with lime, and also with sulphur, but neither appeared to do any good.—J. W. L.

*** Yours is one of the baffling cases so often described in this paper. There is no possible remedy; the diseased condition must, if possible, be prevented by good ventilation, a free circulation of air, and perfect root action in good compost. When the fungi peculiar to the Cucurbitaceæ once fix themselves on their victim, cure is hopeless. Sulphuring is very good when fungoid diseases are attacked in their early stage, but no amount of sulphuring will replace rotten tissue with sound, or stop the progress of internal decay. —W. G. S.

NOTES OF THE WEEK.

Nerine Fothergilli major.—From Mr. Mansell's garden in Guernsey comes a very fine spike of this plant. His gardener, Mr. Peters, describes it as having been taken from a potful of bulbs bearing ten such spikes. He also remarks that this variety always blooms a few days earlier than any others. Some, we hear, are relinquishing the cultivation of these beautiful plants because they do not produce their spikes together, but in succession; such, however, does not appear to be the case in Guernsey. This is certainly one of the best of the Nerines.

Hymenocallis macrostephana is already the acknowledged best of the cultivated plants of this genus, but it may not perhaps be known to all who grow it that when planted out in beds in shaded places and where there is always plenty of moisture, this fine species is perfectly happy and flowers abundantly. Some clumps of it now flowering in the Palm house at Kew prove conclusively that the treatment here recommended is not only safe, but probably the most suitable for this grand bulbous plant.

Antirrhinums. — These old-fashioned plants are now in great beauty at Swanley, where Mr. Cannell has for some time past been paying more than usual attention to them, and the results obtained are very satisfactory. We like the self-coloured ones best, or those with white throats; but amongst flakes and stripes we also noticed some good things. Although Antirrhinums will grow in almost any soil, some little attention paid to their requirements will be amply rewarded by increased vigour, and flowers larger and finer than they otherwise would be.

September flowers from Dublin.—Do you remember telling me that the rose-scarlet Picotee Painted Lady grew abundantly in Peel Park, near Manchester? It is very like, but larger and not so fine in make or colour as the true old Painted Lady which we grow here, and, as you can see by the specimen sent herewith, it is a very sportive plant. The one stem sent bears two distinct forms and intermediate gradations between them. The curator at Peel Park sent me cuttings last season, and I find his form a better grower than ours, which is delicate, and apt to die out unless stopped from flowering too freely. Amaryllis Akermanni is again in flower here, along with the lovely rosy Crinum Powelli. I send also three seedlings of Gladiolus Lemoinei, now in bloom from seeds sown in October, 1884. We sow as soon as ever the seed ripens in a light and well-prepared open-air bed. The seedlings are very pretty, and good as cut flowers. Tupa Feuillei is an old favourite here, and is now flowering at 3 ft. in height. I enclose a small cluster of Mrs. Clarke, a sweet-scented, creamy-white Viola, which is much admired by nearly all our visitors. The Colchicums and Cyclamen hederæfolium album are now quite lovely, making our Indian summer seem like a second spring-time.—F. W. Burbidge, *Trinity College Gardens, Dublin.*

*** The Viola is very sweet-scented, large, and, with the exception of a small yellow eye, pure white. The Pink, too, which is scarlet fringed with white, is in its best form a charming variety. —Ed.

Lilium auratum Wittei.—I send you a spike of this Lily cut from one of the borders in my garden. It seems to me to be one of the finest forms of L. auratum. The unspotted purity of its flowers, relieved, or rather illumined, by the bright yellow stripes, is very charming. It grows as freely with us as L. auratum, but does not grow so tall; it appears, too, to be quite as hardy. The spike sent you is, of course, from a bulb which went safely through the last severe winter in the open ground.—W. H. Tillett, *Sprowston, Norwich.*

*** A noble spike, or rather two spikes joined together, the stem being fasciated. The number of blooms is eighteen, and, as Mr. Tillett states, their purity of colour—white, with yellow stripes —is quite charming. They are compactly arranged, and in size somewhat smaller than that of most of the varieties of L. auratum.—Ed.

Crinum angustum is worth noting as an easily grown noble stove Crinum which flowers freely and is pleasant to look upon all the year round—more than can be said of a good many species of Crinum. A plant of it now in flower in the Palm house at Kew has a thick stem-like neck to the bulb, broad-channelled bright green leaves 5 feet long and holding themselves up as boldly as those of C. asiaticum do; its flowers are on a flattened stalk, the upper part of which is red, and about a score of long-tubed, fleshy, crimson and creamy-white flowers are arranged in an umbel on the top of each stalk. For large warm houses there is no better Crinum than this. C. giganteum, C. asiaticum, C. Hildebrandti, C. Commersoni, C. Mooreanum, and an unnamed kind from Queensland are also now bearing handsome flowers in the houses at Kew.

Tuberous Begonias at Swanley. — The Begonias in Mr. Cannell's nursery form just now, in themselves, quite an exhibition, five houses, each house 100 feet long, being full of them. Here may be found flowers of almost all colours, from the purest white to rich yellow, salmon, rose, maroon, crimson, and scarlet, whilst others exhibit almost all shades to suit the tastes of those having a preference for less decided colours. The flowers, too, are remarkably large, some of them measuring as much as from 6 inches to 8 inches in diameter, round and full in outline, and firm in texture. This strain of Begonias is, moreover, distinguished for dwarf compact growth. Amongst novelties for this season with single flowers, the best, perhaps, are Charles Fellowes, crimson suffused with red and orange; Henry Cannell, deep rosy scarlet; M. Brisson, deep orange-red, with a crimson centre; gigantea, fiery crimson; Miss Cannell, rosy pink suffused with purple; Crimson Circle, intense crimson; Lady Kirk, soft salmon; King of the Begonias, deep maroon-red; Countess of Bessborough, rich clear golden yellow, edged with soft red; Marquis of Salisbury, large clear scarlet: W. E. Gumbleton, bright magenta-rose; Mrs. H. Cannell, pure rose, with a light centre; W. E. Gladstone, fiery crimson; and Shirley Hibbard, brilliant scarlet, with a pure white centre. Amongst single flowers not considered novelties the following were the most distinct and effective,

viz., Albert Crousse, rosy red; City of London, deep rosy lake; Countess of Kingston, glowing crimson-red; Mrs. Laing, pure white; Trocadero, bright scarlet; General Roberts, amaranth-crimson; L'Abbe Fromert, bright golden yellow; Rosea magnifica, large pure rose; Royal Standard, deep crimson; Lady Emily, amber-yellow; Alba floribunda, pure white; Wonder, yellowish buff and orange; and Sir Stafford Northcote, large red, shaded with lake. The best novelties in doubles are, we consider, Louis d'Or, a very distinct and effective shade of yellow; Leon de St. Jean, scarlet-red; M. Paul de Vicq, bright carmine-cerise; Susanna Hatchett, fine rosy pink; Notaire Moens, bright carmine; Dr. Baillon, deep salmon; and M. Legouvé, light creamy buff. Amongst double flowers not considered novelties the following are a few of the best, viz., Louis Banchet, brilliant orange-scarlet; Blanche Duval, creamy white; Othello, deep reddish crimson; Intermedia plena, soft orange-scarlet; Coquette, rich carmine; Candidissima plena, pure white, with a sulphur centre; Flamme de Punch, rich rosy pink; Lucie Lemoine, pure white; Gabrielle Legros, clear sulphur white, changing to soft yellow; Pæoniflora, salmon-rose; Madame Castigny, rosy pink; Madame Arnoult, pinkish blush, with deeper edge; Octavie, pure white; Virginalis, pure white, with a yellow centre; and Madame Crousse, nankeen-salmon. These are mostly beautiful Camellia-shaped and full-sized double flowers, suitable, when wired, for button-holes, shoulder-sprays, or bouquets.

Pentstemons.—We have received some beautiful spikes of these from Mr. Forbes, of Hawick; some of them were upwards of 18 inches long, and well furnished with flowers the whole of that length. Conspicuous amongst them were: Herbert Cutbush, deep crimson, with a pure white throat; Mrs. Milne, flesh-coloured, throat pure white; Lady Margaret, rich crimson-maroon, throat white flaked with crimson; William Robinson, deep red, with a white throat, streaked with scarlet; Mrs. Sharp, lilac or mauve, throat very open, white flaked with carmine; Helen Wood, crimson-scarlet, with large open pure white throat; Provost Watson, rose, throat white, streaked with deep rose; Mrs. Bowley, crimson-purple, throat very large and open, white flaked with crimson; William Forbes, a large scarlet flower, with a white throat; Mr. P. Brydon, creamy white, tinged with pale rose, buds before opening bronzy; Pearcy Wynne, crimson, throat white, with crimson streaks; Gem, deep scarlet, throat white, flaked with crimson; and Samuel Johnstone, soft pink, with white throat.

Solanum atro-purpureum.—A plant at Kew thus labelled will have to find some other name, as the above is already given to a comparatively worthless garden plant, which was introduced by the late Mr. Wilson Saunders from Brazil, and was named and figured in the *Refugium Botanicum*. The new and spurious atro-purpureum is, however, a handsome foliaged plant, for which we are indebted to Messrs. Makoy and Co., of Liège; it has large-lobed, horizontal leaves, which are deep olive-green above and vinous purple below. It is evidently a good plant for summer bedding, as the plant at Kew is in fine health in a border out of doors. A collection of ornamental-leaved Solanums is now a grand show in front of No. 3 museum at Kew, and as the plants are named we call attention to them, so that anyone in search of handsome foliaged plants for summer bedding may make note of the kinds which would best answer their purpose. Solanums are amongst the easiest managed of annuals, but one may easily grow a number of kinds which lack beauty and interest unless he first of all sees what the plants are like by inspecting such a collection as that at Kew.

Passiflora gracilis.—The relationship between the Passiflora and Cucurbit Orders is much more evident in the foliage and fruit than in the flowers of the plants of the two Orders. We noted several of the edible-fruited Passion-flowers a week or two ago, and recommended them as garden plants because of the ornamental character o their large and, in some, prettily coloured fruits, which are usually produced in abundance on strong plants; in addition to these there are some which, although neither edible nor large-fruited, are yet strikingly pretty when seen covered with their bright-coloured berries, P. gracilis being one of these. This species has thin stems, green, smooth, three-lobed leaves, greenish white flowers an inch across, and deep scarlet fruits about as large as and shaped like Damsons. We saw this in the stove at Kew a few days ago, where it is fruiting very freely. Near to this plant there is also a pretty, small-fruited Passion-flower, the leaves of which are three-lobed, rugose and silvery in the middle, and the fruit, which is about 1½ inches long, has prominent ribs as in a Chinese lantern, and coloured blood-red. P. cinnabarina is also fruiting freely in the Palm house; its fruits are as large as bantam's eggs and coloured bright red when ripe.

Helianthus multiflorus maximus.—Here is a plant for the million, but how many gardens—if we except the few where all good herbaceous plants are grown—are graced with its glorious blossoms? Certainly it ought to be in every garden where flower borders are, for it is, in our opinion, the most beautiful of all known Sunflowers. It is as superior to the common Sunflower (H. annuus) as the single Dahlias are to the heavy-headed double ones, and it is a perennial species, too, so that when once planted in a border it remains for ever a noble summer beauty. On good soil it grows 8 feet, or even more, high, and a strong plant will have nearly half a hundred flowers open at one time. Such flowers they are, too, being 6 inches across, the broad ray florets overlapping each other and just irregular enough to be graceful, and the disc not more than 1½ inches across, yellow, with black anthers, so that the whole flower looks almost uniform lemon-yellow. If I had room to grow only one Sunflower I should not hesitate to choose this before all others. Three of its large flowers are now in front of me with their round faces looking almost white in the gaslight. The typical multiflorus is not the variety maximus—a hint that beginners with this plant should take note of.

Lilium auratum at Kew is now in great beauty, and is worth going a long way to see. Grand as this Lily is in pots and treated as a conservatory plant, it is plain that it loses much of its beauty in such when compared with its effect when planted out of doors amongst suitable surroundings, and in masses large enough to make a bold display. Two large beds of dwarf Rhododendrons in one of the most conspicuous parts of the garden at Kew have been planted with bulbs of this Lilium, and there are now towering up high above the Rhododendrons dozens of stout stems, some of them over 6 feet high, and bearing massive clusters of flowers. Here the powerful odour of this Lily is not disagreeable, because the position is an open one, and this openness enables one to see the tall spikes of flowers from a long distance in various parts of the garden. The golden Lily in a corner loses much of its charms, its proper position being that of a prominent feature in a landscape. Such, at all events, is the lesson taught by the effectiveness of these beds at Kew. The life and beauty such plants as this are capable of adding to dull, sombre places in a garden do not appear to be fully appreciated by many gardeners. Liliums have not yet got full hold of the horticultural world, being still confined a good deal too much to the pot and greenhouse. Probably a Lily conference would do much to bring the dozens of beautiful, but almost unknown, species of this genus into prominence. What is to be the subject of the next of the Horticultural Society's conferences?

5516.—**Clematis montana.**—"E. L. R., Halifax," in The Garden of August 28, says this Clematis grows luxuriantly, but will not flower with him. Clematis montana flowers on the ripened wood of the previous year, and should be closely pruned in June after its proper season of bloom, and in wet summers, when the growth is unusually strong, the young shoots should be nipped off from time to time. Some years ago I allowed two plants of this Clematis to grow naturally on my house without pruning, and no bloom was the result. This climber is very accommodating as to soil, and will hold its own with Ivy and tree roots. I have a large plant here growing over and festooning a Holly tree. The effect in early summer is fine, the top of the Holly being covered with white stars. Of course, I presume that "E. L. R." grows his Clematis in a tolerably sunny place; without sun I am afraid no treatment would be effectual.—J. B. W. Thomas, *Belmont, Carlow.*

RHODODENDRON VEITCHI.

To Mr. Robert Veitch, of the New North Road Nursery, Exeter, we are indebted for the photograph from which the annexed illustration was prepared. It is that of a very fine specimen of Rhododendron Veitchi, grown at Watermouth Castle, Ilfracombe. Mr. Parkhouse, Mrs. Basset's gardener at Watermouth Castle, the grower of the plant in question, has kindly furnished us with the following particulars as to its size and his mode of culture: "When the photograph was taken," he says, "the plant was in a 12-inch pot; its height was 6 feet 4 inches, its breadth at 3 feet from the top 4 feet, and it was bearing no fewer than 300 fully developed flowers, some of which measured 8 inches across. The soil in which it grows consists of lumps of fibry peat, a good sprinkling of sharp sand, and very finely broken oyster-shells. It flowered in an ordinary conservatory, after which it was removed to our Camellia house, which is well shaded. It was kept rather close and moist till it had completed its growth and set its buds; after that it was gradually given more air, and now (September 3) the house is open night and day and its contents fully exposed to the sun. To-day I have counted the 'breaks' of this year's growth, and find that they number 130; therefore I am in hopes of having a still better display next year."

A good basket Fern (Gymnogramma schizophylla gloriosa).—The variety of this very beautiful form is much superior to the original introduced to gardens some few years ago, which, on account of its proving difficult to grow, did not find much favour with amateur Fern cultivators. When suspended in baskets this newly introduced form, with its long, pendent, finely divided fronds, is very elegant. The fronds are a light bright green above, sparingly sprinkled beneath with a white farinose powder. This plant is a very free grower, and, like all the Gymnogrammas, easily obtained from spores. To grow it successfully the compost should be rough fibrous peat and Sphagnum Moss. It requires careful attention in watering, otherwise its delicate pinnules soon shrivel.

Trichomanes radicans.—At Waddon House there is a grand plant of the Killarney Fern. It is upwards of 5 feet in diameter and perfect both as regards colour and form.

Microlepia hirta cristata with Mr. King at Waddon is finer than we have seen it elsewhere. It proves to be more beautifully crested than we expected it would be, judging by specimens of it which we had hitherto seen.

Pteris aquilina.—We saw a few days ago, upon a lawn in a Kentish garden, a large clump of this Fern, the effect of which was charming. The fronds, which were 5 feet or 6 feet high, are just now beginning to assume their beautiful autumn tinge.

Adiantum Capillus-veneris.—Doubts are often expressed as to the hardiness of this species. We have recently seen a beautiful mass of it on a wall in a garden at Tooting, on which its spores, escaped from a stove, had doubtless fixed themselves. It has been in its present situation for at least ten years.

Hardy Ferns.—Two beautiful hardy Japanese Ferns are in great beauty at Beddington House—Lastrea prolifica and Polystichum polyblepharum, bold and massive in outline, yet the pinnæ are finely divided, sufficiently so to give them a graceful appearance. Both are desirable additions to a fernery.

Trees and Shrubs.

TREE TRANSPLANTING.

Now that the season for transplanting is at hand perhaps a few practical remarks bearing upon the importance of carefully preserving the roots of trees may be useful to those who contemplate transplanting. The art of transplanting trees has long been in general practice, although not always carried out in a thoroughly scientific manner. Much disappointment from failures often arises from the non-fulfilment of certain principles which are absolutely necessary in order to obtain satisfactory results. Transplanting shrubs may be done, and is done, with adherent balls of earth varying from 8 lbs. to 10 lbs. in weight to as many tons, according to the lifting appliances at the command of the operator. The simplest of all methods is lifting a shrub or tree with an ordinary garden spade, and even by this simple process the greatest difference is observable in the execution of the work by different operators. This is easily seen by the way in which some parties go about such work. Some, from long practice, particularly in nurseries, will lift a small-sized shrub with a good adherent ball, while another, from want of the requisite skill in guiding his spade, will allow the ball to fall to pieces. Retentive soils and frequent transplanting have often much to do with the successful lifting of certain plants. With many deciduous trees and some shrubs it is not always necessary that they should be lifted with a ball of earth, even when of medium size, unless in the case of very rare or delicate specimens, when successful transplanting is absolutely desired. Deciduous trees, both forest and fruit, varying from 4 feet to 6 feet, or even 10 feet in height, where the roots have been prepared by previous cutting or frequent transplanting, can be moved with safety even without a ball, and at any time during the transplanting season. If transplanted without any previous preparation, particularly if 10 feet or 12 feet in height, such trees are apt to lose many of their branches, frequently getting into a sickly condition, and having ultimately to be uprooted.

To carry on the work of transplanting trees and shrubs with some prospect of success, especially with exotic trees, it is of the first importance that every care should be taken to preserve the roots; however favourable an appearance a tree may have at the top, if the roots be mutilated by careless or unskilful lifting, it is not even half a tree, and will have a long struggle for bare life. To lift trees well, the characters of the roots of the various kinds must be studied—their texture and mode of growth. The various aspects of the foliage and branches of trees and shrubs are familiar to all who take any interest in their culture, but I may venture to affirm that but comparatively few are equally familiar with the aspects and peculiarities of their roots. This experience could not be acquired, I grant, except by those who have been much engaged in transplanting; but it is of much greater value to the planter, so far as success is concerned, than any other kind of knowledge. There is a proper way to prepare a site for a tree, and a proper way to plant it; also a proper way to fasten and protect it when planted. If I were to be held responsible for the success of a piece of planting, I should be very careful to see that the lifting of the trees was well performed; for this kind of work the best hands should be employed. I have no hesitation in saying that bad lifting is at the bottom of three-fourths of the failures after planting. It might be stated as an axiom in the lifting of trees, that if the roots be well secured the labour of moving an unwieldy ball of soil may be entirely dispensed with. In practice it will be found, except in comparatively few instances, that to move a tree with a very large ball of soil is a great mistake, as the unwieldy mass of earth attached to the roots dislocates and distresses them; but a small ball of soil, by way of ballasting the top with the roots, will ensure a far greater probability of success in the future growth of the tree after transplantation; in fact, a small covering of earth round the roots of a tree whilst being moved is undoubtedly preferable to no ball, and vastly superior to a large ball of soil that can only be removed with great difficulty.

Rhododendron Veitchi: a specimen grown at Watermouth Castle, Ilfracombe. Engraved for THE GARDEN from a photograph.

While lifting large deciduous trees without balls, or even with balls, it is absolutely necessary that all injured roots be cut off, particularly those partially broken through. The cut parts should afterwards be smoothed over with a sharp knife, as well as all surface-skin damages, instead of having them planted with their roots hacked with the spade, a system which is not unfrequently pursued. It will be found that all clean knife-cut roots will put out young fibres much freer than those that are cut with a spade and planted without any smoothing.

The branch-cutting system, on an extensive scale, is frequently practised on forest trees from 20 feet to 30 feet in height. The roots, although not damaged, ought all to be cut; that is, in cases in which no adherent earth can be removed with them. Large trees so treated often succeed well, and ultimately make as good shaped tops as unpruned specimens removed either with or without a ball of earth. The foreshortening causes them to break more rapidly from the old wood than they otherwise would do; besides, foreshortened specimens do not require the assistance of ropes and props, which are generally

necessary in the case of large deciduous trees where no branches are removed. The percentage of unsuccessful transplants is often very few in point of number compared with trees in which no branch or root-pruning had been carried out.

In order to transplant comparatively rare specimens, both large and small, it is in most cases desirable to resort to machinery or other appliances, however simple, such as surrounding the ball with canvas, staves, and ropes, particularly in cases in which balls of earth must accompany the plants.

Among the many different trees and shrubs that exist, the possibility of lifting them with balls of soil, or even securing their roots, varies much with different individuals, for out of the same description of soil some species will move easily with good balls, while with others it may be almost impracticable. This arises simply from the mode of growth the various roots assume; some ramify in all directions, like the Rhododendron or Holly; others take a horizontal course, as some Conifers. On lifting with a particular aim in view to secure the roots, there is one rule which applies to all sorts, whether small or large, and that is to begin by inserting the spade at a sufficiently wide radius from the stem of the tree or shrub, to work round in a circle, and at once to go down sufficiently deep to be below the roots before approaching nearer to the tree. I have seen a consignment of ornamental trees, excellent so far as the appearance of the tops went, but utterly spoiled from the manner in which they had been lifted, the roots having been cut so short off by the spade that only snags were left, the really vital roots having been left behind. The first cost of lifting should not be considered when it is a question of life and death with the plants. I have found, from considerable experience in lifting shrubs and trees of all sizes, that to get well below the roots in the first instance, and gradually approach the tree, is the simplest and easiest way of securing the roots and reducing the bulk of soil, so as to make a ball manageable. W. D. M.

The Labrador Tea (Ledum latifolium).—This bush reaches a height of from 4 ft. to 5 ft., but flowers freely in a young state. It is not such a regular growing shrub as L. thymifelium, and as the undersides of the leaves are clothed with a rusty coloured tomentum, it is less attractive when out of blossom. The flowers are white, and when in the bud state are not so deeply tinted as are those of L. thymifolium. In a cut state the flowers possess the advantage of lasting a long time in perfection, especially if they are gathered just before expansion; besides which they are so neat and pretty, that they can be associated with the most select.—H. P.

Liquidambar styraciflua. — The brilliant autumnal effects as seen in the landscapes of North American forests are derived chiefly from the Liquidambar tree, a tree of slow growth in this country, but yet perfectly hardy, and one that should be largely planted, not only in the pleasure grounds, but in the woods and plantations on estates, if only for the sake of its autumnal tints. It is very like the Sugar Maple as regards foliage, save in the autumn when its leaves turn to a purplish red, and should frosts be late in coming, this beautiful tree has a fine appearance, which with trees of other colours is most telling in our woods in autumn. The Liquidambar does best planted early in the autumn, just as the leaves begin to turn, which is about the middle of September. Having tried both autumn and spring planting, I have found the former best suited to the Liquidambar.—W. C. Leach.

Catalpa syringæfolia.—This beautiful tree, of which there are several growing in the grounds here, has for the past few weeks been one mass of bloom, its lovely blossoms being borne in hundreds on each tree amidst its large leaves, which are of a beautiful shade of green, a shade peculiar to itself and seldom seen in any other tree. These fine trees have been a sight worth seeing, the more so just now when most other flowering shrubs and trees have long since shed their flowers. The Catalpa is a tree that should be extensively grown for ornament. There are many large places in England where fine collections of trees exist and yet this fine tree is often absent. There is no doubt but what the sunny south suits it best, yet in sheltered places this tree will thrive. It starts into growth very late in the season, and should the summer be cold and little sun, the young wood does not get thoroughly ripened; hence its liability to be cut back with frost should the winter be severe. Yet, for all that, it is, I consider, one of the finest trees in cultivation.—W. C. Leach, *Albany Park.*

CEPHALOTAXUS PEDUNCULATA FASTIGIATA.

At a casual glance this fine tree is readily mistaken for the Irish Yew, but a closer inspection reveals several well marked and distinct generic differences. By several botanists this Cephalotaxus has been placed under both Taxus and Podocarpus (Taxus japonica, Loddiges; Podocarpus koraiana, Gordon), but recently M. Carrière has cleared up the difficulty; he has found that the tree in question is neither a Yew (Taxus) nor a Podocarpus, but belongs to a small, though nearly allied, genus, the Cephalotaxus of Siebold.

The interest attached to this tree is therefore considerable, and it is a curious coincidence that the same means of identification as those employed by Carrière, and described in "Traité Général des Conifères," are now plainly visible in the case of a large specimen in the grounds at Penrhyn Castle, a matter which has induced me to add to M. Carrière's statements regarding this Conifer.

At this point, however, it may be well to explain that in the typical Cephalotaxus pedunculata the branches are horizontal and the foliage distichously arranged; whereas in the present form the leaves are irregularly placed in whorls or spirally arranged, and the branches strictly fastigiate, these wide differences having given rise to the conflicting opinions advanced by several botanists, and to the number of genera under which the tree has been placed. The matter was cleared up by Carrière noticing that a plant of the above produced at a short distance from the ground the usual spreading branches and distichous foliage of C. pedunculata, while both above and below the upright habit and irregularly arranged leaves of the now C. pedunculata fastigiata were prominently revealed.

In a large specimen growing in the park here this peculiarity of growth is just now particularly noticeable, for at 3 feet and 6 feet from the ground several branches are growing in a perfectly horizontal manner or almost at right angles to the main stem, while both above and below these the branches are strictly fastigiate; indeed, nearly as much so as in a perfect specimen of the Irish Yew. The leaves on the horizontal branches are distichously arranged or in two opposite rows, while those on the other portions of the tree are irregularly scattered or nearly spiral by their closeness along the shoots. It is here worthy of remark that in several Coniferæ, notably the tree in question and the Irish Yew, when a fastigiate habit of growth is assumed the leaf arrangement becomes altered from distichous to whorled, with occasionally a normal branch as if to show the parentage. In the common Yew the foliage is arranged in two opposite lines, while in the Irish form, or rather variety, the leaves are tufted or scattered along the shoots, thus presenting an analogous case to that under consideration.

As this Cephalotaxus is little known in British collections, and large specimens but rarely met with, the following description of the principal distinguishing characteristics taken from a full grown tree may be useful to some of your readers. In habit and foliage it nearly approaches the Irish Yew, but the branches are rarely so erect and adpressed nor the leaves of such a deep green as in those of that tree, while it never attains a greater height than about 8 feet. The leaves are bluntly falcate, or more usually sabre-shaped, less than 2 inches long by two-sixteenths of an inch broad, thick and fleshy, and usually furnished with short foot-stalks. Above they are of a deep glossy green with a distinctly raised narrow mid-rib, while beneath two rather indistinct silvery bands run along their full length. Both branches and branchlets have a peculiar channelled or tuberculated appearance, caused by the long decurrent base of the leaves, these, in most instances, reaching half an inch in length and persistent after the foliage is removed. As a compact growing shrub or small tree this Cephalotaxus is well worthy of attention, and, being perfectly hardy and of free growth, may be planted almost indiscriminately, but particularly where a warm, sheltered corner and free loamy soil can be supplied. A. D. Webster.

Penrhyn Castle, North Wales.

TRANSPLANTING EVERGREENS.

From the middle of September to the middle of October, all things considered, is the best time to move Evergreens. The soil at this season works so cleanly and free, that it may be packed in round the roots firmly without becoming hard and unyielding in the future; when a heavy soil has parted with its elasticity, things do not thrive in it. There is, too, at this season more earth-warmth than at any other time of the year, a circumstance which encourages new fibres to spring forth from the lacerated roots. In some localities the soil is of a soft, silky nature, and whenever a plant is moved to a fresh situation in such soils root action recommences at once. In such a soil, too, planting may be done almost at any time. But on heavy adhesive loam or clay, healing wounds or fractures takes some time after removal, let the work be done ever so carefully; therefore early autumn is the best time to plant, especially if numbers of plants have to be shifted. In moving plants larger than one can lift with one hand, it is always desirable, if the soil be of a holding character, to transplant with a ball in proportion to the size of the plant. In light sandy soils balls cannot be had that will move a hundred yards without the greater part falling off. Therefore, the best way is to secure as many roots as possible without attempting to move with a ball.

In making new beds or groups the soil doubtless will have been trenched, as no one deserves success who plants in a hard, unmoved soil. In planting isolated specimens, however, this cannot always be done, and in that case the hole should be made considerably larger than the space which the roots will cover in order to afford room to lay them out straight, and provide a suitable bed for the young fibres to work into at first to fix the plant in its new position. An old-fashioned plan practised by the seaside, and a good one, too, is to place a layer of boulders over the roots as soon as the earth is all filled in. The stones keep the earth moist and cool, and by their weight steady the plant and prevent injury from wind-waving. All newly planted shrubs and trees require water, and the watering should be repeated until the autumn rains set in. Sprinkling the foliage with the garden engine will help to check evaporation till the roots get somewhat established in their new quarters. A mulching with long Grass at this season, immediately after planting, will keep the earth cool and moist, and encourage early root-formation. The staking or otherwise supporting the stems of shrubs and trees of a size likely to be injured by wind should never be postponed.

In purchasing plants from a nursery make sure that they have been regularly transplanted. If this has been done, every plant will grow, but if they come to hand with long naked roots it is a

sure indication that they have not been transplanted lately, at any rate, and unless well looked after some of them will die. I have known instances in which a good many have died. Such plants are generally dear at a gift because of the labour involved in getting them to grow. There is some danger in moving large specimens from a sheltered situation to an exposed one; whenever I have done so I have always improvised some kind of shelter the first year till the plants have become in some measure acclimatised. Transplanted plants should not be placed deeper in the ground than they formerly were; sickly-looking specimens often owe their brown appearance and ultimate death to the 3 inches or 4 inches of extra soil thrown out of the bottom of the hole to fix the plant well in the soil. E. Hobday.

SOME RARE TREES AND SHRUBS.

Crataegus brachyacantha (Hog's Haw).—From Minden, La., and Concord and Longview, Tex. Extremely rare. Our specimen is a bushy little plant only 8 inches high, but who has a bigger one? It has now been planted a year, and was unprotected last winter; but it got a good deal winter-killed, and I am rather solicitous about its hardiness near New York.

Philadelphus microphyllus.—From S. Colorado and southward. Among shrubs, one of the gems of our garden; hardy here also at Boston. The flowers are pure white and deliciously fragrant. Our specimen is a dense little mass, between 2 feet and 3 feet high and 3 feet across; nevertheless, Prof. Sargent tells me that it is the biggest plant of the kind he knows of in cultivation. It blossoms every summer.

Rhus cotinoides.—Our plant is 5 feet 5 inches high, and consists of one unbranched stem, but it is leaved from the base to the tip. It formed several side branches, but I rubbed them off in order to strengthen the main stem. What lovely foliage! This species is extremely rare in cultivation. I hope it may prove hardy. We got our plant last autumn; it was then 8 inches high. I planted it out of doors in rich ground and a sheltered situation, but did not cover it up in any way. It was not winter-killed. When it began to grow in spring, a branch started from every eye, but as I wanted a little tree rather than a bush, I rubbed off all the branches except one.

Stuartia japonica.—Our specimen is 5 feet 4 inches high, 4 feet in spread of branches, and densely furnished. It has beautiful foliage at any time, but most beautiful in autumn, when it assumes a brilliant crimson and gold tint that completely eclipses anything in the way of our American species of the same genus. It has not yet blossomed here. So far it has not been hurt by the winter with us, but at the Arnold Arboretum, near Boston, it suffered a little last winter.

Texas Walnut (Juglans rupestris).—"Valley of the Colorada River (near Austin), west through Western Texas, Southern New Mexico, and Arizona, from 5000 feet to 7000 feet elevation, and in the California coast ranges, from the San Barnardino Mountains to the neighbourhood of San Francisco Bay and the valley of the Sacramento River."—Prof. Sargent. Our largest plant is 6 feet high, of pyramidal form, very branchy, and 6 feet in spread of branches. We have several plants, now two years planted, and they seem to be hardy enough; in some cases the tips of the young wood get winter-killed. Its slender branches and narrow leaflets are in striking contrast to the stout limbs and large leaves of our common black Walnut or the English Walnut. —W. F., in *Country Gentleman*.

The Lombardy Poplar does not appear to be so fashionable with planters now as in years gone by. About a century ago no plantation was made without it, and for shutting out unsightly buildings, &c., in the landscape it was considered invaluable. Even now it may to a limited extent be introduced into plantations of round-headed trees, to give them life and interest, especially when looked at from a distance, its pointed head producing a pleasing contrast to its less aspiring companions. This effect is more particularly apparent in Cheshire, Worcestershire, Herefordshire, Gloucestershire and Somersetshire than in other counties. It associates well with old churchyards, cemeteries, old ruins, amongst pointed-headed Cypresses and Yews; a plant or two of it has also a homely look at the entrance to a village, or it may be on its green. At the same time it would be out of place to plant this Poplar largely anywhere except where it is wanted to shut out unsightly objects.—J. B.

NOTES.

White Lilies.—In the Bronze room of the British Museum there is a mask of Aphrodite which I used to admire as the finest work of art known to me as a gardener until last May I saw the marble Venus de Milo in the gallery of the Louvre. The connection between things artistic and the best of our white Lilies is perhaps nearer than one might at first suppose; at any rate, I never see the one without at once thinking of the other, for as these works of art are irreproachable in their way, so are the white Lilies as seen at their best—the very finest and most satisfying of all the garden flowers known to me. L. candidum, or Madonna Lily, of which there are two distinct single-flowered forms, is perfectly hardy on nearly all soils, but, like the forms of the Japan L. longiflorum, such as eximium, Harrisi, and floribundum, it may be forced into flower for Eastertide if so desired. It may be worth while saying that now is the best time to dig and transplant the bulbs of L. candidum for next year's flowering. Other fine Lilies quite distinct in form are the white varieties of L. lancifolium or L. speciosum, such as Kraetzeri, album, and album corymbiferum. A large bed of the typical L. longiflorum in peaty soil amongst Rhododendrons and hardy Heaths is now a sight worth seeing. Well-grown stems bear from three to five flowers, and these are of glossy whiteness, reminding one of silver trumpets. L. Browni can scarcely be classed with the above as white Lilies, since the back of the flower-tube is of a dull claret colour, but this only serves to intensify the purity of the inner part of the perianth. The best of gardens lacks much beauty unless white Lilies are well grown therein.

The Irish flora is in some ways peculiar, and in all ways interesting—at least to a stranger. We have naturalised in Ireland by the acre, amongst other things, such introductions as Hypericum calycinum, Tussilago fragrans, Sisyrinchium anceps, Arbutus Unedo, Pinguicula lusitanica, Mimulus lutea, and Ophioglossum lusitanicum. I might point out the fact once more that many Narcissi have existed here for years uncultivated and uncared for, especially such of the white kinds as are generally believed to rightly and naturally belong to Spain. As peculiar to Ireland, or nearly so, we have Trichomanes radicans, Polypodium vulgare var. semilacerum (=P. hibernicum), Pinguicula vulgaris var. grandiflora, in white, rosy lavender and dark violet forms. Only two years ago three fine specimens of the North American Huntsman's Cup (Sarracenia purpurea) were found in an isolated and unfrequented bog in Queen's County by a party of sportsmen. I am sure of the plant, having had leaves sent to me for examination, but how it got there is still a mystery to everybody. As a fact, I believe that Sarracenia is there still. But of all the plants of Ireland we took especial pride in, that form of the proliferous Lady's Tresses known as Spiranthes hibernica (=S. Romanzoviana) is the one. This grew in one or two rushy meadows near Castletown, Bearhaven, and was known to exist nowhere else in the world except in North America. Whether it really exists in Ireland to-day no one truly knows. Its former habitats have been cultivated—the one field is sown with corn, the other planted with Potatoes! There are some things too deep for words to express, and this uprooting of a rare plant is one of them. If perchance the plant really does exist to-day in Ireland, it is to be hoped that some steps will be immediately taken to render its extirpation impossible.

Crinum Powellii.—Without a doubt this plant is one of the very finest introductions of recent years. It is a long, broad-leaved species, not unlike those semi-tropical kinds which one may see well grown in the Palm house at Kew. The great advantage of this rosy C. Powelli (and of its snow-white variety) is that it is perfectly hardy in the open air. If planted deeply in sandy soil at the foot of a south wall, so much the earlier and better will its great flower-scapes appear. Here and there in England, as in Devon and Cornwall, or near the Hampshire coast, or over in the Isle of Wight, and in Scilly, in Valentia, in the south and east of Ireland much may be done with reputedly tender bulbous plants, especially if the soil be deep and dry. In such soils one may plant bulbs 12 inches to 18 inches deep with a certain hope of their coming up alive and vigorous after the coldest winter we are ever likely to experience. The whole secret and mystery of a bulb's dying is more often too much wet rather than too much cold. But this noble Crinum will withstand both wet and cold, and become stronger and more floriferous year after year in at least seven gardens out of ten that are in England and Ireland.

Juncus zebrinus.—We have several plants of this zebra-striped Rush, best described, however, by saying that it is like a long quill stolen from the back of the "fretful porcupine." A gentleman visitor, the other day, told me that its right name is Scirpus Tabernæmontani foliis variegatis zebrinis. I remember Mr. Nicholson, of Kew, pointing out this correct nomenclature some months ago in a contemporary paper, but Juncus zebrinus serves all practical purposes, and is as much as I ever want to write. The plant is from Japan, the home of variegated leaves. I shall never forget the variegated plants which I saw in Siebold's nursery garden at Leyden, where nearly everything was variegated in some way or another. Our best plant of Juncus zebrinus has some of its longest quills now at least 5 feet high and many of them 4 feet, and, as so seen, everyone is struck by its beauty, distinctness, and decidedly ornate character. We grow it in good loam, and the pot is standing in a saucer of water. It is growing in a close plant house warmed by sun-heat only, and gets plenty of subdued sunshine. There is no difficulty in growing the plant either in a pot indoors or outside in a pond, provided that it be planted below the water level. Not having heard much of this plant lately, I wish to say that, when vigorously grown, it is very effective.

Pothos celatocaulis.—This is a plant with a decided "call" or mission. Naturally, in Borneo, it grows up the shady side of moist tree trunks in the damp malarial forests, but its mission in English gardens is to cover bare damp hothouse walls in a beautiful manner. When it first made its *début* at the Chelsea Nursery, it was fairly well grown, but, nevertheless, I am afraid that no one thought much of the little stranger with its soft green velvety leaves. But at last someone received inspiration, and a few pieces of it were planted to cover the bare gable end of a wall inside the wonderful Nepenthes house. That simple action, accidental as it might have been,

decided the fate and future of this plant. With it Ficus stipulata (Ficus repens, Hort.) had been planted, and the two plants grew up the moist warm wall together. The little crumpled leaves of the "Creeping Fig" set off to perfection the rich soft larger leaves of the Pothos. The sight was as lovely as when beauty of sweet seventeen walks abroad with a protector in the shape of her pretty little sister of seven. Everyone who went to see the wonderful Pitcher plants stayed a moment to admire the leafy picture embroidered on the wall, and so Pothos celatocaulis is a good plant to have in stock to-day. The moral is plain: Beautiful as a plant in itself may be, when seen in a suitable position it becomes ten times more charming.

Double Tiger Lilies.—As seen really strong and happy—say 8 feet in height, with twenty to thirty flowers on a stem—the double Tiger Lily is a noble garden flower, and a worthy companion for the more popular gold-rayed species of Japan. I used to think the double Tiger Lily rather a poor and undecided plant until I saw it in peat earth near the margin of an ornamental pond at Newry, where it grew fully as high as I have just stated, and bore its flowers aloft in the most perfect manner. It is now flowering here in deep rich loam amongst Brake Fern and the effect is lovely, but one can easily see that a few sods of peat would be an improvement. When planted in amongst other things its bulbs are apt to be preyed on, especially during winter, by little black slugs, but a handful of Cocoa-nut fibre around each root is a preventive worth adopting with these and other bulbs vulnerable by snails. I used to lose Iris reticulata year after year until a friend told me that Cocoa-nut fibre refuse thwarted these silent little robbers, and since then our patches of the netted Iris have increased year by year. Planted in a deep peaty soil amongst Bamboos or Rhododendrons, the double-blossomed Tiger Lily is well worth a place in the garden.

Helianthus and Ricinus.—Some of the most effective of plant arrangements in the garden are chance ones, and by noting the best of them as they occur one may often make permanent improvements on these accidental successes. The note-book is invaluable in all good gardening, since by its use we should strive to fix in the memory not only the best plants to use, but also the worst ones to avoid. A good strong clump of the large single-flowered perennial Sunflower had a bare circle of earth around it as it grew up last May, and somebody planted around it some seedlings of Gibson's purple-leaved Ricinus. The effect is now a very bold and satisfactory one, which is worth repeating another year. Formerly we used to manure the earth where this Sunflower was planted. The result was we had more big leaves than golden blossoms. Now we dig deeply and merely add a little old lime rubbish, and the result is a more floriferous display. The same treatment causes a great improvement in many other robust-growing things, Dahlias and Hollyhocks to wit, which here with us grow leafy and out of all bounds if manured. On nearly all soils this judgment, founded on experience, is necessary if hardy flowers are to be grown and seen at their best. The thing is to find the medial line between starvation and overfeeding.

Telekia speciosa.—One of the most robust and effective of all the golden-rayed Composites now in bloom is the above, which bears enormous corymbose heads of rich orange-yellow flowers on stalks, 6 feet in height, the lower stems being clothed with large soft green heart-shaped leaves. Individually, the flower-heads remind one of those of Inula glandulosa, and they are very effective in colour and good in form as arranged in vases or tazzas indoors. The plant is very vigorous in habit, and may well be added to the list of good hardy herbaceous plants which luxuriate under the partial shade of trees. We raised a strong lot of seedlings some years ago and planted them out under trees, and their beauty, as so seen, has surprised some of our visitors. It is readily increased by division, but is a little too leafy and coarse-habited for the best of beds or borders. As a hardy sub-tropical plant it deserves attention, or it might be very effectively employed in plantations near the house, or beside the more frequented of woodland walks or drives. A friend of mine planted the large Crimean or Hungarian Bindweed (Calystegia sylvatica) in his home plantations two or three years ago, and the effect just now as contrasted with common red Torch Lilies in the more open and sunny positions is very beautiful. There is a whole world of beauty in the right use of common things.

Good leaves for vases.—There was a time when Maiden-hair Ferns only were considered the right thing for associating with cut flowers. Now-a-days we are broader in our sympathies, and some of us find more difficulty in obtaining beautiful foliage for indoor uses than is experienced in the providing of flowers. For the Iris flowers, especially for the bulbous kinds of May and June, we use the leaves of Typha or Bulrush. The bronzy leaves of Heucheraare lovely in their own way for shallow vases, as are also those of Tellima; but for the lovely Gladioli and Torch Lilies, now so plentiful, nothing for grace equals the leafage of Eulalia zebrina, or for fresh greenery the leaves of the common Maize or Indian Corn. Both the last are free-growing Grasses, the Eulalia being a hardy perennial, and the Maize an annual, easily raised by sowing the Indian Corn in the open air during March or April. The common Mahonia affords plenty of good, clean, bronzy foliage, and the golden leaves of the Wistaria are very useful just now along with purple Clematis or blue Bellflower. The different kinds of Ruscus, as R. racemosus or R. androgynus, are very fresh and durable, and even those of the common Butcher's Broom may now and then be utilised with good effect. Purple or bronze-leaved Ivies are especially welcome in the winter, and harmonise well with Violets, or contrast effectively with snow-white Christmas Roses. Will someone give us a good list of hardy plants worth culture for their beautiful foliage?

Hybrid Orchids.—One of the most recent of hybrid Orchids is that raised in the Royal Exotic Nursery at Chelsea, between Sophronitis coccinea (=S. grandiflora) and Cattleya intermedia, named Lælia Batemanniana. Only a year or two ago such a production would have been called a bigeneric hybrid, but now-a-days good things are more valued than arbitrary and artificial names. Lindley's first guess at the plant now known as Sophronitis grandiflora was that it was a Cattleya (Cattleya coccinea, Lindl., Bot. Reg., xxii. (1836), p. 1919). If he had perchance counted the pollen-masses, he would have seen that having eight instead of four it was a Lælia. But this does not matter, since Mr. Dominy long ago proved that Cattleyas and Lælias breed together freely, and now we can also reduce the whilom genus Sophronitis to Lælia. If any should think this too marked a change, I should like to remind them of Cattleya citrina, which in habit and structure is far more distinct from Cattleyas generally than is Sophronitis from the dwarf Lælias. Apart altogether from the beauty, rarity, or garden value of these hybrid Orchids, their teaching value is incalculable, for by hybridisation or by grafting only can real botanical relationships be definitely settled. In a word, what the botanist guesses or assumes the gardener can actually prove beyond all questioning. This is the theory and practice of botany as united to that of gardening.

Gloxinia maculata.—Why is this fine old plant so rarely seen? The old, old story, I suppose, is accountable, viz., with the constant influx of novelties, old friends are sometimes neglected, and then disappear. Mr. Douglas, when at Loxford Hall, used to grow this plant to perfection, and in the Cambridge Botanic Garden Mr. Lynch has it planted out in some of the stoves with the best results. As a pot plant it is always interesting from the moment the great dark bronzy leaves appear from the big caterpillar-like corms in spring until the stems die down during the winter months after blooming. In a word, apart from the soft lilac, dark-throated flowers altogether, there are far less effective plants grown, especially for their foliage, than this spotted Gloxinia. It is a South American species, figured in the Bot. Mag., t. 1191, and is said to have been introduced as long ago as 1739. It grows well in a well-drained compost of loam and peat on a well-drained bottom, and when in full growth a little weak manure water adds freshness and vigour to its leaves. The flowers are solitary in the axils of the upper leaves or bracts. A well-grown specimen, in a pot, 3 feet in height and as much or more in diameter, is worth seeing when in bloom, or at any previous period of its growth.

Gladiolus Lemoinei.—All the now numerous varieties of G. Lemoinei are perfectly hardy on our deep light soil, and are very interesting when in bloom. The two original forms, G. Lemoinei and G. Marie Lemoine, are even yet, as I believe, the best of the group, all things considered. They are quite distinct from the florists' hybrids in shape of flower, and increase more rapidly by offsets from the parent bulb. Mr. W. E. Gumbleton, of Queenstown, who has made a speciality of these hybrid Gladioli, kindly gave me seeds from his collection for the past two or three years. These seeds bloom the second or third year after sowing, and we have now seedlings in bloom which we think better than the named kinds if we except the two just named. The seeds should be gathered and sown as soon as they ripen in a deep rich bed of light soil. They come up the following spring, and some of the strongest of them will flower the first year, but most of them will do so the second, so that the amateur has not long to wait for results. The long and graceful spikes of these hybrids are very useful if cut just as the lowermost bud expands and placed in water. So treated every flower expands to the very tip of the spike, and, what is more, the flowers endure fresh and perfect in shape longer indoors than they would have done on the plant outside, and the bulb itself is relieved of a great strain, and so bettered in condition.

Torch Lilies (Tritomas). — I wish Mr. N. E. Brown, of Kew, would let us have his long-promised monograph on these beautiful flowers. The distinctions among the garden species—or species so-called—are so slight, that I expect, as is usual in such cases, the gardeners will have to christen their best forms for themselves. Here we have five or six varieties of the common T. Uvaria, some of which are actually out of bloom even at this early date, having thrown up their spikes late in July, while others are not even yet in flower. T. media begins to bloom in November, and its spikes keep on in flower until April if the weather be mild during winter. Then in May and June the stately T. caulescens throws up its stout scapes of red and

yellow flowers. T. Saundersi is one of the best, free in growth and brilliant in colour. Two of the prettiest little kinds in the whole group are T. Macowani and T. corallina, both in bloom on a dry rockery, and their scapes are not more than 15 inches to 18 inches in height. There are other species and varieties, but so far the above have done better with us than any others of the group. I should like to meet with the true Tritoma pumila (Bot. Mag, vol. xx., t. 764), which, if the plate is to be trusted, as I believe it may be, must be a very beautiful and desirable plant. M. Max Leichtlin, of Baden-Baden, has made a cultural study of these showy flowers, and I wish he would tell us something about the rarest and most beautiful sorts.

Gaillardia hybrida.—Seeds of this sown about eighteen months ago now repay us for the little trouble they took in the rearing, and we find the rich yellow and red flowers most serviceable and effective for cutting and use indoors. There are several varieties, but G. hybrida grandiflora seems the hardiest and best, yielding a richer harvest of blossoms here with us than does any other form. The flowers are 3 inches to 4 inches across, the broad ray florets being dentate at their apices and of a rich yellow colour stained with dull crimson or dark red at the base and arranged around a dark centre. On a warm sunny day these flowers show out most brilliantly from amongst the stems of other things, which serve to support them in a more natural way than stakes and ties would do. In a gentle warm breeze the flat florets of these gorgeous flowers flutter up and down in a very pretty way, reminding one of the wings of a Red Admiral butterfly sunning himself as he feasts on an over-ripe Pear. One great advantage possessed by these perennial Gaillardias is their continuous habit of blooming. Our plants have been in bloom since June, and seem prepared to go on until the frost king comes with his scythe.

Senecio pulcher.—This capricious Groundsel from South America is now in flower again, and is interesting as an earnest of the many beautiful hardy or half-hardy plants yet to come to our gardens from the highlands of Chili and Peru. I call it a capricious plant, although here, in a deep, light, moist soil, it grows freely and flowers from August until cut down by the frosts of November. Wherever it is grown in quantity, however, plants may be well watered a day or two in advance, and then, if dug up and potted firmly and shaded in a close cold frame for a day or two, they will go on blooming until Christmas and make quite an addition to the conservatory at that late season. The plant was introduced by Mr. Tyerman years ago, and is most readily increased at this time of the year by making inch-long cuttings of its thick, quill-like roots in pans of sand. The cuttings should be nearly covered with sand, and kept in a cold frame near the light where they will form leafy growths, and may be planted out in the open air in May or June. In habit and colour this plant is quite unique among the numerous Daisy-like blossoms of the autumn season, and it is well worth treating as a pot plant in situations where it will not grow well outside. Veronica.

Weeding walks.—Weeds never grow upon a solid walk so plentifully as upon a loose one; we therefore gave up hand-picking, and applied clean agricultural salt for two seasons. The result is, not a weed in a hundred yards; the walks are hard and smooth, and never looked so well before. I admit that sometimes the Grass at the edges suffers, but this is owing to heavy rains dashing the salt on to the Grass. This may be remedied by taking a fine rosed watering pot and just dissolving the salt with water near the edges of the walks. The cost of salt is not near so much as that of hand-picking.—D.

Flower Garden.

IRIS PALLIDA.

If among the Flag-leaved Irises one had to choose a queen, the crown of royal beauty would, no doubt, be awarded to Iris pallida, the subject of our engraving. Taller and statelier than any among the several species and numberless garden varieties broadly classed together under the name of Flag Iris, this one is always conspicuous for beauty and importance. The pale lavender-blue flowers are carried proudly on strong, straight stems, and the flat sheaves of sword-like leaves, broader and larger than those of others of the family and of a pale glaucous colour, proclaim the identity of the plant when out of flower.

The Great Purple Iris. Engraved from a photograph for The Garden.

Ivy on walls.—It has often been said that Ivy has a tendency to make buildings damp; but, wherever that has been the case, it arises from neglect in not having it properly trimmed in, or in allowing it, and this it soon does if neglected, to take possession of the water gutters or pipes, and so cause an overflow. To have Ivy in good condition it should be cut in close to the wall, taking off all the old leaves every spring. About the end of April is the best time, as it breaks into growth, almost immediately covering the walls with a beautiful mantle of bright green foliage, the leaves so placed one above the other that no rain or damp can ever penetrate. In the case of old walls or ruins, it is not necessary to trim it so closely as on an inhabited dwelling, as, by so doing, its fruiting is prevented; and thus one of its most beautiful features at this season of the year is lost.—H.

ROCKS AND ROCKERIES.

I notice that the professional rockery-maker lays great stress on imitating Nature, and, as a rule, he prefers to proceed on the "stratification" principle of building ledge upon ledge, providing accommodation for the plants as well as the circumstances will permit. This is all very well, and a rockery so constructed may look well enough, but it is troublesome and expensive to make, and it is the worst kind of rockery for plants that require something more than a bare scarp and a handful of soil to make them grow. Nature's rockeries are not always made on this principle. On precipitous cliffs there is often a top ledge in which the strata preserve their natural forms, and such formations are usually almost bare of plants; but at the base of such cliffs rocks of all shapes and sizes are usually tumbled about in the greatest confusion, and it is in such places that the plants and shrubs are found growing most abundantly. I could show anyone miles upon miles of Derbyshire and Yorkshire scenery of this kind. In some places the Heaths and Bilberries fill up all the crevices among the stones, the grey Lichen-covered faces of which project prominently here and there, and sometimes the rocks project from the smooth green turf above, sometimes thickly and sometimes thinly, but always in an irregular manner, but in almost all cases in a way that can easily be imitated artificially, and that without much study. It is only necessary that the stones selected be of different sizes and shapes and shot on to the space where they are to lie without too much scheming after effect. This done, it is wonderful what a charming aspect can be given to the spot by filling up some of the spaces in the background at once with good flakes of Blackberry bushes, Heath, and other low and suitable shrubs, and the rest of the spaces with Grass or plants, as may be desired. It is an expensive plan piling stones upon stones to form a rockery, ending in but a pigmy heap at the best, but any ordinary slope, be it a steep or only a gentle incline, may be made into a rockery with comparatively few good sized stones half buried in the soil here and there. A background of Firs or coniferous trees is, of course, desirable, though not indispensable; but the greatest pile of rocks should be at the top of the mound, and the others should be scattered thinner and thinner towards the bottom, as if the ridge had been suddenly upheaved and the fragments had toppled down the hillside. This is the way many natural scenes of the kind have been formed, and when the delicate-tinted Bilberry shoots and the Heather are pushing up among the stones in early summer the picture is delightful, and so is it in autumn when the Heather is in bloom. Of course the addition of a greater variety of suitable plants would enhance its beauty, and can be easily introduced into such places. W. S.

Verbascum olympicum.—I send you a photograph of a plant of this Mullein which I had blooming in my gar-

den this summer. It was about 5 feet high, and attracted the attention of everyone who saw it. The great drawback to its usefulness is the length of time it takes to produce a blooming plant from seed. The seed from which my plant came was sown in March, 1884, and this plant is the only one which has thrown up a spike; all the others are waiting another year.—A. R., *Bowness*.

SEPTEMBER FLOWERS FOR CUTTING.

The present season has been very favourable for hardy outdoor flowering plants, for although the spring was so late, the summer has been cool and moist, with the exception of one short spell of tropical heat; consequently flowering plants have made a long and uninterrupted blaze of colour. The second bloom of Roses and many other plants has been more lasting than the first. The following is a brief list of plants specially suitable for cutting from. First on the list is Achillea Ptarmica, a clear white, very double flower, that continues to send up its branched heads of bloom for weeks in succession. It is of very easy culture, the roots running in the soil like Couch Grass—a real gem for every purpose for which cut flowers are grown. China Asters of various kinds, but especially the Victoria, are about the best of flowers raised annually from seed. We sow in March in gentle heat and plant out in April on a warm border for early supply, and in April we sow in cold frames for a late supply, planting out in May in open ground, and very few plants grown give such a variety of colour or such beautiful lasting blooms as a good strain of Asters. We find a bed of clear white sorts invaluable for wreath-making. Campanula persicifolia alba is one of the very best of herbaceous plants, either for cutting in large spikes or in single blooms for bouquets; when well grown and mounted with leaves of green Euonymus, the flowers very much resemble Gardenias. This year they are flowering freely long after their usual season, the rains having induced a second crop of bloom to spring from the old flower-stalks. Among the Cactus Dahlias now so popular, Constance, a good white, and Juarezi, scarlet, are the best. We grow them to a good size under glass, and when planted out in May they commence flowering at once and continue the whole season. Of Harpalium rigidum, the Prairie Sunflower, I planted half a dozen small plants last year in August, and the quantity of bloom they have produced this season has surprised me—a single clear yellow flower with very dark disc and good long stalks, so that you can cut the expanded bloom without cutting any buds. Helianthus multiflorus is another good Sunflower. It has clear golden yellow double flowers of a suitable size for cutting. I find these perennial Sunflowers do best when replanted once in two or three years. The Flame flower (Tritoma Uvaria) forms striking masses of colour at present. The large spikes of bloom are most useful for harvest festivals and other massive floral decorations. These plants stand for several years without removal, and the larger the clumps the more bloom. The variety called Burchelli appears the most persistent bloomer. J. Groom.

Gosport.

Kniphofia Leichtlini var. distachya. This curious and pretty plant received from Herr Max Leichtlin, of Baden-Baden, in the autumn of 1884, is now blooming with me for the second time. But this year the specific variation from all other varieties of this family known to me of the second or subsidiary flower-spike branching off from the main stem, at a height of 2 feet 4 inches from the ground, is much more distinctly marked than it was last year, when only a rudimentary pip or two were produced at the base of the main spike instead of a distinct second spike, as this year. The height of the flower-stem from the ground is just 3 feet 5 inches, and it also differs from all other varieties of the family in commencing to expand its flowers from the top instead of from the bottom of the spike. The type K. Leichtlini is figured in the 109th volume of the *Botanical Magazine*, plate 6716, but the figure there given hardly gives an accurate representation of the deep orange colour of the flower as seen in Nature, which consists mainly in the deep shade of the protruding stamens, which are more conspicuous than the paler tubular flowers from which they come. This variety is a native of Abyssinia, whence it was sent to Baden-Baden by the traveller Schimper. It is quite deciduous, and also appears to be perfectly hardy in this climate.—W. E. Gumbleton.

SOME USEFUL ANNUALS.

In following up my note on useful herbaceous plants I desire to supplement it by adding the names of a few useful annuals, and would keep the same object in mind; in so doing, I would interpret the word "useful" in the same sense as in the former paper—useful, that is for cutting for home decoration. I think that annuals ought to play rather a more important part in the garden than they have done. As long as the bedding-out system was *de rigeur*, annuals were almost banished from gardens. Where the Geranium, Calceolaria, Ageratum, &c., reigned supreme, there was no place for them, however beautiful they might be; but now, when in early spring and on to June the borders are pretty full of plants, bulbs, &c., there must of necessity be considerable gaps in them. Some persons are in the habit of filling these in with Geraniums, and a few of them are doubtless effective, but I do not think nearly so much so as annuals, and while all credit must be due to Mr. Thompson, of Ipswich, and others who have of late years so largely enriched our seed catalogues with their introductions from various climes, it must be noted that a great many of the old-fashioned annuals are still unsurpassed for beauty and perfume. One might go through a carefully bedded-out and carpetted garden and not get one whiff of sweet odours. Not so now-a-days. Some of the "banished ones" have been restored, and one's olfactories are delighted by the fragrance of such old-fashioned flowers as Sweet Peas and Mignonette. In the list that I shall now give I shall take note of those which are useful for both purposes. There are many which, very beautiful in the garden, are of little service when cut, as they shut up. Nothing can be more lovely than the blue of Convolvulus minor or more bright than the yellow of Eschscholtzia, but, unhappily, when cut and put into a vase, they close up their petals. All such flowers, then, are unsuitable for this purpose, and, however beautiful in themselves, I must exclude them from my list. In the same way the beautiful scarlet Flax (Linum grandiflorum), although very useful for the garden, is of no use as a cut flower.

Marvel of Peru, too, deliciously fragrant as it is at night, shuts itself up during the day, and even if it did not, there is so much foliage about it, that it is hardly a good flower for cutting; but those who wish to have a bed of sweet fragrance would do well to try this old-fashioned plant, so easily grown and so very vigorous.

Brachycome iberidifolia (the Swan River Daisy) makes a beautiful dwarf clump either in the front of the border or on the rockery. It is of a delicate silvery blue colour, and covered with flowers, and continues in bloom for a very long while.

Chrysanthemum Dunnetti and Carnation bicolor.—There are small varieties of these annual Chrysanthemums which are very useful for cutting. Some are very remarkable in the arrangement of their colouring, and contrast well with other flowers. The old Cornbottle, too, is very beautiful, much more so, I think, than that which is called an improved variety of it, which is apt to come semi-double, and then its beautiful, simple character is destroyed. There is also a double variety of Dunnetti, which is not nearly so pretty as the single one.

Gaillardia picta.—This and its variety nana are very beautiful in their bright orange and crimson colouring and are always very much admired in bouquets as well as in the garden, where their bright colouring always shows up well. They are far more effective, I think, for both purposes than the new double one, Lorenziana, which, although curious and even remarkable, is not at all equal to the type; in fact, there are very few double flowers which are as good for decoration as single ones of the same species; they are too heavy when put with other flowers, and by themselves never form a pleasing object. It is for this reason, I think, that bouquets of Roses are so seldom effective.

Centaurea moschata (Sweet Sultan).—There are three varieties of this, white, lilac, and yellow. Of these the last is the most beautiful, and I have been surprised to find how little it is known. Whenever I have had visitors, they have always asked what is that beautiful fluffy-looking yellow flower. It is not only good when mixed with other flowers, but forms a very pretty bouquet by itself. The lilac and white are also useful, but not so much so as the yellow, which no garden ought to be without. Why it has its name of Sweet Sultan I cannot quite understand, for there is nothing very fragrant about it, although I find the honey bee likes it much.

Cyanus minor (the Cornbottle).—This has become a very favourite flower, both naturally and artificially, especially since it became known that it was the German Emperor's favourite flower. Although not quite so popular with ladies as the Marguerite, it may still be seen in all manner of decorations. It is very effective for bouquets, too, as its delicate blue is a colour most needed, but amateurs must beware both of this and the Corn Marigold; they are native plants—weeds, we may say—they will scatter their seed all over the garden, and have to be constantly watched, or they will smother other things. Happily, they have not very tenacious roots, and so they are easily eradicated.

Burtonia aurea.—Another very beautiful yellow flower, very bright in colour and free flowering, continuing in flower, too, for several months; well worthy of cultivation.

Mignonette.—There is no need to recommend this deliciously fragrant annual, and yet how many gardens have I been into where not a plant of it was to be seen. I merely mention it here to say that I am not at all sure, notwithstanding the many improved varieties, whether the old-fashioned variety is not the sweetest and best. Size is of no great advantage in cutting flowers for a bouquet, and it is size in which most of these newer sorts are supposed to excel.

Salpiglossis.—It is impossible to exaggerate the beauty of this old-fashioned, but too much neglected annual. The flowers have almost the appearance of jewelled enamels, and vary very much in colour, from straw colour to beautiful lilac and gold. It grows tall, and is best where it can rest upon other annuals, or it must be staked, otherwise the long slender stalks will trail on the ground.

Sweet Pea.—Who can doubt the excellence of this most fragrant flower of which one can hardly have too much? Besides the old-fashioned varieties there have of late years been introduced several very beautiful kinds, such as Salter's Butterfly, Invincible Scarlet, Invincible Crimson, and others equally fragrant with the older sorts, and adding much to the beauty of a row or clump by their colouring. If, when the first crop has bloomed, the pods are taken off and the tops cut off a second crop of blooms will be produced, and thus continue the blooming season on until late in the autumn.

Godetias.—I can hardly look upon these as satisfactory, for although when they first come out they are very pretty, yet seed-pods are so soon formed, they disfigure the spray and make it of very little use for the purpose.

Coreopsis Drummondi, tinctoria and atrosanguinea.—Nothing can be more useful and brilliant than these bright and showy annuals. Of slender

growth and bearing their flowers in profusion, they are just the very thing for cutting. The former of these, with its brilliant crimson centre and yellow petals, is a most beautiful flower, attracts the eye in the garden, and stands out prominently in the bouquet, giving it great lightness and at the same time brilliancy of colouring.

Such are a few of the annuals which I have grown and found useful both for decoration in the garden and also for cutting, and, as I said of herbaceous plants, so I say of them, I should be very glad to be told of others which are available for the same purpose. I may add that this summer, finding that having almost daily to gather them from the borders necessitated a good deal of treading on them, to the manifest injury of other plants, &c., we this year, at my daughter's suggestion, had a border of about 30 feet long by 2 feet wide given up to them. They were sown in rows, and the whole was very showy and effective, while it afforded an increasing supply of flowers. The cheapness with which seeds are now to be purchased makes this a very easy matter where there is room, and does away with the objection that is sometimes made of disfiguring the borders; and I think that persons will be very difficult to please if they have not a good deal of enjoyment out of the selection I have given above. DELTA.

PINGUICULA GRANDIFLORA.

THE native Butterworts are more or less plentiful in boggy or marshy places, and are extremely interesting as well as beautiful. The conditions, however, under which they thrive best debar most lovers of hardy plants from attempting their culture. A wet treatment is most generally recommended for them, yet we have seen them growing wild by the thousand on the hill paths as "dry and hard as a bone." In the winter season, however, these paths are under water and impassible for at least four months of the year—quite the opposite to our treatment. We might take a lesson from this fact, for it is in the winter season, when the leaves have disappeared, that most damage is done to Pinguiculas under cultivation, for the winter buds, which are all that is left of the plants, during that season are scratched up by birds, leaving them to wither on the surface. Pinguiculas, we find, will thrive with only a very limited supply of water, and by means of a little shade might be grown very successfully without the specially prepared bog, and the same might be said for the common Sundew, which we found also in abundance close to the Butterworts. Of the four native species, the Irish Butterwort (P. grandiflora) is most worthy of notice, being twice as large as the ordinary P. vulgaris, much easier grown, and altogether a better garden plant. It is amenable to pot culture, and makes a charming pot plant. P. alpina, lusitanica, and vallisneriæfolia may also be kept as curiosities. P. caudata, a greenhouse species and a very charming plant, would, no doubt, be found to do well in the open in summer time, although questionably hardy. K.

Verbena venosa.—This is a most useful plant, as it grows and flowers abundantly in almost any kind of soil or situation. When all the ordinary varieties of Verbenas fail this one is sure to give satisfaction. It is easily kept through the winter, and if its fleshy roots are stored thickly in boxes any number of plants may be propagated in spring from the young shoots that are abundantly thrown out. It should be planted rather thickly, and pegged down until the ground is covered, when it will continue to flower until the last of the summer flowers are removed or destroyed by the frost.—J. G.

Helianthus cucumerifolius.—This annual Helianthus is a Texan plant, growing from 3 feet to 4 feet or 5 feet high. The flower-heads measure 3½ inches across, terminating the branches. They are bright yellow, with a disc of a deep black-purple. Treated as a half-hardy plant, it commences to bloom in June, and continues in flower till the arrival of frost. Being free from the coarseness of so many of the other species of Sunflower, it is an important addition to border annuals, as it is not only very showy, but a continuous bloomer.—T.

NOTES ON HARDY PLANTS.

Gentiana septemfida.—Of this Gentian there are varieties, some very dwarf and others somewhat tall and of erect habit. But I think the prettiest variety of all is one grown under the name of cordifolia. This has slender and short stems, closely furnished with small cordate leaves somewhat acute. It has a procumbent habit, and flowers quite as large, though fewer of them, as are generally seen on the taller kinds. It is, moreover, a free grower, and may be easily raised from seed, which comes true. The seedlings flower freely in their second year.

Androsace Chamæjasme is now in full leaf. In the cultivation of Androsaces the leafing period is a most important one: you may then not only pretty well judge with what measure of bloom or

Pinguicula grandiflora.

otherwise you will be gladdened the following spring, but you may greatly help in bringing about the desired end. In our climate these Androsaces continue to grow until late in the summer, and I imagine not a few of us would be surprised to see the number of pests which trouble these little plants—pests which probably, from their small size and the smallness also of the plants, escape notice. The fresh green leaves of the present season are liable to injury by aphis and red spider, as well as slugs, which find most convenient lodgment under the close tufts. We know too well that either of these, if left undisturbed, will kill the most hardy and robust plant. What I wish to point out is that imperfect leafing means an unsatisfactory condition of the plants in winter and spring, that we should see to the cause now, and be on the alert for those pests we might not have suspected, attributing the want of healthy growth to climate or something else than the true cause. This, one of the prettiest European species, is especially liable to red spider, and often the leaves are stopped in their growth when not half the size they would otherwise attain. This, it need hardly be explained, not only leaves the plant with its round winter leaf buds much under the natural size, but without that full supply of dried and persistent herbage which is so unvaried and essential a feature of the whole family. All the Androsaces should now have their healthiest appearance, and if not they should be examined. I find brisk syringing on fine mornings a good practice, and a dusting of white wood ashes or tobacco powder in the evening after three or four applications clears the fly, and if applied with the puff-pot to the under sides of the leaves, the clearance is more thorough.

Propagating Ramondia.—My experience in seed-raising of R. pyrenaica has shown it to be one of the slowest processes, and after what I have found out respecting propagation by old leaves, I should never think of raising seeds again. Just about a year ago I set old leaves, and they are now forming beautiful plants of six leaves. I see, by the dating of the label on the seed-pot, that it is nearly three years since I set a pot of seeds, and the plants are not more than half the size of those a year old from old leaves. It is therefore, to my mind, clear beyond a doubt that by leaf-cuttings is much the best way to propagate it. In all cases I have used decayed peat or Cocoa-nut fibre. The latter seems to be especially adapted for the plant in its young stages. As the plants get older I add a little turfy loam, and if they are turned on to their sides by setting the roots in the side of a pot which has had a triangular piece broken from it, they seem to make all the quicker progress.

Œnothera macrocarpa.—One hardly knows which to admire most, the fresh flowers or faded ones of this evening Primrose. The great lemon-yellow flowers, so fragrant in the opening stage, are certainly very beautiful, and in the evening of, perhaps, the second day, when the flowers have closed for ever and become somewhat twisted, the colour having changed from the bright yellow already mentioned to one beautifully tinted with apricot, they are none the less flowers of great beauty—beautiful in their fading stage. A week or two ago I mentioned a ready process of propagating this plant. To do so now by cuttings is, so far as I am aware, quite out of the question, and the next best thing to do is to look after the seeds. Plants, however, so raised are only serviceable for flowers the second year.

Mertensia maritima.—Throughout the summer my one plant of this has been flowering, and from the earlier flowers there is now a nice bit of seed. There can be no wonder that the harvesting and sowing of this seed are a little puzzling. I imagine that to deal with the seeds successfully from tradesmen's seed boxes would be a greater puzzle still. In the first place, the seeds which we see in threes have a fleshy covering, which remains green for a long time, at least two months. After that the pulp skin (but no longer containing pulp) turns quite black, but remains somewhat inflated; inside is the loose and black-brown seed. If seeds are taken at this stage and sown, germination is most rapid; they sprout almost in a few days. A sandy or gritty soil on a damp bed—such as one made of spongy peat—is the best material I have found in which to sow them. I am not sure that it will be the best plan to leave out the seedlings of two or four leaves all the winter. Of course, they are perfectly hardy, but the action of frost is very liable to throw them completely on to the surface, and should the winter happen to be rather open, scarcely a less danger awaits them in the form of slugs, which are very fond of this plant.

Sedum populifolium.—This distinct shrubby Stonecrop does not bear showy flowers, but they seem to harmonise beautifully with the form of leaf of their own plant. The shrubby habit and fleshy, somewhat small, and irregularly toothed leaves render it very unlike an ordinary Stonecrop. The flowers are pinkish white, borne in corymbose clusters and freely produced. It is deciduous, and though it has a somewhat

tender appearance, it is one of the hardiest of its family.

Rosa caroliniana.—One does not see much of this, but I should think it would be difficult to mention another single dwarf Rose to supersede it for beauty, and especially in delicious perfume, which is a sort of concentrated Dog Rose scent. The Willow-like growths are 2 feet to 4 feet high. Each blossom is about 2 inches across, of a delicate rose colour.

Primula obconica is a capital plant for summer effect, and may be said to solely represent its family by normal and abundant flowers out of doors in the late summer. I believe its hardiness has not yet been satisfactorily proved, though the plant has been left out on rockwork all winter in Yorkshire where it survived, but the winter of 1884-5 was not severe; besides, some protection was employed. We know, however, that plants in a fairly leafy state will endure many degrees of frost under dry conditions, but this does not imply much. This Primula affords considerable variety when raised from seed; there may be, so far as we at present know, more difference in the foliage than the flowers, but perhaps most in the scent of the bloom; this feature becomes worthy of note when we otherwise find the plant affording so many flowers suited for picking. There may be found in a batch those with varying perfumes distinctly resembling Violets, Lilac, and Auricula. The flowers differ a little in both shade and size; the leaves by comparison may be described as varying—Dock-like, Coltsfoot-like, and Geranium leaf-like—in shape; the substance is as irregular also as the shape of the edges. All this suggests that this variable species is capable of being improved by cultural skill, and surely a more worthy plant could hardly be named, especially when we recall that its sweet pale mauve flowers may be had all winter in a cool greenhouse.

Potentilla lanuginosa is one of the sweetest little shrubs imaginable for the rock garden. It is perfectly happy in a rubbly soil deeply mixed with a little loam and leaf mould, with the fullest exposure to sunshine. It occupies far less space than many of the herbaceous sorts, and for all practical purposes it may be reckoned a smallish plant rather than a shrub. The leaves, which are thickly coated with white silky hairs, are rendered almost white, and as the young wood, so short and freely produced, is nearly red, the effect even when flowerless is very pleasing. The big glistening yellow flowers, however, which just now are beginning to appear, make these little bushes, of but a foot or so high, positively gay. It is a truly handsome subject for a rockery of the dwarfest shrubs and plants, but one hardly ever sees it. It is strongly to be recommended for the hottest side of rockwork, and its hardiness is beyond question.

Geranium argenteum is certainly one of the most charming alpines we possess; it may be termed a twilight plant in the sense that, seen at that period of the day in late summer, it is more than usually winsome; then this stemless plant may have its long leaf-stalks erect, and the lax umbel of flowers will assume their pretty cup form, and the too arid effect of the sunny daytime is quite changed. How is it that for all the plant is so well known and is such a general favourite, that it is still a scarce plant? I have found that it seldom comes true from seed, even when its spare seeds can be secured; then it is not one of the freest to perpetuate itself by offsets, which, by the way, are not so easily established as those of other hardy Crane's-bills. Again, old plants are apt to go off when five or six years old, and whenever this habit belongs to a plant so desirable, it need not be said how important it is that young duplicates should be looked after. These facts may in some degree account for the comparative scarcity of the plant. Without deprecating the practice of raising the plant from seed to make sure of the true form, it should be increased by offsets; in obtaining these the crown and root should be treated more in the way of those of the allied Erodiums. Split both crown and root (after first cutting the former) by the tearing process; this will allow the fairest and safest share of root to each division. But the more important point is to do this at the right time in early summer, when each division is not only sure to grow, but make a strong established plant. Whether set in a pot or rockwork, the soil should be free from undecayed vegetable matter. Old plants live longest in dry, sunny situations, with a deep and porous soil, such as could be provided by mixing loam and grit, and supplying it for a depth of 18 inches.

Campanula Zoysi, exquisite both in growth and flower, is, I find, a rapid grower in the summer time, and we may not have much left to complain about if the plant can be fully secured from slug grazing. I have latterly grown this distinct Harebell in a pan, in a soil composed of washed sand from the gutter of a country road and very old mould got from stable manure and Bracken. The advantages seem to be more rapid growth, quickly developed flowers, and immunity from slugs, the latter being mainly the result of a free use of wood ashes. There may be a little cause for fear that in such rich stuff the roots may not go to rest and ripen as soon as they should, but the fact of the plants being in pans gets one over this difficulty without much trouble. If set in the open or on rockwork, as I know many admirers of alpines prefer, I see little chance of so small a species becoming an effective plant, unless slugs and snails can be kept off it, for one hungry slug could eat off the growth of many days at one meal, and everybody practised in slug-slaying knows that the same slug will regularly visit the same plant for a long time together if not stopped.

Grass of Parnassus never fails, with the most off-handed treatment, to yield its chastely-beautiful, if not showy, flowers. A number of roots, years ago, were brought when in full flower from different habitats both distant and near home; all must surely have lived and thriven, as well also as the Sundews which unintentionally came with them in the soft black earth. The little sods were packed into cracked loaf-dishes which held moisture in the bottom, and they were placed behind the coign of a building where only the very early and two hours of the western sunshine could reach them; they have long stood there, and give no further trouble than that of pulling out a bit of the longest Grass. It is interesting to notice the difference of growth and size of flowers in specimens from the Adel bogs, the fens of Lincolnshire, and the moors of Ardrishaig. All the plants seem happy, but year after year the distinction is sustained. What has puzzled me most is a little batch which came from near Weatherby. The plants were taken up, or rather down, in flower. I say down, because they were found on a conical mound of dry marly material quite exposed to the full sun. These plants were set under similar conditions to the others, but most died the first winter, possibly because, from the loose nature of the soil, the roots were injured by the untimely removal; those still living are the smallest in every way. Is it not a very unusual thing to find Parnassia palustris on a lofty dry mound? But to prove how accommodating such plants are, I may mention that I saw this bog plant make quite a showy effect in Dr. Appleton's garden at Beverley last year. He grew it in big potfuls; the plants were 6 inches to 8 inches high, and the big flowers reminded one of those of Ranunculus amplexicaulis. They were the finest I ever saw, and suggested that something could be done with the Grass of Parnassus in the way of floral effect. I believe the doctor raised his plants from seed, and, likely enough, he would coax them with the scientific soil mixtures and rich plant foods he is so fond of experimenting with. Indeed, he did so, and the impression on my mind was that by his method we could grow this plant so as to be one of the most beautiful for pots in or outside or in the open garden.

Tunica Saxifraga is one of those plants bearing insignificant flowers, but which, from the myriads produced, has a good effect. The long flower-stalks are very thin, and leave the rosy little flowers full play to shew themselves, which they do in a charming manner. A good feature about this plant is that the succession of bloom is sustained for a long time by plants a year or two old, and another that the plant will prosper under any conditions if in plenty of sunshine. Plants above two years old, however, are impatient of removal, and they are not increased so well by division as by seed raising. Seedlings, if from seeds autumn sown, will flower the first year, but they are much more leafy in proportion, and otherwise look different from older plants. J. Wood.

Woodrille, Kirkstall.

Garden Flora.

PLATE 561.

VALLOTA PURPUREA AND VARIETIES.

(WITH A PLATE OF THE VARIETY MAGNIFICA.*)

There is but one species of Vallota, and this is a native of South Africa, whence it was introduced by Philip Masson in 1774, and afterwards figured in the *Botanical Magazine*, t. 1430, under the name of Amaryllis purpurea, this figure representing what is now known as the variety major. Linnæus called it Crinum speciosum, and Dean Herbert renamed it Cyrtanthus, altering it afterwards to Vallota, in compliment to the French botanist Vallot. The close relationship between it and Cyrtanthus was noticed by the Dean, who wrote concerning it: "This beautiful plant is so closely allied to Cyrtanthus, that I have even entertained doubts of its being distinct, and should wish to see it ascertained by further experiments whether it is capable of mingling with that genus." Recently we have had proof of this affinity in the hybrid raised in the garden of Sir Trevor Lawrence, of which Mr. N. E. Brown, who named it Cyrtanthus hybridus, says: "I think this plant can scarcely be claimed as an example of a hybrid between two distinct genera, but rather as proving that Cyrtanthus and Vallota are not really distinct genera, but merely different types of form belonging to the same genus." This view is supported by the close resemblance of the two parents to each other and the small difference between the Vallota and the hybrid named as above. All this is interesting as showing that probably others of the beautiful and varied genus Cyrtanthus might be crossed with the Vallota, and if some of the vigorous constitution of the latter could be infused into the hitherto delicate species of Cyrtanthus, a valuable race of distinct greenhouse bulbs might be thus obtained. Bearing in mind what has been done in this direction with the Hippeastrum (Amaryllis), this surmise does not seem unreasonable. Leaving, however, what might be and turning to what is, we have in V. purpurea one of the most beautiful and useful of the vast number of bulbous plants introduced from South Africa, and one which will thrive satisfactorily in a cold greenhouse or frame under the simplest treatment. It is hardly necessary to go into the details of cultivation for a plant which has been a popular favourite in gardens over a hundred years; still, a few particulars relating to treatment may be given for those readers who are not successful with Scarborough Lilies, as these plants are called, a name which, by the way, we have been unable to trace to its origin, the only reason for it that we can find recorded being suspiciously like what is told of the Guernsey Lily (Nerine), namely, that a Dutch barque was wrecked off Scarborough, from which bulbs of

* Drawn in the New Plant and Bulb Company's nurseries at Colchester, Sept. 21, 1886.

VALLOTA PURPUREA MAGNIFICA.

the Vallota were washed ashore, and became established there as garden plants. Perhaps some of our readers can give us an authentic account of the origin of this name.

The cultivation of Vallotas is practised on a large scale by market growers, and it is stated that some of these succeed in blooming their plants twice in the same year, namely, in midsummer and again in winter. With us flowers do not appear more than once annually, although our plants are treated well and flower freely. By resting some of the plants longer than others the blooming season for Vallotas may be made to extend over about three months, from July onwards. The bulbs should be planted thickly in the pots they are intended to occupy for two or three years, using a rich loamy soil without any sand, notwithstanding the fact that in their native habitats Vallotas are found only in boggy peat. Whilst growing, abundance of water should be given, as they delight in wet, thriving even when placed in water. About May frequent waterings with weak liquid manure will help the flowers. From November till March

Vallota purpurea; showing habit of growth.

the soil should be kept just moist, but total drought is often harmful to these plants. A cool greenhouse or frame is suitable for them. Instances of their thriving out of doors in sheltered places have been recorded, but such are exceptional, and not to be taken as proving the hardiness of Vallotas in England. Some of the finest Vallotas we have seen have been grown by cottagers in their windows.

V. PURPUREA typical has a flower-scape about 1½ feet long, bearing an umbel of about six flowers, each 2½ inches across and coloured blood-red. A figure of it is given in the *Revue Horticole* for 1870, where it is named V. grandiflora, no mention being made of the older name. The variety major has a scape 3 feet high, and flowers over 3 inches long and wide; minor is smaller in all its parts, a figure of it being given in the *Botanical Register*, t. 552, under the name of Amaryllis purpurea var. minor. A very fine variety was distributed from Mr. Bull's nursery about ten years ago as var. eximia, and obtained a first-class certificate from the Royal Horticultural Society; it has flowers 4 inches across, the segments broad and of good substance, and at the base of the divisions whitish feather-like blotches; this is hardly distinct from the variety represented in the accompanying plate, though its raisers, the New Plant and Bulb Company, Colchester, consider it larger, brighter in colour, and a much more robust grower than any other kind. It was exhibited by them this year with tall scapes bearing magnificent flowers 5 inches across, whilst the leaves were large and as stout as those of Hippeastrums. W.

SOUTH AFRICAN PLANTS.

An official handbook of the Cape of Good Hope, its history, productions, and resources, has just been issued. It contains an exhaustive account of all that concerns the colony, including the subjects of agriculture, Vine culture, woods and forests, and, lastly, a lengthy sketch of the flora of South Africa, by Mr. H. Bolus, F.L.S., and as extracts from this sketch may be interesting to our readers, we append a few. In speaking of the richness of the South African flora, Mr. Bolus says:—

"Ever since the time of its first settlement the Cape has been a constant source of pleasure and delight to the botanist and the gardener. Though Cape plants have somewhat gone out of fashion of late years, it is still probably true that no single country in the world has contributed so largely to European conservatories and gardens as the Cape of Good Hope. The despatch of plants, indeed, began before the settlement by Van Riebeek, for we find that one Heurnius, a missionary *en route* to the East, had sent to his brother at Leyden several curious plants which were figured by Staple in his edition of 'Theophrastus' History of Plants,' published at Amsterdam in 1644. These are the earliest known figures of Cape plants, and amongst them was the well known Orbea variegata of the Lion's Rump, which was called a Fritillary, and an Oxalis which, with equal reason, was styled a Trifolium! But those were the days before Linnæus had arisen with master mind to reduce to order the rapidly increasing stores of vegetable forms. In 1772 came Thunberg, the father of Cape botany; in 1810, Burchell; in 1825—1834, Ecklon, Zeyher, and Drège. All these made journeys of thousands of miles, and of several years in duration, exploring the vegetation of the country. Besides them were others of less note, and a host of gardeners and collectors of seeds and living plants. From 1775 to 1835, Cape plants may be said to have been quite the rage. The conservatories, temperate houses, and gardens of England and the Continent teemed with the Pelargoniums, Heaths, Proteas and other handsome flowering shrubs, and the lovely bulbous plants of Iridaceæ, Amaryllidaceæ and Liliaceæ; and the pages of the *Botanical Magazine* and other similar periodicals were filled with figures and descriptions of them.

"The public taste of that day was amply justified. Perhaps the recently increasing exportation of flowering bulbs may be taken as an indication that the fashion will be revived. But though fashion in flowers may be variable, the interest of science is more permanent; and, notwithstanding the diligent exploration of the country for the last hundred years, the constant discovery of new forms, even up to the present day, has largely occupied the attention of systematic botanists.

"I propose, therefore, to regard South Africa as including five natural regions, two of which extend beyond its limits, while the others are included within them. These are:—

(1) The South-Western Region		
(2) The Tropical African	„	(Grisebach's 'Soudan.')
(3) The Karoo	„	
(4) The Composite	„	
(5) The Kalahari	„	(Grisebach)

"The South-Western Region has for the most part furnished the largest number of garden plants, as it is the home of what has been for the last hundred years popularly known as the Cape flora. It is an angular littoral strip, bounded on the west coast by the Oliphant's River and the mountains near it, but including properly the mountain range from Cedarbergen up to the Khamiesbergen; on the east by the Van Staden's Mountains; and inland by considerable mountain chains under various names. Its greatest width does not exceed eighty miles, and probably averages not more than fifty miles. The inland mountain chains referred to may average 4000 feet in height, attaining sometimes (Great Winterhoek) 6800 feet. The surface of the region is extremely diversified, sandy and bushy tracts alternating on the coast with grassy downs, and vast mountain slopes of the most barren appearance when lying a short distance inland, but clothed with an immense variety of small plants.

"The prevailing aspect of the vegetation of this and the whole Cape colony, except the eastern coast region, is that of a number of low-growing scattered shrubs of a dark or bluish green hue. With considerable exceptions this is, nevertheless, the appearance which most commonly meets the eye. Almost everywhere the 'bush' is present. Interspersed among a host of other genera are numerous plants of the Orders Orchidaceæ, Iridaceæ, Amaryllidaceæ, Liliaceæ, with scattered tufts of Restiaceæ, Sedges, and Grasses.

"In the deep ravines of the mountain sides are dwarf trees, growing closely, with dark foliage. Few indigenous trees attain a greater height than 25 feet to 30 feet; and amongst these is the Silver Tree (Leucadendron argenteum), peculiar to the Cape Peninsula.

"There is little change in the aspect of the vegetation even at greatly varying heights on the mountains; and near the coast especially it is much less affected by altitude than is the case in Europe. On Table Mountain some species are found from the bottom to the top, having thus a vertical range of 3500 feet; and there are many with a range of from 1000 feet to 2500 feet.

"The flowering season begins about the end of May, immediately after the first winter rains. The numerous species of Oxalis first make their appearance, and these are soon followed by great numbers of Iridaceæ, Amaryllidaceæ, Liliaceæ, and other bulbous plants, besides Mesembryanthemums and various Compositæ. On the mountains the flowering begins later and continues longer; but though few plants may be found in flower in March and April, yet they are never wholly absent. The imported Oak has shed its leaves for a period of six or eight weeks only (during May and June) before the new growth begins. Everything points to the fact that the true winter, the period of rest, is here the dry season, viz., March—May; as soon as rain falls even the winter temperature is sufficient, and vegetable life is at once aroused to activity.

"A few of the most beautiful, striking, or curious vegetable forms of the region may here be mentioned, the majority of the examples being taken from the highly representative and rich flora of the Cape Peninsula lying on its western extremity. The palm of beauty must be awarded to the Disa grandiflora, the grandest of southern terrestrial Orchids, as Cypripedium spectabile is of the northern hemisphere. This is abundant on the streams of Table Mountain, and is found also on the Hottentot's Holland Mountains, thirty to forty miles inland. Other fine Orchids are Satyrium cordifolium, a brilliant orange; S. carneum and S. erectum, Disa longicornis, a lovely blue; D. secunda, the delicate white D. fasciata, and others; Pterygodium acutifolium, a fine deep golden yellow; Ceratandra chloroleuca and C. Harveyana, the brilliant blue Disa (Herschelia) graminifolia (long known as H. cælestis) and the allied D. venusta and D. purpurascens; and, finally, the small beautifully fringed, spider-like Bartholina pectinata and B. Ethelæ. Close upon these presses the so-called Arum, the Richardia africana, with its pure white spathe, almost as common an ornament of all moist, low-lying ground as the common Dock is an accompaniment of English ditches.

"The Proteas are universal objects of admiration, and few plants can surpass P. cynaroides, with its

flesh-coloured involucres, P. speciosa, P. coccinea, and a few others. The singular Leucadendron argenteum, or Silver Tree, is a striking ornament of the mountains about Cape Town. Next come the Heaths, whose names would be legion. The most beautiful, and those with the largest flowers, are denizens of the mountains lying between the Hottentot's Holland range and the town of Swellendam, being especially abundant about Caledon and Genadendal. On Table Mountain, Erica cerinthoides, E. mammosa, E. coccinea, E. spumosa, and E. hirta are amongst the finest, the latter sometimes making a whole mountain-side glow with its warm pink tints. There are probably 350 species of true Heaths found in this region alone. Amongst Compositæ, Gazania has some fine species, while Helichrysum vestitum and Phœnocoma prolifera are amongst the showiest of the Everlasting flowers, the heads of the first named being gathered, dried, and exported in large quantities to Europe as immortelles.

"Iridaceous plants are abundantly represented in handsome species of Romulea, Geissorhiza, Ixia, Gladiolus, Watsonia, Babiana, &c.; Amaryllidaceæ in Amaryllis Belladonna, Nerine, Brunsvigia, Vallota, &c.; Scitamineæ in the peculiar and noble Strelitzia. Liliaceæ are very varied and numerous. The most conspicuous are the Aloes—A. plicatilis with an arborescent trunk, attaining a height on the western mountains of 12 feet to 15 feet; the beautiful blue Agapanthus, the star-like Ornithogalums, Kniphofia alooides, and many others. Prionium Palmita is a remarkable plant with the flower of a Juncus and the habit of a Pine-apple, which in some parts fills the beds of certain western rivers, and reaches a height of 8 feet or 10 feet. Some Restiaceæ and Cyperaceæ attain to 6 feet or 7 feet, and often form a striking feature in the landscape. Ferns are not very abundant, chiefly occurring in the deep ravines, where the arborescent Hemitelia capensis is found several feet in height; and Todea africana forms a handsome plant. Osmunda regalis is sparingly met with, while Pteris aquilina is more commonly scattered on the open hillsides." T.

WORK DONE IN WEEK ENDING SEPT. 7.

September 1 to 7.

Through pressure of other duties, daily notes of our work have again been neglected, and only a very cursory account of the same can, therefore, be given. The long-wished-for rain descended on the 2nd and 3rd inst., and, if possible, made us more busy than the previous drought, owing to the labour of watering, for Lettuces, Cabbage, and late Broccoli were all waiting to be planted, and which have now been accomplished, as have also thinning out and earthing up of the last lot of French Beans. Planted out Strawberries and pricked out into nursery beds numbers of runners, some of which will probably be required to fill up gaps in the plots next spring, and others to give to friends that may not have been so fortunate as ourselves in the procuration of runners. Other kitchen garden work has been earthing up earliest Broccoli and Celery, staking latest Peas, picking the old Beans off runners to keep the plants in bearing, and digging up Potatoes at every opportunity, for since the rain the disease is spreading very rapidly; it has even attacked Tomatoes, a circumstance that has not occurred for three or four years. Two new kinds that we have just lifted are worthy of special note: they are Abundance and a seedling; the crop of each is simply wonderful, and the appearance and quality are of the first order, and both are nearly free from disease. They have much of the robustness of Magnum Bonum in their constitution, and this no doubt accounts for their comparative freedom from the affection. Flower garden work has been purely of a cleaning-up description, which, as a matter of course, includes keeping off bad and seeding flowers, and the groundwork and outlines in formal bedding arrangements true to design by clipping or pinching as may be required. Propagation of the various kinds of plants for next year's use is done as opportunity presents to take off a few cuttings without their ever being missed, our rule being that no gaps shall be made in the arrangements by propagation—a rule that with due care we are generally able to adhere to. Of kinds that will propagate quickly in spring we only take a sufficiency now to afford stock in spring. Lack of space in houses and pits to winter the same makes this a necessity, and perhaps a desirable one, for spring propagated plants are, as a whole, better than autumn-struck, which are apt to get stunted. Herbaceous and mixed flower borders have renewed their growth; they have not been more gay this year than they now are, and we have had a considerable amount of labour in tying up Gladioli, Liliums, Pentstemons, Sunflowers, Michaelmas Daisies, Dahlias, and many other tall-flowering plants. Stocks, Asters, Zinnias, Salpiglossis, and Scabious are all exceptionally good, and that for a very good reason, namely, because we have taken greater pains than usual with them, for, like every other branch of gardening, their better doing is due solely to increased attention. Successful gardening and hard work are synonymous terms, for without the one the other is impossible. The gathering of Apples and a few of the earliest kinds of Pears has occupied a few hours of our time. Of the former, Devonshire Quarrenden, Peach, and Red Astrachan have been harvested; the crop is a short one, as it is also of Pears. Beurré de l'Assomption, Williams' Bon Chrétien, and Beurré d'Amanlis we have not yet gathered. Peaches and Nectarines are ripening on the open walls very rapidly, and these we gather before they are quite fit for table; they keep longer than if left till dead ripe, and the flesh is less mealy and of a higher flavour. Plums of the dessert section we treat in like manner, but preserving varieties we allow to ripen on the trees, that is, when the wasps will allow this, and, for a wonder, this is the case this season, there being as yet but few about. Indoor work has been potting Hyacinths and Tulips, also potting on Cinerarias, Primulas, Poinsettias, Bouvardias, and also a few more Pine suckers. Trimming up and thinning out the growth of ridge Cucumbers and Vegetable Marrows; an overcrowded state of the wood, now that the nights are getting cold, and damp soon settles the fruit-producing powers of the plants by causing them to damp off before they are well formed. No further artificial watering will now be necessary; rain and the strong dews that occur nightly will be ample. Partially pruned earliest vineries by cutting back all secondary growths into the hard wood, and should new growths again start pinching will again be had recourse to. To fully ripen up late Grapes—Gros Colmar and Lady Downes in particular—we have since the rain raised the night temperature by fire-heat to 75°, and this will be continued till quite the end of the month, when the Grapes may be expected to be fully ripe. A little top air is kept on night and day.

Hants.

FRUITS UNDER GLASS.

Peaches.

In cold, unfavourable districts, where outdoor Peaches cannot be depended upon, the latest house is not unfrequently a host in itself, as a good selection of sorts will keep up the supply until wall fruit in warmer localities is over. The weather just now is forcing late varieties on rather too fast, but no one will complain, as it is doing so much good in every way, not the smallest benefit being the perfect maturation of the wood for another year. Where midseason varieties are coming in faster than they are wanted, the roof may be lightly shaded for a few hours through the hottest part of the day. Every door and ventilator may be set and kept open, and the floors well damped with cold water until we have a change to cooler weather. Shading at the end of the season is not, however, commendable, neither is it necessary, as we have such an endless variety to choose from, and those who know anything about Peaches will have no difficulty in selecting choice melting sorts, which will succeed each other in their order of ripening. There is a race of late Peaches, including Princess of Wales, Lord and Lady Palmerston, and Salwey, very handsome and large, but decidedly inferior. These, for two reasons, I would not give a place under glass, as quality should be the true test of merit; and fine melting kinds, like Barrington, Walburton Late Admirable, Sea Eagle, and the Nectarine Peach, will keep up the supply until chilly autumn carries away the feeling that Peaches are a necessary adjunct to the dessert. Lord Palmerston, it is generally admitted, is the handsomest Peach grown, and if some catalogues are truthful, Princess of Wales is good, but one of the best growers assures me he piles them up for the guests to admire and hands better varieties round for eating. Where suitable sorts have not been planted, now is the time to visit the nurseries for the twofold advantage of having the pick of the full stock, and seeing them in full leaf, as good foliage is one of the best tests of a sound and healthy constitution. Removal, it is hardly necessary to say, must be deferred until the buds are well filled and the foliage shows signs of changing, when well managed trees will lift and travel with perfect safety. The nursery is not, however, the best place to go to for trees for direct planting under glass, as much valuable time is lost in training them up to a fruiting state. Every fruit garden should have its reserve wall well stocked with trees, from two to four or five years old, from which suitable varieties can be selected for filling up vacancies as they occur, the great advantage gained being the ability to root-prune annually, and so fit them for removal before the leaves fall. By adopting this plan and keeping the reserve wall replenished with maidens the outlay is trifling; the trellises in the forcing houses can always be kept uniformly covered, and the grower can train from the bud, or cut back to four or five eyes if he thinks well to do so. Midseason and early houses must still have plenty of water and full air by night and day until the wood is ripe and the foliage begins to fall. If the trees are weak, an occasional watering with diluted liquid will be of great service, otherwise pure water through the hose will suffice, but they must have copious supplies, as the roots of Peach trees are never at rest, and they rarely cast their buds in the spring where this important matter is properly attended to. All root-pruning and top-dressing must now be pushed on with vigour and new stations prepared for the introduction of fresh trees, when, according to the way in which they have been prepared, they can be lifted with safety. Our first and second houses were root-pruned about the middle of August, and, notwithstanding the fact that the weather has been intensely hot and dry, the trees have never flagged, but are making fresh laterals, and the foliage, which we never brush or switch, will hang until the end of the present month. Many remove the roof-lights as soon as the fruit is gathered, and I used to adopt this plan, but I now allow them to remain until the leaves fall, and, the weather being fine sometimes, strip for painting and repairs in October.

Melons.

The weather during the past month has been all that could be desired both for setting and swelling late Melons, and we may now congratulate ourselves upon having had one of the best seasons we have experienced for some years. This tropical heat cannot, however, be expected to last much longer, neither must it be allowed to interfere with the regular attention to bottom heat, as this both early and late is the mainspring of good flavour. If in pots, as all late Melons should be, let the fermenting material be regularly turned and replenished to keep the heat up to 80°. Top-dress with fresh loam and bone dust in preference to manure; keep the house scrupulously clean and sweet; thin out all superfluous spray and laterals to let in sun and light, and while giving plenty of warm diluted liquid to the roots avoid a sloppy condition after nightfall.

Pits and frames.—As days decrease in length and nights become cold, the plants will require extra care and attention. If bottom-heat is en-

tirely dependent upon fermenting material, the linings must be regularly renovated with good stable manure and an extra mat at night, or, better still, a piece of oil canvas while throwing off cold rain will prevent the escape of heat and moisture. Assuming that the fruit is well advanced and the foliage is clean and good, let each Melon be raised on an inverted pot well above the level of the bed, where it will be partially, but not entirely, exposed to the sun and safe from insects and ground moisture. The great drawback to late frame Melons being a superabundance of confined or condensed moisture, all watering or flooding, without wetting the vines, should be performed early on fine mornings, and overhead syringing must be entirely suspended. Treated in this way, fruit of good quality can generally be obtained as late as the middle of October, but much depends upon the season, as a long continuance of cold, dull weather not unfrequently checks the plants and results in sudden collapse from chills or canker.

Cucumbers.

The last sowing of seeds for the season having been made, the young plants must be kept in or over a good bottom-heat, where they will have full exposure to light until the pots or beds are ready for their reception. Having so recently given directions for the management of plants intended for coming into bearing about Christmas, it is only necessary to repeat that their every want in the way of heat, air, and water must be anticipated. For supplying the first, if not already prepared, the fermenting material, be it Oak leaves or tan, must be well worked and frequently turned to free it from rank steam and injurious gases before it is taken into the pit. Of the two, the majority of growers now give preference to leaves with a small quantity of stable litter placed over the bottom of the plunging pit, as the two combined give off ammonia and moisture so congenial to all stove plants when making their growth. Moreover, the decaying leaves form an invigorating medium for the roots of fruit-bearing plants when they find their way through the apertures and over the sides of the pots. If the pits are shallow and hot-water pipes lie near the surface of the rubble, good sods of turf should be placed over the manure to prevent the roots from striking into it, but where they are deep and the fermenting material is always settling, inverted pots or dry brick pedestals should be introduced for the fruiting pots to stand upon. The danger of strangling will then be avoided, and the leaves can be turned and renovated at pleasure without disturbing them. For my own use I give preference to the brick pedestals, as the open joints through which the warm liquid passes form a genial home for the roots on their way downwards, while the freedom of escape renders over-watering an impossibility.

Fruiting plants must be encouraged to make steady short-jointed growths by feeding with tepid liquid, soot, and guano water alternately, by light cropping, and cutting the fruit in a young state. Keep the Vines thinly trained, and stop every lateral at the first leaf beyond the fruit; also remove all male blossoms as they appear, as a profusion of these and allowing the swelling fruits to attain their full size tell prejudicially on the plants when daylight is counterbalanced by darkness. Cleanliness being a very important point, remove every particle of decaying stem and leaf, top-dress frequently with pure maiden loam and bone-dust or old lime rubble, and limewash the walls at short intervals. The glass, it is hardly necessary to say, will be washed to free it from conferva and other light-obstructing matter, and direct syringing will be regulated by the state of the weather. The temperature for the present may range from 66° to 70° by night, and as high as it will go after closing with sun-heat and atmospheric moisture. If ground-line ventilators are at command, they should be kept more or less open, as a current of fresh air from the south side, between or beneath the hot-water pipes, combined with cleanliness, is the best safeguard against canker and mildew.

Figs.

If any of the early forced Figs still remain in the houses or pits and potting has been neglected, no time should be lost in getting this work finished, as the ripening foliage will favour the formation of new roots before they go finally to rest. The Fig is a most accommodating tree, and submits to severe root-pruning apparently without undergoing the slightest injury; indeed, I have always found sharp disrooting and repotting in fresh compost as soon as the fruit is formed and the foliage is ripe a sure mode of preventing dropping in the spring. Young trees, which it will take a year or two to work up into full-sized fruiting pots, can be shifted on at any time during the season of active growth, but others which it may not be desirable to repot into larger sizes will now be in a fit state for turning out and paring down with a sharp knife, when they may be returned to the original pots with 1 inch or so of fresh compost. The pots, it must be understood, should be washed and dried, and re-crocked with clean, dry drainage during the time the balls are under manipulation, and the latter, if sour and inert, may be picked out and douched if necessary after they have been reduced with the paring knife. The best compost is light, rich, turfy loam, corrected and enriched with bone dust or lime rubble; this must be firmly rammed with the potting stick, and the pots should not be made too full, as room will be required in the spring for top-dressing. When all is finished, the trees will require a good watering to settle the soil about the roots, and root action will be quickened by returning them to the shelter of the glass, where they can be shut up with sun-heat and occasionally syringed. This treatment must not, however, be continued too long, otherwise the embryo fruits will get too forward; therefore, as soon as the roots have made a new start, give full air or remove them to a sheltered spot out of doors where, with the exception of morning frosts, they can have a month's exposure to the elements. If any of the trees do not require potting, they may go out at once, or the roof lights may be taken off to insure complete rest during the remainder of the autumn.

Permanently planted trees in the early and succession houses may also be taken in hand as soon as the second crops are gathered. The compost recommended for the pot trees well mixed some time in advance and kept dry will suit them admirably. If annual root-pruning is practised and a good ball exists, remove the old compost, correct the drainage, and having shortened all the roots to within a few inches of the past year's pruning, relay the points in a horizontal position. Make the compost very firm as the work is carried on, but guard against making the addition too wide, as a foot of new soil encircling the old ball is quite sufficient for one season. Many Fig growers divide their planting pits into sections by running 4-inch brick walls across them, but I prefer building walls of turf round each ball and filling the intervening spaces with fermenting leaves when I commence forcing. Treated in this way, each tree gets new compost in proportion to its requirements, and the roots revel in the warm elastic turf which it is difficult to overwater, and gradually find their way into the decaying leaves before the second crop commences swelling. Late houses in which the fruit is now ripe will require liberal ventilation, and perhaps a little gentle fire-heat to maintain a constant circulation of warm air. When late Figs commence splitting or spotting, fire-heat with plenty of air is the remedy, as either of these defects conveys unmistakable evidence that too much stagnant vapour is present in the atmosphere. Reduce this, and not only will spotting cease, but the fruit will hang until it shrivels, colour will be perfect, and the flavour exquisite. Warm diluted liquid, it is hardly necessary to say, must be regularly supplied to the roots on bright mornings after the fruit has been closely picked especially, and the syringe must be laid aside until the best of the crop is gathered. Wasps have a great liking for good Figs, and persistently force their way through the smallest crevices to get to them. Haythorn's hexagon netting is the most suitable material for keeping them out, as it is light, strong, and open, and does not impede the free circulation of air when strained over the ventilators.

W. Coleman.

Rose Garden.

NEW ROSES AT WALTHAM CROSS.

Roses this season are freer from the ills that usually assail them than they have been for many years. All of us now-a-days have ample opportunity to inspect Roses at exhibitions, and boxes filled with freshly cut blooms in their setting of bright green Moss have a fine appearance; but, after all, one must see Roses growing to form a correct estimate as to their value for the garden. The varieties mentioned (p. 66) I was able to inspect in the Waltham Cross Nursery in the shape of standards and dwarf bushes. Grand Mogul is a very fine dark Rose. It is quite of the A. K. Williams type and a more vigorous grower. The fault of A. K. Williams is its want of constitution. It refuses to grow after several years' culture, requiring yearly renewing by budding on vigorous stocks. The flowers of Grand Mogul when half opened are maroon-crimson and superb in form. Mr. William Paul has many of these rich crimson-scarlets and crimson seedlings. I noticed and drew attention to one particularly bright and of good form, but it had been condemned as too thin, and this after many plants had been propagated. Others are discarded after trial if the colours do not stand well. A good standing colour is a valuable characteristic in a new Rose. Florence Paul is dark crimson and a full globular Rose; the plant is vigorous and of good habit, producing flowers at the end of every growth. Silver Queen is vigorous in habit and very floriferous; the flowers are pale rose-pink in colour and quite distinct. Lady of the Lake has light clear rose flowers, full and globular, and forms a handsome plant.

After a close inspection of the various quarters comprising standards and half standards, Roses on the seedling Brier, on the De la Grifferaie and Manetti, as well as a large collection on their own roots, the following were noted as the very best in the various sections. Amongst pink and rose-coloured Hybrid Perpetuals, Lady Mary Fitzwilliam holds high rank; it is supposed to partake of the Tea section, but is certainly nearer the Hybrid Perpetuals. It is rosy pink with darker centre. Heinrich Schultheis is a large and handsome variety. Queen of Queens is rosy pink, paler at the edge than in the centre of the petals, and very free flowering. Pride of Waltham is deep salmon-rose, fine in form, and vigorous in growth. Of some varieties, such as Baroness Rothschild, Captain Christy, and La France, whole beds and long rows in the quarters are grown. To the above ought to be added Comtesse de Serenye, Comtesse de Mortemart, Duchesse de Vallombrosa, Emilie de Hausburg, Jules Finger, Nardy Frères, and Victor Verdier.

Amongst white Roses belonging to this section are Boule de Neige, very vigorous and free flowering; Helen Paul, flesh coloured; Madame Lacharme, Merveille de Lyon, and White Baroness. Pride of Reigate is unique as a striped Rose, but it has a tendency to revert to the variety Comtesse d'Oxford, whence it sprung. Emperor, a very dark blackish crimson variety, is quite the best of this colour to cut for button-holes. Prosper Laugier, crimson-red, is a full, well formed variety. Lord Frederick Cavendish, bright red, is also full and well formed, and of a colour that stands well. Benoit Comte, crimson-red, is a really good garden Rose. Ella Gordon, bright cherry-red, is free and good in form. Others are Comtesse de Casteji, crimson-scarlet; Ulrich Brunner, deep rosy crimson, a fine, free, garden variety; and Star of Waltham, very fine this year. This variety lasts long in good condition. To these must be added Charles Darwin, a very distinct and good dark

variety; Duchess of Bedford, a charming crimson, vigorous in habit, and excellent in a half-opened state.

Tea Roses are now very numerous, and during recent years many valuable varieties have been introduced. There are large collections of them at Waltham Cross. Amongst the most desirable may be named Jean Ducher, a vigorous grower with large yellow and salmon-shaded flowers; Madame Chedane Guinoisseau, deep yellow, beautiful both in bud and flower; Madame Charles, buff, and not so well known as it ought to be; Madame Joseph Schwartz, whitish, free; Camoens, rose colour; Edouard Gautier, light buff, with creamy edge; Souvenir de Thérèse Levet, crimson, with a rosy flush in the centre, beautiful in the bud state, and one of the most distinct of Tea Roses; Anna Ollivier, creamy white, with a buff centre; Hon. Edith Giffard, centre whitish, rosy buff, a grand variety; Comtesse de Nadaillac, flesh coloured, with soft apricot suffusion; Souvenir d'Elise Vardon, well known as one of the best; Madame de Watteville, very distinct and handsome, being of a peculiar rosy tint, and yellowish at the base of the petals; and Grace Darling, rose, with a yellowish centre, very distinct.

Perle d'Or, of the Rosa polyantha type, is a charming little Rose. There are many more beautiful Roses which might be added, but I write of what I saw and can recommend. I say nothing of pot Roses, but large quantities are in preparation to flower in 8 inch pots. These sizes are adapted for small as well as large gardens. It is astonishing what a large number of flowers are produced from a plant in an 8-inch pot, whether it be a Tea or a Hybrid Perpetual. Liberal treatment is of course required and careful culture. Our own plants, which have been carefully potted, are in a good position out of doors. They must be kept quite free from mildew and green fly. For pot culture Roses should either be on their own roots or budded on the seedling Brier. Plants worked on the Manetti seem to have a tendency to be afflicted by mildew. Mr. Paul informed me that this pest usually attacks Manetti-stock Roses first. It ought also to be more generally known that most of the best Roses succeed well on their own roots, and when cultivated in that way the more suckers the better. Tea Roses should either be on their own roots or on those of the seedling Brier. J. D. E.

Marechal Niel Rose.—I have often heard it remarked that this Rose only lasts for a short time early in the season, and that if it should show for a prolonged season of bloom, it is a bad sign as to the well-being of the plant. Our outdoor Maréchals on the wall are now, however, giving us handfuls of very fine blooms, quite equal to any cut in early summer. I did not cut away any of the wood after the first season of bloom, as is often done, but I gave a good watering with house sewage twice a week all through the summer.—J. R. Hall, *Fox Warren, Cobham.*

SHORT NOTES.—VARIOUS.

Rose cuttings (*G. W.*).—Now is as good a time as any to put Rose cuttings in in the open ground. Those with a heel attached to them succeed best.

Monthly Roses.—Can any of your readers say if the monthly Rose Chameleon may still be obtained in nurseries? I have been struck by the truth and force of the remarks of "D. T. F." (p. 185) on the fraudulent value of the term Hybrid Perpetual.—Rosa.

Rose William Francis Bennett.—This Rose, says a writer in an American paper, can never take the place of the General Jacqueminot, as has been claimed it would do. It is almost as single as Safrano, and though handsome and well coloured in the bud state, soon opens and has a tendency to fade. As a Rose to be used only while unopened, it will no doubt prove valuable.

Variegated Jacob's Ladder (Polemonium).—This has been one of our best plants for edgings to borders and beds this season. It is perfectly hardy, and may be propagated without trouble, though it strikes root but slowly.—B.

Parochætus communis.—Mr. Bartholomew, Park House, Reading, desires us to state that he will be happy to send plants of Parochætus communis to anyone (as long as the supply lasts) who will forward to J. Healey, Park House, Reading, a suitable box (wood or tin) and stamps to cover postage.

Indoor Garden.

HOW TO GROW CYCLAMENS.

It is the general impression that Cyclamens can only be grown in a specially located structure, such as a house with a north aspect, or so situated that they get little or no sun. Houses so situated are, no doubt, the best for these plants, and many unsuccessful cultivators give up growing them because they do not possess a convenient north house. I have been a successful cultivator of Cyclamens for some years, and have grown them in all aspects. I have managed to get from 200 to 300 flowers on plants two years old, and from 50 to 100 flowers on what are termed the annual or seedling plants, and from plants grown in the ordinary pots, 6 inches wide, facing full south. The following is my mode of proceeding: In the early part of September I half-fill with crocks some 4½-inch pots, and cover these with a little Moss. I then rub some half-rotted leaf-soil through a fine sieve, add to it one-fourth of sharp silver sand and a dash of charcoal dust. This is well mixed, and then the pots are filled, making the soil moderately firm; afterwards it is gently watered. In each pot I sow about two dozen seeds evenly, and cover with about an eighth of an inch of the same soil. I lightly press the surface with another pot, then cover the surface with Moss. The pots are placed in a warm shady end of a greenhouse, away from draughts, and the Moss is kept moist until the seed germinates. The Moss is then gradually removed, but the seedlings are shaded from the sun. From this stage they are kept near the glass, in a temperature through the winter from 55° to 60°. When they have made three or four leaves, they are pricked off into pans, adding one-third of turfy loam to the seeding soil. In removing them from the seed-pots we handle them very carefully, and the soil is not pressed too firmly round the young roots. This, I find, is a great point in their culture; and another point is to particularly avoid cold draughts and strong sun in all stages of growth. About the first week in March the seedlings are placed in 2½-inch pots and carefully shaded from the sun, the leaves being occasionally dewed over with a fine-rosed pot. Through the future stages of growth the shading is carefully attended to, but as soon as the sun is off the plants the shading is removed, so as to prevent their becoming drawn. About the end of April I put them into 3-inch pots. In the third week of May this season I had a space in a brick pit facing the south and heated, and in which had been growing Beans on a bed of Oak leaves. The soil was removed, and the bed of leaves covered with about 6 inches of ashes; the leaves were slightly warm, but it was hardly perceptible. The plants were plunged in the ashes, and kept from 55° to 60° night temperature, with a chink of air on all night, covering the glass with mats. About the end of June they were again shifted into small 4½-inch pots (a size suitable in our case), and in this sized pots they were flowered. The soil I use at the final potting consists of one part half-decayed leaf-soil, one part of very turfy loam, with enough sharp sand and charcoal dust to make the whole feel gritty. In this soil the plants are potted rather lightly. I have tried various composts, but find that the plants make more roots in the soil here recommended than in any other that I have tried. My plants are growing in an ordinary 6-foot pit facing full south. The plants are plunged in the ashes, from 1 foot to 18 inches from the glass. They are shaded as soon as the sun is observed to fall on the foliage. For the shading I use two pieces of scrim canvas, commencing to shade with the scrim single thickness, and as the sun gets higher I put on a double thickness. The pits keep cooler this way than by single thicker shading; and, again, I can regulate the light better until it is entirely removed in the afternoon when the sun is off. During the early part of summer I am very careful with ventilation, and throughout the summer I dew the plants over with rain-water on bright sunny days whenever they appear dry. I always water the plant with rain-water when it can be obtained, and about once a month give them a small pinch of Clay's Fertiliser or fish manure, and water it in at once. I am very careful not to let any of these concentrated manures fall upon the foliage or into the hearts of the plants. As soon as the summer evenings get warm, the lights are pulled off for the night to allow the plants to catch all the dews, and I always let my plants have the steady rains. These Cyclamens grown in full south pits are now nearly a foot in diameter, well set for bloom, and look quite as robust as any I have grown in houses or north-facing frames. J. R. Hall.

Fox Warren Gardens, Cobham.

CALADIUMS AND THEIR CULTURE.

In the genus Caladium we have a vast number of beautiful plants, both in the case of those introduced from their native countries and in that of those obtained by cross-breeding in English and Continental gardens, the latter being by far the most numerous. In our earlier days, the varieties from which we had to select were few and (judging from our present standpoint) poor in colour. The principal of these were hastatum, bicolor, argyrospilum, pictum, picturatum, præcile, and bicolor splendens (the latter form, by the way, is well to the front even now). After these came Belleymei, Brongniarti, Houlleti, Baraquiniana, Newmani, argyrites, and various others, all plants with beautiful leaves. Caladiums, being easily raised from seeds and easily fertilised, have been persistently worked upon by the cross-breeder; every year, therefore, brings us, if not exactly new forms, at least new shades and combinations of colours almost endless. Great, however, as have been the improvements effected by means of cross-breeding, there is yet room enough for work in the same field. Hybridisation with the Alocasias, for instance, in all probability would give us not only greater diversity of colours, but also a change of form. Alocasia zebrina, Jenningsi, Thibautiana, and Sanderiana appear to us to be both good forms and good colours with which to invest our Caladiums. A Caladium with leaves like those of Alocasia Sanderiana and the markings of Caladium Belleymei would, we think, be desirable. Again, colour like that of Alocasia Jenningsi worked into Caladium Belleymei would be an important change. But Caladiums, independently of their gay colours, have a special claim upon the attention of those who have but a limited extent of glass, inasmuch as they are deciduous, and do not occupy space during the winter months, to the exclusion of other plants. The months of March or April, as convenience may dictate, will be time enough to start them into growth. By that time the stove or propagating pit will be relieved of a portion of its winter occupants; therefore the Caladiums may be introduced into either of these structures, and by the time they have grown sufficiently to require more space, the remainder of the hardier indoor plants will have been entirely removed. In C. Meyerbeer, the kind here illustrated, the ground colour is white, the primary veins and mid-rib red, and the interstices are filled in with a pleasing shade of green. The following is a selection of the best forms in their various sections:—

Selfs.—Aïda, deep transparent rose; Comte de Germiny, deep red, yellow beneath, and spotted with white; Duchesse de Mortemart, pure transparent white; Golden Queen, a uniform bright yellow; Ibis Rose, deep rich rose, and very dwarf in habit; Louis Poirier, reddish crimson spotted

with white; Uranus erubescens, bright crimson, very dwarf; Mithridate, rich crimson-lake; Prince of Wales, rich golden yellow; Splendidum, deep carmine; and Triomphe de l'Exposition, rich crimson.

Green grounds.—Argyrites, pale green, blotched with white, very dwarf; Auber, green spotted with pink and white; Auguste Riviere, deep green profusely spotted with crimson; Alphonse Karr, green, spotted with deep red; Blanquærti, deep green, veined and spotted with white; Barral, bright green, deep red centre, spotted with rose; Ceres, brilliant green with a rosy salmon centre; Lucy, apple-green, with red centre and white spots; Lurline, pale green spotted with white; Madame Alfred Mame, pale green with deep rosy centre and white spots; Spontini, green, spotted with white, and ribbed with deep rose.

Red and rose grounds.—Amœnum, soft rose ground, primary ribs red, veins rose suffused with violet, margin green; Aristides, deep rose with a broad green margin; Auguste Carpentier, scarlet ground, centre carmine, margin golden yellow; Bellone, deep maroon ground, centre soft rose; Cardinale, bright red dotted with gold and greenish yellow; L'Aurore, reddish violet, primary veins carmine, margin white; Madame Lemoinier, pale rose, primary veins deep rose, small veins white; Rubrum metallicum, deep reddish violet with rosy centre shaded with blue, margin bronzy red; Souvenir de Dr. Bleu, brilliant red, margin green; Souvenir de Madame Bernard, bright red, spotted with golden yellow, white, and green, margin pale green.

White grounds.—Albo-luteum, white suffused with greenish yellow; Agrippini Dimitry, white with rosy centre, margin and veins pale green; Adolphe Adam, white suffused and veined with rose; Candidum, clear white ribs, veins and margin green; Comtesse de Condeixa, white suffused with deep rose, primary veins red, smaller veins and margin green; Duchesse de Mortemart, pure white veined with green; L'Automne, creamy white, sparingly spotted with pale blue; Madame Marjolin Scheffer, metallic white, primary veins rose flaked with lake, smaller veins and margin green; Prince Albert Edward, white, veins rich crimson; Reine Victoria, white spotted with red, veins and margin green; Virginale, brilliant white, veined with bluish green.

Yellow grounds.—Gerard Dow, soft yellow, mid-rib deep carmine, veins red; Madame Dombrain, yellowish green shaded with rose and spotted with white and rose; Ornatum, rich yellow, mid-rib and primary veins deep rose, smaller veins rosy violet; Princess Alexandra, deep salmon veined with green; Princess of Wales, rich golden yellow spotted with crimson; Princess Royal, golden yellow with deep red centre; Princess of Teck, deep orange veined with deep red; Rubens, yellowish green suffused with deep red.

Cultivation.—Caladium tubers, after passing the winter in a dry state, may be potted and started into growth at any time, but under ordinary circumstances—say early in March. The soil in which we have found them to thrive best consists of equal parts of fibrous peat, turfy loam, good mellow leaf-mould, and well decomposed, but not exhausted, manure. This compost should be chopped up with the spade, not sifted, and to it should be added a fair proportion—say about one-fourth—of silver or river sand, which will tend to keep the whole porous and sweet, but if too much sand is used it impoverishes the soil. The pots should be well drained, as Caladiums require copious supplies of water; which, however, must not be allowed to stagnate about the tubers. Plant at first in somewhat small pots, but when these have become well filled with roots shift them, from time to time, into pots of a larger size, being guided in this respect by the situations which the plants are intended to occupy. If required for indoor decoration small pots will be best, but if for exhibition or for embellishing large stoves, then larger pots may be used. When first started, a slight bottom heat will be advantageous, but when some few leaves have become developed, bottom

Caladium Meyerbeer. Engraved from a photograph.

heat will not be necessary. They enjoy a high air temperature, and manure water should be given them about three times a week. The atmosphere should also be well charged with moisture; if this is done, they should not require syringing. By avoiding the use of the syringe in the case of these plants the leaves are not in any way disfigured. Caladiums may be used for general decorative purposes indoors, but they do not succeed in the open air. At the end of the season, when the leaves show signs of decay, water must be gradually withheld, and when they have fallen it should be entirely stopped, and shortly after this the tubers should be shaken from the soil, covered with dry sand, and stored in a cool place until wanted again in spring. During winter they should be examined occasionally to see that they are not decaying, and if inclined to shrivel moisten them slightly. From experience we are convinced that many lose more Caladium tubers during the resting season from over-dryness than from keeping them slightly moist.

Acacia armata.—This, though one of the oldest of cultivated Acacias, is certainly one of the most ornamental. For general purposes it is best grown in moderate sized pots, in which it can be employed for vases and baskets with the best effect. To keep it within bounds the shoots may be clipped well in annually after flowering; this will cause it to furnish thickly without any further training. I usually pot it at the same time, reducing the roots considerably and returning it to the same sized pot again, keeping it in the greenhouse all summer, where it makes good growth before winter and plenty of flower buds. Peat chiefly, with a little loam and sand, suits it perfectly.—J.

Planting out in conservatories.—The two great advantages to be obtained from planting out in plant houses are a diminution of labour and greater luxuriance of growth; and, in the case of certain plants grown upon an extensive scale, where a structure can be specially devoted to them, there can be no doubt that planting out is the right thing to do. In houses, on the contrary, where a miscellaneous and varied collection of plants is grown, judgment and discrimination must be exercised in respect to the permanent position of individual specimens. Still, although an advocate for planting out in the way mentioned, it is a system that cannot be carried beyond certain limits; if flowers are required in mid-winter and early spring, the plants which are to produce them must be subjected at times to a strong artificial heat; and, in order that they may thrive under such conditions, the pots must be full of healthy active roots; in other words, they must be what all practical men understand by the term established. In order to force Strawberries, for instance, successfully, they should have the soil in which they are growing matted with roots; and the same rule holds good with nearly all plants that are to be subjected to a strong heat. Cyclamens, Azaleas, Camellias, Pelargoniums, and most kinds of bulbs will not force well unless the soil which sustains them be thoroughly filled with fibres; planting out, therefore, requires judgment as regards the use to which a plant is to be put, for its blooming season and similar matters must be considered. Plants for the decoration of rooms cannot be too well rooted, for, if not well established, they soon become sickly, the leaves turn yellow, and the whole plant languishes and ultimately dies. Rapidity of growth is generally obtained at the expense of solidity. When grown rapidly during summer, and taken up and potted in autumn, they must be shaded for a time, and do not, therefore, acquire that hardiness of constitution which the autumn sun alone can bestow, and which enables them to withstand the perils of winter much better than plants more tenderly nurtured.—G.

Primula japonica and Sieboldi in pots.—These plants are not nearly so much grown by amateurs as they deserve to be, yet nothing could be more suitable, as they are easily managed, flower in the greenhouse during the spring without much trouble, and are quite as beautiful as many things more sought after, but inferior to them. It is always more satisfactory to grow such plants, the means at

command, in the shape of houses, pits, or frames, being adapted for them, than to attempt others that are less likely to succeed. There are numbers of amateurs who possess no means of protecting plants through the winter, except cold frames. By careful attention a great deal of frost may be excluded from these, as this is nothing more than a question of sufficient covering materials; but the attempt should never be made to winter anything in such places that is liable to suffer from being kept closed up, perhaps for weeks together, should protracted frost render it necessary. There are many very beautiful subjects that may be so kept, and that will furnish the material for many a vase of flowers, that are not to be despised, even by those who have the appliances of heated stoves and greenhouses. The soil in the pots in which these are grown should not be allowed to get saturated with water, as it not only is injurious to the roots, but renders the plants less able to stand the winter. The lights should be drawn off them during winter every day when the weather is dry, and tilted when wet. Nothing can possibly be worse than an insufficiency of air and light in winter for these plants, as the one tends to keep them growing at a time when there should be no further development of foliage, and the other causes a weak sickly condition, calculated to make the leaves tender, and the flowers, when produced, puny.—T.

KALOSANTHES COCCINEA.

This beautiful old plant, such a brilliant flower for the conservatory in midsummer, does not receive so much attention as formerly, when gardeners used to grow specimens of it several feet through, each shoot being furnished at its summit with a broad truss of waxy-scarlet flowers, showy and sweet scented. The plant also grows out of doors freely in summer, and when in flower makes one of the most brilliant and effective of beds. To flower it well it requires to be grown in hot, dry quarters. Cuttings, which strike very easily, should be made from the young shoots which have not flowered in August or early in September. Make the cuttings about 3 inches long; do not stop them, but divest them of a few of their bottom leaves, and pot each singly and firmly in a 3-inch pot, using a light compost of sand, leaf mould, loam, and pounded bricks. They will soon root if placed near the glass in a warm pit or on an intermediate house shelf; carefully avoid damping too much at top or bottom. When rooted remove them to a cool dry greenhouse for the winter, and give scarcely any water till spring; the object at this time is simply to keep them at rest. About the beginning of March the plants may be potted in 8-inch or 9-inch pots, which is a suitable size for those intended to have six or seven shoots. A little heavier compost should be used for this, the final potting, and with it plenty of broken crocks or bricks, taking care also to drain the pots thoroughly. After potting, the plants should have a growing temperature near the light. A warm greenhouse or pit will suit them, but do not give too much water at any time. At this stage some of the plants will break up into a number of shoots at the top, and the others will keep to a single shoot only. The former should be thinned out to six or eight shoots, and the latter pinched at the top to make them break; the young shoots secured in this way will bear the flowers. By May the plants will be growing fast, and at this time they may, in warm localities, be plunged out of doors in a sheltered corner. In front of a hothouse is a good place for them, and it is a common practice to plunge them in sand, which gets hot with the sun; otherwise they need not be plunged, but simply set on a hard surface. In cold localities it is better to grow the plants under glass all summer, with plenty of air and sun. Whichever plan is adopted, let the plants from this time grow uninterruptedly, and before cold weather sets in take them into any house where the temperature is genial and dry. Here they will show flower, if the trusses are not already in an advanced state, and the season of flowering may be prolonged by keeping the plants in cool houses. If the plants are intended for planting out, they must simply be wintered in a cool house, and not permitted to flower, and planted out the following season, when they will be certain to make a bright display.

Q.

Kitchen Garden.

VEGETABLES AT HACKWOOD PARK.

Within the walls of the excellent kitchen garden which Mr. Bowerman has under his care at this place vegetables are admirably grown, and better crops can hardly be found in any similar garden. The area of this walled enclosure is 6 acres, from which something should be abstracted for houses, grass walks, and flower borders. The turf walks are a remarkable feature, for there is not in the kitchen garden proper an inch of gravel or of edging, for the solid, close-shaven, and beautifully kept turf forms both walk and edging, and, thanks to the mowing-machine, the turf is kept as neat and clean as the best of gravel could be, with far less trouble. Doors admit to the garden on either side at the cross walks, and, with a few planks laid, manure is wheeled on to the quarters without any damage being done to the turf. The centre walk is some 12 feet broad and about 250 yards long, and is on either side bordered by flowers, so that it presents a scene of neatness and gaiety seldom met with in similar places. I have rarely seen a kitchen garden of these dimensions where flowers played so important and eminently decorative a part. But if Grass walks are perfection and flower borders neat and exceedingly gay, the more practical part is not less noteworthy. Better crops could hardly be found, and if others produce more highly finished or handsomer samples, at least they have perhaps not to contend with so tenacious a soil as is found at Hackwood. It is certainly holding, but it is also exceedingly tough; hence dry, baking seasons do not favour that pre-eminent beauty which marks vegetables in lighter sandy soils. And yet the samples lifted are first-rate also. Onions, for example, are a grand crop. The chief kinds are Banbury Improved, a good selection of the White Spanish; and Brown Globe, very closely allied to the former, but a little darker in colour and a first-rate keeper. All the tops have been regularly laid, and the sample is one of the most even and desirable I have ever seen. The bulbs are just such as gardeners and cooks delight in—firm, medium-sized, and clean. Adjoining these are a few rows each of those big show sorts Walker's Exhibition and Rousham Park, and it is worthy of note that a man would need a score pairs of eyes to detect the slightest difference in the stocks. Generally the bulbs are large and clean, but still full of growth, so that if they do not split, very fine samples will be found a month hence. It is worthy of note, however, that these big bulbs rarely keep well, and not a few crack on the ground. In a stand of show vegetables these would be preferred by judges before the smaller, firmer, and more serviceable bulbs, but would, of course, be in the long run much less useful. Carrots thrive admirably, the chief kinds being Early Horn for frames, and Early Nantes for borders, and for the main crop that beautiful kind, New Intermediate, or, as sometimes termed, Matchless, and the Long Surrey. Whilst the New Intermediate proves so successful for general purposes until mid-winter, the Long Surrey is the best keeper, and for that reason is specially valued. Beet is represented by two or three selections of Dell's Crimson, some good and some indifferent. It is very easy to see by these how much care is shown in some directions in selecting stocks and how little in others. Celery is remarkably good, although none is specially early. As a salad it is not urgently called for until the cooler weather approaches; hence the bulk is for winter use. Gem, which seems to be a pure stock of the old Incomparable Dwarf White, Major Clarke's Red, and a new, but somewhat irregular stalked, sort named Standard Bearer, are all finely grown and mostly in double rows. It seems very difficult to find two more compact or better keeping Celeries than are the Incomparable White and Major Clarke's Red. Parsnips, of the Hollow Crown strain, are good and full of growth. Potatoes consist of Schoolmaster, Magnum Bonum, Reading Russet, and Reading Hero for general stock, all very fine clean crops, and capital serviceable samples. The Ashleaf is here still largely grown for first early work—indeed, it is in great request so late as November; hence a larger breadth than usual is grown. A few other kinds have been introduced this season, but had already been lifted. So far, although the tops were much affected by disease, the tubers lifted were clean and healthy. The chief element of manure seems to be decayed leaves, and they seem somewhat to counteract the stiffness of the soil, but nothing can do that effectually, especially in wet seasons. Amongst Peas still good were Stratagem and John Bull, the former cropping splendidly. Sunrise had been sown to give the latest gatherings; ordinary Scarlet Runners showed good growth and abundant cropping; Canadian Wonder dwarf Beans, full of fruit, and similar vegetables were all excellent. Then came Brussels Sprouts, Giant Autumn Cauliflower, various white Broccoli, including Model and Ledsham's White, the latter the best of all for late use; Savoys, Cabbages, Kales, &c., make up ample provision in the green stuff department for the winter supply. A good breadth of Seakale shows a capital stock for blanching or forcing later; Asparagus is robust, evidently doing well. Throughout all the kitchen garden there seems to be ample provision made, for there is hardly a yard of vacant ground, successional cropping being admirable. Whilst all vegetable breadths show such excellence, there is no attempt at special or exhibition culture. Really good serviceable samples, such as satisfy the requirements of a household, are rather aimed at than are large or fancy samples. The garden is as clean as it is well cropped, and is alike creditable to Mr. Bowerman and his limited staff as it is to British horticulture.

A. D.

Late Peas.—The Peas usually to be relied on here as late kinds are Ne Plus Ultra and British Queen; Omega, sown quite at the end of June on a warm border, is still bearing freely. This is even a better late Pea than Ne Plus Ultra, and it may be sown from ten days to a fortnight later. A portion, at least, of the last sowing should be made on a warm south border, and mulching and occasional waterings will counteract the effect of drought should the autumn be dry, whilst the additional warmth obtained will cause the pods to fill better.—H.

Drying herbs.—In drying herbs two methods are employed; one is to tie them into bunches, as soon as cut, and hang them up in a room or shed; the other is to first lay them out in the sun to dry; by both these methods the quality is deteriorated. If fermentation takes place so as to discolour the leaves, which occurs, more or less, when herbs are tied up in bunches whilst green and sappy, their best properties are destroyed. In confirmation of this, it is only necessary to point to the extreme care taken by the growers of Lavender, Mint, &c., for distilling; for such purposes they are not allowed to lie together, even for a few hours. If, on the other hand, herbs are exposed to the sun, much of their strength is dissipated; they become quite brown, and that fresh green appearance which they possess when the drying is well managed is destroyed. But when herbs have been improperly treated, loss of strength is not the worst result; there is always imparted to them a disagreeable flavour. In drying herbs, an open shed or room, where plenty of air can be given, is necessary. Stretch out a piece of netting, such as is used for protecting fruit from birds; wire netting, if at hand, will do; on this the herbs, which should be cut when quite dry, are laid thinly; thus treated, air acts upon them from all sides, and they dry quickly, which is the primary object, without losing their best properties. When perfectly dry, put them loosely in white paper bags, tie them up, and hang them where they will be free from damp, or they will become

mouldy. Herbs treated in this way will be found to be but little inferior to such as are freshly cut. —T.

KITCHEN GARDEN NOTES.

Young vegetables.—When Carrots, Turnips, Peas, Beans, and other vegetables become ready for use in early spring they are universally praised for their delicate flavour and tenderness, and if the practice of using vegetables much younger than is commonly done was general, especially in autumn, all vegetables would merit the same commendation; but, as a rule, vegetables are not used young enough, and the difference between produce which has not gained full size and that which has, and even begun to ripen, is very great —so great, in fact, that many who eat vegetables freely in spring often do not care for them at other seasons. By early cutting or gathering, however, all vegetables may be placed on the table now in as delicate and tender a condition as it is possible to have them in spring. Many think that by allowing vegetables to become fully grown before using them they become more remunerative than they otherwise would be, but very few vegetables can be allowed to grow to their full size at this season and still retain their tenderness. Moreover, the remuneration idea as regards matured vegetables is more imaginary than real, as when none are used until they are almost or quite full sized, a large quantity will have become too old for food before they have been all used; these, therefore, must be thrown away; whereas if used from the time, say, when they were half grown, the bulk of them would have been gathered by the time they gained full size, and no waste would be the result. A Cauliflower 3 inches or 4 inches across and perfectly white is delicious, but allow it to grow until it is 10 inches or 1 foot across and yellow in colour, and not one person in a hundred would eat it from choice. Stringy Kidney Beans are detestable, but young and brittle ones are exquisite. Peas that have become wrinkled from age are flavourless, but those which are young and juicy are appreciated by all. Even Cabbages, when eaten young at this season, possess all the delicacy of those so much valued at Eastertide, and I can assure all who think that vegetables are less delicate now than in spring, that it is simply a matter of selecting the proper time to gather them.

Ridge Cucumbers.—The weather experienced this summer has been favourable to the growth of outdoor Cucumbers, and if late they have been bearing very heavily, but a very heavy crop does not augur well for a long succession of fruit, and where it is desired to have tender young Cucumbers until frost comes, every fruit ought to be cut off as soon, or a little while before it attains full size. This is the best way to produce a long succession of fruit, and a supply of young fruit from June or July until November is much more satisfactory than having a glut at one time and none afterwards. Some may think they would like to save seed, and with this object in view allow certain fruits to mature, but two or three pennyworths of seed go such a long way in producing a stock of plants that it is much better to buy the seed in spring than ruin the crop late in autumn.

Lettuces and Endive.—Wherever salads are in demand in winter large quantities of Lettuces and Endive must be grown. The seed of both should be sown in August, or, at the latest, very early in September, and as soon as the young plants are large enough to handle they should be drawn up and replanted in vacant ground anywhere. In districts in which the weather is severe in winter they should be planted on south borders or in very sheltered positions, as no Lettuce or Endive will bear many degrees of frost without deterioration. If a double row can be planted along the bottom of a wall, the latter will furnish a certain amount of protection, and if it becomes necessary to cover them, that is much easier done near a wall than in open quarters. Some recommend planting them close to a hedge, but that is a position I dislike, as the soil near a hedge is generally so poor, that it is a hard matter for anything to develop properly in it. It is a point of considerable importance to have both Lettuces and Endive fully established and growing before the weather becomes very cold, and if they are a good size by the end of October, there will be little difficulty in keeping up a supply of material for salads during the following two or three months. The Improved Broad-leaved Batavian is the best of all Endives for winter, and of Lettuces, Winter White and Black-seeded Bath are excellent.

Vegetable Marrows.—These are not so much used as they should be; many who have only tried large fruiting kinds, overgrown and old before they were sent to table, have been set against Vegetable Marrows; but let me tell such that small fruiting sorts, renowned for their quality, are amongst the most delicious of all vegetables, and only need to be tried in a young state to create a desire for a constant supply of them. Above all vegetables in season just now do I prefer Vegetable Marrows, and on that account I keep up the supply of them as long as possible, but if allowed to ripen now and remain on the plants long after they have become hard and yellow, the supply of young fruits will cease. We have some plants set specially apart for seed-bearing; of late these have been producing many male blossoms, but not a female one; whereas those from which the fruits have been regularly cut are now producing blooms of both kinds and constantly setting fruit. It is, therefore, useless to expect later on young fruit from plants now bearing numbers of matured fruits, and unless these are cut off there will be no late Marrows. All fruits are too old for use when the thumb-nail will not penetrate the skin and flesh freely, and they should not on any account be sent to the table when either large or old.

Winter Radishes.—These are amongst the most useful of all winter salad plants, as they are perfectly hardy and require no protection or forcing in order to have them in perfection through the greater part of the winter. For this reason they are specially to be recommended to those who have no accommodation for housing vegetables in winter. Summer varieties, however, and others which are useful for early spring supplies are useless for winter, the severity of which only one or two can stand. Of these the best are the China Rose variety and the Black Spanish. The latter is very hardy and white and crisp in the flesh. With their culture few can fail. The seed should be sown in a piece of ground recently cleared of Potatoes or some other crop; let it face the sun if possible, and sow thinly in drills 1 foot apart and 2 inches deep. If the young plants come up very closely and have no room to bulb freely, they should be thinned out to 2 inches apart.

Margam, Port Talbot. J. Muir.

Hackwood Park Tomato.—Gigantic fruits of any Tomato are never handsome, and invariably coarse and full of core. Only those weak enough to be delighted with monstrosities, such as persons who send to the local papers notes of the biggest Gooseberry or the most gigantic Cabbage or Potato, feel pleasure in having monster Tomatoes. The sample of Hackwood Prolific sent you the other day was of an abnormal type, and not at all representative of the fruit of this capital variety when seen in true form. I saw a quantity of plants growing at Hackwood the other day, and could not but remark their exceeding productiveness, the fine form and even size of the fruits, and their rich colour. The plants were in pots standing at one end of a plant house, and, judging by the crops they were carrying, appeared to be of exceeding value to the gardener, Mr. Bowerman, who was the raiser. The fruits ranged from 4 ozs. to 7 ozs., and those were large enough for any thing. It is all very well to have handsome and rich coloured fruits for exhibition, but the gardener who has to supply the needs of a family finds that Tomatoes are now in great request; hence a large and even crop is absolutely needful. Hackwood Park seems to satisfy these requirements thoroughly, whilst plenty of its fruits are as handsome as the most exacting could desire. In few places has the need of a special Tomato house been fully recognised. Presently, perhaps, it will be regarded as one of the inevitable requirements of a good garden, just as special houses are erected for Cucumbers, Melons, &c. Such a house should have a narrow border for soil, a moderate pitch of about 6 feet run of roof, and ample ventilation. Still further, one compartment for winter use should have ample heating power, whilst very little artificial heat will be needed for the summer plants.—A. D.

New Zealand Spinach.—This is a most useful vegetable, both for a dish and for greening soups, and the amount of produce which a few plants of it will yield is quite astonishing. I have grown it for many years, and have always found it in great request. It succeeds best sown in 4-inch pots, and thinned out to three plants to a pot. When the pots become filled with roots, a shift should be given into a 6-inch or 8-inch pot, and, when the season has become warm enough, the plants should be turned out and treated like Vegetable Marrows or ridge Cucumbers, and, if placed under handlights to start them, so much the better. From a bed planted with it, 5 yards long and 2 yards wide, I should be afraid to say how many gatherings were obtained, and by covering with a mat or two at night, it will continue to produce till sharp frost sets in. Wherever Spinach is in large demand I can strongly recommend this; it does not run to seed, and it does not take a large bed to furnish a dish every day from July to December. —G.

Which way shall the rows run?—Professor Armsby, of the Wisconsin Experimental Station, in *The Farmer* (St. Paul, Minnesota) gives an account of an elaborate investigation upon the influence of the direction of the rows upon the warmth and moisture of the soil and the growth of crops, made by Professor Marek, of Koenigsberg. It was found, when the rows, ridges, or beds had a north and south direction, the soil was decidedly warmer and drier during the day than when the east or west direction was followed. This difference was greatest with ridge culture, and least with level culture. The higher the ridges the greater the difference. As was to be expected, the ridges became warmest and driest while the furrows were least affected. The effect was the greatest during the hottest months and days. On the other hand, the soil which became warmest during the day cooled off most rapidly during the night, so that in the early morning hours, hardly any difference in the temperature of the soil was observable in the two cases.

Sweet Basil (Ocimum basilicum).—This herb, which is much in demand with some cooks, is an Indian annual, and consequently tender. Its seeds should be sown about the middle of April in a genial temperature, and when the seedlings are large enough to handle, they may be potted off singly, or they may be pricked into boxes or seed-pans, or into a frame on a slight bottom-heat, from which they should be transferred to their positions in the open air about the beginning of June, for, owing to the plants being exceedingly tender, this can seldom be done with safety at an earlier period. Sweet Basil succeeds best in a light rich soil, in which the plants should be inserted at a distance of 6 in. or 8 in. apart; and they should be well watered until they become established. As soon as they come into bloom they should be cut down to within a few inches of the ground, and the portion cut off should be tied up in small bunches and dried in the shade for winter use. As, however, green Basil is frequently required, the plants which have been cut down should have the soil surrounding them slightly stirred up, and the bed should receive a surface-dressing of fresh soil, when the plants will quickly form themselves into healthy little bushes, which will furnish a supply of green leaves until about the beginning of October. A portion of them should then be lifted and potted, or planted in boxes, and should

be placed in a somewhat genial temperature, where they will continue to furnish a supply of green leaves when required throughout the winter.—G.

ORCHIDS.

COOL ONCIDIUMS.

Since the value of cool treatment for Orchids has come to be fully recognised, the various members of the genus Odontoglossum have somewhat monopolised the attention of cultivators; nor can we much wonder at this when we take into consideration their beauty, both individually and collectively, and the great length of time during which they last in perfection. There are, however, many other genera which contain handsome species, and which are amenable to the same system of cultivation, and amongst these must be classed the Oncidiums. Cool Orchids are sometimes called greenhouse Orchids, and therefore many have thought that they may be grown along with Pelargoniums, Fuchsias, Balsams, and similar plants, but although many Orchids require even less heat than greenhouse plants do, they will not thrive in an atmosphere suitable to the requirements of such plants. A house for cool Orchids should, if possible, have a northern aspect; I do not say that such an aspect is absolutely necessary, but if it can be had, the burning heat of summer, so injurious to the majority of mountain Orchids, is more easily tempered. The night temperature for such a house in summer should be about 60°; in the daytime it will run up to 70° or 78°, sometimes higher, but the nearer it can be kept to about these figures, the better the plants will thrive and the more enjoyable will the house be to visitors. In winter the temperature may fall to about 40° at night: indeed, I have seen instances in which it has fallen so low that ice has been formed inside the glass during severe nights in winter; but that is not desirable. In winter the day heat may be increased to 55° or 60°, but not, as a rule, higher than that. The cultivation of Oncidiums is not fraught with much difficulty if daily attention be paid to them. Cleanliness is of primary importance; they will not long survive if thrips is allowed to gain the ascendancy, nor will their flowers be improved in beauty by a fringe of yellow or green fly. Careful washing with clean water is the best antidote for the latter if taken in hand promptly, and this should always be done, as fumigating Orchids with Tobacco I hold to be injurious. Should thrips put in an appearance, it, in most instances, indicates too dry an atmosphere or too high a temperature, or perhaps both combined. The larger and more robust kinds are best grown in pots, but some of the smaller ones thrive best upon blocks of wood, or in baskets suspended from the roof. As to compost, about equal parts of fibrous peat and Sphagnum Moss suit them admirably, and if the top is surfaced entirely with living Sphagnum, it will not only add materially to the appearance of the plants, but provide a cool and moist shelter for the young roots. The drainage should be kept free and open and the atmosphere well charged with moisture, but not drenched with water, or everything will become stagnant and sour. An occasional dewing overhead with the syringe during bright sunny days in summer will be advantageous, but will be unnecessary during the cool season, when less water must also be given to the roots, although even in winter they must not be allowed to suffer from drought; and upon all occasions and at all seasons, wetting the flowers should be carefully avoided.

The following are a few of the most showy and distinct Oncidiums for cool treatment:—

O. aurosum.—This very fine species, from Ecuador, is a robust grower and free flowerer. Its pseudo-bulbs are large and pale green, and bear a pair of ample leaves on the apex, and several broad sheathing ones at the base. The panicle varies from 2 feet to 5 feet in height, is much branched, and bears from 50 to 100 flowers. The sepals and petals are rich yellow, transversely blotched and barred with cinnamon. The lip is of the same rich yellow, stained at the base and on the crests with brownish red. This species usually blooms during autumn and winter, and lasts many weeks in full beauty.

O. cheiropthorum.—An elegant-growing plant, with small pseudo-bulbs and narrow leaves not more than 6 inches long, the whole plant somewhat resembling Odontoglossum roseum. The slender scape is longer than the leaves, panicled, drooping, and densely set with pure bright yellow, sweet-scented flowers, which appear during midwinter. It was originally found by Warscewicz, on the volcanic mountain of Chiriqui, at an elevation of 8000 feet.

O. Cresus.—A small plant, seldom exceeding a few inches in height, with conical-ribbed pseudo-bulbs, and bearing a pair of oblong pale green leaves. The scape is few-flowered, and the sepals and petals are tawny yellow. The lip is large, the middle lobe spreading and bright golden yellow. The basal part and crest are intense velvety black. It should be securely fastened to, and grown upon, a block of wood. It is a summer bloomer. From the Organ Mountains, in Brazil.

O. macranthum.—This is the best of the genus, both as regards size and majestic beauty. It appears to be a common mountain plant in Peru and New Grenada, ranging from 7000 feet to 14,000 feet elevation. It is a bold-growing species, with pseudo-bulbs some 4 inches high, ovoid and furrowed when old, and bearing a pair of somewhat narrow leaves upwards of a foot in length. Its panicle, which is climbing, attains a length of from 10 feet to 12 feet, and bears an immense number of flowers. I have seen seventy open at one time on a spike some 12 feet long, and these measured upwards of 4 inches in diameter. They are round, full, and leathery in texture. The sepals and petals are somewhat orbicular, the former tawny orange, the latter rich golden yellow. The lip is smaller than the petals, hastate, and yellow in front; the side lobes are rich purple and brown, and the crests white. It appears to be an all-the-year-round bloomer, and lasts many weeks in perfection.

O. zebrinum, a species belonging to the same section as the preceding, and in habit of growth and length of spike not unlike O. macranthum. The flowers, however, are very dissimilar. The panicle, which is climbing, bears from fifty to eighty blooms, the sepals and petals of which are oblanceolate, and have wavy margins. They are white, transversely barred with reddish purple. The lip is smaller than the petals, and bears tubercles. It is yellow, sparingly barred at the sides with reddish violet. This species blooms in winter, and, from its colour being unusual amongst Oncidiums, is very attractive. It comes from Venezuela.

O. varicosum.—This is a compact free-growing autumn and winter-flowering species, the beauty of which, like that of the majority of Oncidiums, is dependent upon the enlarged lip. Its pseudo-bulbs are ovate, dark green, blotched and speckled with black, and they bear a pair of ligulate, lanceolate, leathery, deep green leaves. The panicle, which is much branched, bears as many as fifty flowers, the lip is broad and flat and bright golden yellow. It appears to be common in the neighbourhood of San Paulo, Brazil. The variety known as Rogersi has the same habit of growth, but its panicle, which is much branched, is upwards of 2 feet long, and bears from 150 to 170 flowers, the large lip being deeply bilobed in front, upwards of 2 inches across, and rich golden yellow. It is also an autumn and winter bloomer, and one of the most showy in the genus.

O. cucullatum.—This is a common plant in the mountain forests of Ecuador, where it is found frequently growing at from 12,000 ft. to 13,000 ft. elevation. It is a variable plant, some forms of which are, however, constant. Amongst the most distinct may be named flavidum, macrochilum, giganteum, and nubigenum. It is a small plant with oblong compressed pseudo-bulbs, which bear a single leaf. In the normal form the lip is large, deeply bilobed in front, purplish rose, dotted and spotted with rich purple. It thrives best upon a block of wood, and blooms during the winter.

O. Phalænopsis.—This is similar in habit of growth to the preceding, and requires similar treatment. The scape, which is erect, bears from three to six large showy flowers, the sepals and petals of which are creamy white, dotted and barred with purplish violet. The lip, which is fiddle-shaped, is also creamy white, dotted and spotted at the base with crimson and purple; the crests are yellow. It was found on the high mountains of Peru, and flowers in mid-winter.

O. Jonesianum.—This has short, blunt, terete, dark green leaves, and is an abundant bloomer. It bears long branching spikes loaded with flowers, which are white and more or less deeply spotted and transversely banded with reddish crimson; the crest of the large lip is stained with yellow. It appears to be a perpetual bloomer.

O. leucochilum.—This is an old inhabitant of our gardens and very variable, some of the forms being extremely handsome. Its pseudo-bulbs are stout, oblong, and furrowed. The flower-spike is erect, from 3 feet to 6 feet high or more, branched and many-flowered. The sepals and petals, which are about equal in size, are greenish white or yellow, transversely banded with reddish crimson or velvety black. The lip is large and pure white. It is a winter-blooming species, and comes from Guatemala.

O. serratum.—A strong-growing plant belonging to the same section as macranthum, and resembling it closely in appearance. The scape, which is climbing, is from 10 feet to 14 feet long and much branched; bears great quantities of flowers. The sepals and petals are rich chocolate or cinnamon, with a yellow border, the edges of which are beautifully fringed. The lip small, hastate and yellow, streaked with brown. It blooms during winter, and comes from Peru.

O. calanthum.—This, although showy, is comparatively but little known. Its pseudo-bulbs, which are somewhat ovate and deeply furrowed with age, bear a pair of obtuse lanceolate leaves, which are erect and dark green. The scape is long and sparsely furnished with flowers, the sepals and petals of which are nearly equal in size and bright yellow; the lip, which is large, is rich golden yellow, blotched with reddish crimson at the base and on the crest. It usually blooms during winter and early spring. It comes from the Cordilleras of Ecuador.

O. bifolium majus.—A dwarf plant which flowers in spring, and succeeds best upon a block of wood. Its pseudo-bulbs, which are ovate and deep green, are streaked and dotted with black, much in the way of varicosum. The scape is about a foot long and many-flowered. The sepals and petals are small and dull coloured. The lip large, deeply notched in front, and rich golden yellow. It comes from Monte Video. W. H. G.

Phalænopsis grandiflora var.—A very handsome and distinct variety of this species we noticed at Messrs. Laing's nursery the other day. The flowers are large and very round, quite destitute of the orange usually found at the base of the lip, but in its place just a faint tinge of pale lemon.

Cirrhopetalum maculatum.—This is one of the little gems of Orchids we used to find in good collections in bygone days. To our surprise, we found it flowering beautifully with M. Czarnikow, of Elm Court, Mitcham. It is not a showy Orchid. Its flowers are borne in umbels; they are not large, but elegant, the sepals and petals creamy white dotted with purple, and the small movable lip is purple.

Oncidium Jonesianum.—Many fine varieties of this plant are now flowering in Mr. Laing's nursery at Forest Hill. Some of them are producing branching spikes, so that, as the plants become stronger, there is a probability of its proving a finer species than we have as yet had an opportunity of believing. Some of the varieties have large, broad,

white lips, and others less white and more of the crimson spots and bars; whilst the markings of the sepals and petals vary much in intensity of colour.

EXTERMINATION OF SPIRANTHES ROMANZOVIANA.

With both surprise and regret did I this morning receive intimation from Mr. W. E. Gumbleton, of Belgrove, that in all probability Spiranthes Romanzoviana is now a thing of the past in Europe, for its only known stations—two boggy fields in the county of Cork—have been ploughed up and planted with Potatoes. Why this sweet little plant, the rarest and most interesting of our native Orchids, should have thus, in a country of botanical science like Britain, been allowed to pass into oblivion is simply unaccountable, and certainly reflects anything but credit on the numerous societies to whom the preservation of our native flora should be of first importance. To say that a plant on which a Lindley, a Darwin, a Bentham, and a Gray expended such labour and research, a plant that has but one European station, and that a British one, is, for the sake of a couple of perches of almost valueless bog land, allowed to become expunged from our flora is hardly credible, and would never have been tolerated in any country but our own. The Edelweiss and Gentian—by no means rare plants when compared with the one in question—are zealously guarded by continental laws; and yet we British, who profess to hold our own matters botanical, have suffered this pretty and interesting plant to be uprooted and wholly destroyed.

Methinks I hear someone ask the question, What could, say, even the Kew authorities have done to preserve this Orchid? They have no power to enclose the piece of ground or dictate to the owner thereof as to whether or not the fields are to be ploughed up or left fallow. True enough, we reply, but "where there's a will there's a way;" and well assured are we that had the matter been gone right about much might have been done, and in all probability we would not now have had cause to mourn the loss of so rare a plant.

Could not the person who owned the wet, rushy field—a field that was almost worthless for agricultural purposes—have been allowed a small sum annually—say by the director at Kew—to look after British botanic interests in that part of the empire, and to keep the plant from suffering extermination either by ground tillage or at the hands of collectors? This plan works well even in Wales, for in some instances which have come under my own notice farmers have been asked by their landlord or his agent to preserve certain rare plants growing on their ground or buildings, and willingly and heartily have they complied with the request, else in one case at least with which I am perfectly familiar a certain rare plant would ere this time have been totally exterminated. Either this method of procedure, or, better still, a law formed to put, by some means or other, a stop to the ruthless uprooting of our rarer native plants will ere long have to be resorted to; indeed, the matter has already received some consideration at the hands of a few London societies, and it is certainly to be hoped that no half-heartedness will allow the matter to drop until something is done. Long ago, in "Colin Clout's Calendar," did Grant Allen tell us that "the ardour of modern botanists is fast putting an end to the brief career of this Orchid," but little did he think that a more speedy and sure method for its total extermination was nigh at hand.

At present the only known stations for this pretty flower are a few of the cold upland bogs of the three Northern States of New England, but even there it is by no means abundant; and it is certainly to be hoped that the enthusiasm of our American cousins as to the preservation of their native plants will never become tainted with British neglect and unconcern in matters of a similar kind, but that the rare and sweet little Spiranthes Romanzoviana will be cherished and zealously guarded in its now only known stations in North America. A. D. Webster.

Llandegai, Bangor.

The Dove plant.—This truly beautiful Orchid (Peristeria elata) has lost favour with the majority of growers of this family, because it is such a shy bloomer. Mr. King, at Waddon House, has at the present time some plants in 6-inch pots flowering most profusely—not a single example, but quite a group of them. The pseudo-bulbs are large and the plants very healthy; they are grown in strong heat and moisture.

Lælia elegans Turneri.—We have received from Mr. E. Harvey, Aigburth, Liverpool, a grand spike of this Orchid. It had upon it fine large flowers some 6 inches in diameter. Its peculiar spoon-shaped lip, the brightest part of the flower, is rich deep violet, shaded maroon-purple. From the same garden also came a very good variety of the true Vanda insignis and Angræcum Scottianum, all three being extremely good September-flowering Orchids.

New hybrid Orchid (Lælia Batemanniana).—A remarkable hybrid Orchid has just flowered in Messrs. Veitch's nursery at Chelsea. It has been raised by Mr. Seden between the old C. intermedia and the little scarlet Sophronitis grandiflora. In growth it much resembles the Sophronitis, except that the bulbs and leaves are larger, and produced in pairs. The whole plant measures from 3 inches to 4 inches high. The flowers resemble those of the Cattleya parent, as they are almost as large, but the form is altered, and particularly the colour. The sepals and petals are of a peculiar tint, which can only be likened to that of Odontoglossum roseum, or of Mesospinidium vulcanicum. The lip is more like that of the Cattleya: the upper part is white, stained with light yellow in the anterior; the anterior lobe is of a beautiful violet-crimson. It may prove a valuable ornamental Orchid, especially if it habitually flowers.

Odontoglossum vexillarium superbum.—Among the many so-called varieties of this Odontoglossum, none are, to our mind, so distinct or so beautiful as that which bears this name. A beautiful specimen of it has just been sent to us by Mr. R. H. Measures, from his collection at The Woodlands, Streatham. It seems to us to be exactly identical with Sir Trevor Lawrence's famous variety, which, we believe, is known also as Lawrenceanum. It differs from the normal form of O. vexillarium considerably. The flowers are small, only about half the size of what would be termed a good variety of the original. The great feature about it is its colour, which is a very deep rose-pink, the centre adorned with a large blotch of an intensely deep crimson, with lines radiating from it. It seems to be a late-flowering form, like Mr. Bull's rubellum and that named Lehmanni. It is quite a treasure, and Mr. Measures is fortunate in possessing such a fine specimen of it. His plant has borne three spikes this season.

Orchids from Cambridge Lodge, Camberwell.—Some very fine Orchid flowers have been sent us by Mr. R. J. Measures. Amongst them is a spike of Oncidium Jonesianum measuring upwards of 18 inches in length, and bearing the largest flowers we have yet seen of this species. The sepals and petals, which are broad, are white, profusely banded transversely with cinnamon. The lip is very large and spreading, the middle lobe being pure white, side lobes twisted and bright canary yellow, dotted with reddish crimson. The crest is almost covered with small cinnamon dots. This species promises to rival in beauty its near relatives, the Odontoglossums. Associated with this were several varieties of Odontoglossum bictoniense album, amongst which one with chocolate-brown sepals and petals and a large pure white lip was conspicuous; also Cattleya bicolor, a richly coloured variety, and a spike bearing four flowers of the best variety of Cattleya Harrisoniana we have yet seen. Its flowers measure some 4 inches in diameter. The sepals and petals, which are very broad, are bright purplish-violet, and the convolute lip the same colour outside, while the middle lobe in front is creamy white stained with soft yellow. This we consider a thoroughly distinct and beautiful Cattleya, and one well worth a varietal name.

Dendrobium Fredianum is an objectionable name, which someone has thought fit to fasten on to D. longicornu: at least, such appears to be the case, judging by some flowers sent to us by Dr. Duke, of Lewisham, with the information that the plant had been purchased at an auction sale under that name. Probably the plant's godfather for the new name did not know that Lindley had named, described, and figured it about sixty years ago from plants flowered at Chiswick; but that ought to have been sufficient reason for his letting the work of naming alone. The plant was not new because he did not know it. D. longicornu is related to D. Jamesianum and the new D. Williamsoni; it has erect slender hirsute pseudo-bulbs, linear-lanceolate leaves, and terminal flowers in fascicles, which are remarkable for their long straight funnel-shaped spur. The lip is scoop-shaped, the edges fringed and the inside striped with orange-red, the rest of the flower being white. The sepals and petals are short, and remain half closed instead of spreading, as in D. Williamsoni. This species is a native of Nepaul. It is said to require rather cool treatment. Of course it is a pretty Dendrobe, and interesting in the structure of its flowers.—B.

Societies and Exhibitions.

DAHLIAS AT THE CRYSTAL PALACE.

The Grand National Dahlia Show annually held at the Crystal Palace in connection with the fruit show, took place as usual, and large numbers of very fine flowers were staged. There were four collections of forty-eight varieties of show Dahlias in the nurserymen's division, and equal first prizes were awarded to Messrs. Keynes, Williams, and Co., Salisbury, and to Mr. Charles Turner, Royal Nursery, Slough. The following blooms were very fine in Messrs. Keynes and Co.'s stand, viz.: Imperial, Mrs. Langtry, Harry Keith, Buttercup, Miss Cannell, Cardinal, Clara Wyatt, Vice-President, William Rawlings, Mrs. Gladstone, Shirley Hibberd, Ethel Britton, Gloire de Lyon, Lord Chelmsford, Hugh Austin, Henry Walton, Prince Bismarck, Seraph, Illuminator, a distinct and striking new variety of much novelty of character; Prince of Denmark, Defiance (new), Rebecca, Mrs. Foreman, Mrs. Jeffard, Georgiana, Mrs. Harris, Royal Queen, and Rosy Morn. In Mr. Turner's collection could be seen the following, very fine: Mrs. W. Slack, Statesman, John Wyatt, Sunbeam, Georgiana, James Service, Prince of Denmark, Flag of Truce, Mrs. Kendal, Imperial, George Rawlings, James Stephen, Bendigo (new), T. J. Saltmarsh, Thomas Hobbs, Joseph Ashby, Mrs. Shirley Hibberd, Prince Bismarck, Seraph, Mr. G. Harris, Constancy, J. N. Keynes, Burgundy, Herbert Turner, Hope, and Ovid. The third prize went to Mr. William Boston, Manor Farm Nursery, Carthorpe, Bedale; and the fourth to Messrs. Heath and Son, Cheltenham. Then came a class for twenty-four blooms of show Dahlias open to nurserymen not showing in the previous class, and seven collections were staged. Mr. John Walker, Thame, was first with some fine blooms, especially the following: Rebecca, J. N. Keynes, Mrs. Rawlings, Vice-President, George Rawlings, Annie Neville, Flora Wyatt, Mrs. P. Wyndham, Joseph Ashby, Seraph, J. W. Lord, Goldfinder, John Standish, very fine; Countess of Ravensworth, Earl of Ravensworth, Harrison Weir, Mrs. Gladstone, Mrs. Langtry, and C. Wyatt. Still another class for nurserymen, and open to exhibitors not competing in the two preceding ones, and here Mr. G. Humphries, Kington Langley, Chippenham, was first with capital blooms. There were three classes open also to amateur cultivators, and, as in the case of those set apart for nurserymen, no person could show in more than one of them. In that for twenty-four varieties, Mr. R. Petfield, Diddington, Buckden, Huntingdon, was first with a fine lot of blooms, consisting of Miss Cannell, Joseph Ashby, Seraph, George Rawlings, Constance, James Stephen, Mrs. Langtry, Prince Bismarck, Primrose Perfection, Imperial, Flag of

Truce, J. W. Lord, T. J. Saltmarsh, Earl of Ravensworth, James Vick, Harrison Weir, William Rawlings, John Standish, Royal Queen, and John Wyatt. In the class set apart for twelve varieties there were as many as fourteen competing stands, and here Mr. Charles Hockney, Greenfield House, Stokesley, was first with fine flowers of William Rawlings, Criterion, Prince of Denmark, Ethel Britton, Earl of Ravensworth, Pioneer, Mrs. Gladstone, Shirley Hibberd, Goldfinder, James Vick, Clara, and Harrison Weir. In the class for six there were ten competitors, and here Mr. James Perkins, London Road, Chippenham, was first with Mrs. Langtry, Mrs. Gladstone, James Stephen, Hope, Mrs. Harris, and Aurora.

Fancy Dahlias.—Two classes each for nurserymen and amateurs followed, in all cases an exhibitor being able to show only in one of them. In the nurserymen's class for twenty-four blooms, Messrs. Keynes, Williams and Co. were first with a superb lot of flowers, chief among them being James O'Brien, Duchess of Albany, Pelican, General Gordon, General Grant, Miss Letty Large, Fanny Sturt, Hercules, Adventure, Gaiety, Rev. J. B. M. Camm, Henry Eckford, Mrs. Friselton, Charles Wyatt, Annie Pritchard, John Forbes, Salamander, Mrs. Saunders, Henry Glasscock, Professor Fawcett, and Rebecca; second, Mr. C. Turner, with only slightly inferior blooms of Professor Fawcett, Chorister, Hugh Austin, Grand Sultan, Miss Browning, Peacock, Pelican, Miss Letty Large, Neptune, Gaiety, John Lamont, James O'Brien, Mandarin, Laura Haslam, Henry Glasscock, Eric Fisher, Henry Eckford, Rebecca, Duchess of Albany, and Mrs. Saunders. In the class set apart for twelve blooms there were nine competitors, and Mr. John Walker, Thame, was first with Clara Wyatt, John Salter, Fanny Sturt, Flora Wyatt, John Forbes, Professor Fawcett, Tippy Bob, Chorister, Peacock, Miss Browning, Florence Stark, and Prospero.

In the amateurs' class for twelve blooms there were five competing collections, and Mr. C. Hockney, Stokesley, was placed first with good blooms of George Barnes, Fanny Sturt, Gaiety, Mrs. N. Halls, Mrs. Saunders, Rebecca, Henry Glasscock, Polly Perkins, Prospero, John Forbes, Flora Wyatt, and Peacock. In the class for six varieties there were fifteen collections, and Mr. Arthur Whitton, Askew, was first, with Mrs. N. Halls, Hugh Austin, Florence Stark, Trotty Veck, Mrs. Saunders, and Clara Wyatt.

When the judges were called upon to undertake the almost impossible task of awarding premier prizes to the best show and the best fancy Dahlia selected from the whole exhibition, the first was found in John Standish, shown by Mr. John Walker; the second in Henry Eckford, shown by Messrs. Keynes and Co.

Pompon Dahlias.—These were shown in bunches of eight or ten blooms, and so handsome were they and so effectively arranged, that they proved one of the most attractive features in the exhibition. Mr. C. Turner had the best twenty-four varieties, and they were set up in excellent fashion. The varieties represented the cream of this class of Dahlias in cultivation; they consisted of Dora, Little Arthur, E. F. Jungker, Darkness, Isabel, White Aster, Princess Sophie Sopieha, Favourite, Golden Gem, Amelie Barbier, Thomas Moore, Calcilie, Louis Rodani, Fashion, Titania, Gem, Fanny Weiner, Fair Helen, Rosalie, Ernest, Rosetta, Lady Blanche, Comtesse Von Sternberg, and Butterfly. Messrs. Paul set up in good form Little Bobby, Fortmeister G. Schwerin, Little Mabel, Fanny Weiner, Darkness, Gem, Dora, Fair Helen, Pure Love, Carl Miendal, and Royalty. For six varieties Mr. Henry Glasscock, Bishop's Stortford, was placed first with unnamed flowers.

Single Dahlias.—These, like the Pompon varieties, made a very pretty display, being set up in bunches of eight or ten blooms. There were five collections of twelve varieties, Mr. C. Turner being placed first with striking bunches of the following: Harlequin, Juno, Defiance, Dorothy, Duchess of Westminster, Mary Anderson, Paragon, Yellow Queen, Mrs. Bowman, Rupert, Ellen Terry, and Negress; second, Messrs. Keynes, Williams and Co., who had, in addition to the foregoing varieties, Crimson Beauty, Miss Flitt, White Queen, Mauve Queen, Magnificent, John Cowan, Victory, Yellow Queen, and B. Barkaway. For six varieties of single Dahlias, Mr. T. W. Girdlestone, Sunningdale, was first with varieties mainly of his own raising; among them one named Calico, pink margined with white, was pretty and distinct.

The Turner Memorial Prize.—This is in the form of a handsome silver cup, and was instituted last year, when it was won by Mr. Henry Glasscock, Bishop's Stortford. It is required that a stand of twelve show and six fancy Dahlias be shown; on this occasion it was won by Mr. J. T. West, Cornwalls, Brentwood, with a stand of bloom inferior in merit to the leading ones found in the other classes. The cup will therefore have to be competed for another season.

Seedling Dahlias.—First-class certificates of merit were awarded to the following new Dahlias: Florence (C. Turner), yellow self; Bendigo (C. Turner), crimson-purple; Defiance (Keynes and Co.), pale red; Colonist (Keynes and Co.), fawn colour and purple, very distinct; R. J. Rawlings (Rawlings Bros.), yellow self; Mrs. Theobald (Rawlings Bros.), pinkish lilac; Nellie Tranter (J. R. Tranter), clear golden yellow, single; Chilwell Beauty (T. S. Ware and H. Cannell), buff, edged with dull red; Amos Perry (Ware), rich maroon; Mrs. Coninck (Ware), pale lilac-purple; Cactus Dahlias Cherry Ripe (H. Cannell and Sons), pale ground, edged with pinkish purple, and Black Knight, shining black, very fine.

The following were highly commended: A large collection of Dahlias, &c., from Messrs. H. Cannell and Sons, Swanley; the same from Mr. T. S. Ware, Hale Farm Nurseries, Tottenham; and the same from Messrs. J. Cheal and Son, Lowfield Nurseries, Crawley.

The Fruit Show.

It is long since so fine a display of fruit has been seen in London as was staged here, the competition in most of the classes being of a remarkable kind and very keen. Generally very fine quality prevailed, but, of course, some mediocre exhibits were present, though few. In some classes really first-rate exhibits had to be left out in the cold, the average being so high. The chief drawback was found in the eccentric arrangement of the classes, which necessitated a vast amount of locomotion needlessly, and much inevitable bewilderment, without in any way adding to the merit of the show. The tables were arranged in quadrangular blocks on either side of the east nave, and in many cases a few lots in a class were on one table and the rest on another; indeed, judging seemed to be carried on under exceeding difficulty, whilst the public must have been equally puzzled. There was not the least necessity for this mixed form of arrangement, and it is but reasonable to assume that the usual exhibition authority must for the time have been overruled by some higher power. Happily, at shows of this kind some sort of consecutive order prevails, otherwise to reporters, as well as to the public, all would be chaos.

Collections of fruits.—That no less than seven collections of twenty dishes and upwards were in competition for the premier class showed the heavy duty cast upon the judges—indeed, this class alone occupied an hour or more before the awards were made. Mr. Goodacre came eventually first with twenty-three dishes, consisting of capital Hamburgh and Alnwick, black, and Foster's and Muscat of Alexandria, white Grapes; good Queen Pines, Walburton Admirable and Bellegarde Peaches, Elruge Nectarines, Brown Turkey Figs, Apricots, Hero of Lockinge Melon, &c. No doubt here Grapes proved of material assistance. Mr. McIndoe followed, having also fine Grapes, including Gros Maroc, Trebbiano, and Duke of Buccleuch; C. Rothschild Pines; Scarlet Premier, Monarch, and Best of All Melons; good Peaches, Nectarines, &c., with some Citrons, Shaddocks, &c., making thirty-one dishes. Mr. Roberts was content with twenty dishes, including capital Grapes and other fruits, but a little weak in a Melon and one or two other dishes. Mr. Wildsmith had a very fine lot of outdoor fruits, but Grapes, though good, were in small bunches, having thirty-five dishes. Mr. H. W. Ward had twenty-five, Mr. Miller twenty, and Mr. Miles twenty-five dishes; all these collections contained much beautiful fruit. In collections of twelve dishes the competition was more limited, Mr. Roberts here being a good first with beautiful Muscat and Gros Maroc Grapes, C. Rothschild Pine, W. Tillery and Blenheim Orange Melons, Peaches, Williams' Bon Chrétien Pears, very fine, &c. Mr. McIndoe was again second, having fine Trebbiano and Black Hamburgh Grapes, Golden Eagle Peaches, Humboldt Nectarine, Melons, &c., all excellent. Mr. Miller was hardly less good with his exhibits. Then a class for eight dishes brought Mr. Pratt, of Longleat, to the front, his Muscat of Alexandria and Black Hamburgh Grapes proving strong, as did also his Peaches, Nectarines, &c. Other fresh exhibitors were found in Messrs. Pulman (Dorchester) and Oclee (Aylsham), who had good exhibits. Collections for fruiterers brought three of a very ordinary character from Brighton, the big sum of £24 being literally thrown away upon these collections, which were devoid of merit or interest. This sum divided amongst some of the other classes might have been productive of good.

Grapes.—These were in great force, no fewer than seven lots of twenty bunches being staged in one class. Generally there were no great bunches, but all were good and serviceable. Mr. Goodacre was fortunate in being again placed first, having capital Madresfield, Lady Downes, Alicante, Black Hamburgh, Alnwick Seedling, and Muscat Hamburgh, the latter wanting rather more colour—blacks; and of whites, Foster's Seedling, Muscat of Alexandria, Golden Queen, and Duke of Buccleuch, berries fine, but bunches small. Mr. Ward followed, having good Trebbiano, Foster's, and Muscat of Alexandria, whites, and excellent Alicante, Alnwick Seedling, and Gros Maroc, blacks. Mr. Wildsmith came next with a very beautiful lot, the bunches simply wanting more size, but otherwise admirably finished. The champion bunches of the show were found in the collection of five kinds, Mr. Taylor here beating his successor at Longleat, though only in point of freshness. The former had splendid Madresfield Court, Alicante, Gros Maroc, exceptionally fine; Alnwick Seedling, and Muscat of Alexandria. Mr. Pratt showed massive Muscat of Alexandria, hardly ripe; big clusters of Alicante and Black Hamburgh, Lady Downes and Mrs. Pince. Mr. Elphinstone was third with very good samples. Eight lots of three bunches of Black Hamburghs competed, the best, huge clusters, coming from Mr. Pratt; other very fine samples followed; whilst there were nine lots of Muscat of Alexandria, Mr. Pratt again being first with very fine bunches of that Grape; Mr. Roberts followed with smaller samples admirably finished. Some few of the bunches shown were either unripe or rough-looking. There was good competition with the fine-looking Grape Gros Maroc, Mr. Elphinstone having superb samples, those from Mr. Rivers and Mr. McIndoe being also first-rate. Six lots of Madresfield Court competed, the samples being fine, but generally wanting in finish. Alicantes were excellent, nine lots being staged, Mr. Howe, of Streatham Common, being in fine form with superb clusters, beating Mr. Pratt, who was also strong. With any other black kind Mr. Ward was a good first with capital Alnwick Seedling; the same kind took the next prize for Mr. Hudson, and Gros Colman followed for Mr. McIndoe. In the any other white class not less than ten lots were put up of very varying degrees of merit, rather small bunches of Mrs. Pearson taking the first place for Mr. Wallis, handsome Foster's Seedling coming second and third, the latter three weighing over 14 lbs. Duke of Buccleuch and Buckland Sweetwater were very fine in this class. Baskets of Grapes constituted a very unsatisfactory class, arrangements being so diverse, some exhibitors showing in baskets as packed for market or windows, others making mounds or heaps of their bunches. With blacks, rather moderate Hamburghs were placed first and second, whilst finely finished Alnwick Seedling from Mr. Hudson had to be content with a third place, flavour governing saleable appearance. Again, in the baskets of white kinds Muscat of Alexandria, having a formidable array of stems, beat Mr. McIndoe's splendid laterally laid-in Duke of Buccleuch. Something more clear should be defined as to what con-

stitutes a basket of Grapes, and for what particular object such classes are instituted.

Pine-apples were chiefly remarkable for the grand pair of Smooth Cayenne, each about 9½ lbs., from Mr. Ross, of Welford Park.

Peaches were in great force, Violette Hâtive, Stirling Castle, Golden Eagle, and Princess of Wales forming the best four dishes; Lady Palmerston, Royal George, and Barrington being also good in the second collection. Grand Prince of Wales were the best fruits in the single dish class, Late Admirable and Violette Hâtive following in order. There were 117 dishes in that class, and 169 Nectarines, very fine, Elruge coming first, Pine-apple second, and the same kind third. In the class for four dishes of Nectarines, Elruge, Pine-apple, Violette Hâtive, and Pitmaston Orange were the best, these kinds being chiefly shown. A class for six dishes of Peaches and the same of Nectarines seemed uncalled for, as only the same kinds were reproduced with no special merit in either case.

Plums.—Of these there were three classes of four dishes. Some dissatisfaction was caused by the fact that in each case the first prize was taken by a Brighton fruiterer, who has, of course, ample means of selection. The best four red Plums were Magnum Bonum, Prince of Wales, Victoria, and Cooper's Large, the second lot including both Frogmore and Denyer's Victoria, Goliath, and Pond's Seedling. The best yellow or green kinds were Egg, Golden Drop, Green Gage, and Washington, while Magnum Bonum and Jefferson were also good. Of purple Plums, Goliath, Black Diamond, Mitchelson's, Purple Gage, Kirke's, Prince Engleheart, and Belgian Purple were the best. In all these classes the competition was remarkably good.

Melons were in great force, some fifteen green fleshed and twenty-five scarlet fleshed being staged. In the latter, none were first-class; the best were Hero of Bath and Bloxholm Hall, whilst the best green fleshed were Golden Perfection and Hero of Lockinge, these two being first-rate in appearance and flavour.

Apples were very good, the best three ripe kinds being Red Astrachan, Hunt's Early, a local Kentish kind, and Red Quarrenden; Duchess of Oldenburg, Kerry Pippin, and Irish Peach were also good. The best kitchen kinds were Stone's Pippin, Peasgood's Nonsuch, Warner's King, Stirling Castle, Lord Suffield, Echlinville, and New Hawthornden. In Mr. Waterman's twelve dishes he had, of dessert kinds, Cardinal, very handsome; and Marshall's Seedling, also rich in colour and very striking.

Of Pears, the ripest three dishes were Williams' Bon Chrétien, Beurré d'Amanlis, and Windsor, the latter richly coloured, whilst in the larger class for ten kinds, capital samples came from Sittiogbourne of Louise Bonne, Brockworth Park, Windsor, Clapp's Favourite, Desiré Cornélis, Beurré de l'Assomption, &c.

Tomatoes were well shown, though some dishes needed sharp scrutiny to detect differences amongst them. The selected six for the first prize were Acme, Veitch's Criterion, Stamfordian, Trophy, Hathaway's Excelsior, and Reading Perfection. Other lots included Dedham Favourite, Green Gage, Hepper's Goliath, and Hackwood Park.

Miscellaneous collections of hardy fruits, chiefly Apples, came from Messrs. Paul and Sons, Waltham Cross, who had some two hundred dishes of good samples; also from Messrs. G. Bunyard, Maidstone, whose kinds showed great size, beautiful form, and, in the case of dessert kinds, rich colour; and from Messrs. Cheal and Sons, Crawley, who had a very fine and interesting collection. Messrs. Thomson and Sons, the Tweed Vineyard, showed a basket of fine Duke of Buccleuch Grapes; and from Sir Herbert Maxwell's gardens came a huge bunch of White Nice Grapes weighing 21½ lbs.

A full prize list is given in our advertising columns.

Calanthe Veitchi.—This plant forms quite a speciality at Elm Court, Mitcham. The excellent way in which it is grown there is worthy of remark. To our inquiry, how are these fine bulbs produced? the answer was, by means of cow manure given in a diluted state now and then when the plants are in active growth.

ROYAL HORTICULTURAL.

September 7 and 8.

This exhibition was, as far as the competitive classes were concerned, chiefly devoted to Grapes and Dahlias, both of which were shown in considerable quantities and of fine quality. The subjects before the floral committee were limited, the following being those selected for first-class certificates: Davallia retusa, a handsome spreading Fern, the pinnæ being pale green and elegantly cut; a very pleasing addition to the Fern family. Phryninm jucundum, a kind resembling a cluster of small Arums, the foliage spathe-shaped and alternately cream and green; a native of the Dutch Malay Islands. Both the above came from Messrs. Veitch. Vanda Dearei, a variety having somewhat inconspicuous yellowish-white flowers with deeper yellow lip, came from Baron Schröder. Cactus Dahlias Lady E. Dyke, bright yellow; Charming Bride, white ground flushed with rosy lilac; and Black Knight, deep maroon, from Messrs. Cannell. Dahlia Mrs. Bennett, a single-flowered kind, with an orange ground flushed and flaked with red, from Messrs. Cheal. Dahlia Colonist, as certificated at the Crystal Palace last week, from Messrs. Keynes. Dahlia Mrs. Theobald, a pleasing, rosy-coloured kind, very fine in form and good in substance, from Messrs. Rawlings.

Special votes of thanks were awarded to Messrs. Hooper and Co., Twickenham, for a fine specimen of Dasylirion glaucum, carrying a lofty spike of inflorescence; to Messrs. Laing and Mather, Kelso, for seedling Carnations; to Mr. R. Dean for cut blooms of seedling Pentstemons; to Mr. Heath for Orchids in variety; also to Messrs. F. Sander and Co. for a basket of the Galeandra Baueri, finely in bloom and admirably grown. The general exhibits consisted of the usual baskets of hardy flowers, including Liliums, Gaillardias, Helianthemums, with a varied selection of show, fancy, Cactus, Pompon, and single Dahlias, from Mr. T. S. Ware, Tottenham—a very striking display. A grand bank of Gladioli, consisting of spikes rich and beautiful in colour; Quilled Asters, Gaillardias, &c., came from Messrs. Kelway, Langport; a fine bank of cut Roses and hardy flowers in great variety from Messrs. Paul and Sons, Cheshunt; Liliums in great variety from the New Plant and Bulb Company, Colchester; a grand and very varied collection of hardy foliage trees and shrubs from Messrs. C. Lee and Sons, Hammersmith, boxes of the beautiful Cactus Dahlias Juarezi, Mrs. Hawkins, Cochineal, picta formosissima, and the white Constance and a big bank of Roses from Messrs. W. Paul and Sons, and a remarkable display by Messrs. H. Cannell and Son of Dahlias in great variety, and very effectively arranged.

Dahlias.—The first prize for twenty-four blooms, show or fancy kinds, fell to Mr. Turner, although the flowers sent by Messrs. Keynes, Williams and Co., and Mr. Walker, who were placed equal second, were excellent. These comprised kinds referred to in the report of the National Dahlia Show, and were very finely formed flowers.

Pompon Dahlias, by reason of their being set up in bunches, seemed to be unusually attractive; Mr. Turner was here a good first with richly coloured flowers, not too large and of fine quality. Of good form were Isabel and Gem, scarlets; Dora and White Aster, whites; Golden Gem and Catherine, yellows; and Favourite and Rosetta, crimsons. Several collections of twenty-four kinds were in competition. The singles were very attractive, Messrs. Cheal and Sons, of Crawley, coming out very strongly indeed with a grand lot of flowers, fine in form, rich in colour, and very admirably displayed. The four competing lots made a very effective bank. Very charming kinds were Negress, Amos Perry, Mrs. Bowman, H. Irving, Formosa, Paragon, Mrs. Bennett, Mary Anderson, Ellen Terry, and Rosalind. The flaked and edged forms now cropping up give increased interest to these single kinds, and also add much beauty to them. The floral part of the exhibition was deeply indebted to Dahlias, and especially to the Cactus and single kinds. It is worthy of remark, however, that the best coloured forms of the Pompon section, because of their durability, are the most popular amongst growers of flowers for market.

Asters were shown in capital condition, Mr. Walker, of Thame, having the best twenty-four quilled flowers, very pure in colour and very perfect; whilst the twenty-four Victorias staged by Mr. Jones were equally so, quite putting into the shade, in the estimation of the judges, the very beautiful and exceedingly rich coloured Pæony-flowered forms from Mr. Walker, which richly deserved notice. Hollyhock blooms were first-rate, the best, quite perfect flowers, coming from Saffron Walden. Stove and greenhouse flowers in bunches were remarkably fine, but far too crowded in the boxes. Canon Bridges had some forty to fifty kinds, which suffered from excess of labelling. Mr. James, of Norwood, put up a fine lot, associated with small Maiden-hair Ferns, with capital effect. These things always need ample space to show them to advantage. Amongst other miscellaneous exhibits was a fine display of Vines, Pears, Apples, and other fruit trees in pots from Mr. Rivers; a grand group of Begonias from Mr. Laing, Forest Hill; Liliums in pots from Mr. Gordon, of Twickenham; Roses in baskets from Messrs. Paul and Sons; and other interesting exhibits. There were also early Chrysanthemums and Gladioli, all fairly good.

Fruit.—It was but natural that great interest should centre in the Grape classes, for Grapes constitute the premier products of the indoor garden, and seem in a large degree to give the measure of a gardener's capacity. Generally, the exhibits in the various classes were good, some exceptionally so, but some were inferior. The prizes were not large enough for a two days' show, but still they attracted good competition. The schedule was arranged in alphabetical order, Alicantes coming first, two bunches in each case being shown. Five pairs were staged, and all capital samples, Mr. Taylor's being exceptionally fine, tapering, and handsome, and superbly finished. Others from Uttoxeter and Streatham Common were of less regular form, but still very fine samples. Eight lots of Alnwick Seedling were put up, the Bath grower being again to the front with grand bunches and berries large and well finished. Those from Cheadle were good, but smaller, and those from Elvaston somewhat triangular in shape. Black Hamburghs made a poor class, six lots being put up, the best being smallish, but fair bunches, Messrs. Roberts and Hudson, both of Gunnersbury, being first and second. Some large bunches showed shanking or much rubbed berries. Only two lots of Black Prince were staged. The best pair of bunches from Mr. Goldsmith were exceptionally good. The small competition shows that this Grape is now but little grown. Probably the berries are considered too small in these days of Dukes, Colmars, and similar large-berried kinds. Five pairs of Buckland Sweetwater competed, the best, really good samples, well coloured and clean, coming from Oakley Court, Windsor, where Mr. Lockie grows Grapes so admirably. Smaller bunches, still fairly good, took the second place for Mr. Roberts; and others a little past, from Mr. Ward, came third. Duke of Buccleuch was represented by four lots, those from Gunton Park showing an unusual amber tint on the berries, but the bunches were excellent. Colour in this Grape is so seldom seen, that Mr. Allan's success in securing some bright tints on his berries deserves special mention. Foster's Seedling came next in order, and was a fairly strong class, Mr. Roberts having handsome bunches of it and of good size and with richly-coloured berries. The second lot, from Mr. Miles, were good, but hardly ready; and those from Mr. Ward just a little past. Only three pairs of Gros Colmar were put up, the largest coming from Shipley Hall, but rather rubbed. The second lot was smaller in bunch, but better preserved. Gros Guillaume was not good, the big bunches from Mr. Ward wanting colour. Other bunches were smaller, but better finished. In the class for Gros Maroc some trouble was given to the judges, arising from the remarkable similarity between the finest bunches and Gros Colmar, the berries lacking that deep black tint which characterises Gros Maroc when ripe. Eventually the exhibitor got the benefit of the doubt; this was Mr. Taylor, whose bunches were unusually fine and the berries very round, but still wanting colour. Very beautiful samples, though in smaller bunches, came from Messrs. Wallis and Elphinstone. A very strong class was Lady Downes, nine pairs of bunches being put up, the best coming from Mr. Baker, of

Ottershaw, who is a capital Grape grower. With few exceptions the exhibits were exceedingly good and well finished. Six lots of Madresfield Court were shown, some indifferent, others very good. The best and largest bunches came from Bath, berries large and finely finished. Some smaller, but superbly finished, bunches from Gunnersbury Park were here, oddly enough, left out, larger bunches of inferior quality coming in before them. This same error in judging was noticed in the class for Mrs. Pearson, only four pairs being put up; the biggest, from Ottershaw, being far from ripe and ungainly. The second lot, from Gunnersbury, were far more worthy of a prize, being capitally finished samples. Five lots of Mrs. Pince competed, fair samples coming from Longleat, Mr. Pratt so far not having been successful in other classes. Other fair samples came from Rood Ashton and Heytesbury Park. The same number of pairs of Muscat Hamburgh were staged, the best, both in size and colour, coming from Elvaston. Others were irregular in form and rather red. A strong class was Muscat of Alexandria, nine lots being presented. Here Mr. Pratt was in good form with superb bunches and very fine berries. Those following from Mr. Gray and Mr. Roberts were, if smaller, admirably coloured. Only two lots of White Tokay were shown, but better results were seen in the final class for any other variety, there being put up two Golden Queen, three Trebbiano, Chatsworth Seedling, a Hamburgh-looking Grape, and Cooper's Black, bearing a close resemblance to Gros Maroc, and yet believed to be distinct. Golden Queen, having richly-coloured berries, came first; Cooper's Black, second; and Trebbiano, third.

Special prizes.—Messrs. Carter and Co. offered prizes for Tomatoes in single dishes, very handsome samples of their Perfection being shown by Messrs. Beckett, of Penn, and Waite, of Esher; only five dishes were presented. For Messrs. Sutton and Son's prizes for single dishes, to include twelve fruits, grand samples of their Perfection from Mr. Waite only failed to take first place because one of the fruits was a little past, and Mr. Lockie came first with Main Crop, which here resembled Trophy, Mr. Beckett came third with smaller fruit of Perfection; nine dishes were staged. Some remarkable Carrots of this firm's Early Gem, a huge form of the Nantes, were presented; the finest, really wonderful samples, coming from Mr. Richards, of Somerley Park; the next best being from Shrivenham Park, and Mr. Fye, of Newbury, which, if smaller, were not less clean and handsome.

The fruit committee had before it a quantity of dried and preserved fruits from the commissioners of Western Australia, chiefly Raisins, Pears, and Olives, all capital samples, which were highly commended. Four handsome Melons came from Mr. Hudson, which were not cut, and four seedlings from Mr. Lockie, two of which were tasted, but failed to obtain mention. Mr. Miles showed a beautiful dish of President Strawberry, rich in colour. A big lot of Sutton's Imperial Green-flesh Melon came from Farnham. Messrs. W. Paul and Sons showed some 100 dishes of Apples, mostly excellent samples. Messrs. Veitch and Sons had about sixty dishes of Apples and Pears, mostly fine kinds, well represented. Messrs. Lane and Sons, Berkhampstead, had six of their huge pot Vines finely fruited, and a large collection of some twenty-six kinds of Plums. Messrs. Cheal and Sons put up an excellent collection of Apples, Pears, Plums, &c. Messrs. Roupell sent some pot Vines, not specially good, and dishes of Grapes, the best being Madresfield Court. Messrs. Vilmorin-Andrieux and Co., Paris, sent a collection of some twenty kinds of Haricot Beans, the pods being nearly ripe, and purple, red, white, and green in colour. Mr. Goldsmith sent from Beckenham some eighteen diverse Melons, all good fruits; and from Messrs. Veitch and Sons was shown a collection of Carrots of their own growth under twenty-four names. Matchless and the New Intermediate were good types of their kind; Nantes and Scarlet Model, apparently alike; Altringham and Long Surrey were the best long kinds; French Forcing the best short form; and White Vosges and White Olthe the best light coloured varieties.

At a meeting of the fruit and vegetable committee, held at Chiswick on September 8, present, Mr. John E. Lane in the chair; Messrs. Woodbridge, Norman, Smith, Saltmarsh, Paul, Burnett, Silverlock, and Miles, the collection of Potatoes growing in the garden was examined, and, on being cooked, first-class certificates were awarded to the following varieties: Fyvie Flower (R. Farquhar, Aberdeen), white kidney, rough skin, yellow flesh, medium size; heavy cropper. Seedling A I (A. Harris, Woburn, Beds), large white kidney, smooth skin, white flesh; good cropper. Bouncer (T. Laxton, Bedford), white round, smooth skin, white flesh, very handsome; moderate cropper. Maggie (J. Murdoch, Rothiemay, N.B.), large white round, smooth skin, white flesh, deep eye; very heavy cropper.

A full prize list is given in our advertising columns.

NATIONAL CHRYSANTHEMUM SOCIETY'S SHOW.

This exhibition, held at the Royal Aquarium on September 9 and 10, taken all in all, was a very good one. It was, however, a trifle too early for Chrysanthemums in pots, but, judging from some of the cut flowers shown, it seems difficult to define what is early and what not. Groups from amateurs were well represented, but they wanted quite another fortnight to develop their beauties. In some of the groups, however, Madame Desgrange was excellent, thus showing what a beautiful and useful variety it is, especially where white flowers are required in quantity. The nurserymen's class was not represented as far as groups for competition were concerned, but Mr. James, of Norwood, staged one, composed chiefly of Madame Desgrange.

Cut Chrysanthemums were very good. In the premier stand the following blooms were well shown, viz.: M. Lacroix, Isidore Féral, Orpheus, Madame Levin, M. Astorg, and Ile des Plaisirs. Dahlias, both double and single, were numerous and good. The singles were set up with their own foliage in some cases, a more effective plan than associating them with sprays of Asparagus, as is sometimes done. Of Gladioli, a very fine display of cut spikes was made by Messrs. Kelway. Begonias of the tuberous section were shown by Messrs. Laing, of Forest Hill, and Mr. Owen, of Maidenhead; the former exhibitor's plants were evidently just lifted from the open ground. Zinnias from Mr. Cannell were grand in colour, variety, and shape, as were also his Dahlias of different sections, not staged for competition. Hollyhock blooms were staged by Mr. Blundell, of Dulwich.

GARDEN IN THE HOUSE.

LEAVES FOR GARNISHING DESSERT.

Those who grow stove or greenhouse plants in quantity—and especially climbers—or force early fruit and flowers, will hardly ever be scarce of choice leaves for the garnishing of their desserts. And yet it is by no means every pretty or fine leaf that is suitable for this purpose. For instance, all Pelargoniums must be set aside, from their excess of perfume. There are other beautiful leaves, again, that are too thin to go creditably through a dinner without shrivelling up into useless incumbrances of the dessert. Such is to a great extent the case with Abutilons of all varieties—very fresh and beautiful, but fragile. The leaves of the variegated and the common form of Cobæa scandens have the same failing. Again, there are some of the Passion-flowers that give out a disagreeable odour, and some of them, like P. quadrangularis, are too large; and kermesina, in a young state, is almost too tender. Still, this noble family is rich in leaves for garnishing. P. alata, edulis, and racemosa being among the very best species, are also rich in beautiful leaves; but some are fragile, and those that are suitable have more or less scent. Camellia leaves are models of smooth, glossy beauty, but no one cares to gather them for fruit garnishing; while those of Oranges, Lemons, &c., are too highly perfumed. Stephanotises are too leathery, were one inclined to pick them off. The early forcer of fruit and flowers can seldom, however, be at a loss for choice foliage for garnishing desserts. Even common leaves out of season acquire an uncommon beauty. Of course those who have Vine leaves need no other; nothing can supersede nor equal them. They are the best of all, from the time the tender picking will barely pass through the dinner till the winter leaves of many colours crumple into a handful of dust in our fingers. Early Fig leaves are also admirable. Later in the season they seem too rough and common for choice fruit; but the early leaves have a soft freshness that is most pleasing. Even early Peach, Plum, Pear, Apple, and Cherry leaves are admirable; while the leaves of forced Roses have a cleanly beauty that is seldom seen on those out of doors. The Lily of the Valley leaf, with a flower or two here and there, gives one of the choicest, sweetest finishes to a dessert, without flavouring the fruit. A fine Czar Violet and leaves of the common Primrose are by no means to be despised. The most useful of all plants for cutting, the Astilbe japonica, yields a harvest of exquisite leaves for the adorning of the dessert. Again, forced Lilacs, especially all the varieties of the Persian, are invaluable. Doubtless a considerable proportion of the charm arises from the fact of the leaves being out of season; but they are likewise more beautiful, that is, more fresh and green, when produced under the shelter of glass. It is astonishing how much variety of garniture adds to the interest and beauty of the dessert. And this reminds me of another set of leaves which I have not named, that are amongst the most useful and beautiful of all—those of the Strawberry. This fruit never looks so well as when nestling upon its own leaves; and doubtless desserts generally would be far more interesting and beautiful than they are if, as far as practicable, early fruits were adorned with leaves or branchlets belonging to them. B.

Maiden-hair Ferns in rooms.—The general impression prevails that these somewhat delicate Ferns are not suitable for rooms. For many years I have kept them in my drawing-room, not only without damage to their appearance, but also greatly to their advantage. My Ferns are always bushy and of the brightest green, and seldom without a few young fronds just piercing the soil to replace those that are failing. I find that they give far less trouble than any other pot plants indoors, except, perhaps, Begonias. My method of culture is very simple. I repot them once a year in January, using pure peat mould; I water every two or three days liberally with lukewarm rain water, if I can get it, and I do not stop until it comes through into the large deep saucer in which the plants always stand. It is not necessary to keep them always standing in water; probably the saucer may become dry the next day, but much will depend on the heat of the room. Mine has a large fire on most days in winter, but my Ferns have had to endure occasional trials of perhaps two or three frosty days together without a fire, and have not been hurt. In summer we have constant thorough draughts also, without any harm arising to the plants.—Q.

Nicotiana affinis.—This plant fails to arrest attention in the daytime, but in the gloaming it is a veritable gem, being both fragrant and beautiful.

Ornithogalum aureum.—We have received from Mr. Kingsmill two flowers of this plant which differ greatly in colour; one is orange, the other canary-yellow; both are, however, equally handsome.

Single Dahlia.—From Mr. Hartland, of Cork, come examples of a very floriferous Dahlia called Pantaloon. It is in the way of Paragon, but differs from it greatly in colour, no two flowers being exactly alike in that respect.

Names of plants.—*E. H. B.*—1, Hibiscus syriacus, rose coloured var.; 2, Clematis Flammula; 3, Leycesteria formosa; 4, Polygonum cuspidatum.——*E. S. A.*—A good form of a light variety of Cattleya Gaskelliana.——*D. D.*—Mesospinidium vulcanicum.——*J. Harris.*—Anemone Pulsatilla (true).——*W. T. A.*—Bolbophyllum cupreum; a good example of this species, apparently well grown.——*B.*—1, Rudbeckia conica; 2, Spiræa callosa alba.——*Mrs. Young.*—Lasiandra Fontanesiana.——*J. T. S., Alnwick.*—Bupleurum rotundifolium.——*F. Habgood (Faringdon, Berks).*—Valeriana officinalis; poor specimen.——*J. S. (Jersey).*—1 and 3, send better specimens, and say country, if possible; 2 is Indigofera Gerardiana.——*F. G. H.*—A species of Buddleia in fruit.——*M. S.*—1, Prince's Feather; 2, Centaurea candidissima; 3, Arundo Phragmites; 4, Agathæa cœlestis.

Names of fruits.—*C. H.*—Plums: 1, Victoria; 2, Jefferson; 3, Washington.

WOODS & FORESTS.

THE PINE SAWFLY.

(LOPHYRUS PINI.)

Among all the insects which are injurious to vegetation, the sawflies must be included with those which commit the greatest amount of damage. As is generally the case, the perfect insects are harmless, but their caterpillars or grubs are very destructive. The grubs of the Pine sawfly are no exception to this rule, as they are very voracious, and soon strip any tree of its leaves which they may attack, and at times they even gnaw the young shoots. Kollar states that a full-grown grub will devour twelve healthy leaves in a day; and as a sawfly lays about a hundred eggs, it is easy to see that when this insect is abundant, Fir trees may suffer very much from their presence, which will be all the more annoying if they attack specimen plants on lawns and in pleasure grounds. On the Continent the Pine sawfly does an immense amount of mischief at times in the Pine forests.

In the case of forests or large trees, it is almost impossible to do anything effectual in reducing their numbers. When smaller trees are attacked many of the grubs may be destroyed by shaking the trees or their boughs, and crushing on the ground all that fall; or if the tree be not too large, they may be picked off by hand, or it may be well wetted by a garden engine or syringed with the following mixture: One wineglassful of paraffin oil to twice that quantity of soft soap, well mixed together and dissolved in three gallons of water. The cocoons or chrysalis cases should be gathered from the branches whenever they can be found. Any of the sawflies which can be caught should be killed. They are not usually rapid in their movements compared with other winged insects, and it would be well worth while if any trees had been attacked to look them well over next spring, in April or May, and catch the insects that may be found in a small butterfly net. If the trees be shaken some may fly out which were not visible before. This insect may be recognised by its generally dark appearance and its wide, flattish body.

The natural enemies of this insect fortunately serve in a great measure to keep its numbers in check. Several insectivorous birds feed on the grubs, squirrels eat a great number of the chrysalides, and various kinds of ichneumons destroy the eggs, grubs, and chrysalides. Many of the chrysalides which are formed near the foot of the trees fall a prey to field mice. Bad weather has a most unfavourable effect on these insects when the caterpillars are young or changing their skins. Wet or cold weather will kill thousands of them, and must also have a very detrimental effect on the flies if it occurs just as they are leaving the cocoons. The female sawfly is furnished at the extremity of its body with a saw-like organ, with which it is able to make slits in the leaves. This organ in bees, wasps, and their near allies takes the form of a sting, and in other families more nearly allied to the sawfly of an instrument capable of boring holes in timber, or of a long tube composed of three longitudinal pieces through which the eggs are laid.

The saw of the sawfly is composed of two flat-toothed plates, which the insect works with an alternate motion; when an incision down the leaf is made the eggs are passed between the saws into the slit prepared for them. In about a fortnight or three weeks the eggs are hatched, and the grubs, which are then very small, increase rapidly in size and soon destroy the leaves they are on, leaving nothing but the midribs remaining. They are nearly always found in large numbers together; when food fails they at once move to another part of the tree. When a grub is disturbed it immediately raises its head and ejects a drop of resinous fluid from its mouth; and it is stated by Kirby and Spence in their well-known work on entomology that if one grub acts in this manner, all the others which are near it do the same, thus, as it were, firing a volley, the scent from which would probably disconcert any of its insect enemies. In about two months, having changed their skins several times, they attain their full size; they then form cocoons round themselves, within which they assume the chrysalis state. These cocoons are formed among the foliage on the stems, or sometimes among Moss, &c., at the foot of the trees.

The insects remain in this condition until the following spring, when, in April or May, according to the weather, the perfect insects make their appearance. The male and female Pine sawflies differ somewhat in general appearance; the male is considerably smaller than the female; it is about three-tenths of an inch long, and measures six-tenths of an inch across the wings when they are fully extended. The female is four-tenths of an inch long, and measures eight-tenths across the wings. The antennæ of the male are doubly pectinated (deeply toothed like a comb on both sides), while those of the female are merely serrated (toothed like a saw). The male is black, with the exception of the lower part of the legs and feet, which are yellowish. The head of the female is nearly black, and the antennæ, except the three basal joints, which are yellowish, are brown; the thorax is brownish-black, with the front angles brownish-yellow; the body is very broad, of a dull yellow colour, with a dark brown patch in the middle covering nearly the whole of the third, fourth, and fifth joints, and part of the sixth and seventh; the legs are yellowish. The wings in both sexes are large, iridescent, and much veined; on the front margin of the upper pair is a dark spot. The full-grown caterpillar is about an inch long, and of a greenish-yellow colour, with a black spot on either side of each joint over each foot. Each joint bears a pair of feet except the fourth. The cocoon is oval, nearly half an inch long, of a hard papery substance, and of a brownish colour. G. S. S.

HOME-GROWN WOOD FOR SLEEPERS.

One of the latest substitutes for wood railway sleepers seems to be the steel sleepers. It is true that even were the metal sleepers largely used it would not affect the English grower so much as it would the foreigner; still, there is an appreciable quantity of home-grown wood consumed for sleepers in one form and another. In the most popular sense the term sleeper is used for the framework upon which the rails for rail and tramways are laid, but there are many other purposes for which sleepers are required, notably in house building. As is well enough known, the principal railways have, for their permanent ways, hitherto used sleepers manufactured from foreign woods, but during the process of construction of a new line it is a very usual thing to see home-grown wood in use. Providing the supply was plentiful and at a low enough cost, there is no doubt that Larch would be the wood used, but as it has a higher value for other uses, Scotch or Spruce is made to do duty. A new line of rail is occasionally in this way a good thing for the owner of Scotch or Spruce plantations in the neighbourhood. From the nature of their use this class of sleepers does not suffer so much from natural decay as from continual wear and tear and knocking to pieces. There is very little expended upon them in manufacturing, and from the lowness of the value of the wood in its raw state, the whole cost is low; therefore, there does not seem to be any immediate fear of this kind of temporary sleeper being displaced by a new competitor. Much, of course, depends upon the district where the work is going on, as transit is really everything.

For permanent sleepers on tramways connected with the various rail systems there is a considerable bulk of wood used yearly. This, unless near ports where foreign wood can be more easily obtained, mostly consists of home-grown wood. Being of a permanent nature, the Scotch and Spruce are not well adapted for use in these positions, but Larch is generally sought after. Failing this, Elm is substituted for it. On the face of it, it would appear that the variation in price between the Elm and the Larch would not be much, but in practice the Elm is obtainable at a much lower figure. The reason probably is, that the bulk of Larch timber only grows to a small size, and consequently the boles of the trees—the best of the wood—have to be cut up. In the case of the Elm, these small sleepers can be sawn from the larger branches after the tree itself has been turned to better account. The length and sizes will, of course, vary according to what they are required for, but for the narrow lines of tramway from stone works and the like, from 4 feet to 5 feet in length, and about 6 inches by 3 inches, are the usual sizes; so it will be seen that very large wood is not necessarily required.

Reference has been made to sleepers for use in house building; these are in most cases cut from Oak, and are of an altogether different and more expensive character. They are virtually joists, but the term sleeper is adopted for the sake of distinction, as they are always used upon the ground or upon a course of brickwork, raising them a few inches. In this situation it is obvious that the most lasting material is wanted, and such as will withstand damp. Scantlings sawn from heart of Oak answer to these requirements better than any other wood. There is one old manor house I know where, instead of horizontal sleepers, the joists were laid upon sections of small Oak trees, merely sawn off to the necessary length and placed upon end. In this way the floor was raised to a good distance above the ground level, and consequently kept dry. The vertical sections of Oak also seemed to have answered their purpose, as when the floor was taken up a few years ago for repairs or for relaying—I forget which—they were in good preservation, and previous to this it was not known that the floor was not laid upon sleepers in the ordinary way. Sleepers are, of course, used in other positions in buildings than for the floors of dwelling-houses. For barns and floors of sheds of various kinds they are wanted, but they require less preparation. According to the nature of the work they may either be partly sawn or entirely hewn, but when coming in direct contact with the soil should always, if possible, be of Oak. D. J. Y.

The Mountain Pine as undercover.—I fear some of the statements in Mr. Gilchrist's essay, published in last week's *Woods and Forests*, are suppositionary. Pinus montana, he says, is "admirably suited for undercover," and I take the liberty to say that the essayist probably never saw a single example proving what he says. I would like to see it thriving permanently among Scotch Firs that have "lost their own bottom branches" through crowding, as the essayist suggests. The idea is preposterous. A native of exposed mountain tops is as unlikely a subject for underwood in this country as anything could well be. In fact, few or none of the Fir or Pine tribe make good underwood, and by underwood I mean trees or bushes that grow under the shade of other trees. Trees to fill up open spaces in woods are another thing. Firs will do very well in such sheltered spots if their tops have light, but not as underwood.—Yorkshireman.

Measuring trees.—A contributor sends to an American paper the following rule for measuring trees, which he says he has tested to his satisfaction: A stick of timber is desired, say 50 feet long; select your tree, measure 50 feet in a direct line from the foot of the tree, on as near level ground as possible; now cut a stick the exact height of the observer, and stick it in the ground exactly perpendicular; now let the observer lie flat on his back, his feet against the stick and head in the line of the tree and stick, and look directly over the top of the stick, and where the line of vision strikes the tree will be the length of stick, 50 feet, desired. If the ground is not level, the measure will not be exact, but allowance must be made.

A good fence.—A post and rail fence, cheap and strong enough to keep out horses and cattle, may be made as follows: Set the posts 9 feet apart, or 2 feet less than the length of the rails used. Bore 1¼-inch holes through the posts 1 foot from the ground, and at right angles with the direction of the fence. Bore three holes above this, about 9 inches

apart, one above the other, and drive in wooden pins in all four holes to project 4 inches on each side of the post. Lay the rails on these pins, close to the post on each side. Bore a 3-8ths hole above the top rail, and another one 1½ inches below the bottom pin. Take a piece of wire 10 feet or 11 feet long, and pass half its length through the top hole, and cross it under the top rail; cross it again under the second rail from the top; cross it again under the third rail, and finally cross it under the bottom rail by slipping the ends of the wire through the small hole, and bring them around in front of the post and twist them together. If sheep are kept, a board should be nailed at the bottom, or a fifth rail added.—A. A.

ONTARIO FORESTRY REPORT.

During the past year, an arbour day for the schools of Ontario has been made the occasion for planting over 30,000 trees, the planting being accompanied by addresses on forestry to the scholars, practical lessons being thus learned that will be likely to render effective service in future. The work of the Forestry Board has been aided by the distribution of eight thousand copies of reports, and seven hundred articles on the subject have been inserted in Ontario newspapers, for which nearly two hundred journals have lent their assistance. An important movement has been made by the Government for preserving the Pine forests, in offering to lumbermen to pay half the expense of a staff detailed during summer to prevent forest fires, and to enforce the provisions of the Fire Act, and over forty persons have been thus employed during the dangerous months of summer. The value of timber screens is shown in a statement of Mr. Phipps, in an account of his journey through Illinois, where the Osage hedges had been allowed to grow up to trees along the exposed sides of orchards, none of the trees in which were lost; while many valuable ones were destroyed by the cold and sweeping winds where this precaution was not taken. A more distinct evidence of the value of timber shelter is given in notes from Massachusetts. In the old colony region much of the land had remained idle and barren, the home of a few wandering sheep, in great ranges of wind-swept hills. Twenty-five years since, a gentleman, Mr. Fay, planted Pines largely, and still more largely sowed their seed broadcast. Others followed his example, and groves sprung up in all directions. There are now more than 10,000 acres of Pine plantations in this vicinity, many of them containing trees 40 feet high. This planting has greatly sheltered and improved the country. The Pine plantations on the hills hold the moisture of rains, and the former floods have ceased. Some of the plantations are in blocks of over a hundred acres. The opinion is quoted from high authority, that "a country cleared of three-fourths, and one-fourth remaining in wood, will grow more in cultivated crops than one wholly cleared." This statement is doubtless true of all regions of country where the winds have a free sweep over its surface.

The report furnishes some information on the success of planting black Walnuts. In Douglas County, Ill., is a grove of between 2000 and 3000 large Walnut trees, raised from the nut thirty years ago, and now 80 feet high, and some of them 1½ feet through. This grove, with its tall, pillar-like stems, is a picturesque object seen far across the prairies, and affords one of the best proofs of the success of black Walnut culture. The nuts were first planted with corn and cultivated with the crops for the first four or five years, and after eight years the shade excluded other crops. They were at first 10 feet apart, and gradually thinned till 20 feet asunder. After twenty years the ground was covered with short, wild Grass. The value of the Walnut, when large enough for broad boards, was strongly expressed to Mr. Phipps by a farmer in Indiana, who said he had almost cleared his farm of a natural Walnut forest, mostly large trees, 3 feet or 4 feet through. "If I now had them," he remarked, "they would be worth £200,000; instead, I have a farm without them worth about £1000." It is asserted in the report that for rapid growth the wild Cherry is greatly superior to the Walnut, and will give in thirty years as large a tree as the Walnut in sixty.

The deficiency of natural timber in Kansas has induced the railway board there to give particular attention to tree-planting, and has established in Kansas the largest artificial plantation of forest trees in North America. They first had a square mile planted with young trees of the Catalpa and Ailantus, and afterwards as much more. These are near the town of Farlington. Carriage roads pass through the dense plantations at intervals. The two portions were planted two and four years ago, mostly with Catalpa, a portion with Ailantus, and some with white Ash. The first planted are about 25 feet high. The whole number is about 3,000,000 trees. They are first set 4 feet apart to shade the ground, and they are subsequently thinned. Those only who have seen the original forest, with trees growing hap-hazard (we quote from the report), little and big, have but a very vague idea of the large amount of wood these closely-planted groves can spare in their process of growth. In the different States there are not less than 60,000,000 railway ties used yearly, which means the annual destruction of 30,000,000 young trees.

This report is largely occupied with interesting and valuable information on the interests and progress of forestry in the different States, much of it from personal observation, and nearly half is a full descriptive list of the trees of Ontario. The *Country Gentleman* speaks of it as one of the best reports on the general subject and on its various and numerous details, and furnishes a large amount of practical information for the growth of artificial forests.

TREE PLANTING ABROAD.

What may be accomplished (says the *Australasian*) by a single community in the way of tree planting, and of transforming the physical aspects of a particular locality in an arid district, has been remarkably exemplified at Jamestown, in South Australia. Five years ago the corporation commenced the plantation of a previously treeless region with timber. Up to that date the place must have been as undesirable a town to live in as could be found in the bare plains upon which it had been established. In summer there was nothing to mitigate the blinding glare of the sun, or the intolerable radiation of the heat from the fissured surface of the hard-baked earth. The hot winds swept across a wide expanse of scorching country, bringing with them clouds of all-penetrating dust. In the winter there were no natural means of breaking the force or diminishing the inclemency of the gales which came howling down from the north. But the corporation has changed all that. "It has planted over 20,500 trees of various kinds, and the once glaring and dusty streets are protected, shaded, and ornamented with several beautiful varieties of Gums, now in flower, and standing 25 feet to 30 feet high—and this after having been twice lopped during the five years since they were first planted. But Gums are not the only trees, for they are relieved by hundreds of Pines, Catalpas, Tamarix, Ficus, Willows, Cypress, Olive (doing splendidly), Acacia lophantha, and a lot of others." Private enterprise has supplemented municipal effort, and some of the leading people of Jamestown have planted trees in such numbers on their own properties, that at the present time "the town appears, from the distant heights, to be buried within a forest." Not only so, but the once bare ranges in the vicinity of the place have been clothed with young forests for a distance of 8 miles; and the experience of other countries justifies us in hoping that, as soon as these have attained a certain stage of growth, they will exercise a marked and beneficial influence on the climate and rainfall of the district. About 70,000 trees have been obtained from the Forest Board of South Australia, and the 30 acres planted by the corporation of Jamestown do not cost it more than £70 per annum to maintain in good order. Probably the time will come when, by a judicious system of yearly felling and replanting, the timber in the reserves and parks may become a source of revenue. In the meanwhile, what are the results of this admirable proceeding? According to a seven-years' resident in the town, the character of the place has entirely changed. It has ceased to be "a mud-hole in winter, and a dust-heap in summer;" and there is a marked decline in the prevalence of ophthalmia and sand-blight, both of which had not unnaturally become endemic. It has also been found practicable to introduce modes of culture which were previously out of the question. Sheltered and screened by the rapidly-growing belts of indigenous timber which have been planted in the district, orchards have been formed, vineyards and gardens laid out, and fruit trees are thriving in localities where all former attempts to establish them resulted in failure, because, as our informant writes, "the cutting winds of summer and winter, sweeping over the unsheltered and treeless plains, would not allow of the trees growing."

PLANTING FOREST TREES.

The tools required for raising and planting forest trees are simple, but they should be handy in size and of the best materials. The following will be found useful: A small three-pronged fork, light enough to be used with one hand, for lifting seedlings; a larger fork for trenching alongside the rows and opening out the plants; a light handy spade for notching and refilling the holes with soil; a dibble or planting iron for opening up the ground which has already been notched for the reception of the plants; a pick and mattock, which may be combined in one implement, for use in stony or upon very hard ground.

In notch planting with small subjects, and upon very thin and light soils, a marker precedes the planter, and with a cross-cut of his spade indicates the position of the tree. The planter afterwards drives his iron into the ground at one extremity of an arm of the cross-cut, presses down the handle, and thus opens the slit at the centre, into which the carrier pushes a plant, and the ground is afterwards closed by the foot. In this way from 1200 to 1500 small trees may be planted in a day by an active man and a boy.

Wherever large plants are pitted in prepared holes, care should be taken to put them very little, if any, deeper than they stood in the lines of the nursery; and while the soil is being filled in, the holder should by a slight vertical motion of the plant settle the soil well under the roots and scatter these regularly throughout the soil. Where the soil is light and dry some treading may be necessary to steady the tree in its new quarters; but wet soils are best untrodden at the time of planting, though they may be subsequently rammed down and consolidated in dry weather.

B.

Moving trees.—Some have an idea that a tree cannot be moved successfully without a large ball of earth attached to it, but where there is not machinery sufficient for that purpose, failure in that case is often the result. My system is to begin at some distance from the base of the tree, rather further, in fact, than is usually practised, and to comb the soil away from the roots, injuring them as little as possible. If a tree be gone properly round in this way and the roots saved, one is often more certain of success than when trees are transplanted with large balls; such, at least, is my experience.—D. S. G.

Thick planting.—In crowded plantations there is a marked difference between the trees on the outside and those in the centre; the former, having their branches and leaves fully exposed on one side, grow with comparative vigour, and form excellent timber on that side of the stem where light and air are admitted; while the latter, hemmed in on all sides, are drawn up like bare poles, and produce a small amount of ill-conditioned wood. A crowded plantation, in which the trees are allowed to increase in size until they interfere with each other, cannot be easily reclaimed; for every attempt at thinning in this advanced stage of growth is accompanied with the risk of exposure to the blast, which speedily levels trees having no firm hold of the soil.—Scot.

No. 774. SATURDAY, Sept. 18, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

BASKET FERNS.

THERE are numerous species and varieties of Ferns that naturally grow upon trees and in the crevices of rocks, and that do not conform kindly to ordinary pot culture; indeed, many species can only display their beauties to perfection when placed in elevated positions. Such positions are plentiful enough in ferneries built with stone or similar material made to represent, more or less, natural rocks. But in ordinary plant houses these points of vantage occur less frequently, and, therefore, the next expedient is to plant in baskets and suspend them from the roof. Basket Ferns need not be confined exclusively to glass houses; on the contrary, there are numerous kinds which flourish admirably when suspended in the windows of dwelling-houses, or even in the open air, if shaded situations are selected for them. Ferns in baskets need more care in order to produce handsome specimens than is necessary under ordinary pot culture, inasmuch as the roots are more liable to suffer from drought, and if their wants in the way of moisture are not properly met, the fronds speedily shrivel, and, except in the case of those of leathery texture, never recover so as to be perfectly satisfactory. The best baskets for Ferns are those in which the wirework is tolerably close, as in that case the soil does not get washed away so readily as it would be in the case of baskets in which the wires are further apart. A thick layer of living Sphagnum Moss should be placed on the bottom and round the sides, and upon this may be laid the soil. The Sphagnum, from its tendency to hold water longer without rotting than any other kind of Moss, not only prevents the soil from falling through the meshes of the wire, but maintains a more uniform degree of moisture about the roots than could be obtained by the use of any other kind of material. Rough fibrous peat, turfy loam, leaf-mould, chopped Sphagnum Moss, and a small portion of sharp sand form a good compost for basket Ferns. To these ingredients may also be added some nodules of charcoal, which tend to keep the soil open and porous, and do not add materially to the weight of the basket when hung up. In basketing Ferns of a robust habit of growth, a much larger proportion of loam is necessary for their maintenance than is needed in the case of more delicate kinds, but all of them require copious supplies of water, which, until the fronds become too large, may be given them by immersing the basket in a tub or tank. The following varieties will be found suitable for basket culture, viz.:—

SCHELLOLEPIS SUBAURICULATA, known also as Goniophlebium and Polypodium, I place first upon the list, because I look upon it as the best of the drooping Ferns. It produces fronds from 6 feet to 12 feet in length, and of a pleasing shade of green. When fertile, the sori, being immersed in the pinnæ, form little umbones or bosses on the upper surface, which add to the beauty of the pendulous fronds. This species will test the cultivator's skill, inasmuch as the pinnæ are jointed with the rachis, and if allowed to suffer from drought, they fall out from the joints and leave bare stems, a sure indication of neglect. It comes from the Malay Islands, and it requires the temperature of the stove.

S. VERRUCOSA.—This is similar in habit to the preceding. The fronds, which attain a length of from 4 feet to 6 feet, bear broad, deep green pinnæ, and produce, when fertile, raised protuberances on the upper surface. It comes from Malacca, and enjoys a high temperature.

GONIOPHLEBIUM APPENDICULATUM.—In this genus the pinnæ adhere to the rachis, and consequently do not exhibit the effects of drought in such a marked degree as do the various members of the preceding family. The fronds of this species attain a length of from 12 inches to 15 inches; they are pinnatifid and pale green, the rachis being deep red, and the whole frond prettily netted with lines of reddish crimson. It is a native of Mexico, and thrives admirably in a cool house.

LOPHOLEPIS PILOSELLOIDES.—This is a diminutive West Indian species, with a thin, wiry, creeping rhizome, bearing dissimilar fronds; the sterile ones are ovate and about 2 inches long, the fertile ones narrow and some 3 inches in length, bearing large, bold, deep brown sori. The fronds are pale green and squamose on both sides. It forms a charming object in small baskets.

NOTHOCHLÆNA TRICHOMANOIDES.—This is a choice plant for a medium-sized basket. Its fronds, which are pinnate, are from 12 inches to 18 inches long and pendulous, and the rachis is black. The pinnæ, which are somewhat ovate, are intensely green on the upper side, clothed with a white tomentum beneath, and ornamented with jet-black marginal sori. It enjoys strong, moist heat, but does not like watering with the syringe. It comes from Jamaica.

N. RUFA.—As regards treatment, the requirements of this species are similar to those of the preceding. Its fronds, which are from 12 inches to 18 inches long, are pendulous and pinnate, the pinnæ being smaller than those of N. trichomanoides. The fronds are clothed with short rufous hairs below, and also ornamented with a reddish tomentum. Jamaica.

N. SINUATA.—This elegant New Mexican Fern thrives best in a greenhouse temperature, although it objects to a dry atmosphere. In habit and size it resembles the two species just named, but is, nevertheless, very different from either of them. The pinnæ, which are pale green above, are densely clothed below with white or ferrugineous scales, toothed on the edges, and there ornamented with dense black marginal sori.

DAVALLIAS.—The majority of Hare's-foot Ferns, as the Davallias are called, are eminently adapted for cultivation in baskets. From their stout, creeping rhizomes are produced great quantities of fronds, elegant in outline, and in most instances of a pleasing shade of green. The soil for Davallias should not contain much loam, and what is used should be rough and turfy.

D. BULLATA.—The rhizomes of this species wind round a basket rapidly. They are clothed with bright ferrugineous scales, a circumstance which has obtained for it the popular name of the Squirrel's-foot Fern. Its fronds, which are freely produced, are somewhat triangular in outline, finely divided, and of a lively green in colour—thus, when well established, making an effective plant. It is however, only to be had in full beauty half the season, as it is deciduous, losing its fronds in autumn. During its season of rest it must not be dried up or neglected; on the contrary, a fair amount of water should be given, in order to keep it from shrivelling. If wintered well, the young fronds break up from the rhizomes in spring with increased vigour, and in their young state are of a lovely shade of green, somewhat resembling that of young Larch. It requires strong heat to start it in spring, but after the fronds are well developed, it will thrive in a cooler temperature.

D. PALLIDA, perhaps better known in gardens by the name of D. Mooreana, makes a grand specimen when treated as a basket plant, although it is for the most part cultivated in pots. The fronds of this species, which are upwards of 3 feet long, are much divided and pale green. Its fronds are beautifully arched, and spreading. The plant when well grown forms a large and majestic specimen.

D. TYERMANNI.—This species is much less robust in habit than the preceding. Its rhizomes are stout and densely clothed with large, pure white, chaffy scales. The fronds are from 6 inches to 12 inches in length, somewhat rigid in texture, triangular in outline, and intensely green. Independent of the attractiveness of this Fern as a basket plant, I have found its fronds to be most useful in the composition of button-hole bouquets and shoulder sprays, its rigidity enabling it to resist curling or flagging. During summer it may be grown in a cool house. It comes from Northern India.

D. FIJIENSIS PLUMOSA.—This is distinguished for its beauty, even in a family remarkable for its general elegance and ornamental properties. The rhizomes are slender, creeping, and clothed with ashy-grey chaffy scales. The fronds are from 2 feet to 3 feet in length and much divided, the segments being slender and of a vivid green colour. The general outline of the fronds is that of a beautiful drooping ostrich feather. It requires stove heat.

D. CANARIENSIS.—This is a beautiful greenhouse Fern, which, although somewhat less graceful than some of those already mentioned, cannot be overlooked. The rhizomes are stout and densely clothed with rusty-brown chaffy scales. Its fronds, which are upwards of a foot high, are broad and much divided into narrow deep green segments, which, when fertile, are enlivened by numerous reddish-yellow sori. D. canariensis is the type of the genus, its scaly rhizomes presenting a striking resemblance to a hare's foot. It comes from Madeira.

ADIANTUM CUNEATUM GRANDICEPS.—A bold growing form of the Maiden-hair Fern most commonly used for bouquets and general purposes of decoration, but with this addition—it develops upon the ends of its fronds broad and branched crests and tassels of great beauty, which render it a conspicuous object when used in the manner here recommended. It may be grown in a cool house.

ADIANTUM CAUDATUM.—This species produces fronds of a pinnate character, and pendulous and proliferous at the apex. The young plants thus formed attain considerable dimensions upon the plant, and thereby enhance its beauty. The colour of the pinnæ is ashy-grey. In the variety Edgworthi the pinnæ are very much divided at the edges, thus affording a striking contrast to the normal form. It comes from the East Indies.

WOODWARDIA RADICANS CRISTATA.—This is an admirable plant for an elevated vase or large hanging basket, and one which, from its robust constitution, may be grown in the open air in summer if placed in the shade. Fern growers usually keep this plant in too strong a heat, the result of which is its pinnæ get disfigured by thrips. The growth is decumbent, producing beautifully arched fronds from 6 feet to 7 feet in length, and furnished with young plants near their ends. The pinnæ are coarsely serrated and bright green in colour.

DRYMOGLOSSUM PILOSELLOIDES.—This pigmy Japanese Fern seldom makes fronds more than a few inches high; it may be grown in a Cocoa-nut shell or small basket, and suspended in a sitting-room window, where it forms an interesting object. Its rhizomes, which are creeping, bear two kinds of fronds; those that are sterile are somewhat obovate, less than an inch high, thick and fleshy in texture, and bright green, and more or less clothed with stellate hairs; the fertile fronds are linear in outline, some 2 inches or 3 inches high, and the same colour as that of the sterile ones, but enlivened beneath with a broad, continuous marginal band of yellowish sori.

GYMNOGRAMMA SCHIZOPHYLLA GLORIOSA. — The old form of this plant, though a favourite, was difficult to grow, which this variety is not. Its fronds, which are long and pendulous, are very finely divided, the segments being bright green on the upper side, and slightly dusted below with a white farinose powder. It should be placed in a medium-sized basket, kept in stove heat, and carefully watered, as from the extreme delicacy of its fronds it speedily withers if allowed to become dry.

MICROLEPIA HIRTA CRISTATA. — A bold-growing plant, suitable for any situation, be it the exhibition table, the plant stove, an elevated vase, or a basket. It produces long arching fronds with much-divided segments, the apex of most of them bearing a large crest or tassel. Although it enjoys strong heat in winter and spring, it succeeds well in a cool house in summer.

Asplenium bulbiferum.—This is a very free-growing and handsome Fern, suitable for greenhouse decoration and sitting-room windows. The fronds, which are broad and spreading, are arched and bright pale green, the upper surface being densely covered with little bulbils, which eventually produce young plants. W. H. G.

BRITISH FERNS AND THEIR VARIETIES.

Dr. Spruce's name having been mentioned by "G." in connection with the discussion in reference to crested Ferns, I wrote to him asking the result of his experience, and have received the following reply: "I am afraid I cannot contribute any information as to the variation of tropical Ferns in a state of nature that would be worth recording. I have no specimens here, but I have my notes, often made on the fresh plant, and the names of most of them as supplied first by Hooker, then by Moore, and lastly by Baker. That Ferns vary quite as much on the equator as in the north temperate zone I can safely assert. The genus Asplenium is perhaps the most variable of any, and the so-called species often pass into each other by such insensible gradations, that (to me, at least) no actual limit was traceable. Asplenium falx, *Desv.*, is a variable subject, so is A. radicans, *Sw.* A. fragrans is often scarcely distinguishable from luxuriant A. Adiantum-nigrum, except by the odour. The Hymenophyllaceæ all vary much. Crested, or otherwise deformed, varieties are mostly (as in Britain) sterile. The botanical collector naturally tries to get everything in as perfect a state as possible, but I have no doubt that a lover of malformations might find as great a variety of them on the equator as in lat. 50°—60° N." The above, by a botanist of note like Dr. Spruce, should convince "G." that his theory as to climate cannot stand. It would be a very curious coincidence indeed that such a change as he speaks of should begin exactly at the time Moore's folio "Nature Printed Ferns" was published, and that it should be confined to the British Islands. Dr. Spruce makes a slip when he speaks of British varieties being mostly sterile. Probably he has the plumose forms in his mind. P. Neill Fraser.

Rockville, Murrayfield, Edinburgh.

New Zealand edible fungus.—Could you inform me the name of any book in which I could find a chemical analysis of the New Zealand edible fungus, or where I could procure a specimen of the same in this country?—T. V.

*** Your question is too indefinite for a definite reply. You will see an example of Ileodictyon in the food department, Bethnal Green Museum. This is said to be eaten by New Zealanders under the name of Thunder-dirt. Cyttaria Gunni is also eaten. The Native Bread of Australia is a fungoid growth named Mylitta australis, said to be very nutritious. For analysis of fungi, see "Guide to Food Collection, Bethnal Green Museum," by Professor Church. Good examples of Mylitta, &c., may be seen in the public room, Botany, British Museum, South Kensington, where further information may be obtained.—W. G. S.

Daffodil seed.—Noticing that seed of the sulphur Hoop-petticoat (Corbularia citrinus), crossed with a white Trumpet Daffodil (Minnie Warren), is advertised for sale at a high price, I think it only right to say that such a cross is probably quite impossible, and that the seed offered will merely reproduce one or the other of these two Daffodils. Dean Herbert, a skilful and successful hybridiser, tried for years to get the Corbularias to cross with the Trumpets, and failed. For many seasons I have made the same attempt myself without success. In my opinion, it is wrong to offer seed representing any particular cross; it must always remain doubtful until blooming time whether it has really been effected, unless, indeed, every flower made a seed parent has been absolutely isolated and had its anthers removed before opening, a laborious task which could not be carried out where seed is harvested in sufficient quantity for sale.—G. H. Engleheart, *Appleshaw, Andover.*

NOTES OF THE WEEK.

Lapageria rosea and alba.—The long corridor at the entrance of Messrs. Veitch's nursery at Chelsea is just now very gay with these two plants, the whole roof being covered with their pendent bell-shaped flowers, whilst the intermingling of the two colours (rose and white) has a very pleasing and pretty effect.

Vallota purpurea eximia.—A three-flowered spike of this beautiful variety of Scarborough Lily has been sent to us by Mr. Hartland, of Cork, who evidently grows it well. The variety is similar to that which we figured last week under the name of magnifica, except that the flowers are smaller, and we doubt if it is such a robust grower.

Pampas Grass at Hampton Court.—The one fault of this Grass is the late season at which it blooms. We recently saw a specimen of it at Hampton Court bearing upwards of a hundred of its beautiful feathery plumes in full beauty. It had evidently been in flower a long time, whilst other plants close beside it, equally strong, are only now just pushing up their spikes. This early-flowering variety is certainly worth increasing, as it comes in before the unsettled weather of autumn impairs its beauty.

Heaths at Norwood.—We were pleased to find the other day that some fine specimens of what are termed hard-wooded Heaths still exist in the neighbourhood of London. Mr. James, of Norwood, has quite a large collection of them, amongst which the best for blooming at this season is E. tubæformis, with a deep red tube tipped with pink; another very useful kind for late flowering is cerinthoides coronata, with a large dense head of brilliant scarlet bloom; also MacNabiana rosea, which blooms twice in the season; the second crop of flowers is now opening; the blooms are large, with a deep rose tube, spreading, pure white limb, and deep purplish black ring round the neck.

Oxypetalum cæruleum.—I send you sprays of this plant raised from seed this year. It seems suitable for a cool greenhouse. I have no knowledge of it in a mature state, but it looks a pretty plant, and the colouring of the flowers—palest turquoise-blue, shot with palest pink, with ring of anthers of full turquoise, inclining to peacock-blue—is rare and beautiful. From the habit of the young plant it appears to be a climber.—G. J.

*** This lovely shrub is best known in gardens under its synonym, Tweedia cærulea. Being a native of Buenos Ayres, it succeeds admirably in a cool greenhouse.—Ed.

September flowers.—I send you specimens of September flowers now in great beauty with me. The tall growing and large-flowering Linaria triornithophora is rather a handsome late blooming annual; the pretty L. tristis also is singular in colour, and very fragrant in the evening. Here in rich moist soil Pinks are blooming again as freely as in June, so are Pyrethrums and Delphiniums, and the lovely Lychnis Flos Jovis has bloomed in the freest manner all through from early summer. The deep orange form of Papaver nudicaule is a striking plant, and the low-growing Delphinium sinense is very beautiful in both the blue and the white forms; the rare and charming D. sibirica fl.-pl. is in full flower again. In fact, flowers now abound, for we have not only abundance of the usual autumn subjects, but also a reappearance of those of early summer.—T. Smith, *Newry.*

Autumn Crocuses.—These are now beginning to bloom. C. Sharojani, the only orange-coloured autumn-flowering species, took the lead a month or more ago. If these autumn kinds should be taken in hand and developed, as the spring ones have been, this Sharojani will, no doubt, be the chief one to be worked with, bringing in, as it does, a colour hitherto unknown among Croci in autumn. The next to follow is C. vallicola, a pale cream-coloured sort, lightly veined in the inside with purple, and furnished with two small orange spots near the throat. The great peculiarity of this Crocus is that the segments become fine threads at their extremities, giving the blooms a curious Crinum-like appearance. C. Suwarowi, a variety of the above with a beautiful orange stigma, we have not seen, although we believe in cultivation. The next is C. zonatus, from the Cicilian Mountains, the flowers of which are prettily veined lilac, and orange or golden at the base. It is perhaps the freest flowerer of the three, and requires no special treatment.

Begonia Ameliæ.—This is one of the hybrid Begonias recently distributed by M. Bruant, of Poitiers, who devotes himself to the less popular species of this very diversified genus, and has already obtained some very pretty new forms. That here named is the result of crossing B. Lynchiana (Roezli) with B. semperflorens, and the offspring combines the characters of the two parents most markedly. The habit is that of B. Lynchiana, as also is the size of the foliage and the flowers, whilst the other parent is represented in the herbaceous texture and colour of the foliage and the comparative paucity of the flowers in each raceme. The hybrid is also like semperflorens in its habit of flowering all summer from the young stage onwards. We believe B. semperflorens rosea to be a most useful Begonia, also originated with M. Bruant. When treated liberally, B. Ameliæ develops into a bold-leaved ornamental stove plant, and it is deserving of cultivation for the sake of its handsome rose-coloured flowers. We saw it in flower in the Begonia house at Kew a few days ago.

Chirita Mooni.—This is a pretty and very distinct flowering plant from Ceylon, which has not become known as a garden plant, although it is now many years since it was introduced and flowered at Kew, where it may be seen now in healthy condition and flowering freely. It is widely different from the old Gloxinia-like C. sinensis, which used to be a common stove plant, but is rarely seen now-a-days, the Ceylon plant having a shrubby habit, growing to a height of about 2 feet, branching freely, and being covered with lance-shaped foliage, which has a silvery sheen produced by the copious white silky hairs which cover the whole plant. The flowers are large, not unlike those of Thunbergia grandiflora, their colour being pale violet with a broad streak of yellow in the throat. We have seen this Chirita every summer at Kew for the last half-dozen years, but have never met with it elsewhere, notwithstanding its beauty and accommodating nature. It belongs to the same category among stove plants as Meyenia erecta, Pleromas, Exacums, and such like soft-wooded bluish-flowered plants.

Fuchsias at Hackness Hall, Scarborough.—I have been so charmed with the great variety of Fuchsias to be found in this old and interesting garden that I send you a few for inspection, feeling sure that if more generally known we should see more hardy Fuchsias than we now do in every garden where autumn flowers are desired. Fuchsia gracilis is, of course, the common and somewhat weedy looking bush that is too much grown. F. virgata is of more upright and floriferous habit, with leaves much smaller and flowers much more abundant, and slightly smaller than those of F. gracilis. This is a most beautiful and distinct bush Fuchsia. F. globosa var. is also a very fine and distinct Fuchsia, midway in habit and size of flower between F. globosa, with its low growth and globular buds, and F. Riccartoni, with its sturdy, shrubby habit and smaller flowers; here it is more beautiful and effective than either of those well-known kinds. The fourth one I send is an old garden variety that makes an excellent contrast to the blush-pink Venus de Medici, another old and well-known kind which needs no remark from me. As these Fuchsias have all been planted here for very many years, there is no doubt of their perfect hardiness in every way, and if amateurs will search old gardens in various parts of the country I am sure other good species and varieties might be found.—E. H. W.

Crinum flaccidum and giganteum.—C. flaccidum is a dwarf species in comparison with that noted last week, but it has charms of its own in the delicious odour of its flowers and their elegance. A plant of it may be seen in flower at Kew in the T range. It bears an erect scape 18 inches long and an umbel of slender-tubed narrow-petalled flowers, the petals being 3 inches long, spreading, and pure white, whilst the slightly curved filaments are purple and bear yellow anthers. This plant is interesting a

coming from Queensland, where it is said to be plentiful, although it is only recently that living plants of it have been secured for English collections. C. giganteum is not well named, as it is not, by a long way, so large as many other species either in leaf or flower. But this matters little to us, if the plant is in itself beautiful, and such it is, and, besides beauty, it has also to recommend it a vigorous constitution, which makes its cultivation as easy as that of the easiest-managed of Crinums. It does not exceed 1 foot in height, its leaves being numerous and clustered, whilst its flowers, which are borne on scapes 1 foot high, are bell-shaped, about 3 inches across, and pure white. It is now flowering in the Palm house at Kew.

Tecoma radicans.—This has flowered exceptionally well out of doors in the south of England this year, the long spell of bright, hot weather in August having been favourable to the healthy, vigorous growth of this year's shoots, upon the ends of which the clusters of large funnel-shaped, dull crimson flowers are developed. Mr. W. Paul exhibited at South Kensington last week a basketful of flowers cut from a plant in his nursery, and we have seen several copiously-flowered specimens of it on the south side of cottages in the London suburbs. If we could rely on this plant to flower annually, it would be one of the most desirable of climbers for covering buildings; but we cannot make our own sunshine, and this alone is the element wanting in ordinary English summers to the success of the North American Cross Vine. T. grandiflora, the Japanese species, is also flowering out of doors. This has a shorter flower, a more irregular limb, and brighter colour than the American kind; it also differs in the raceme being much longer, that of T. radicans being so short as to appear corymbose. Both these plants may be grown in pots, so as to make them flower almost every year; but they are only seen at their best when draping the front of a house outside with their long leafy branches and brilliant trumpet flowers.

Mucuna maerobotrys.—We learn that plants of this new Chinese climber have been secured for the Kew collection, and that there are some good reasons for believing that it will prove hardy in England. Should this prove to be the case, then we have in this plant a rival to the princely Wistaria itself. Here is a short description of this Mucuna which we received from a friend who has seen it growing wild: "I found a very old plant of the Mucuna on the Tai-mo-shan Mountain, and you can imagine to what a size the plant will grow from the size of the stem of this specimen, which I measured and found to be 7 inches in diameter. The leaves are trifoliate and Bean-like, whilst the flowers are in immense pendent clusters, as in the Wistaria, one cluster which I measured being 17 inches long and 10 inches across the shoulder, the individual flowers being large and cream-coloured. Here is a magnificent plant for some of your gardeners to look after." Those who have seen the large clusters of black-purple flowers produced by M. imbricata in the Palm house at Kew will be able to form some idea of the magnificence of this new kind, the racemes of which are apparently twice as large as those of M. imbricata.

The Torch Lilies (Tritomas).—I send you a photographic illustration of my five-year-old Torch Lily (Tritoma Uvaria), now truly a grand sight, furnished as it is with its ninety odd flower-spikes, making a blaze of colour in the warm autumn sunshine, and a charming contrast to the less brilliant, but graceful, Michaelmas Daisies that are its companions in that particular corner of my garden. I read with great interest and pleasure "Veronica's" note on the Tritomas in THE GARDEN (p. 240), and as an admirer of the family and a cultivator in a small way, I, too, hope that soon the long-promised monograph may make its appearance. T. Saundersoni is truly a grand and stately plant, and T. Macowani makes a most charming specimen either on the rockery associated with plants of a similar character, or on a dry warm border. I grow it in the latter way, and find that it just exceeds 3 feet in height, and is altogether a larger plant than T. corallina. T. Uvaria nobilis is the earliest to bloom with me in Hereford-hire, and is a distinct and handsome kind. T. Hooperi is quite distinct from all the larger kinds that I am acquainted with, and deserves a place in every good collection; while T. Uvaria maxima globosa is the latest flowering kind I have of the Uvaria section; it does not usually bloom here till the end of October. At some future time I hope to send notes of many other kinds I possess, but have not yet succeeded in flowering, and I hope to have an even greater pleasure in sending "Veronica" a spike, if not a plant, of T. pumila as a souvenir of my pleasant visit to his charming garden.—W. J. G.

*** The photograph in question shows a grand plant of T. Uvaria—such a plant as one rarely sees. "W. J. G.'s" notes promised at some future time will be welcome.—ED.

Bertolonias and Sonerilas.—A group of the most distinct of the many varieties of these two genera may now be seen in the T range at Kew, and the beautiful markings of the foliage on the kinds here shown are almost equal to what we find amongst Anæctochili, which, by the way, were once a feature at Kew in the same position as that occupied by the plants here referred to, but which apparently have disappeared, as, unfortunately, these delicate little beauties are wont to do. But Bertolonias and Sonerilas have not this fugitive character; on the contrary, they are very easily grown and kept from year to year. For the Bertolonias, leaf-cuttings may be made to yield a stock of young plants as freely as Gloxinias or Begonias, and these young plants are always preferable to the old ones kept through the winter. Sonerilas may be propagated in spring or autumn from cuttings, and they are not difficult to keep through the winter if prevented from flowering by pinching off the buds as they appear. The soil which these plants prefer is peat and leaf-mould, two parts of the latter to one of the former, with plenty of silver sand. Water may be given freely always, and a position close to the glass in a slightly shaded stove suits them admirably.

Amasonia punicea.—This does not appear to have become as great a favourite among growers of stove plants as we anticipated from the exquisite beauty and singularity of its inflorescence. Several plants of it may now be seen in one of the stoves at Kew; they are 18 inches high, and have dark green leaves a foot long, the upper part of the branches being clothed with numerous brilliant red, leaf-like bracts, which come several weeks before the flowers and remain long after these have faded. From the axil of each bract a flower is developed, this being 1½ inches long, tubular, creamy white, and nodding, the colour of the rather large calyx being similar to that of the bracts. The plant grows freely, always looks healthy if kept in a moist stove, and seems never to fail in developing its flowers; a coloured plate of it will be found in THE GARDEN for last February. We grow a considerable number of plants which owe their attractiveness to flower appendages rather than to flowers; such are Poinsettias and Euphorbia jacquiniæflora, Mussændas and Howardia, the large white leaf-like appendage being an enlarged calyx-lobe; Castilleja indivisa, a very pretty hardy annual; and the Anthuriums, Arisæmas, and other Aroids. We call them all flowers, though they have nothing whatever to do with the true flowers, unless, perhaps, as wrappers or to serve as an attraction for insects.

Weeds.—Some industrious observer has been to the trouble of noting for himself the productiveness of some of the commonest weeds. He says that, upon one plant of Shepherd's Purse (Capsella Bursa-pastoris) he has found 3100 pods, containing an average of twenty-five seeds each—ascertained by taking twenty pods from the plant at random, and counting the seeds in each—making 77,500 the total number of seeds produced. Another plant bore 2500 pods, or 62,500 seeds, the average number of seeds per pod being the same in both plants. A large common Plantain (Plantago major) bore thirty-three spikes, each having from 139 to 448 fruits, each containing from two to six seeds. The average number of seeds per fruit was 4·5 and the average number of fruits per spike 293·4, the total number of seeds per plant being 43,569! This reckoning gives one an idea of the wonderful fecundity of weeds, and from it we can more fully comprehend the significance of the adage, "One year's seeding makes seven years' weeding."

MARKET GARDEN NOTES.

GROWERS have of late been suffering from overstocked markets, consequent on a moist, dripping season having maintained uninterrupted growth in the case of all kinds of green crops, and prices have been very low; in fact, some kinds have been fed off with sheep or given to pigs in preference to sending them to market. This, of course, only applies to crops that are of a perishable kind, or that must be cleared from the ground to make room for successional ones. The prices of Potatoes vary from 2s. to 2s. 6d. per cwt. for really fine samples. The disease has spread of late considerably, and those that have good sound crops will keep them back until prices are higher; but Potatoes will probably be both plentiful and cheap this year, provided crops in the north are good. Cauliflowers (Autumn Giant) are now coming in by wagon-loads—magnificent heads, each large enough to dine a family. Runner Beans have been more plentiful this season than usual, and as they realise only about 6d. a bushel, some have left their crops for seed; others have kept on picking for the sake of getting a late crop, for even a few left for seed stops at once the bearing property of the plant. Cabbages for early spring crops are being put out in quantity, as they nearly always sell well. The supply of plants this year is abundant, and the land being in moist condition they soon recover from the check sustained by removal, and if mild weather prevails will be large enough for pulling up and bunching by Christmas should a demand for them arise. Late crops of Turnips are now being thinned. A good deal of land has been sown lately with them, for if not large enough for market their tops are appreciated in spring, and last spring they were a very remunerative crop.

Plums have been very plentiful and common sorts very cheap, but good ones fit for dessert have sold fairly well. Many of the old orchards want grubbing up and new sorts planted, good fruit being the only thing that will keep the English growers at the head of the market. Apples are scarce, and good sorts fetch high prices; coloured varieties, like the old Red Quarrenden and the new Worcester Pearmain, have been realising 8s. per bushel. Pears are plentiful and common sorts cheap, but good Pears are always saleable. The best on bushes and pyramids are Pitmaston Duchess, Marie Louise, Beurré Bosc, Beurré d'Amanlis, and Williams' Bon Chrétien.

Tomatoes have been the best crop of the season as regards meeting with a ready sale; no matter how many boxes or baskets happen to be landed from abroad, our home-grown ones fetch double their price, and the more there are grown the more demand there appears to be for them. J. GROOM.

Gosport.

Epacrises.—These most useful greenhouse plants endure hardships better than Heaths. If they happen to lose their foliage and appear almost dead, from being left too long in warm dry rooms in winter, they seldom fail to push forth as freely as ever again in spring if kept a little warm till they start, and occasionally dewed overhead. They must be badly used indeed if they fail to revive under such treatment. From among the many varieties of these now in cultivation the following is a good selection: Alba odoratissima, carminata, Alberta delicata, densiflora, elegans, grandiflora, Kinghorni, multiflora, Mont Blanc, splendida, and Queen Victoria. They require a compost of peat and silver sand, firm potting like the Heath, and efficient drainage. Unless large specimens are desired, the plants will do well enough if potted once in two or three years. They should be cut down after flowering, and I have always noticed that, unlike soft-wooded Heaths, which prefer the open air in summer, they do best in a cool greenhouse or pit during the season. Some of the varieties make long straggling shoots, but these are not unsightly, and the longer they are the longer will the wreaths

of flowers on each shoot be, if the plants have been grown under a good light, with plenty of air, and are well ripened. It is best to use the Epacris for flowering in early winter or spring, which gives the plants time, after being cut down, to make a good growth the following summer; when cut down late the flowers are not so abundant nor so fine. Their roots will stand pruning when it is needful to keep them in small-sized pots.—S.

ORCHIDS.

Oncidium Kramerianum (Penfold's variety).—This is a remarkably large and richly coloured form of Kramer's Butterfly Orchid. It is now in bloom at Beddington House, Surrey, in which garden it was first flowered by Mr. Penfold.—W. H. G.

Oncidium Jonesianum.—This was shown at Bath by Mr. R. B. Cater, and though there were three forms of it in one pan, the specimen thus made up was worthy of notice, on account of its distinctive character and the beauty of its flowers. O. Jonesianum has curious, erect, thick, fleshy leaves and produces fairly strong spikes of bloom, some of Mr. Cater's carrying thirteen fully developed flowers. The sepals and petals are yellowish white, the lip nearly pure white; the whiter it is the more valuable is the plant.—W. I.

Orchids at Streatham.—We have received from Mr. Measures, of The Woodlands, Streatham, a very fine spike of Saccolabium Blumei, which appears to be the variety called Russellianum. The spike in question was cut from a plant bearing twelve similar spikes. It measures upwards of 2 feet in length and is very dense; the sepals and petals are prettily spotted, and the lip deep rich rosy purple. From the same establishment also came fine forms of Cypripedium œnanthum superbum and C. Schrœderi. This genus appears to succeed exceptionally well at The Woodlands.

Dendrobium bigibbum.—Mr. Cypher, of Cheltenham, possesses the finest pan I have yet seen of this lovely Dendrobe. It was recently exhibited at Bath, and was greatly admired, especially by those who are aware how seldom it is seen in perfection. I counted thirty racemes of bloom on this specimen, none of which is at all weak, while the strongest of them carried as many as seventeen blooms in different stages of development. This Dendrobe is of rather dwarf habit; the flowers are rich rosy purple, and altogether, though not easily cultivated, it is a most desirable species. Mr. Cypher treats it similarly to other Dendrobes, all of which are grown together.—W. I.

Saccolabium Hendersonianum.—This pretty miniatnre species from Borneo is a grand acquisition. It is never imported in large quantities or pieces; consequently it is by no means plentiful; but those who have once seen it in flower are generally ready to purchase a good plant of it when one is met with. It produces from the axils of the leaves upright flower-spikes from 5 inches to 6 inches in length. The flowers, which are compactly arranged on the spike, are of a rosy flesh colour, the labellum being pure white and peculiar in shape, not dividing or hanging loose, as in the case of most Saccolabiums. It is not one of the easiest to cultivate; the best plants of it we have met with are at The Woodlands, Streatham, where they are growing suspended in baskets near the roof in a warm moist house. Mr. Fraser's experience is, that to a small Teak rod fixed in the basket at the back of the plants is due his success, the plants having apparently left the Sphagnum and established themselves on the wood. Plants of this Saccolabium must not be without water winter or summer.—V.

Dendrobium formosum.—This plant does not usually continue in vigorous health after the first year of its cultivation in gardens, but it would appear that the failure of this fine Dendrobe is due to wrong treatment. We saw some healthy plants of it in a collection lately visited, and these had been cultivated over three years, yet they have just completed a growth of strong thick pseudo-bulbs and are now in bud. The treatment they have had was simply a long rest in a cool, dry, sunny house immediately after the flowers had faded, and, on the new growth making its appearance, the plants were removed to a hot steaming atmosphere where they had plenty of light. Here they grow vigorously, no doubt because they had had a long cool dry rest. We believe a good many of these upper Burmese Orchids are happiest when thus treated—Saccolabium guttatum, ampullaceum, Blumei, Aerides affine, odoratum, and even Vanda cærulea being equally healthy when treated as above. Many gardeners pay too little heed to the resting of plants, and the consequence of perpetual growth is precisely that which happens to most plants when forced, namely, weakness and disease.—B.

Moss litter for Orchids.—I shall be glad to know if any of your readers can give information as to the use of German Moss litter for Orchids. The great difficulty and expense connected with getting good peat for such a purpose make one desirous to obtain a substitute, provided it is equally good, but it will not do to be penny-wise-and-pound-foolish. I am therefore for myself, and for all lovers of Orchids, anxious to obtain what information can be given for our guidance. I had about five months since a Lælia attached to a block on which was what appeared to me to be some pressed material different from our English peat; finding the roots pushed through it, and were numerous, vigorous, and healthy, I examined it closely last week, and found on comparison that it was undoubtedly the German litter now in such general use in our stables. I am greatly induced, seeing how well this plant is doing, to try the same material by way of experiment, but should not like to risk much without, if possible, having the experience of others. I have heard that it has been tried, and after a time got slimy and was discontinued; whether it would be different in a pot from what mine is on a block remains to be proved.—H. J. Buchan, *Milton House, Southampton.*

Cattleya Dowiana.—If this plant could be grown into as large specimens as is possible with the commoner Cattleyas, such as C. Mossiæ and C. Trianæ, it would deserve to be placed first among Orchids, and, even as seen now, it has only very few equals. Its chief drawback is the difficulty usually experienced in keeping it in healthy growth and free from spot. Some growers recommend tropical treatment, others intermediate, and a few profess to grow it in a cool house. Probably the right treatment has not yet revealed itself. Meanwhile it may be worth while recording the result of intermediate treatment with plenty of water during summer, and only a little in winter—the plant under notice being established on an upright piece of Dicksonia stem, the lower end of which is secured in a pot. The roots of the Cattleya have spread very freely in the Fern stem and down into the pot, but the advantage of this plan is in the perfection of the drainage, so that copious waterings never result in stagnation. A plant of Adiantum cuneatum has established itself on the Fern stem, and this produces a very pretty effect when the flowers of the Cattleya are expanded. The plant thus treated produced two growths on the same rhizome, both of which flowered last year, and it is now again in flower, whilst the leaves are in perfect health.

Lissochilus Krebsi.—This is one of the few terrestrial Orchids of South Africa which are both handsome and easily managed in English gardens—African Orchids, like many bulbous plants from that country, being, as a rule, difficult to manage. Amongst the Orchids we have, however, the grand-flowered Disa, and perhaps D. megaceras (at least, Mr. Moore, of Glasnevin, has this), a Satyrium or two, and a few Eulophias and Lissochilus, L. Krebsi being as easily kept in health as any of them. It thrives in a warm greenhouse, preferring a dry rather than moist atmosphere, plenty of light, and liberal supplies of water at the root whilst growth is active; a stiff, loamy soil, such as is used for Calanthes suits it best. In habit, pseudo-bulbs, and leafage this plant may be likened to Phaius grandifolius, but it does not grow quite so large as that plant. The flowers are borne on stout, erect scapes 2 feet to 4 feet high; sepals 1 inch long, narrow, dark brown; petals broad, as long as the sepals, and standing erect somewhat like the wings of a butterfly, their colour being bright yellow; lip dark yellow, with a short spur and two side wings coloured brown. As many as fifty flowers are produced on one spike by healthy, strong plants. Several specimens of this Orchid are now in flower at Kew.

ALPINE PLANTS ON WALLS.

In "K.'s" list of plants for this purpose (p. 228) I find no notice of one of the most useful and showy of all wall plants, the Myosotis dissitiflora. Its power of living and thriving on stone walls has, like many other useful things, been discovered accidentally. In clearing off some old plants and throwing them over an outside boundary wall a few of them or some seeds lighted on its top and sides. Next year these came forth in plenty and flowered in great perfection, and since then this gem of all the Forget-me-nots has taken care of itself in its hard home, however severe the winter or dry the summer. Neither are these Forget-me-nots on walls hardly ever without flower, either in summer or winter. The severe frosts have often made sad havoc among our fatted thousands of earth-grown plants, but have seldom harmed any of the hardier waifs and strays on the wall. We naturally associate a damp site or water with Forget-me-nots. But this splendid species hies from a mountain home, I believe, and hence, perhaps, its thriving and holding its own on what it can find on a dry stone wall, built chiefly of flints and without any addition of earth or other root-hold. Arabises and Aubrietias also often thrive well in such positions; and I can bear personal testimony to the suitability of nearly all the other plants mentioned by "K." The idea of clothing old walls thus is admirable, or even building rough walls for this purpose. As to sunk fences, there is this objection: There is seldom much height of wall on the garden side, and the stock would make short work of the plants that might spray with beauty the bald surface of the wall on the pasture side. All the members of the cow tribe are most curious about boundary lines and fences. Let the latter be straight and bare, and continue the same day after day and year by year, and the stock are satisfied and take no note of it. But alter the line, plant anything on its top or even on the garden side within view of such stock, and every cow, calf, or bullock must needs come on a tour of keen scrutiny, and ten to one but any plant within reach and the wall itself may disappear under their strict and severe surveillance. But there are many places in most gardens for wall gardening besides dividing fences within reach of stock, and few things afford a wider scope for the display of taste and the development of genius than the skilful manufacture of make-believe old walls and ruins where none exist. This, if carried out with the least amount of skill, would far exceed in artistic beauty and cultural usefulness the majority of piles of stones, bricks, or other hard matters thrown into heaps and dubbed rockeries. Unfortunately, this name is a libel upon every honest bit of rock, while they are not seldom so misconstructed as to starve or kill rather than to foster and beautify the plants posted rather than planted on them. But rough walls composed of earth and stones or other hard matters might readily be moulded into picturesque objects of beauty in themselves, and would afford telling coigns of vantage for the effective display of such plants as "K." enumerates (p. 228) and many others. D. T. F.

QUESTIONS.

5517.—**Wasps.**—Although we had an unusually large number of queen wasps during the spring, I have not seen a wasp for some months; nor have I heard of a nest having been seen in this neighbourhood. Is this the case in other parts of the country?—D. Walker, *Bunordan, Tonbridge Wells.*

5518.—**Tree roots in flower borders.**—I am going to rearrange a long herbaceous border, about 8 feet wide, at the edge of a lawn and backed by a gravel path. I had intended to plant a Yew hedge at the gravel side as a back with plants 3 feet high. I have been told by several people that to do this would be a mistake, as the roots of the Yew would spoil the border, and that the hedge would also harbour snails, slugs, and all kinds of vermin. I should therefore, before proceeding with the work, be glad of a reliable opinion upon the matter.—H. R. C.

Flower Garden.

VANCOUVERIA HEXANDRA.

Some of the loveliest of hardy exotics introduced into our gardens of modern times have been the wood plants of North America. When we think of Cypripedium spectabile, Trilliums, Dodecatheons, various Columbines, and many fine Lilies, we see how largely we have been enriched by that continent within comparatively late years. A more modest plant, but one of exquisite beauty, is Vancouveria hexandra, a native of Oregon. The flowers, though not conspicuous, are beautiful in their delicate structure, and highly interesting on close examination. The foliage, like that of a dainty Epimedium, also reminds one of an Adiantum, and, like that Fern, has a thin, wiry stem, the whole aspect of the leafage being graceful and Fern-like. A plant in a suitable position soon spreads into a good tuft; it enjoys shelter and partial shade. It is a plant highly to be recommended to those who appreciate refined types of vegetation apart from merely showy qualities.

Flower-sprays of Vancouveria hexandra.

Chrysanthemum Madame Desgrange.—This variety is not only very good for supplying blooms from plants grown in the border; but I hold it to be of equal importance for pot culture. I find it, however, somewhat capricious as to the time of flowering. I put in some cuttings in September, 1885, and again early this spring; each batch was grown on and finally potted in 9-inch pots; the September plants were stopped twice, and the spring plants only once. With me the September-struck cuttings made grand plants, and were in full bloom by the middle and end of August, one dozen flowers being on each plant—about 6 in. in diameter. I may say that I disbudded to one bloom on each shoot. The spring-struck are only now showing bud, the same as ordinary early pot plants. I have now put in a batch of cuttings for next year's blooming plants, the white blooms of which are indispensable for wreath-making and general cut-flower arrangements in August and September.—J. R. Hall, *Fox Warren.*

Transplanting white Lilies.—In The Garden (p. 193) I observe "E. H." gives useful instructions for transplanting the common white Lily (L. candidum), but, unless for increase of stock, I would strongly advise all to let well alone in regard to this Lily. As a rule, it hates disturbance, and resents it by weakness of growth or flowerlessness for two or more years afterwards. We had here one of the finest rows in the kingdom as a back to a ribbon border, and I thought I would grub it up carefully and make many more fine patches in other borders. But from that day now (ten years since) to this we have never regained the grandeur and magnificence of the original row. So to anyone about to transplant this grand Lily I would say, "Don't."—D. T. F.

Veronica Andersoni.—I am glad to see "W." record the merits of this beautiful and almost hardy Speedwell. It is one of the most beautiful and useful plants in the garden, yet, nevertheless, belongs to a class that needs now and then to have its substantial merits recorded to prevent its falling out of cultivation. The variegated-leaved variety makes one of the most effective window plants alike out and in flower. On warm sites and light soil the plants are easily carried through the winter by such simple expedients as "W." points out, but in colder localities it deserves the extra care of lifting and storing under glass throughout the winter in a similar way as the fine Fuchsia fulgens and corymbiflora used to be treated. These two last seem now almost lost to our outdoor gardens, yet I have seen avenues and beds of Fuchsia corymbiflora that nothing more modern can match in drooping grandeur and beauty either in the garden or for furnishing tall vases and stately epergnes, while Fuchsia fulgens formed a splendid edging to its taller relative or such plants as Veronica Andersoni.—F.

Self-sown Asters.—I was surprised this year to observe how well some Asters bloomed that came up from self-sown seed. What surprised me most was their time of blooming as compared with others raised and transplanted in the ordinary way. I should have thought that they would have been quite a month behind; whereas they flowered almost or quite as soon as some sown under handlights. Our soil is a sandy loam, which is, of course, favourable. In the northern counties this way of growing Asters might not be successful, but in the warmer districts the culture of this flower should be a more simple matter than is generally the case.—J. C., *Surrey.*

BLUE PENTSTEMONS.

Why is it that these fine flowers are seldom seen in gardens? Were I asked to select twelve of the finest herbaceous plants, one at least of the species of Pentstemon would be among them. I say "species" because these blue Pentstemons are distinct from the florists' varieties, which are, I believe, the offspring of P. Hartwegi or gentianoides. Among the latter no true blue is found. This distinction is, in one respect, to be regretted, for the two classes cannot, so far as I am aware, be bloomed together. We are unable, therefore, to grow together for contrast the fine scarlet of the florists' varieties and the fine blues of the species. We shall be debtors to anyone who can show us how to achieve this without the laborious and expensive forcing under glass of the former. Thus, I suppose, the result might be reached. These blue species bloom in June and July. P. heterophyllus succumbed to the severity of last winter here, but the others which I am about to name are all hardy with me. I should premise that the natural soil here is chalk, and probably the dry bottom thus secured may help the plants through the winter. Probably, too, it may help to intensify the colouring. I need only add, before tabulating the six or seven species I have bloomed here, that the whole apparently prefer a rich, rather moist, soil, albeit they have seemingly appreciated a dry bottom in winter.

P. speciosus has with me flowers of a fine brilliant blue. It remains a month in bloom, and is excellent for a rockery or select border. It has a neat habit at all seasons. It was cut down to the ground last winter, but came up in spring none the worse. As regards size, the flowers of all these species are much smaller than those of the florists' varieties. P. heterophyllus is similar to the preceding, but the flowers are of a somewhat lighter blue and rose-tinted in the throat. It is a lovely plant, but seemingly more delicate in constitution than the others. The flower answers the description of P. Jefferyanus, which I have not bloomed nor seen. I believe it is to Mr. Thompson, of Ipswich, we are indebted for the introduction of most of the fine species in question. P. glaber, better known than the preceding, is dwarf, generally prostrate in habit, a fine blue, but at times the colour is marred by a purple tint.

The three foregoing much resemble each other in general character. Indeed, I believe that P. speciosus has been classed as only a fine and upright variety of glaber. It is, however, very distinct. P. ovatus is altogether different in character both from those above and those hereafter named. It is very hardy; the flowers are loosely

arranged on the spike, which is from 2 feet to 3 feet high. In the early stages of development the flower is a very poor tone of blue, but, as a rule, it increases in intensity with age. The plant is altogether grosser in character than any of the others, and must, perhaps, be put last in order of merit. I have, however, found it to be very valuable for associating with a large plantation of Poppies, and for supplying the blue tone which that family does not yield. P. nitidus (P. procerus), a brilliant and useful hardy plant, is inferior to the three first named, the individual flowers being much smaller. P. confertus is similar to the last, but neater. Indeed, it makes an excellent "carpeting" plant while its bloom lasts. P. pubescens is the last which I have bloomed. It is a delicate, chaste, and distinct species, but not very effective. It is best, I think, treated as a pot and frame plant. It cannot properly be called blue; it is too purple, and there is a white admixture.

I have unbloomed seedlings of P. Palmeri, and Mr. Thompson's catalogue contains the names of some other fine species which are at present unknown to me. Possibly some one who has wider acquaintance with the subject will supplement what I have thought it worth while thus to communicate. The plants of, I think, all the species enumerated cannot, if raised from seed, be relied upon to bloom until the second year after sowing. —H. S. Leonard, *Guildford*, in *Garden Work*.

PHLOX DRUMMONDI.

This is one of the very best and most durable of all annuals for bedding purposes. It may also be successfully treated as a biennial, that is, cuttings of the finer strains may be rooted in the summer or autumn, preserved throughout the winter under glass, and planted out next season in the same way as Verbenas, Pelargoniums, and other bedding plants. It also seeds freely, and the different strains come pretty true from seeds if grown widely apart. These strains, too, are marvellous in their brilliancy of tint and delicacy of colouring, covering the entire range from fiery crimson and the most brilliant scarlet to the purest whites. The size, form, and substance of the flowers have also been marvellously improved. The habit of this lovely Phlox also favours its continuous blooming. Unlike a Candytuft and so many other showy annuals, it does not expend its strength in developing one great head of bloom and then perishing, but while expanding one shoot of bloom its branching habit is busily preparing successional displays; thus, under fair treatment and in good soil, the Phlox Drummondi goes on growing and blooming from June to November. It will do this all the better if the seeds are picked off as they ripen; or, better still, if the bunches of withered flowers are picked off before allowing them to ripen seeds. It is impossible to exaggerate the beauty of a bed of some of the finer modern strains of Phlox Drummondi, whether the beds are filled with one strain of colour or with a mixture of many hues. Sheets of bloom are no exaggerated description, and the form of the flowers, the bunches in which they are arranged, the habit of the plant, the form and size of the leaves, all contribute to heighten the general rich and satisfying effects of this fine old annual in masses. Perhaps no annual, not even excepting the Aster and the Zinnia, owes more to the painstaking care of our modern florists than the Phlox Drummondi. Amateurs intending to go into its cultivation must see to it that they obtain their supply of seeds from those who have made its cultivation and improvement a speciality.

D. T. F.

Achillea umbellata.—This little silvery-leaved plant is perfectly hardy, and certainly requires less manipulation than the dwarf Cerastium tomentosum when grown as an edging. The latter requires renewing every year; whereas the former will be as effective the second and third years as the first. For carpet bedding it is a gem in every way, and only requires to be known to be appreciated. It is easily increased by cuttings taken off in September or October and dibbled in very thickly under a wall. They give no more trouble than this—after a severe frost in spring, to sprinkle a little sifted leaf-mould over them, and with the hand to press into the soil those that have been forced out by the frost. The few leaves falling from the fruit trees give sufficient covering now until rooted, after which they will take care of themselves.—C.

TUBEROUS-ROOTED BEGONIAS.

It is best to speak of the merits of plants during the season when they can be seen in a condition to show that they are deserving of what is said in their favour, and it is through the latter end of summer, and so far in autumn as the frosts happen to keep off, that one of the chief merits which these Begonias possess—that is, their endurance—can be fully realised. In the flower garden, when Pelargoniums and other free and continuous-blooming plants begin to look unhappy and produce few flowers, the Begonias keep on blooming profusely, and so long as there is an absence of actual frost they show little signs of the waning summer, keeping up their bright cheerful appearance when comparatively few flowers remain. When the suitability of a plant for any particular purpose is proved by those who happen to be first in the field in trying it, it takes much longer than might be supposed before its merits become generally known; and so it is with the plants in question, for though it is now several years since their ability to thrive and bloom freely out of doors was proved, they have yet been slow in making their way.

One of the advantages attending the use of these Begonias in modern flower gardens is that either alone or associated with other plants, flowering or fine-leaved, their appearance is such as to take off much of the formality, which is one of the chief objections belonging to most of the plants that are usually employed in this style of gardening. Those who require beds all of one colour and even in growth, with or without an edging of something else, can have what they want by using one variety; whilst where beds of mixed colours are preferred, tuberous Begonias afford more variety through all the shades of pink, scarlet, and red to the deepest crimson, and from white to straw, sulphur and the various shades of yellow than any kind of bedding plant that I can call to mind. And it is in combinations of colour that these Begonias are seen to advantage, either in beds confined to them alone, or where associated with other plants. Arranged in the last-named way, where suitable things are selected to go with them, either flowering or fine-leaved, or both combined, the Begonias stand unequalled. One of the best combinations is a mixture of pink and red Begonias with white Fuchsias, such as Rose of Castile, or any free-blooming variety, standing at distances of about 2½ feet apart. In the early part of the season the points of the lower shoots of the Fuchsias should be pinched out once or twice to induce spiral growth, so that they may stand well up above the Begonias, and in this way avoid the formal even surface. A few plants of Grevillea robusta or Acacia lophantha—the former looks best—are an improvement.

One of the most telling beds I have met with consisted of red, white, and yellow Begonias interspersed with Amarantus salicifolius and Grevilleas. In another, blue Violas were used as a setting for the Begonias, which were put in at about 2 feet apart. Red and white Begonias with single-stemmed plants of the variegated Abutilon Thompsoni and Panicum variegatum look well.

If, in place of the formal even surface of a single colour and the straight ribbon-like lines that have been so generally adopted in flower gardens, mixtures of plants possessing various colours and shades had been used, intermixed with others differing in their habit of growth, modern flower gardening would not have been open to the objections that have done so much to bring it into disfavour. It is not the kinds of plants used that are condemned by those who object to summer bedding as it is often yet carried out; it is the objectionable way in which they are employed, further aggravated by the studied exclusion of every plant that could soften the masses of glaring colours and the stiff formality of growth.

Apart from their use in combination with the ordinary summer bedders, tuberous Begonias are equally adapted for introducing amongst herbaceous plants in beds or borders, especially with the early-flowering kinds, bulbs in particular, which, when they are over, leave flowerless blanks for the rest of the season. So employed, with forethought and judgment there need be no unsightly bare places; all that is needed is to plant the Begonias, as soon as it is safe to trust them out of doors, in the positions where something will be required to take the place of the plants that either die down altogether, or are flowerless after spring or early summer. For beds where summer-blooming bulbs, such as Lilium candidum and L. auratum, or Gladioli are grown, Begonias are unequalled; when put out as early as the weather will permit, the Begonias at once commence flowering. When the Lilies are in bloom, their appearance is much improved by the presence of the Begonias, which keep on blooming after the Lilies have died down. Not the least of the advantages attending the use of these plants for growing out of doors in the place of ordinary summer bedders that require propagating annually, and take a good deal of attention and room in the winter when there is often little of the latter available either in large or small gardens, is that with ordinary care the bulbs will last for years, and they can be stored anywhere out of the reach of frost, where they can be kept dry from the time the tops have died down until they begin to move in spring; then all they require is putting in pots big enough to hold them and the soil for the necessary support to the growth till the time comes for turning them out. When to be planted out in this way, the pots only need to be a little larger than will admit the bulbs after they have attained a considerable size, as no great amount of growth will be made before the time for planting out has arrived, provided they are kept quite cool. No more heat should be given after the first spring when the plants are raised from seed than is requisite to keep out frost, as the cooler they are the more close and compact the growth will be, a condition which is essential to their subsequent appearance during the season, for if the shoots are at all drawn the plants are half spoilt, as nothing that can be done for them afterwards will remedy the defect.

There are two ways of proceeding for those who intend beginning the cultivation of these Begonias, either to procure plants, or to raise them from seed. The latter will be the course which those who require them for growing out of doors will most likely adopt, especially as the largest flowered varieties are by no means the best for growing in this way (or, for the matter of that, for pot culture), and the general run of seedlings is usually much smaller flowered than the largest of the named varieties raised by the leading trade growers, and which are selected from thousands of seedlings annually grown. Tuberous Begonias will flower well the same season in which they are raised from seed, that is, if treated aright. To get the seedlings on without check or delay they require to be somewhat differently treated from the generality of other plants; consequently a few details respecting their management may be of use to those who have not had to deal with them.

With these Begonias, as with most things raised from seed, there is a marked superiority in the character of the flowers, and in the habit of growth of plants that are raised from a good strain, as compared with those that result from an inferior one. It is, therefore, important that none but the best seed be procured. It should be sown soon after the year comes in; a mixture of sifted peat, leaf-mould and sand is the best material to use. Drain some ordinary seed-pans and fill with the material, press it down and make the surface

smooth ; on this scatter the seeds evenly, but not too thickly, cover very slightly and press the surface a little, stand in a temperature of 55° or 60°, keeping the soil damp, but not over-wet ; when the seedlings appear the pans must be stood in a light position near the glass. There is one peculiarity in the treatment of seedlings of these Begonias necessary to bear in mind to prevent their receiving a check when moved—that is the little plants must be pricked off while they are yet much younger than is necessary with most things; this should be done before the radicle, the first root produced by the seed, has emitted any lateral rootlets, for if the plants stand in the seed-pans until these are produced, they are almost certain to get injured in pricking off, the effect of which would be that they would take some time to recover. The little plants should be put 2 inches apart in pans or shallow boxes, giving them soil similar to that in which the seed was sown; after this keep them in a temperature like that already advised, standing them where they will get plenty of light, and applying as much water as is necessary to keep them moving freely. Seedlings of tuberous Begonias, when well managed, grow faster than many other things, and care must be taken that they are not allowed to stand so long after pricking off as to admit of their roots getting so numerous that the plants cannot be separated without these being broken ; before there is danger of this occurring they must either be moved separately into little pots, or if there is a large number to be dealt with, they may again be moved into boxes, giving them more room. Whichever course is adopted they should finally be moved into pots from 4 inches to 6 inches in diameter, still encouraging them to keep on growing freely with plenty of light and a moderate amount of moisture, admitting more air and giving a little shade as the sun gets more powerful. By the end of May or beginning of June they should be planted out where they are intended to flower, previous to which they ought to be hardened off in a greenhouse or cold frame. They like soil fairly enriched with manure and of a moderately free nature. In autumn, when the tops are cut down by frost, the tubers should be taken up and allowed to become quite dry before being put away ; a greenhouse shelf, or anywhere where they will get enough air to effect the drying process, will answer. Afterwards they must be kept cool, but, as already said, out of the way of frost. So treated the tubers will last for years, increasing in size and in the number of shoots and flowers which they will produce. In ordinary winters the roots will live out of doors with some protection, but I prefer taking them up, especially as this, with the wintering and potting in spring, entails little labour.

Those who wish to grow these Begonias in pots can do so even if they have no accommodation under glass more than ordinary garden frames, or even without the aid of these if the tubers, after they have begun to grow and potted in spring, are stood in the window of a room where they will get light and air until there is no danger from frost, after which they will be better out of doors. When in bloom they make effective window plants, so long as they are not too large to be used in that way. But to have them compact and bushy so that the stems require no support, a condition in which they look much the best and produce the most flowers, they do better out of doors, for, except in the lightest and most airy greenhouses, their stems are liable to get drawn before the end of the summer has arrived.

T. B.

Ferula tingitana. — Among the handsome-leaved Ferulas, this species is one of the most elegant in habit, and as vigorous as it is graceful. It takes several years to form the strong tufts, which all who have seen them so much admire when bursting into their stately verdure in spring. The best way is to plant the young Ferulas where they are to remain at first. The position should be most carefully chosen. The mixed border is not suitable, as the plants die down in early summer, and would leave blanks that could not easily be filled. The best way is to place them singly, or in small groups, a little beyond the margin of a shrubbery, or isolated on the Grass, and so placed that their verdure might be easily visible in the garden landscape in early spring. Deep free soil should be supplied before planting, if the soil be not naturally both good and deep. It would be a good plant to associate with Daffodils and other early-flowering bulbs, which also die down in early summer. The Ferulas are most readily raised from seed, which should be sown as soon as gathered in a nursery bed in the open air.

HARDY FLOWERS AT SANDHURST.

At an exhibition held recently at Sandhurst hardy flowers furnished by Messrs. Sutton formed an interesting feature, and showed how many really valuable things can be grown in the open ground at this season of the year. There was, first of all, the pretty blue Cornbottle (Centaurea Cyanus), now so much employed in a cut state, an easily grown hardy annual of the most valuable character. Then came the following annual Chrysanthemums: C. tricolor Burridgeanum, with its rich dark zones of colour; tricolor Dunnetti, double, white and yellow; coronarium aureum and inodorum plenissimum, an excellent group, showy and gay. Next came the dark Coreopsis tinctoria, and with it an annual not so much grown as it deserves to be, namely, Cosmidium Burridgeanum, with yellow Coreopsis-like blossoms. Then there were single Dahlias in variety, and some fine seedling forms of Delphinium hybridum, Dianthus Heddewigi, and Indian Pink, in its varied double and single forms—all charming in a cut state. Gaillardias were shown in bold and striking bunches, and consisted of such varieties as picta grandiflora, marginata, fistulosa, Lorenziana, and amblyodon. Helichrysum monstrosum was also there in fine variety. Then there were Hollyhocks of excellent quality, concerning which it is worthy of remark that they were raised from seeds sown this year, and that they had reached a height of from 8 feet to 10 feet. Next came the double crimson form of Senecio elegans, the double Jacobæa of the seed catalogues, a subject that well deserves to be grown as a summer bedding plant. Some pretty Rocket Larkspurs were also shown; by some they are regarded as formal-looking, but they supply very pleasing tints of colour. The annual Marigolds were well represented by the orange and lemon African types and by the dwarf, tall, striped, and miniature forms of the French types. Of Sweet Peas there was a capital lot shown in bunches of distinct varieties, so that visitors could clearly distinguish as to their differences in making a selection. Then there were Salpiglossis, bold and extremely showy subjects, that give colours rarely found among other hardy annuals. The strain shown at Sandhurst is best known under the name of Salpiglossis grandiflora. Such wonderful sweet Scabious I think I never before saw; they had huge double Hollyhock-like blossoms, and must have been grown on good soil; they were one of the floral surprises of the show. Then there were giant Sunflowers, and what is known as the New Sulphur, a very showy form indeed, well worthy a place in the garden. The white, yellow, and purple Sweet Sultans (Centaurea moschata) were represented by very showy bunches; the first is much grown now-a-days for cutting. Dotted about were also handsome plants of the striped Japanese Maize. All the foregoing subjects were raised from seeds sown in the open ground this year.

Asters, including such fine types as the giant Pæony-flowered, Victoria, Chrysanthemum-flowered, Crown or Cockade, Fire King, a brilliant red or scarlet Aster, which must be showy in a mass, and several pretty dwarf-growing varieties, were all shown in good condition. Phlox Drummondi, of the grandiflora type, was also contributed in great variety, but in separate bunches; the flowers were very fine and showy. How is it that beds of mixed Phlox Drummondi are not more grown in the flower garden than they appear to be? They are very showy and continuous in bloom, but in order that the beds should be thoroughly effective, the decaying flowers should be picked off to prevent the formation of seed-pods. I also noticed bunches of very fine Ten-week Stocks, all emitting a delightful fragrance. Lastly, there were fine spikes of Gladioli interspersed among the subjects just named.

If promoters of flower shows were to encourage the growth of hardy flowers by the bestowal of prizes on large and small collections, so as to suit the resources of all, instead of for Pelargoniums, Fuchsias, Balsams, Verbenas, &c., that are too frequently produced in very shabby form, and quite unworthy of the many prizes offered for them, a distinct gain would be the result. Especially should this feature be introduced into flower shows held during the two last weeks in July and on to the middle of September. It is done to a small extent, but it is a feature requiring larger development. During the eight or nine weeks just named many country shows are held, and there is also then an abundance of hardy flowers—annuals, biennials, and perennials.

R. D.

NOTES ON HARDY PLANTS.

Helianthemum Tuberaria.—This is so beautiful on rockwork, that we do not begrudge it the extra trouble which it costs to carry it safely through our winters. It cannot be considered to be quite hardy, but it will withstand a good deal of frost. Fogs and wet are its greatest enemies. In a cold frame plants of it in pots are safe enough, and as it is a good plan to root cuttings, say three or four in a pot, in early summer for next year's use, there need not be any lifting and potting of old plants at the end of the season, which, moreover, is not such a pleasant occupation as preparing young stock, to say nothing of the uncertainty of old roots doing well when dug up late, for as the plant keeps on flowering until well into autumn, it is not advisable to take it up early. I am aware that in some parts it lives out all winter, but this is the exception rather than the rule.

Linaria anticaria.—This is an interesting plant, but not nearly so effective as the richly coloured and netted annual L. reticulata with its gold and purple flowers. As regards size, the flowers are larger than those of that kind, and very diverse in their hues and markings, but all the colours—mauve, yellow, brown, and pink—though prettily blended when closely examined, are so indistinct and wanting in effect, that this Linaria is not likely to be everybody's choice. Moreover, the plant is but a very indifferent perennial, at least with me; but most of the Linarias said to be perennial are faulty as regards duration in our climate.

Campanula nitida.—This is at once one of the most beautiful and effective, and perhaps the most shy bloomer of all the dwarf Bellflowers. May not the scarcity of its flowers account in some degree for the limited use made of the plant? Its flowers are large and striking, and there are both white and blue-flowered kinds, and double and single. The single flowers are especially handsome, being nearly 2 inches across, and hang sideways from the dumpy spikes of but a few inches in height. I grew this species for years and only got few and imperfect flowers from it. I could not tell what ailed my plants, for I had seen some in other gardens much happier. Latterly I have grown them in rich soil, nearly all thoroughly decayed leaf-mould, and now the flowers come out beautifully, so I suppose C. nitida likes rich food, and it certainly delights in full sunshine.

Wild Chicory.—It may amuse some to see this native herb recommended for pleasure garden decoration, but it has flowers of a most desirable shade of blue, and they are much liked in a cut state. One old plant has stood here for some years. It grows on a trellis along with sprays of the Virginian Creeper, and is now very pretty. The otherwise naked stems are almost 5 feet high, and are freely studded over nearly down to the ground

with bright azure-blue heads upwards of an inch across. The colour is rich and good, but I believe something is due to the fact that the plant is closely shaded on all sides, though clear overhead. The roots are practically in stones, sand, and manure, for a thick dressing of the latter is given annually owing to the poorness of the soil. Thus circumstanced the results are most satisfactory, though they were not so under other and, as I thought, more favourable conditions.

Gentiana brachyphylla.—This lovely variety of G. verna is now in flower. To say that the blossoms are equal in beauty to those of the type is no mean praise; they are, perhaps, even of a little lighter and brighter shade—a matter which one might expect, seeing that they are produced under a clearer sky than that under which those of verna are brought forth; they are also a little larger, too, and set close on dense tufts of foliage. The foliage is not a deep green, but somewhat glaucous. A good plant, some peat and turfy loam, a flat, moist position in full sunshine, are the conditions which have answered here, but all this dwarf section seem to be benefited by a summer top-dressing of leaf mould and sand.

G. alpina or excisa, as it is sometimes called, is also now in flower—perhaps later than usual, owing to being overshadowed by a tree. It is in all respects smaller than the typical G. acaulis; the palish blue tubes are charmingly spotted inside, and when well grown the plant is excellent in all points. It succeeds under similar conditions to those under which acaulis thrives. Flowers of these Gentians associate well with those of autumnal Colchicums, and there is no reason why the season of the Gentians should not be much more prolonged in our gardens than it now is.

Sedum Ewersi.—This late-flowering and high-coloured Stonecrop is neat and pretty in every way. Its round, thick glaucous leaves are set on such slender stems, that they rest on the ground, the rosy corymbs merely erecting themselves sufficiently to be seen like a setting in a blue-green carpet. If all the Stonecrops were better cultivated, they would be very different from what we nearly always see them. If set back in the ground every year or two years at furthest they would be less scraggy, more abundantly flowered, and better in colour. This kind especially is improved by such cultural care.

Delphinium velutinum.—If I have got this true from seed I must say that it is no beauty. It may interest people fond of the singular amongst plants, but for a garden where pretty forms and good floral effects are desired it is useless. It is all the more needful to state this precisely, because, as a rule, Larkspurs are showy plants. At this season the soft character of the whole plant gets changed into one of roughness, owing to the bristle-like quality of the hairs. The flowers are half closed, of a dull purple colour, with black centres in the form of a bee. The flower-colour is further detracted from by the hairy covering which renders it dingy. The spikes are but laxly furnished with flowers.

Stokesia cyanea.—The flowers of this are now fully expanded—a circumstance anything but usual in Yorkshire in the first week of September. The two drawbacks in connection with this fine Composite from the warm climate of Carolina are want of hardiness and a too tardy habit of flowering. If you set it in the ordinary way with other herbaceous perennials it either proves incapable of taking care of itself or grows so rampantly by means of underground stems, that a flower is rarely seen. Buds may be had in abundance, but they are so long in developing and so late that the heads seldom open. Old hands who have known Stokes' Aster for over twenty years say they have never yet seen it flower. There can be no question as to its beauty and worth, but all, of course, depends on whether it can be made to flower early in September. This may be done by setting strong plants with at least one bold and matured crown in light sandy soil in the full sunshine. It will probably make more progress under than above the surface, but if flowers are the object, all, except one or two, suckers should be removed. This treatment has been adopted here, and besides the big heads, nearly 4 inches across and of a light purple colour, resembling a magnified head of the double Catananche cærulea, the two barren crowns are extra strong for next year. In light soil and sun it is comparatively safe in winter, and quite so if a shovelful of coal ashes is heaped over it. In stiff cold soil it is sure to perish.

J. Wood.

Phytolacca decandra.—This ornamental plant is very suitable for the back of the herbaceous border, or for growing in spare open spaces amongst shrubs. The plant is herbaceous, and has huge fleshy roots that penetrate deeply into the earth in search of food, thus rendering it independent of the weather, as regards moisture, and of easy cultivation. Early in spring it sends up from its crown several stout shoots that soon run to the height of 4 feet or 5 feet, when they divide into numerous branches. These send forth numerous bunches of flowers, greatly resembling those of the Currant, and when these are ripe the plant has a very striking appearance, on account of their great profusion and rich colour. The berries, which are of a bluish black tint, are about the size of Peas, but are rugged and furrowed, and generally contain ten or twelve seeds. These should be sown early in spring, and when the seedlings are up and large enough to handle they may at once be transferred to the positions intended for them. Should the soil be at all rich, they must be allowed plenty of room, or they will soon overgrow anything that may be standing near. Although this plant will not attain a large size in poor soil, it will be found to fruit more freely. Grown as a pot plant, it is valuable for winter decoration in large conservatories.—J.

Yellow Paris Daisy.—Although I have always had a high opinion of this so-called Daisy for indoor culture, I never considered it effective in the open air until this year. Young plants, I have found, do not bloom quite freely enough; they are apt to run away into strong growths, especially in damp summers. The best plants for the open air are those which have become woody and somewhat stunted in their growth. Such plants put out in soil of not too rich a description become a mass of bloom by the end of July, and the flowers as they glow in the sunlight look very bright and cheerful. I advise any reader of The Garden who may have been disappointed with this Paris Daisy in the open to try older specimens. A good way is to put in some cuttings late in spring, and grow them on through the summer till they get well established in 4½-inch or 6-inch pots. If the buds are kept picked off, these will bloom well through the winter, and will then come in for the open air. A two-year-old specimen that had given hundreds of blooms in winter and spring was put into the open ground in June. For a couple of months it has been smothered with bloom, and will probably remain so till frost comes. I think one large specimen such as this is much more effective than a number of small plants crowded together. —John Cornhill.

SHORT NOTES.—FLOWER.

Chrysanthemum coronarium.—This is one of the most useful of annuals for flower borders. Self-sown plants of it yield a supply of flowers early in summer, while those sown in spring keep up the supply till frost sets in. Amongst them we have two very distinct colours, one bright yellow, the other creamy white.—E. B. L.

Veronica rupestris.—This little trailing Speedwell forms on the rockwork at Kew dense glossy mat-like masses of bright green foliage completely covering the stones. The flowers are of a deep rich blue, paler beneath, and are borne on slender spikes. At first sight it looks exactly like Lithospermum prostratum, but its foliage is brighter and fresher, and its flowers are fully as beautiful, although not so durable.

Dianthus Ragged Jack.—Those who are fond of sweet-scented flowers should add this variety of Indian Pink to their collections. Seeds of it should be sown on a warm border early in spring and during the summer, and till cut down by severe frosts it will produce a great profusion of ragged and somewhat insignificant flowers, but which scent the garden agreeably for some distance around them. This scent is especially strong in the mornings and evenings. —W. I.

NEW CARNATIONS AND PICOTEES.

Of the new Carnations and Picotees which have made their first appearance during the season just passed, I put in the first place scarlet bizarre Robert Houlgrave, raised by Mr. Samuel Barlow, of Stakehill House, Castleton, Manchester. It is in the way of that well-known and popular flower, scarlet bizarre Admiral Curzon, but regarded by the florists of the north to be superior to it. It was awarded a first-class certificate at the National Carnation and Picotee Society's exhibition at Manchester on August 14. Mr. Douglas, Great Gearies, Ilford, who has raised several fine seedling Carnations and Picotees, showed several at South Kensington on July 27. Among them were scarlet bizarre Thetis, pure white ground, marked with rich maroon and scarlet, good petal and substance; crimson bizarre Duc d'Aumale, rich crimson and purple, fine form; pink and purple bizarre Felicity, a beautiful pale pink variety, flowers of large size and full substance, in the way of Sarah Payne; scarlet flake Alisemond, well formed petals and good broad scarlet flakes on a white ground; rose flake Thalia, large and full, good broad petals, flaked with pale rose; Diana, flaked broadly and regularly with bright cherry-rose on a white ground (both Thalia and Diana were awarded first-class certificates by the National Carnation and Picotee Society at South Kensington in 1885); and Corisande, pale rose flake on a pure white ground, very full and good. This and Felicity appear to possess great distinctness of character.

Of new Picotees, I think that Mrs. Sharp, raised by Mr. J. P. Sharp, of Birmingham, must head the list. It was shown at the meeting of the Oxford Carnation and Picotee Union in 1885, and again at Manchester on August 14 last, and in both instances it was awarded a first-class certificate. It was shown by Mr. R. Lord, of Todmorden, by Mr. B. Simonite, Sheffield, and by the raiser, and, wide apart as these districts are, it was fine in character in each instance. It has massive broad petals, pure in the ground, and is broadly edged with the liveliest rosy scarlet. Mrs. Anstiss, raised by Mr. Thomas Anstiss, Brill, is a fine, heavy purple-edged flower, in the way of Muriel, pure, fine in the petal, and having a solid edge of bright purple.

Of new purple-edged flowers I may mention Woodkins (Wood and Ingram), the white ground very pure, petal moderately broad, with wire edge of bright deep purple—a good addition to the light purple flowers; Queen Adelaide (Wood and Ingram), heavy purple, large full flower, with solid broad margin—excellent in form; Juliette (Fellowes), medium purple, good broad smooth petal, fine large full flower, quite distinct in character; Catherine (Fellowes), heavy purple, pure white ground, petals of fine form, broad and smooth; and Mrs. Nicholay (Fellowes), light purple, a very large and full flower of excellent quality, and having a good free habit of growth.

Of rose and scarlet edged flowers there are Henreuse (Douglas), medium edge of rose, full flower, broad petals with a regularly defined edge; Mrs. J. Wood Ingram (Wood and Ingram), medium rose edge, the white pure, petals of good substance—one of the best of its class; Duchess (Fellowes), heavy scarlet edge, very large full flower, quite distinct and very attractive; Maud (Fellowes), light rose, fine broad smooth petals—a very chaste and fine flower; Mary D. Anstiss (Anstiss) is a very pleasing flower, broad stout petals and an edging of rosy scarlet—said by the raiser to be a good grower and very fine (this was awarded a first-class certificate of merit at the South Kensington meeting on July 27); and Orlando (Fellowes), light rose edge, large, full, and fine. Singular to state, not a single new red-edged Picotee has put in an appearance during the present year, to my knowledge.

Of yellow Picotees some few new varieties have put in an appearance, especially those raised by Mr. J. Douglas. Smith Barry (Wood and Ingram) has a bright yellow ground heavily margined with crimson, and is decidedly attractive. R. D.

Victoria Aster.—This, in my opinion, is the best of all Asters. We have grown a quantity of it this season for cutting, and most serviceable it has

been. This Aster likes rich food. Our best plants of it are growing on a border well manured from the pigstye; they were sown thinly in boxes in April, and as soon as large enough, were planted out in rows 1 foot apart; the season being genial, they have grown and flowered most satisfactorily. I may add that not the least amongst the many good qualities belonging to this Aster is the way in which plants of it may be transferred from the open ground to pots without so much as shedding a leaf. In lifting them we take a fork, and thrust down deeply so as to get all the roots. We then carefully shake away the soil, and having fitted the plant into the pots, fill up with finely sifted soil, and press all down firmly. We then set them in a pit where they can be kept rather close for a day or two and shaded from bright sunshine; they soon get established, and may then be utilised indoors. The clear whites and various shades of pink or rose are very bright under artificial light, and on the dinner-table strikingly effective.—J. G., *Hants.*

Rose Garden.

PROPERTIES OF GOOD ROSES.

The general principles or properties laid down as influencing the staying properties of Roses are likely to prove most useful. Depth and substance of petal are doubtless solid bases for the building up of staying power, and are more than a match in this connection for mere numbers, though the latter are by no means to be despised. A curious sample of staying power came under our notice this year in regard to one Rose sometimes cited as mostly wanting in this useful property—Merveille de Lyon. A bloom of this variety was awarded the highest honours as the best Rose staged at a show in competition with such good staying Teas as Souvenir d'Elise, Innocente Pirola, Maréchal Niel, La Boule d'Or, &c. Instead of staring at the judges with open eye, as usual, it continued perfect in form throughout a long, hot summer day in a rather close tent without speck or flaw, and was allowed by the exhibitors of some of the finest stands of Teas ever seen by the writer to be without doubt the most perfect Rose among many hundreds shown. La France seems to make up by the number of its petals for its want of substance, and under favourable conditions stays well. The petals are so crowded together, that they do not seem to have room to fade, while it is rare indeed that it can open its eye. But, fragrant and exquisite as La France is, it would doubtless be yet more valuable were its petals thickened. In that case, however, they would also have to be thinned, or the Rose enlarged to something like the size of Pæonies, for we very much doubt if we have a Rose with so many petals as La France. How far liberal culture extends the staying property of Rose blooms is a most interesting inquiry. Possibly a moderate *regimen* will be found the best for fostering or developing the endurance of individual blooms, on the same principle as temperate or even hardy living develops to the uttermost the strength of athletes. Be that as it may, it seems almost certain that our pampered treatment and gross feeding of our Rose trees not seldom result in floppy blooms, that suddenly collapse, or have staring eyes, when expected to look their very best on exhibition tables.

Those blooms suddenly cut off from a full larder are the likeliest to fade or lose colour the soonest unless their wants can be supplied afterwards—a feature of Rose culture as yet hardly attempted, but which may become important if the present fever-heat of Rose showing is to be kept up. Possibly as our knowledge of vegetable life and nutrition is enlarged it may be as easy to suckle Rose blooms on or off the plants as it is to suckle prize Gooseberries, each tube containing its special mixture to uphold substance as well as sustain colour. Meanwhile, those rosarians are likely to be the most successful who are careful to avoid over-feeding, on the one hand, and semi-starvation on the other. For example, I have seen most of the exquisitely delicate pink that constitutes one of the chief charms of La France washed out of it through overdoses of soapsuds and house slops; while the petals, always thin, have been run out into gossamer-like texture by gross over-feeding. The idea that there may be a fixed sum of excellence, to be equally divided into colour, size, form, substance, vigour, floriferousness, &c., or more or less converted into one or more of those qualities, is at least ingenious and deserving of careful consideration. That the constitution of our Roses is being undermined and their individual life shortened in the feverish race for enlarged and improved blooms can hardly be doubted. The earth sickness that affects our modern Roses, their craving for maiden root runs, and refusal to do their best unless these are provided, are modern symptoms of culture and experience that were wholly unknown to our not remote progenitors. Their Rose bushes virtually lived for ever; ours, in many cases, are annuals, biennials, or triennials at the longest. We want to link on all modern improvements to the hardiness and longevity of the elder Roses. Whilst willing and anxious to devote the utmost care and skill to the perfecting of Rose blooms, we demand of the raisers of new Roses that they shall be endowed with sufficient stamina to bear the forcing strain of modern cultivation in its fast gallop towards perfection without being crippled or killed through the strain or by the speed.

D. T. F.

Branch of Sweet Brier (Rosa rubiginosa).

Rose Cramoisie Superieure.—I was much struck the other day with the effect produced by this bright little Rose in the Handsworth Nurseries. There was a large bed of it in which the bushes were about 18 in. high and smothered with flowers. It is a capital Rose at this season.—W. G.

SWEET BRIER.

Few flowers are more full of charm than the old Sweet Brier. It fills the air with sweetness in the first warm days of April, when its leaves are only half grown; bears a wealth of bright little Roses at highest summertide, and a heavy load of scarlet hips to cheer the short late autumn days. It is at home in the poorest soil, growing willingly in almost pure sand. A double line of Sweet Brier forms an impenetrable and most beautiful hedge, the interlacing prickly branches giving it strength and stiffness.

ROSE NOMENCLATURE.

Turning to the catalogues of the florists, one man says a certain Rose is a Tea, another a Hybrid Tea, another a Hybrid Perpetual, and another, perhaps, a Hybrid Noisette, till I am at a complete loss to know what it is. This leads me to look up the botanical classification and history of the Rose, which, although very interesting, fails to throw much light on the particular variety in question.

Under this state of affairs the best that we can hope for is a garden classification, but let us have one that will give the purchaser some idea of the nature and habit of the plant he is asked to buy. All florists admit that the term "Hybrid Perpetual," under which, perhaps, the most interesting of our Roses are classed, is a complete misnomer. These Roses are not perpetual bloomers, as the term implies, but bloom at intervals or stated periods, usually in spring and autumn, although they are frequently treated in ways best known to the florists, so as to bloom in the winter and other periods of the year. The French term "Remontant" (meaning literally "to grow again") is more significant and certainly a much better term than "Hybrid Perpetual."

The ever-blooming or Monthly Roses are not strictly ever-blooming, but bloom at random, or apparently without any definite periods. This term, however, is not as objectionable as that used to designate the preceding class, and conveys a tolerably accurate idea as to the blooming habit of the varieties it comprises, but I should consider "random-blooming" a better term.

The term "Bourbon" designates a class of Roses which originated in the island of Bourbon [here we have a geographical name], and was undoubtedly the result of a cross between the Damask and Bengal Roses. It is usually classed as an Ever-blooming Rose. It does not, however, possess the same habit of bloom as the Bengal and Tea Roses, but blooms periodically, the periods being more frequent than with the Remontant Roses.

The Noisette Roses are a class supposed to have originated from a cross between the White Musk and the China or Bengal Roses, and created some excitement when first introduced. They are certainly a remarkable and beautiful class of Roses, but there appears to exist some confusion in these with the climbers and Teas, and they are usually placed in the catalogues as a distinct class. Most of the Noisettes, I believe, are climbers, but some are not, or at least are not so distinctly characterised. They were named in honour of the man who originated the variety. But historical and geographical names are not wanted in our catalogues; we want something indicating the character of the plant.

The Hybrid Teas are Roses of recent introduction, the result of crosses between the Remontants and Teas, and are undoubtedly destined to supplant some of the older varieties in popularity, as they combine in varying degrees, according as they favour the Damask or the Tea, the robust habit and brilliant colouring of the Remontants, with the exquisite perfume, delicate tints, and more constant blooming habit of the Teas. The La France and Bennett are types of this class. By the way, I would like to ask as a matter of curiosity, how the yellow shades in our Tea Roses were derived. Are they natural to the species canina, or do they originate from crosses of this species with some other, the sulphurea, for instance, which is distinctly characterised by its deep yellow flowers?

The Hybrid Noisette is another class of recent introduction. The Ball of Snow, Coquette des Alpes, and Coquette des Blanches belong to this class. The white Musk origin is apparent in the pale tints of the flowers. The last two classes are in some confusion, and are indiscriminately classed by florists as Hybrid Teas or Hybrid Perpetuals.

But it is easier to find fault, I suppose, than to apply the remedy. It does seem to me, however, that some effort should be made to extricate the most beautiful and charming flower that Nature has given us from the confusion into which it has so sadly fallen.

After revolving the matter in my mind for some time I have finally, for my own convenience, adopted the following classification: First, I divide all Roses under two heads—shrubs and climbers—as all the varieties can, as a rule, be readily assigned to one or other of these divisions, which indicate the habit of the plant. These divisions I sub-divide into three classes each, significant of the bloom: 1, annual blooming Roses, or those which bloom but once a year; 2, periodical blooming Roses, or those which bloom at certain periods, more or less defined as the case may be, such as the Remontant and Bourbon Roses; and, 3, random or ever-blooming Roses, or those which bloom apparently at will, such as the Bengal and Tea Roses. (I prefer to retain the title "ever-blooming," as it is a term in common use and pretty generally understood.) This gives me six distinct classes.

First, annual blooming shrubs, which may be designated by the general title of "shrub Roses," including the Damask, Provence, Moss, French, White, Hybrid Chinese, Hybrid Bourbon, and Hybrid Provence, or most of those now classed as "garden Roses."

Second, periodical blooming shrubs, including the Remontant and Bourbon Roses. If the term "Hybrid Perpetual" must be retained, let it be a title for this class.

Third, ever-blooming shrubs, including the Bengal, Tea, some of the Noisettes, and perhaps also the Macartney and microphylla Roses, which may be designated under the general title of ever-blooming Roses.

Fourth, annual-blooming climbers, including the Sweet Brier and hardy climbing Roses.

Fifth and sixth respectively, periodical and ever-blooming climbers, including the Musk and certain of the Noisettes. I am not sufficiently familiar with the latter varieties to say just which class they should be placed in, nor can I say from my present limited knowledge under what classes the Hybrid Teas and Hybrid Noisettes should come, but I imagine it would lead to a division of these now popular Roses.

I offer these remarks as a suggestion to our horticultural societies, with a faint hope that they may lead to a better classification of the Rose than we have at present.—William Hewett, in *Rural New Yorker*.

Rose Lady Mary Fitzwilliam. — In "J. D. E.'s" interesting notes on the new Roses at Waltham Cross (p. 247) occurs the following statement: "Amongst pink and rose-coloured Hybrid Perpetuals, Lady Mary Fitzwilliam holds high rank; it is supposed to partake of the Tea section, but it is certainly nearer the Hybrid Perpetuals." Now, I have grown this fine Rose for some years, and in foliage, habit, form, and even perfume, should pronounce it almost three-quarters Tea—assuredly much more closely allied to the latter than Hybrid Perpetuals. Not only this, but by virtue of its autumnal blooming it is also a Tea, and this latter quality adds greatly to the value of this perhaps the finest of all the pedigree Roses yet sent out. I forget at the moment what Mr. Bennett says of its parentage, but its whole character proclaims it a Tea, and no doubt one preponderating parent was a Tea. At a time when every grower is seriously setting about expanding his Teas at the sacrifice of his so-called Hybrid Perpetuals, I must utter my protest against removing such an obvious Tea as Lady Mary Fitzwilliam from this favourite family of Roses.—D. T. F.

NOTES.

Old Chrysanthemums.—One of the first, if not the first descriptive account of this now popular flower was that written by Mr. Sabine (*vide* Trans. R. H. S., vol. v., p. 322) in the year 1826. It is well known, and has often been referred to by more modern writers. I have just come across another and less well-known contribution to the history of the Chrysanthemum, written in 1833, by Mr. A. H. Haworth, and published in the *Gardener's Magazine* (vol. ix., p. 218). Haworth mentions "various seedling varieties as having been recently exhibited," and these he further tells us were "chiefly obtained from seeds of the Early Blush, Early Crimson, and the Two-coloured Red." In this paper he prophesies that the Chrysanthemum would be immensely improved by seed-saving from suitable kinds. "We must try the seeds whenever we can procure them; and their unequalled sportiveness will reward us for the trouble of rearing them, by countless numbers of new forms, faces, and colours, surpassing all we at present know. The sports of colours in the flowers by casual branches from old plants are well known, and capable of being propagated and perpetuated." Haworth describes forty-eight varieties, and mentions such as have seeded in our climate, or have yielded bud sports, and he refers to the figures at that time published. All the varieties are at this date known by descriptive names only, such as the Tasselled Salmon or the Clustered Pink, and even at this early period synonyms were not unfrequent. It is interesting to find Haworth doing for the Chrysanthemum what he also did for the popularity of Narcissus.

Scarborough Lilies.—Here and there in sunny windows one may see the old Vallota in bloom again. It is nigh on thirty years since I first saw it blooming in a window in the town of Norwich, where flowers have long been valued and largely grown. A friend lent me the other day an interesting old book, called Threkeld's "Synopsis stirpium Hibernicum," which is, if not the first, certainly one of the first of essays in the English language on the plants of Ireland. Caleb Threkeld was a Cumberland man, who practised medicine in Dublin about 150 years ago, and it is he who tells us that the white Clover is the Shamrock or Seamer-oge of the Irish people. Threkeld, in speaking of Melilotus germanica, a plant more recently known as Trifolium cæruleum, tells us that "the Norwich people strive in their floralia who may outvie each other in the finest flowers, and he who grows the prettiest flower wins a flowery garland as a conqueror." "Hence," he concludes, "they boast that their Norwich is a city placed in a garden, or a garden placed in a city, whichever you will." We have now four or five varieties of this fine old Vallota purpurea, viz., magnifica, major, eximia—the white-eyed variety—all differing more or less from the type, but the finest form I have ever heard of is that grown at Bicton, which produces from five to ten flowers on a scape, the individual blooms being large and rich in colour. Of all evergreen bulbs, the Vallota is perhaps the best as a window plant, but at Muckross Abbey, near Killarney, it luxuriates in open-air beds and borders, as it may possibly do elsewhere in light sandy soils near the sea.

Convolvulus Scammonia.—The Scammony plant is a great success if planted on deep sandy soil and treated as an ornamental climber, and it has the advantage of growing well where its near relative the Jalap plant fails to bloom. We have a Scammony plant here on a pyramid of stakes about 6 feet in height, and it is quite covered with its piquantly-shaped, angular-pointed leaves, and every morning the little white cups open out by the hundred in the sunshine. It is a very rapid growing plant on deep, rich, light soils, and would soon cover a trellised porch or arbour with its flowery growths. Our plants of this species came from Mr. Ware five or six years ago, and were in 2½-inch pots; but they soon grew rampant after being planted outside early in June. There is a little secret in the treatment of all half-hardy plants which are to be risked out of doors entirely. It is this: always plant them out in May or in June, so that they may make a good long summer's growth outside before the frosts come to cut down their leaves. So treated, their roots become firmly established ere winter comes, and a little protection in the form of dry ashes, turf mould, or Cocoa-nut fibre is pretty certain to preserve their land-locked roots from injury. As so treated, Scammony would be hardy nearly anywhere, and it is so distinct and effective as to be worth a little trouble.

Oriental Poppies.—When we cut off the seed-pods and flowering stems of these big red Poppies about two months ago I thought we had done with them for this season, but I see that a few stray blooms are again opening their showy petals. No doubt these Poppies become cross-fertilised when growing near each other, and so it sometimes becomes difficult to distinguish between P. orientale and P. bracteatum in our gardens to-day. Just now we have blooming here for the first time a soft rosy-salmon variety of P. orientale, given to us by the Rev. Denis Knox, of Virginia. It might be called a pale crushed strawberry colour, and is certainly the most distinct of all the five or six varieties known to me. It has the characteristic dark blotches near the base of the petals. One of the most showy of all our varieties is one which came from Mr. Clarke, of Weymss Castle, under the name of P. bracteatum var. pulcherrimum. It is stately and rigidly erect in habit, bearing great glistening blood-crimson-hued flowers nearly a foot across when expanded in the sun. Four or five years ago I obtained a pod of seed from a good form of P. bracteatum growing isolated in a neighbouring garden. We reared two or three dozen of healthy young plants, but scarcely two are quite alike. One is very dwarf, flowering at 18 inches, the flower being open and large. Another tall, slender, erect growing kind has the flowers half open, so that, as "A. D." once remarked, they appear somewhat like an old-fashioned wine-glass. As seen well grown in a mass, these Poppies are very effective, and it is pleasant to be able to expect finer forms from seed.

Snapdragons.—The best varieties of these are very beautiful and well worth a place in all good gardens. Last autumn I obtained seeds of a very dwarf-growing variety with white flowers, which I saw growing in Messrs. Ireland and

Thomson's nursery, near Comely Bank, Edinburgh. It comes nearly true from seed—say, 90 per cent. of the seedlings are pure white like the parent—and its flowers are now very useful. A good long row or a bed of this variety would be very serviceable wherever white flowers are in demand at this season. We also grow a deep rich kind having flowers of a dark blood-crimson colour, and both are so good that we hope to keep them pure and strong by putting in a batch of slips every year. Either alone or contrasted together, this snow-white variety and the velvety crimson one are so fine in their way, that we have rooted out the common kinds which formerly luxuriated on the tops of our old walls, and have sown the seeds of these, Belvoir Yellow, and best crimson Wallflowers, and hope that they will supplant the poorer kinds. So far as I know, no plants are more showy or grow better on walls or ruins than do these Wallflowers or Snapdragons (Antirrhinum majus), but along with them seeds of Stonecrop, Sempervivum, and Saxifrage may be tried, and Erinus alpinus and Linaria alpina, although not always at home on the borders, are generally a success on old walls.

Cyperus Papyrus.—All things considered, is there a more stately, graceful, or more interesting foliage plant, usually grown in hothouses, than this Sedge, once so important in the world of letters? It grows like a weed if divided now and then and planted in a larger pot of pure loam, and if the pot be drained with broken bones instead of crocks, so much the more luxuriant do its tufted wands become. In some places where it is cultivated these tufted stems are very highly valued as indoor ornaments, and if placed in vases of water refreshed from time to time they endure long in beauty. They also keep a long time in a dried state, and so used are an addition to the winter vases of stems, Grasses, and dried fruits. The plant exists yet near Syracuse in a wild or naturalised state, but is generally to be seen in botanical gardens, while rolls of Papyrus, and the materials for writing or drawing on them, may be seen in most museums of antiquities. Apart, however, from history or romance, the Papyrus is really the most stately and beautiful of all the Sedges grown in our hothouse gardens, and it does not require a very high temperature to grow it well. A good specimen passed the winter in a warm greenhouse, the temperature of which often descended as low as 45°. It does best if planted on a mound of earth in a tank of water, but may be grown nearly as well in a large pot plunged in a pan or saucer.

Lobelia ignea.—Of all herbaceous plants we have had but few at the same time so distinct and effective as this crimson-flowered Lobelia. It is not hardy everywhere, but well worth the trouble of protection during winter, seeing that its crimson-scarlet spires are now so brilliant as contrasted with the white Rose-like blossoms of the Japan Anemone. This Lobelia may be readily reared from seeds sown as soon as ripe, or they may be kept until the spring following—say February, and then if sown on a gentle hotbed will germinate quickly, and soon grow on large enough for pricking out in prepared boxes or into open-air beds in May. A quicker mode is to divide old tufts just as they begin to grow in the spring, at which season this plant breaks up quite safely and readily, every shoot forming a flowering plant. Some of the finest beds and groups of this plant I ever saw were formed on this plan of division in the spring, after which the shoots were planted about 12 inches apart in deep rich soil. Either as a flowering plant, or as grown for its purple leaves and stems, it is one of the most distinct and desirable of all the herbaceous plants known to me. L. splendens, L. cardinalis, and the white, red, and blue forms of L. syphilitica are pretty, but none, as I think, equals L. ignea, or Queen Victoria, as it is sometimes called.

Calceolaria Kellyana.—Of all the Slipper flowers introduced from time to time to our gardens none baffled cultivators more effectually than did the curious C. Fothergilli, a native of the windy Falkland Islands. I have had seeds from thence and also living plants, but never could grow this dwarf and singular species, and all I really know of its flowers is derived from Edwards' drawing in one of the earlier volumes of Curtis's *Botanical Magazine*. But the best substitute for the wild species is a hybrid obtained years ago between C. plantaginea and C. Fothergilli by the late Mr. Kelly, a nursery gardener of Edinburgh, and now known under his name as above. It is a dwarf plant, nearly hardy, possibly quite so in mild dry soils, its hairy leaves lying flat on the surface of the soil, and its two to three-flowered scapes being about 6 inches in height. As a plant for edgings or for a sheltered nook in the rock garden it is unique, its flowers and habit reminding one somewhat of its parent, C. Fothergilli, but it is a much more easy plant to grow. Although hardy or nearly so, we generally pot up a plant from the open air and preserve it through the winter in a greenhouse or cold frame. It is easily increased by cuttings or by division of the tufted root stock. It has long been grown in the botanical garden at Edinburgh, from which northern Eden our stock of this and other good things originally came. Veronica.

NOTES ON LILIES.

In a discussion which took place in The Garden a year or two ago on Lily culture in pots I asserted that the annual disturbance to which the bulbs are subjected is not so necessary as it is generally supposed to be, and that a maximum of development may be obtained by keeping them for several years in the same soil. Subsequent experience enables me to confirm the statement then made, and I am now sure that in the culture of Lilies in pots a great deal of labour might be saved. Several years ago, having a number of Japan Lilies in pots, some of them through lack of time were not repotted. These started very strongly into growth, and nothing was done to them with the exception of giving them plenty of water with occasional doses of weak liquid manure when in full growth. In other respects the treatment was identical with that given to those that had been shaken out and repotted in the usual manner. Some of these were large specimens in 12-inch pots, and they carried individually nearly 200 blooms, which in size and colour left nothing to be desired. Being wishful of further proof, I last year purposely left some pots untouched, with identical results. The most convincing example of the non-necessity of annual repotting was found in an 8-inch pot, which contained a plant with 70 good blooms, one stem alone bearing 18. This was as perfect a specimen as could be grown in a pot of that size; not a leaf turned yellow, the foliage having that deep glossy hue which characterises the varieties of speciosum when in perfect health. From the time these plants started into growth the pots were packed with roots, and as soon as they commenced to grow freely they were top-dressed with Clay's fertiliser, and when they were in full growth they had frequent waterings with weak liquid manure. L. auratum I have also grown in the same way, and I have an idea that some of the more delicate-rooted kinds, such, for instance, as Krameri, would give better results if they were allowed to remain undisturbed for a year or two.

Lilies are not like many bulbous plants; the roots do not die away, but remain in a more or less active condition all through the year. When the stems die down in autumn the soil will be found to be full of white fibres, and in the process of shaking out the bulbs to repot, some of these, even with the best care, will be lost or injured. This may not inflict much injury in the case of strong-rooting free-growing kinds such as speciosum, but in that of those of more weakly growth and feebler rooting power this root-disturbance must be to a great extent detrimental. In the case of plants in small pots it is very easy to shift them on, giving a small shift; the active fibres do not then suffer, but soon begin to enter the fresh compost, which they will almost fill by the time top growth commences. When at length they come into pots so large that it is not considered advisable to re-shift, they may remain for two years therein, and if fed regularly from the time they begin to grow they will bloom satisfactorily. The great point in the case of Lilies thus grown is to commence feeding as soon as the plants begin to grow. If this is deferred until the buds form, as is generally done in the ordinary way of culture, the flower-stems will be lacking in strength.

Lilies in groups.—The fact that Lilies are not shown to the best advantage unless planted in masses is not so fully realised as it should be. This is especially the case with such hardy kinds as the Tiger, the Orange, umbellatum, and the varieties of speciosum and candidum. What finer garden picture can be formed than by having a half hundred of the lovely Madonna Lily planted together, especially when the purity of the bloom is enhanced by contrast with the deep hue of Evergreens of some kind? The bright tints of the Orange and Tiger Lilies are equally effective, and I never remember to have seen anything more pleasing than a long border rather thinly planted with dwarf shrubs with a row of Elms at the back, the overhanging branches of which gave grateful shade, and in the subdued light of which the glowing colour of masses of the Orange Lily was seen to great advantage. When this border was first planted a few bulbs were set here and there, but as no digging was ever done and short Grass and Moss covered the soil between the shrubs, they had waxed in strength and increased in number with each succeeding year, so that they had more the appearance of being a natural growth than of having been planted. The hardier kinds of Lilies, if planted in the first instance in well-prepared soil and left alone, will increase rapidly, but the soil around them should not be deeply dug; simply hoeing to keep down weeds with an annual mulch of decayed manure or leaf-soil applied at the commencement will preserve the roots intact, guarantee the bulbs against mutilation, supply them with nourishment, and, in a word, will ensure to them the conditions the most natural, and consequently best fitted for their welfare. In planting Lilies of this description, and which can be relied on to resist with impunity the trials of our climate, it is better to thoroughly prepare a smaller area of ground than to dot in the bulbs indiscriminately.

By planting a number of bulbs together, that particular spot is consecrated to them, and they are not likely to fall victims to forgetfulness, which is often the case when they are dotted about indiscriminately. Whenever Lilies are planted in this way, a position, if possible, sheltered from high winds should be chosen for them. A strong westerly gale accompanied by heavy rain will batter the flowers and beat the stems down to the ground unless staked, and the staking of any quantity of Lilies is often not practicable. Although in some instances the planting of Lilies in mixed flower borders is unavoidable, it is to be shunned as much as possible; they should always be sheltered by an undergrowth of some kind. To my mind, there is something unnatural in the appearance of Lilies springing from the bare earth; the slender stem, with flowers out of proportion to its strength, plainly bespeaks the need of support or shelter of some kind.

L. auratum in the open ground.—How many thousands of this Lily are annually put into the

ground to perish it would be hard to say; but the number of bulbs that in a general way can be found in a tolerably populous neighbourhood in the enjoyment of truly perennial vigour may be counted on the fingers of one hand. Here and there, however, one comes across one, the long-continued health of which is a matter for surprise, seeing that the conditions under which it has thriven are to all appearance identical with those that have proved fatal to so many bulbs. Why it is that some bulbs remain sound and increase in bloom-bearing power from year to year, whilst their near neighbours speedily decay, is difficult of explanation; but it would seem that the bulk which can be carried safely through two years in the open ground will in all probability enjoy a long life. A friend of mine has a bulb that has bloomed in more counties than one, and, notwithstanding the removal, is this year flowering with unabated vigour. In a small garden near here there was a bulb which the owner grew year after year among his Gooseberry bushes. It had no protection in winter, but bloomed with great vigour, the bulb eventually attaining the dimensions of a good sized lamp-globe, when it suddenly collapsed, dying apparently of old age. I believe that in the case of imported bulbs destined for the open ground it would be better to grow them one year in pots, if possible under glass, and not dry them off in winter, planting out with roots intact the following spring. It would also be well not to allow flowers to form, picking off the buds as they form. In all cases it would be advisable to do this, so as to concentrate the energies of the plant on the formation of the bulb. There is no doubt that the deprivation of the bulbs of active roots for a considerable period is contrary to the nature of Lilies, and this, in conjunction with a long voyage, has the effect of reducing vitality. The flowers produced are the result of the previous year's growth, so that the close of the blooming time finds the bulbs in a flabby, exhausted condition, and not able to stand against the effects of our damp English winter. There is, however, one point in connection with the growth of this Lily in pots that has to be taken into consideration. The common practice is to allow but little soil for the bulbs to root into, reserving the greater portion of the space for the nourishment of stem-roots, which undoubtedly play an important part in the formation of good blooms. I am of opinion, however, that these stem-roots may be made in a great measure to usurp the functions of the real roots, and by reason of their excessive production and the small amount of food at the disposal of those that issue from the base of the bulb, these latter come badly off for nourishment. It stands to reason that the bulbs cannot be so well fed when they have but 2 inches of soil under them as when they are enabled to enjoy all the pot can hold, and as our object in the present instance is not the production of flowers, but the strengthening of the bulb, therefore I think it better to pot the bulbs, so that the roots that come from them can obtain as much food as possible. Imported bulbs treated in this way are almost sure to retain their plumpness, even if they do not increase in size much for the first year or so. When they are planted out they immediately lay hold of the soil, and are sure to make good growth. It is a moot point whether home-grown bulbs are in the long run more satisfactory than imported ones. It would also be interesting to know the difference, if any, in the behaviour of those raised from seed or from scales. It is reasonable to suppose that seedlings would possess the greatest vigour. I am strongly inclined to the belief that our gardens will never be properly stocked with this Lily until we get a plentiful supply of home-grown bulbs. The question of deep *v.* shallow planting has often been discussed in The Garden, but this, I think, must depend upon soil and locality. Locality, too, must influence the choice of position.

In the colder districts of Great Britain I doubt if L. auratum can have too much warmth; indeed, I doubt whether this Lily should ever be grown in shady places; the more warmth the greater maturity and, consequently, solidity of growth. In Japan it is found in full exposure, but springing from Grass and low Rushes, and the bulbs are but slightly buried, which points to the need of their being within the influence of solar heat. The finest results in the open-air culture of this Lily have been obtained by planting among Rhododendrons, and Bamboos, Bracken, and various other things that have been recommended for shelter. I have never, however, seen the common Bramble mentioned in connection with this subject, although I doubt if anything better could be found. Some support for the slender stems, with shelter to the roots from hot sun as well as from frosts and cold winds, when starting into growth is necessary, and this the common Bramble is capable of affording.

When Lilies are planted amongst Rhododendrons or other Evergreens, these in time become so rampant that the Lily stems do not get sufficient light in their earlier stages of growth; whereas in the case of the Bramble it is easy to cut them down now and then. The interlacing branches would afford just the right amount of support, whilst enough foliage remains on through the winter to shield the tender Lily shoots when beginning to grow in spring. Of course, Brambles would not be admissible in the dressed portions of the flower garden, although the double-flowered kind might be used there even, but there are in many places positions where clumps of Brambles would fit into the surroundings. Some of the American kinds might be tried in this way, thus combining fruit and flower culture in a very happy manner. Not only auratum, but some of the hardier kinds of Lilies might be extensively used in this way.

Lilies in sunshine and shade.—It is generally accepted as a fact that Lilies enjoy a partially shaded situation during the hot summer months, and there is no doubt that leaf and flowers attain a higher development when screened from the fiercest rays of a midsummer sun. It is a question, however, whether many of the Lilies that we attempt to grow in the open air get as much heat as it is their nature to require in an average summer in this country. Such vigorous kinds as the Tiger will do anywhere, but the more delicate texture of an auratum, Krameri, or japonicum would seem to need the direct influence of solar heat to mature the bulbs and to enable them to bear a lengthened contact with the cold, damp-rooting medium to which they are subjected with us. A good Lily grower once said that he would guarantee lengthened vitality in auratum if good sound bulbs were planted at the foot of a sunny wall or hedge, and doubtless this Lily and others of a kindred nature would frequently succeed in similar positions when failure has attended the attempt to grow them in shady places. Very often bulbs planted in a chance manner succeed infinitely better than those set out in presumably ideal conditions. I was much impressed some time since by a discussion which took place in The Garden on the relative behaviour of Lilies in the sun and in shade. A remarkable instance of this was recorded by a correspondent who wrote from the Isle of Wight. Now, if shade is necessary to the growth of Lilies anywhere in this country, one would naturally suppose it to be absolutely so in that warm locality. A bed, however, made in the approved method, well drained and in a north aspect, proved a complete failure.

The remarkable feature, however, was the contrast afforded by some bulbs of auratum, which, not being required for the bed in question, were dotted about indiscriminately. One of these in the hottest place in the garden bore the second year sixty good blooms. This points to the fact that Lilies, especially the tender kinds, need a considerable amount of ripening, not exactly in the sense that a Hyacinth or Tulip does, because no Lily should become devoid of roots, but they should be subjected to solar influence sufficiently to endow them with solidity of tissue. I feel quite convinced that with deep culture, so as to allow of the roots running down after moisture, and a living mulch of some kind many of our intractable Lilies would do far better planted in the full sun than in the cosy, sheltered, more or less shaded positions so often chosen for them. With respect to Lilies in pots, they, being grown under more artificial conditions, are undoubtedly the better for shelter during July and August. By experiment, however, I have proved that they make a stouter growth if exposed to the full sun until July, and after August they should again get all the sun possible. This exposure I find influences the growth of the bulbs to a considerable degree. J. C. B.

Garden Flora.

PLATE 562.

FRENCH POMPON ZINNIAS.*

By the introduction of this new race of Zinnias another beautiful addition has been made to the list of those half-hardy annuals which render our open-air gardens so brilliant during late summer and autumn. The development of this race has been the work of many years, for it has always been the aim of florists, especially those on the Continent, to produce a strain of Zinnias which would combine a refined and fully double flower with a dwarf and neat habit of growth. The present race, which has been aptly called dwarf Pompon-flowered combines these characteristics admirably, in addition to a wonderful range of colours which are more varied even than are to be found among Dahlias. The value of such a beautiful dwarf strain of Zinnias as this is cannot be over-estimated, for it is capable of producing a more brilliant effect than any other class of plants.

Single flower of Zinnia Haageana.

These Pompon Zinnias have been developed from the old Z. elegans, but this has been a very slow process when we consider how long this beautiful Mexican annual has been in the cultivator's hands. It was introduced as long ago as the first year of the present century; for many years no break was made from the original type, which was, of course, single. A few years ago double Zinnias were a thing unknown, but when the double forms did appear they were warmly welcomed, because at that time double flowers were in fashion. Perhaps, some day, the single Zinnias, which are in danger of being driven out of cultivation by the double flowers, will be recognised in the same way. The double Zinnia has been the subject of improvement ever since the double forms first appeared; single forms have become almost entirely lost in large, full, double forms, the size of many of them being nearly equal to that attained by many Dahlias. But the uniform perfection of shape is

* Drawn from flowers sent by MM. Vilmorin, Paris, August 30, 1885.

FRENCH POMPONE ZINNIAS

yet wanting in the case of tho large growing strain of Zinnia, perfect as some of the flowers are; and, in addition to brilliant colours and variations in point of size, we also get differences of shape, which really lend an additional attractiveness to the flowers.

Without doubt the introduction of the existing beautiful double forms into these flowers has materially enhanced them in popular esteem.

Double-flowered Zinnia elegans.

The period of steady, though certain, development into perfect doubleness in any flower is always a difficult one, because semi-double flowers seldom please anyone, and usually are rough and irregular. For semi-double Zinnias little can well be said; indeed, the single-flowered forms, like that of Z. Haageana, are far more pleasing than are any of these intermediate flowers. Some of the single Zinnias are very beautiful, such as the yellow, carmine, rosy purple, scarlet-crimson, and orange. These, with the white, which is after all not a good white, will be always acceptable for their large showy blossoms and brilliant colours.

The form of the flowers in the Pompon race is of the most perfect type, while their colours are extremely varied, some being flaked, striped, and spotted, and some even parti-coloured, being half one hue and half another. The self coloured blood-reds, plums, orange-reds, soft mauves, and other hues are truly beautiful, and the dark ones especially show richness combined with brilliancy. There can be no doubt that, in the process of doubling, the Continental florists, who have accomplished so much in this direction with other flowers, have also succeeded in materially improving the Zinnia's habit. This has been largely done apart from the dwarf or compact-habited strains, for the robust kinds are now much less tall than were the old singles, and exhibit much more compact and sturdy growth. The average height of any really good strain of the strongest growers is from 20 inches to 24 inches, while the dwarfer strains range from 12 inches to 16 inches in height, and are very dense and bushy. In both sections there is great variety of colour, and, what is more, hues which some other more popular flowers fail to present. The double Zinnia Haageana and the hybrid Z. Darwini are both beautiful, scarcely inferior to the forms of Z. elegans.

Zinnias have not yet become so widely grown as they deserve to be; indeed, it is probable that many who garden have not seen a fine double strain, and therefore are ignorant of the handsome forms, rich colours, and the various other admirable qualities which Zinnias possess. Still, it cannot be long ere we shall see them as common as are more popular tender annuals. In the production of masses in big beds, for instance, it would be difficult to excel in beauty the strong-growing forms of Zinnia elegans if planted in good soil and given ample room for growth.

Zinnias come under the denomination of half-hardy annuals. The seed should be sown in a gentle bottom heat about the first week in April, and the plants hardened off and put out into the open ground to flower. Many spoil their plants by keeping them in the seed-pans and boxes till they are planted out, and in consequence the plants become drawn and grow tall, instead of fine, free-branching examples. When they are grown thus thickly together the roots cannot well form good balls with soil adhering to them, and when transplanted the plants are some time before they make a start, and when they do they seldom branch out. Those who pay special attention to Zinnias prick off their plants from the seed-pans into other boxes, or into a bed in a cold frame, where they are put sufficiently far apart to form good balls of roots. It is a good plan to pot a few of the earliest of the plants, and grow them on to come into flower as soon as possible, so as to produce a succession. The soil for the Zinnia should be of a light, rich nature. Leaf mould, manure, and a good sandy loam make an excellent compost. In this the plants root freely, and when they do this, they seldom fail to do well.

Crocus zonatus.—Our first Crocus now in bloom is a delicate leafless little thing with soft lilac flowers nearly white inside. At the base of the perianth segments and surrounding the style is a bright yellow, orange-tinted ring or zone; hence, I suppose, its specific name. It is a brave, although delicate-looking, little blossom, and reminds one of springtime as its blossoms sway and flutter in the autumnal sunshine. The Crocus of autumntide is C. speciosus with purplish blue flowers, but as yet there is no sign of its buds appearing. The real difficulty with these tall, slender-tubed autumnal bulbs, both Crocuses and Colchicums, is to grow them well, and at the same time shelter their fragile blossoms from the equinoctial gales. One good way is to grow them in deep cylindrical Hyacinth pots, and then, as soon as their flower-buds appear, they may be plunged in a carpet of suitable leafage. It is next to an impossibility to grow them well under any permanent carpet of vegetation, nor do they, as a rule, exist long if planted on the Grass. Now and then they do fairly well on dry sandy unmown banks in full sunshine; but any, except the most common sorts, are as yet far too valuable to be experimented with on a large scale.—F. W. B.

Double-flowered Zinnia Haageana.

WORK DONE IN WEEK ENDING SEPT. 14.

September 8 to 14.

We had a welcome rain—0·52 inches—on the 10th, but, excepting this, the weather of the week has been fine and sunny, and our work has gone on uninterruptedly. Propagation of flower garden bedding plants and of hardy perennials, such as Phloxes, Pentstemons, Carnations, Pinks, and Pansies, we have continued as opportunity offered. Soft-wooded plants, such as Alternantheras and Coleus, that require the heat of a pit to strike them, are all now in, and a commencement has been made to take the offsets off the hardier succulent bedders, which we dibble into light soil in any sheltered corner, and by-and-by protect them with any old spare lights that may come to hand, and in the depth of winter cover them up with mats and Bracken. Besides the propagation of flower-garden plants, this department has taken up the bulk of our time to keep the whole free from the appearance of weediness, that at this season soon sets in if there is the least neglect in respect of picking off decayed blossoms and foliage, or of keeping the growths of plants within the restricted bounds of designs, such small items of labour we are specially careful not to neglect, and consequently our flower-beds are just as bright—frequently brighter—in the early days of October as they are at the end of August—a condition that is surely worthy of the bestowal of a little more than the usual labour throughout the whole of the present month. I do not overlook the fact that there are cuttings to be taken, and this necessarily thins out the beds, but with care such thinnings can be made to improve the appearance of the beds, and if only old hands that have become experts at the work be entrusted with it, this will be the case; at least, it is so in regard to ours. Grass edgings

and framework edgings to beds—Herniaria glabra and Sedums—we trim up once a fortnight, and all groundworks are picked over once a week. Our most effective flowers at the present time are Fuchsias, Sunflowers, Marguerites, single Dahlias, Lilium auratum, Hyacinthus candicans, Violas, and herbaceous Lobelias, and our best foliage plants are Castor-oils, Hemps, New Zealand Flax, Acacia lophantha, Solanums, Cannas, and Fish-bone Thistles. The mixed borders of flowering plants are now exceptionally brilliant with Stocks, Asters, Zinnias, seedling Verbenas, Gladioli, Tigridias, and Phlox Drummondi. These we keep free of weeds, the tall growers tied up, and all in something like order by occasionally cutting away portions of plants that are getting so thick as to cause premature decay by rotting if left to themselves. Since the rain kitchen garden work has been at high pressure. We have thinned out seed beds and planted other small plots of Lettuce and Endive, and the last lot of winter greens; sprouting Broccoli; pulled up Onions and laid them on the walks to dry, and after weeding the ground they had occupied, drills were drawn in readiness for planting out Cabbages for early spring use when next we are favoured by rain. Earthed up Broccoli and part of Celery, and partially thinned out plants of winter Spinach. Potato digging still goes on with all the rapidity that time from other necessary labour affords. Fruit gathering will not wait, and on most days an hour or two has to be given up to this kind of work. We have gathered the few Pears we had of Williams' Bon Chrétien and the following other early kinds, of which we have moderate crops: Beurré Hardy, Beurré d'Amanlis, Beurré de l'Assomption, and old Early Bergamot. Apple gathering is not a formidable operation this season, hence the few we have are doubly watched to harvest them as soon as the birds have found out that they are ripe. Plums, Peaches, and Nectarines we look over every day to gather all that are ripe. The heavy crops that the trees have borne will, with a view to next year's crop, necessitate the bestowal of a good deal of labour on the trees as soon as the present crop is gathered. Washings of foliage and drenchings at the root and rich top-dressings must now be the rule if good crops are expected next year. Strong-growing trees of Peaches and Nectarines must be root-pruned; we shall begin at once; our mode of doing this is of the simplest description. We dig out a straight trench, and cut off all roots 3 feet from the stem of the trees (the remainder is not disturbed, except to scrape off the old mulching and loose soil, which we replace with new); this trench we fill in with good loam, a few half-inch bones, and a small percentage of chalk, then we trench the remainder of the border, which we crop with vegetables, and the work is complete. This mode of root-pruning we have now practised biennially for many years past, and our first failure to obtain a crop of fruit has not yet occurred. Indoors we have been busy with the like kind of work; some of the trees in our early and second Peach houses needed curtailment at the root, as the wood was getting too gross, and by doing the work thus early there will be no loss of fruit next year. Watering and mulching are essential as soon as the work is done, to induce the roots to work in the new soil before the sap becomes sluggish in action. In this part of the country we have abundant sunshine to ripen the wood, without closing up the house, but in districts not so favoured it will be advisable to keep the lights on, and even warmth in the pipes, when the nights are chilly—of course, combined with a fair amount of ventilation. Early vinery borders are now being given their annual dressing of fresh soil and manure; the old surface mulching we take off till the roots are reached, and then about 4 inches of new loam, bones, charcoal, and mortar rubble are given, and pressed down firmly, and over the whole a dressing of good manure, which presently, on the approach of cold weather, will be supplemented with a deep layer of long litter by way of protection from frost. Planted out Violets in frames. Though the plants have lifted with good balls, it will be necessary to keep them somewhat closely shut up till established in their new quarters, after which they will be fully exposed to the atmosphere till frosty nights begin. Gave Strawberry plants greater space, weeded them, picked off runners and rubbed off small side crowns; we never allow them to want water or to get overcrowded, or the roots to descend into the gravel, and to these small details of culture is no doubt due that thorough maturity of the crowns that has always, without exception, been the lot of our plants, and, as a matter of course, satisfactory crops of fruit have resulted. Cut the remainder of early Muscat Grapes, put them in bottles, and partially pruned the Vines by cutting back the shoots to within a few buds of the one to which they will be finally pruned a couple of weeks hence. The inside border as soon as well watered will be top-dressed, mulched with clean straw, and will then be utilised for winter flowering plants, some of the Chrysanthemums being already fit to house. Hants.

FRUITS UNDER GLASS.

The Orchard House.

Although a great deal of the fruit has been gathered, the next six weeks include a very important period in the successful management of orchard houses. Every tyro now knows that trees requiring potting should be taken in hand as soon as the fruit is off, otherwise new roots cannot be formed before the leaves fall. This work cannot, however, be performed in one day, or under any set of cut-and-dry instructions, as late kinds which are quite as valuable as earlier sorts are still in fruit, and none would think of hastening the ripening for the sake of potting. The compost and the mechanical part of the work are, of course, always the same, but the management of late trees differs in one great essential—the wood and roots must be thoroughly ripened. Early started trees can be removed to the open air as soon as they have recovered from the potting; late ones, including Walburton Admirable, one of the finest Peaches grown, must be kept under glass, not only until they have recovered, but until every leaf has fallen, and the dry, bracing air of the house has hardened the wood and plumped up the silvery blossom buds. In bad seasons it is sometimes necessary to warm the pipes every day for a few weeks; this year it is possible, nay, probable, fire-heat will not be needed, as the abundant supply of air given during the hot weather has favoured a short-jointed growth of moderately strong wood well set with terminal buds. These late sorts cannot, however, be over-ripened; therefore, it will be well to err on the safe side by giving a little fire heat with plenty of air during wet, cold weather. This important point secured, late trees may be taken out and kept with the early ones until the time arrives for housing in January. The next item of detail is pruning—if a little thinning can be called pruning; every shoot that has done its work must be cut out close to the young growth left to grow at the time of disbudding; also any gross shoots which have been pinched and repinched, but partake too much of a sappy nature to produce perfect flower-buds. When this has been done the knife may be sheathed, as shortening back is best performed after the fruit is set in the spring. In course of time shortening back becomes unnecessary, as old trees make short growths with a wood bud at the base, another at the point the removal of which would render the shoot useless, as it would die back to the base bud, and the fruit from that shoot would be lost. Experienced gardeners who can distinguish wood buds and approve of shortening often venture on cutting back in the autumn, but I do not approve of the system, as it checks the roots of newly potted trees and can be avoided by judicious summer pinching.

Potting up is included in the period I have named; every tree intended for future forcing should be potted up in September or very early in October. The nurseryman's trees may not be ripe enough to bear lifting and sending a considerable distance, as the check and delay in transit often affect the foliage to an extent from which it never recovers. Trees, it is true, must be bought in every year, but every forcing garden should have its reserve ground for the reception of newly purchased trees, be they maidens or cutbacks. The first, which have never felt the knife, I prefer, as they can be pinched and trained into neat pyramids or bushes in one season, and lifted for potting very early the following autumn. If the shelter of glass can be afforded until the roots have taken to the compost, so much the better, otherwise they may be plunged to the rims of the pots in a warm sunny border, well mulched and syringed on fine afternoons, and remain there until the late house is furnished in January. For Peaches and Nectarines I would always strain a point, but Plums, Pears, and Cherries do quite well out of doors, always provided they can be protected from bud-destroying birds.

Selection of trees should always precede the potting up from the reserve ground, as the first-comer gets the pick of the nurseryman's stock. Moreover, an experienced person can tell at a glance by the foliage and growth whether the trees are healthy, and not unfrequently if they are true to name. The best quality is not always found amongst trees which have made strong growth, for either they have not been regularly lifted and transplanted or the ground is too heavily manured. Be the cause one or the other, they invariably suffer after removal to poorer soils, and for this reason alone they should be avoided, but there is yet another objection—gross wood which does not get properly ripened is subject to gumming, and this disease is always followed by disappointment and premature death. The nurseryman who lifts and transplants annually does not stand so prominent in the eyes of the inexperienced, but those who know a good tree when they see it invariably select his trees, for they know the moderate wood which they have made is hard and ripe, and short fibrous roots are plentiful. Unkind or unsuitable stocks sometimes produce a weak growth, but then that growth does not look healthy, and no one would think of taking a tree whose stock is not clean and free and the union perfect.

Late houses should be cleared of Pears and Plums as the fruit is gathered, to make room for Golden Drops and the late varieties of Pears, which must have an abundance of light and air to bring out their best qualities. Although Plums this year are a complete drug and Golden Drops are plentiful, there are very few places in the United Kingdom in which they will ripen or even become passable on open walls, and yet a few dishes of this king of Plums are invaluable for the dessert after Peaches and Nectarines have passed away. Why not, then, now glass is so cheap, devote a whole house to them, either in pots or trained on trellises like Peaches? Once the fruit is set, glass alone is quite sufficient to bring it to perfection in ordinary seasons, but I would not trust to glass without the aid of fire-heat for dispelling damp, which is quite as fatal as frost when the trees are in flower. A flow and return pipe attached to a slow combustion boiler would be found quite sufficient for a large house, and the cost of fuel—a ton of slack—for tiding over that critical period would not exceed a few shillings. Independently of the rich golden harvest, a house or corridor stocked with Plums, next to Cherries when in flower, is one of the most delightful promenades imaginable. Another advantage is the facility with which trees can be grown into a fruit-bearing condition either in pots or on walls before they need protection under glass.

Pines.

As winter will soon be upon us, the final arrangement of the plants should be made complete without delay. Fruiters in various stages should be got together and plunged in a brisk bottom heat with the crowns near the glass, where they can have the advantage of proper atmospheric moisture until the fruit begins to change for ripening. As many of the plants which have recently thrown

up will remain on hand throughout the winter, the structure should be light, compact, well ventilated, and fitted with blinds for running down at night or during severe weather. A sharp air temperature being an important factor, an abundance of hot-water piping, which will produce the necessary heat without becoming overheated, should be at command, as a dry, husky heat at all times, and during the winter in particular, is a drawback which should be avoided. Overhead syringing having been discontinued, atmospheric moisture must be produced by filling the evaporating pans with diluted liquid, and damping the surface of the bed when the maximum heat has been attained and the house has been shut up for the day.

Queens intended for early starting will now be going to rest, and must be kept as quiet and steady as possible for the next two months or more. By rest it must be understood that a free circulation of air not over-laden with moisture and a steady bottom-heat of 75°, with the pots plunged to the rims in a gently declining bed of tan or leaves, will best suit the plants, as a lower temperature will endanger the roots now clustering round the pots and in the drainage. The supply of water must also be reduced, and in course of time discontinued, but for the present an occasional watering with guano or liquid manure in a diluted form whilst feeding the roots will let the plants down gradually, and a sudden check will be avoided.

The next important batch is the stock of strong spring-potted suckers now filling their fruiting pots with roots, and as these will make a growth before they start in the spring, they may be kept steadily progressing for some weeks longer. All shading on the hottest days must now be discontinued, and the glass kept perfectly clean, as they will make rapid growth this month, and the great secret of success is bound up in keeping the foliage broad, stout, and stocky. These plants should be carefully, but well watered with gentle stimulants as often as may be found necessary, and the beds of sweet fermenting leaves regularly syringed to keep up the proper degree of atmospheric moisture. Get all young stock in small pots plunged up to or over the rims in light pits as near the glass as possible, and see that the fermenting beds do not become dry, as lack of root moisture may cause any that are pot-bound to start prematurely. It is now late for potting, but of two courses it is better to choose that which will favour growth than a check, and as many pits are now well adapted for keeping young stock progressing throughout the winter, this convenience may justify giving a few of the best suckers a shift from 5-inch to 7-inch or 8-inch pots. The pots for this purpose should be liberally crocked, the soil light and fibry or peaty, and a sweet bottom-heat of 80° should be ready for their immediate reception.

Composts.—Without good fibrous turf the Pine grower makes but poor progress, and yet many owners of broad acres begrudge a moderate supply. Bare patches in a conspicuous part of the park or an old pasture field, are no doubt objectionable, but the Pine grower's wants in these days are so small, and the method of taking a strip, say 1 foot wide, and leaving one, is well understood by gardeners, and leaves nothing for the most unpractical owner to cavil at, as what is generally termed inoculation combined with thick seeding converts the bare strips into rich verdure in a few weeks. All soils, it is well understood, do not produce suitable turf; indeed, there are many estates on which it cannot be found; on others, as I know from experience, there may be, perhaps, one small piece of pasture so well adapted to the growth of this fruit, that the grower will risk a trifle for an annual supply. A conscientious man will not ask for more than he requires, but that little should be given him ungrudgingly, as it is very unjust to expect him to make bricks without straw. Now is the time to lay in a stock for spring use, as the herbage is still fresh and the roots are ripe. Moreover, it is not yet too late to top-dress with good garden soil, load for load of turf, and seed down with lawn Grass seeds and Clover. If any restraint were laid upon me, I should select my ground, nick it out with an edging iron, and take every alternate strip for my Pines. The turfing spade is the best tool for this work, as every sod can be taken of uniform length and thickness, and rolled up as for turfing a lawn. If these rolls are stacked one way in narrow ridges where they can be protected from rain and snow, or in open sheds, the air will pass through them and the turf will cut down in excellent condition at any time after the Grass has perished. Turf from an old calcareous pasture is frequently used, but the fibre speedily perishes when it becomes heavy and tenacious and the roots of fruiting plants do not winter well in it. Turf from an upland pasture on the old red sandstone, on the other hand, holds its fibre, and for this reason is the best adapted for Pines, as it never becomes sour or inert, and water passes freely through it. Correctives, including charcoal, burnt earth, sea sand, or broken bricks, one or all are, of course, necessary, and should be kept constantly on hand ready for use. Stiff loams can also be corrected with a good percentage of sandy peat, and I have seen excellent plants and fruit grown in heavy loam to which a good quantity of wheaten straw reduced to chaff in a chaff cutter had been added. Poor soils can always be enriched by the addition of bone dust or other highly concentrated artificial manures when taken for use, but animal manure in a solid state should be avoided; not so in a clarified liquid form when the plants have filled their pots with roots. Clean crocks and pots are important factors, and the best time to cleanse these is during the prevalence of inclement weather in the winter.

Eastnor Castle, Ledbury.

Indoor Garden.

THE CHRYSANTHEMUM IN AMERICA.

I am pleased to state that the Chrysanthemum is extremely well adapted for cultivation in this country. It grows well and blooms superbly. Some of the largest and finest blooms I have ever seen in this or any other country were those exhibited by Mr. E. M. Allen, an amateur of New Jersey, last year, at the New York exhibition, and Mr. Allen has only a little suburban garden and no greenhouse or glass structure whatever. He lifts the roots before hard frost sets in, winters them in his cellar, brings them forth in spring, and divides and plants them out of doors. He attends to staking, tying, watering, cultivating, and disbudding them in the evenings after business hours. In dry greenhouses our Chrysanthemums seed freely. The seeds germinate readily, and from the seeds sown in March we get large blooming plants next autumn, or when the plants are only seven months old.

The next Chrysanthemum exhibition of the New York Horticultural Society promises to be the most important ever held in the United States. The exhibition will be held in Cosmopolitan Hall, from Tuesday, November 2, till Sunday night following, thus giving mechanics, labourers, and others in and around the metropolis a good opportunity of viewing the queen of autumn in its greatest perfection. The hall is to be illuminated in the evenings by electric light. Over £480 have been offered in prizes, but before the middle of October it is expected that this sum will be greatly augmented. In order to justify the society in its liberality and ensure the success of the exhibition, already 49 members have subscribed a guarantee fund of some £366, and it is expected that before the end of another month this fund will be still further increased.

The grand prize—first premium, £50; second, £30; third, £20—is for twenty-five distinct varieties, double, to be shown in pots not exceeding 14 inches in diameter, one plant in each pot, each plant to have a single stem 1 inch or more above the surface of the soil. Among the other principal first prizes are £8, for a group of ten standards; £2 8s. in each case for six plants of pink, yellow white, bronze, and crimson varieties. In the florists' division the chief prizes for plants in pots are £2 in each case for six Chinese, six Japanese, six Pompons, six large-flowered Anemones, six small-flowered Anemones, and six singles, also £3 for six standards. Duplicates of these are also offered in the amateurs' and gardeners' class. For cut flowers, £2 in each case are given for twenty-four blooms, distinct varieties of the several types; and £1 to £1 4s. for twelve blooms. The schedule contains 142 classes, and the prizes—first, second, and third—run in the same liberal strain.

The following "perfection in plants and cut flowers" has been adopted by the society:—

Plants.

	Points.
1. For health, vigour, and freshness combined with size	20
2. For judicious training without contortion and unnecessary support	15
3. For profuse, well-finished, finely developed flowers	30
4. For distinct and effective variety	20
5. For taste in arrangement and harmonious grouping	15
Total	100

Cut Flowers.

	Points.
1. For finely developed flowers	30
2. For distinct varieties	20
3. For freshness and brilliancy of colouring	20
4. For uniformity in size	15
5. For taste in arrangement and correct nomenclature	15
Total	100

W. F.

PELARGONIUM CULTURE.

During June and July few plants furnish a greenhouse or conservatory better with flowers than the different types of Pelargonium; nevertheless, of late years plants of a different character have come more prominently to the front. Growers of plants for Covent Garden Market find that such things as Paris Daisies, yellow and white, bring more money than Pelargoniums, and do not cost so much to grow them to a flowering size. One very large grower told me that it did not now pay to grow Pelargoniums for market, but that he would keep up a fair stock of them for the turn of the market when it did come. It is a mistake to purchase Pelargoniums when in flower, as removal from one place to another at that time causes the petals to drop. We have this week been shaking the plants out of the pots in which they flowered, and have repotted them in smaller pots. This should be done about three weeks after the plants have been cut down; if too long delayed, they receive an unnecessary check. Greenfly invariably attacks the young growths. It is useless searching for it. The best way is to suppose it to be there, and fumigate the house containing the plants before repotting them, that is, if they are not out of doors. They will do very well out of doors from the time when they are cut down until it is again time to repot them. After repotting has been performed they are best under glass, but ventilation must be abundant; shading the glass is, however, not only unnecessary, but injurious. I am aware that many will be ready to say they have but one greenhouse, which it is desirable to keep gay with flowers all the year round; therefore the sun would make short work of the plants that are in flower. To such I would reply that their newly potted Pelargonium plants should be placed in the lightest part of the house and near the glass. It is also desirable not to use the shading more than is necessary. Some are very careless in this respect; they let down the shading with the first glimpse or two of sunshine in the morning, and there it remains all day, whether the sun is likely to be injurious to the plants or not. This is all very well where Ferns or fine-foliaged plants are grown; even then, however, too much shade is injurious, but in the case of a mixed collection of greenhouse plants, shading is required merely to protect the tender blossoms. It may, if carried to excess, utterly ruin the constitution of some

plants, especially such subjects as Cape Heaths and New Holland plants. These, by the way, are, metaphorically speaking, quite as much in the shade as Pelargoniums. The latter will soon make healthy, vigorous growth after they have got hold of the new potting soil, and when the pots are well filled with roots, repot into pots of a larger size.

As regards soil, we use for our Pelargoniums good one-year-old turfy loam, a fourth part of decayed manure, as much leaf-mould, some sand, and an 8-inch potful of crushed bones to each barrow-load of loam. The largest plants are potted from 6-inch pots into 8-inch ones. Pelargoniums shifted as just directed will now grow freely; in many cases the growths indeed will be too numerous and will require to be thinned; remove those that are most slender, allowing the stoutest to remain at equal distances apart, or as nearly so as possible. As winter approaches, the plants should have all the light they can get and plenty of ventilation. The supply of water to the roots must be sufficient, but it is easy to give too much. In the first place, give no water for a week after repotting, and none till the roots are comparatively dry again. In winter give sufficient artificial heat to exclude frost, treatment which applies to all the large-flowered sections, show or decorative. Fancy kinds ought not to have quite such a low temperature; the lowest for these during winter ought to be 40°. They should be placed at the warmest end of the greenhouse, which in most cases is some 5° warmer than the coolest end. The plants keep growing all through the winter, but the experienced cultivator wants them to rest during December, January, and February; and therefore they receive no more water than they actually need; the soil is not, however, allowed to become dusty dry. A close atmosphere with an oversupply of water will doubtless be favourable to the development of aphides as well as be productive of spot on the leaves. The aphides will appear, notwithstanding the most skilful culture, but in winter it is not difficult to destroy it by fumigating.

On one occasion I had a favourable opportunity to compare two collections of exhibition plants growing in the same neighbourhood during winter. The one looked very much superior to the other all through the winter and spring, but by the time the flowers were fully developed the poorer-looking collection was superior to the other, not only in profusion of bloom, but also in quality. I was the grower of the poor collection, and have never forgotten the lesson which it taught me. My only fault was too much anxiety for the plants during winter. I should not have watered too much, nor have been so fearful of the plants being injured by frost. Firing in winter to make all secure from frost may be a safe policy, but the plants may be injured through too much care. The large specimen plants shown at exhibitions have the young shoots carefully trained out during winter and spring until the lower ones are quite in a horizontal position, and the inner ones arranged regularly all over the space from centre to circumference. When the flower-stems are long enough, each of them must be supported by a neat stick. Slender grown Osier stems, with the bark on, are best for this purpose. The shoots of the fancy varieties should be trained out in the same way, but the trusses require no separate support.

Cuttings are generally put in when the plants are cut down in July or August, but this is too late. It is easy enough to obtain a sufficient number of cuttings in May from the plants that are about to flower. If a single cutting is inserted in the centre of a small pot at that time, and the pots are placed on a shelf in the greenhouse, the cuttings will soon form roots, and there will be time to grow them on during the summer and autumn into thrifty little specimens, which will flower well in 5-inch and 6-inch pots the following season. It is easy to obtain seeds of the best varieties, and if sown in March or April they will grow, in the course of the season, into good flowering plants for next year. The tops ought to be pinched out of the seedling plants when they are about 4 inches high; they will throw out three or four growths from under this point, and no more pinching is needed. J. Douglas.

Great Gearies, Ilford.

Lathyrus Drummondi.—I observe that "A. D." writes approvingly of this Everlasting Pea, which I think is very scarce in gardens, probably owing to the difficulty experienced in raising it from seeds, which in my case has hitherto been a bar to my being able to form an opinion as to its merits. If "A. D." can indicate a method of getting up the seed of this Lathyrus I shall feel obliged, for up to the present I have been unable to raise a single seedling of it. The fault, I am bound to own, lies with myself, for the seeds had every appearance of being good. I soaked them before sowing, plunged the pot in bottom heat, and covered with Moss, which I kept continually damp. This treatment I have never before found to fail in the germination of hard-coated seeds. In the case of this Lathyrus it has, however, quite failed, and the seeds are just the same as when sown; they have neither rotted nor shown signs of germinating. It may be that, like some other hard-coated seeds, they require to be sown as soon as ripe.—J. C. B.

Tuberoses in a cold house.—There is an impression abroad that Tuberoses can only be flowered in heat. This is a mistake. If they may be had in bloom in May and June, they must of necessity be forced into flower in heat. But I have this season proved to my satisfaction, as I have no doubt others have previously, that they can be flowered in the finest manner in a cold house. In March last I put two Tuberose roots into a 6-inch pot, using a good light rich soil, and placed the pot on a shelf in my cold house. Here they remained until the beginning of May, and then I noticed both bulbs began to grow. From that time until now they have grown strongly, and have occupied the sunniest and airiest position. The plants are now nearly 5 feet in height, and they have developed fine spikes of bloom; each will carry two dozen or so flowers in pairs; some are already fully expanded. They are as fine as any I have ever seen grown in heat, and of pearly whiteness. Therefore anyone with a cold house in a sunny and open position may rest assured that they can grow Tuberoses, and that this is no longer an exclusive privilege enjoyed by the gardener who has the command of artificial heat. Why, then, should not amateurs grow and flower Tuberoses? I am sure there is no reason why, and I hope the practice will become much more general than it appears to be.—R. D.

Solanum jasminoides.—Some one has recently been writing in praise of this graceful and useful climber, rafter or roof plant. It is one of the very best for cutting, as well as for general effect when growing. Small leaves, slender shoots, and innumerable racemes or bunches of small white Potato-like flowers on slender stalks impart to this plant a chaste grace and distinctive beauty possessed by no other cool greenhouse climber, for it only needs frost to be excluded to preserve the plant in safety in winter. The finest plant I have ever seen was in a very cool greenhouse, and in the south and west of England this Solanum endures ordinary winters, with or without protection, on ordinary walls. Grown in the open, however, it is neither so white nor so graceful as grown under glass. Under the latter a temperature of from 50° to 55° is the best suited to develop the purity of the flowers. In very low temperatures or in the open the white is apt to be suffused with lilac, which greatly injures the flowers for bouquet and other purposes. The best place for the somewhat fragile blooms of this Solanum is the outer rim or fringe of bouquets. Here, resting on a fringe of Maiden-hair Fern, they have a grace and delicacy that can hardly be equalled, and assuredly not excelled, by any other flower. Old established plants bloom the most freely, and if the shoots are thinned and the older ones spurred in almost like a Grape Vine annually, it is astonishing what masses of bloom may be produced from a rafter 15 feet or so in length.—Hortus.

CAMELLIAS AS STOVE PLANTS.

A note made of Camellias under stove treatment (p. 227) concludes thus: "The only effect the change of temperature has had on these plants is it causes them to open their flowers earlier, so that, judging from the above facts, Camellias should force easily." But they do not, as all experience proves. The writer does not say how long these particular Camellias had been under stove temperature, or whether, in fact, they had actually bloomed in tropical heat. As to the forwardness of the flower-buds at the present time, that really proves nothing, and is just what was to be expected. It is during the opening of these forward buds that the effects of stove-heat will be felt, and if three-fourths of the buds are not shot off in the process of expansion, the writer's experience of Camellias under high temperatures is different from that of ninety-nine out of every hundred of your readers. Instead of Camellias forcing easily, they will not submit to be forced at all in the ordinary sense of the term. Hurry their pace at opening, and the flowers simply throw themselves off in the bud state, or a step beyond it, in pailfuls. And they have done so from the beginning, do it now, and to all appearance, unless their nature is changed, ever will do so. The only season or condition in which Camellias will bear a stove temperature, say from 60° to 70° or more, is when they are making their young wood, and up to within a little of the period of their forming their flower-buds. With partial shade and semi-aquatic treatment at top and bottom during these stages, a high temperature may not be hurtful, but helpful; but beyond this stage it is dangerous to the crop of bloom. It is also injurious to the plants by forcing them to grow out of season, and if persevered in is likely to keep the Camellias in a feverish state of semi-perpetual growth, or to prove fatal to any bloom at all. To all who may be about to try a stove *regimen* for their Camellias, or to believe that they should force easily, we would utter an emphatic "Don't."

Hortus.

Tacsonias.—Among greenhouse climbers I think that the beautiful Tacsonia Van Volxemi ought to be in every house. It has large crimson flowers that are borne on thread-like stems, which vary from 12 inches to 18 inches in length, and, as these occur at almost every joint, some idea of the effect produced by such a number of flowers depending in this way may readily be formed. Although not so vigorous as mollissima, it is sufficiently so for ordinary purposes, and will cover as much space in a season as can generally be devoted to one variety. T. exoniensis is a hybrid between the varieties above named. The flowers are of a deep rose-pink colour with a violet throat, and possess the good qualities of those of both parents. Unfortunately, most of the Tacsonias are subject to scale, which, if not looked after and kept in check, increases to a great extent, and soon throws the plants out of health, but, as these pests are mainly on the stems, they may be destroyed by using a stiff brush and some of the insect-destroying compounds.—J.

Planting out Gardenias.—Growing Gardenias in pots is, as every gardener knows, a tedious plan. In order to grow them well the roots must have a run among good feeding material. But it is not the mere gain in the way of growth to which growers in general have to look; it is the crop of flowers. Well, then, if anyone wishes to have them by the bushel, make a young plantation, as is often done with Camellias, and let the plants have their own way for a while, and there will be abundance of flowers at more than one season. I used to grow them in the ordinary way in pots, but since I have been convinced that planting out is the best plan I have discarded pot culture. The way I did was to take a portion of a warm temperate house in which there

was some staging; I had a compost of loam, peat, and leaf mould mixed together, to which was added some sand. This was placed on the stone bench, levelled, and then planted, and half the attention needed for pot Gardenias served the purpose in this case. Several dozens planted in this way yield quantities of bloom to succeed Camellias and to take their place up to November. The sorts which I have used are G. Fortunei and radicans; the former is a vigorous grower and needs pruning; the latter may be allowed to go on as it likes. Syringing and occasional brushing are all that is necessary to keep the plants clean. I have advised numbers to try this method of cultivation; and, so far as I have been able to learn, all have done so with satisfaction and success — J. A.

Garden in the House.

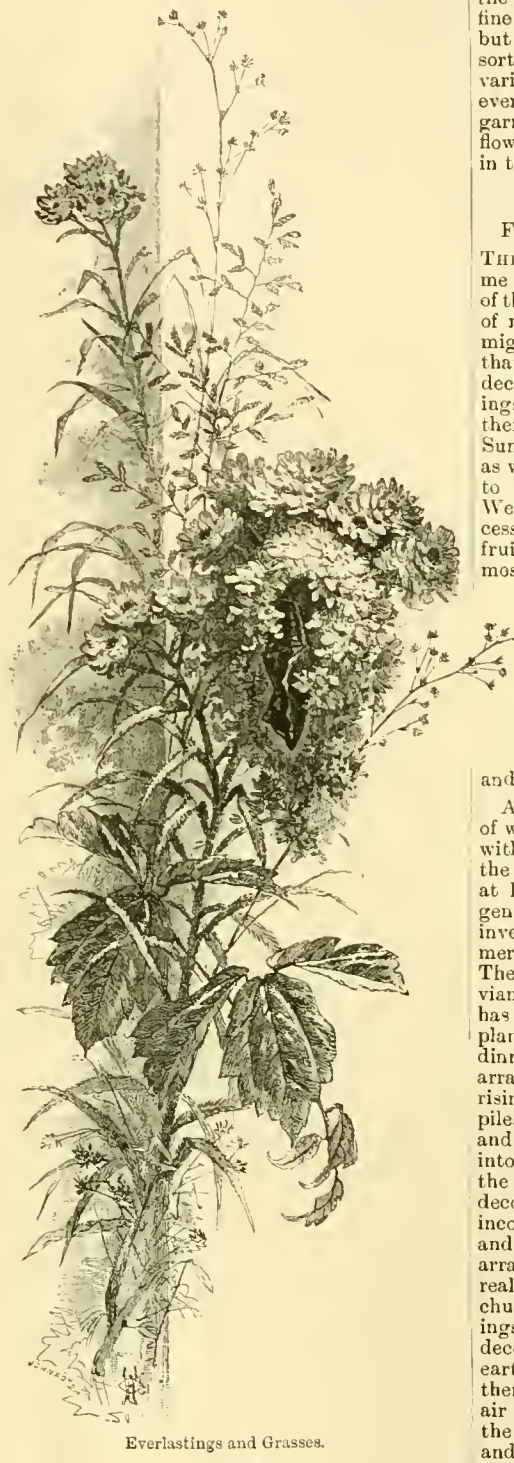
EVERLASTINGS AND GRASSES.

The class of flowers represented by the annexed illustration has become now-a-days almost as indispensable for decorative purposes during the winter as other classes of plants are during summer. Helichrysums, Antennarias, Gnaphaliums, the Australian Helipterums, Acrocliniums, Rhodanthes, Ammobiums, Xeranthemums, and many others are now largely grown and carefully dried before the flowers have become fully open, bunched and sold for winter decoration with some of the more ornamental Grasses. Their cheapness, too, brings them within the range of everyone; indeed, no one need be without a bouquet of Everlastings. Most of them are annuals too, and a little corner of the garden could be devoted to their culture, which is easy enough. They should be sown in spring, and, when up, thinned out to the required distances apart. We have seen Rhodanthe Manglesi sold for a mere trifle by street hawkers, and charming in the shape of plants it looks, while cut and placed in vases it is no less beautiful. The Ammobium is white with a yellow centre, as are also a few of the Helichrysums and Xeranthemums. The Grasses, many of which could be gathered by the wayside, make excellent bouquets by themselves, but mixed with Everlastings, Statices and a few Eryngos, if obtainable, they form most interesting winter bouquets. K.

White Agapanthus.—I am glad to find "F." (p. 212) commending the merits of this most useful variety. Singularly enough, though that and the variegated type of umbellatus have been long known, neither seems to have made much progress in general cultivation. Nor is the type half so common as its merits, in regard to foliage and bloom, entitle it to. It is one of the most useful and effective of vase or basket plants, and is admirable as an edging to beds of Lilies or other plants either near to water or otherwise. The variegated type seldom flowers so freely or grows so strongly as the green. But then the silvery foliage and graceful habit of the plant place it in the first rank among variegated plants without a flower at all.—D. T. F.

Nasturtiums for window boxes.—All admire the glowing colours of Nasturtiums, but all do not know what capital plants they are for balcony and window boxes. The confined root space checks over-luxuriance, and their ability to withstand drought especially fits them for elevated positions. In order to see their flowers to the best advantage, keep them in separate colours, which range from yellow to velvety crimson, and have only one kind in a box. I find a good stiff loam to be the best soil for them, a light, well-manured soil promoting too rank a growth early in the season at the expense of the late summer display. Good loam, on the contrary, pressed down firmly maintains a healthy growth throughout the entire season. Of course, much of the success attending the cultivation of Nasturtiums depends on regular attention to watering and, above all, to picking off the seed-pods, for no plant can continue to flower for months at a time if loaded with an exhausting seed crop. After midsummer a pinch of Standen's manure given in the water once a week to each box will serve to keep the foliage green and flowers plentiful.—J. G. H.

Scented leaves and flowers.—For indoor decoration there is always a large demand for flowers and foliage that are fragrant. Thus the Lemon-scented Verbena (Aloysia citriodora) is



Everlastings and Grasses.

always a favourite. If planted out against a sunny wall where the wood can get well ripened, it yields an endless supply of fragrant sprays. On the coast it is seldom that the winters are sufficiently severe to injure the old wood, but during severe frost a mat may be put over it. In more inland localities it is safest to put some straw first, or dry Bracken, and then a mat over all. Myrtles being evergreen are always welcome indoors, especially when in blossom. The common white Jessamine is also a capital plant for yielding sprays for cutting. Trained on a fence or hedge it is very floriferous, old plants being much more so than young ones. The scented-leaved section of Geraniums when planted out is valuable for cutting. Heliotropes, especially dark-flowered ones, are very popular indoors. Then there are the Mignonettes, a host in themselves, many very fine and distinct varieties being now obtainable; but for fragrance I do not find any of the new sorts to equal the old well-known small-flowered variety. Sweet Brier should find a corner in every garden; a bush or two of it to supply garnishing for bouquets, or sprays for mixing with flowers in vases, should always find a place even in the smallest of gardens.—J. G., *Hants.*

FLOWERS FOR HARVEST FESTIVALS.

The timely article (p. 185) on this subject induces me to make a protest against the glaring excesses of the majority of harvest decorations. Were masses of material considered to be a desideratum, then might the huge piles of fruits, vegetables, and flowers that litter up our churches and chapels rather than decorate them be admissible. Because the buildings are large is no sufficient reason for decorating them with armfuls or cartloads of Hollyhocks, Sunflowers, Dahlias, &c. Crowd or litter them up as we may, there must needs be room enough and to spare left for the sightseers or worshippers. Were this otherwise, then he who was most successful in converting his church into a barn or fruit, vegetable, or flower market would be the most skilful decorator. Some may be surprised at my reference to vegetables; but one of the most profusely decorated churches ever seen by the writer (it was in Leeds) had a bank of cut flowers and pot plants, almost reaching from the tiled floor to the vaulted roof, resting on a basis of Potatoes, Carrots, Turnips, Parsnips, Beets, Onions, Cabbages, Cauliflowers, &c., the mixture being as incongruous as the mass was overwhelming and the odour anything but inviting or agreeable.

All this massing of vegetable matter in places of worship is out of place, and wholly incompatible with refined taste, which is ever in harmony with the fitness of things. Besides, most decorations at harvest festivals and in other places, or for general purposes, are effective and pleasing in the inverse ratio to their size. The rage for bulk, mere mass, in decoration threatens to abolish it. The remark, that you can neither see guests nor viands at dinner for the decoration, is losing, or has lost, its force. The huge wagon-loads of plants, and flowers, and plate that cumbered dinner tables have generally given place to chaste arrangements of flowers or foliage on the cloth, or rising a few inches above it. But the massive piles turned out as vulgar from our dining tables and drawing rooms seem to have rushed pell mell into our churches and other places of worship, to the scandal of refined taste, the enslaving of lady decorators and others, and the discomfort and inconvenience alike of preachers and people. Little and good, and, above all, chaste and artistic arrangement of material are the main merits in all really successful decorations, whether in the church, the home, public halls, or national buildings. If, on the other hand, these harvest-festival decorations are designed as gifts, first fruits of the earth, for the clergyman or the poor of the parish, then let them be brought and piled up in the open air or in the school-room, and not crowded into the church, to its disfigurement and defilement, and the discomfort or distraction of the worshippers. By this arrangement neither parson nor people could suffer, while the church would gain immensely in cleanliness and beauty by being free from massive overcrowding of vegetable matter during its harvest festivals.

The general suggestions of the writer in question will be found useful. The cutting of Hollyhock flowering stems into lengths for decorative

uses has, however, the serious drawback of leaving a very bald and raw finish on their crowns, where their beauty should culminate. Where largely used for such purposes, either the entire stem should be employed or the crown of it only, the lower part being cut away to reduce it to the requisite height. In this way all the terminal lengths of the spikes would be utilised to the best decorative purpose, while the single flowers could be picked off the lower portion of the stems and used in those flat arrangements for which their brilliant colours and staying properties so admirably adapt them.

Further, where Hollyhocks are greatly in demand for decorative purposes, it is well to prepare them for the work during the growing season. Flowering spikes of moderate strength and length are really most useful for decorative purposes. There are several ways of obtaining these, such as growing a batch of late plants on purpose, growing the plants rather thickly in poor soil, and running a knife through the main stems of Hollyhocks and forcing such stems to break back with generally weaker ones. By such simple methods the decorator will find hosts of suitable spikelets ready to his hand when wanted for church festivals or other decorative purposes. Gladioli are simply magnificent in size and form for church decoration, and the other plants named by the writer just alluded to are useful. As to Sunflowers, though so heavily used by some, I am pleased to find he ignores the commoner and heavier examples, and only recommends the Harpalium rigidum, though some of the other Helianthuses are equally adapted for the purpose. But as so many of our churches have been groaning under their golden burden of enormous Sunflowers for years, I heartily thank him for his aid in abating the Sunflower nuisance by his silence about them. D. T. F.

Grasses for winter.—It is a good plan to lay in a store of the different varieties of Grasses at the present time for use during the winter months when they cannot be obtained in the fields. In cutting them for this purpose each variety should be tied in separate bunches, and care should be taken that they are not bruised together, for, if this is the case, when the bunch is opened each spike will be found to have dried in its crushed position, and its form will thus be quite spoilt, and its value for decorative purposes destroyed. All Grasses should be dried in an upright position, particularly those of a drooping character. Oats while still green are also very pretty in large arrangements, especially ears of black Oats, which I have but very seldom seen used. This variety forms a charming contrast to ordinary Grasses and Sedges, and I have constantly used it myself when I have been able to obtain it. The great value of Grasses is, that, in addition to giving a light appearance to a vase, a large plume of handsome Grasses and Sedges enables you to dispense with many flowers. To some this may be no object, but to many it must be a matter for consideration. The bloom of the Ribbon Grass is extremely pretty for mingling with flowers. It has a silver-like lustre in some stages of its growth, whilst in others it assumes a rosy pink tint, which is equally pretty. In the trumpet of a March vase, which has been dressed with pink and white flowers, a few spikes of the Ribbon Grass bloom help to carry up the colour with charming effect into the green of the other Grasses, flowers, and foliage employed in its decoration. For a trumpet vase the graceful drooping Oat Grass is best adapted. The common Horse-tail is also not to be passed over, as it, like the Grasses, forms a valuable addition to floral decorations, and may be found growing in moist places in country lanes, or on sandbanks by the sea.—A.

Cheap Roman Hyacinths.—We have tried some of the lowest priced bulbs of these Hyacinths and have found them to be so small and badly matured, that one spike only of bloom was produced by each of them; whereas, the best bulbs, which are only from 2s. to 4s. more per hundred, produced at least two spikes each, and we have found many of them to throw up three spikes. Indeed, so inferior are the cheap bulbs, that we can only count on having a hundred spikes of bloom from a hundred bulbs; whereas, we can always depend on having two hundred spikes from bulbs for which we only pay 3s. more money.—J. Muir, *Morgam.*

Fruit Garden.

PEACHES AND NECTARINES.

Of all the fruits under general cultivation, there is no class with which I am acquainted so completely shrouded under false nomenclature as the Peach. In every walled garden south of the Trent, and in many sheltered places north of the Tweed, we find not only good crops, but long lists of varieties of this delicious fruit grown, but how few there are who can name correctly the sorts with which they are best pleased. If Peaches, like Apples and Pears, lived out generations of gardeners, one might not feel surprised, as many of our finest varieties so closely resemble each other, as to render it extremely difficult for those who have not paid particular attention to the flowers and the foliage to distinguish them. This, however, is not the case, as we now rarely meet with trees over 40 years of age, and when we do, the chances are ten to one in favour of Royal George, Grosse Mignonne, or Noblesse. Their having outlived the planters and their labels, then, is not the cause of this false nomenclature, for everyone knows the sorts I have named. Moreover, comparatively new sorts as frequently turn out wrong as right, and often cause great inconvenience to those who have been patiently growing them on to a fruit-bearing state. To those who think a Rose under another name would smell as sweet, the name of a Peach might be of small moment, but let them try their hands at early forcing or planting a wall with varieties for giving a steady succession of fruit from July to the end of October; let them buy, as I once thought I was buying, half a dozen trained half standards of Hale's Early, and, after devoting two years to their management for forcing, find they have been supplied with a Peach quite as late as Walburton Admirable, and they will at once discover that there is something in a name. The Peach in question, which by the way no one, even including the firm who supplied it, seems to know, is a good one, and I would not on any account be without it for winding up the season, but it is not what I at the time wanted and paid a good price for. Many would have blamed the nurseryman; some would have said, never go there again for stone fruit trees; but I have not done either, for I am in love with the excellent stock, and I know the most honourable men get taken in sometimes when absolutely obliged to depend upon others, not only for their supply, but also for the manipulation of the buds. Viewed from this standpoint, it must be admitted that private growers who supply the trade with buds may quite unintentionally make mistakes, and so contribute to the confusion, as it is well known that thousands of Peaches are propagated from trees which nurserymen never see in bearing. When the florist sees or secures a good flower, he never sets full value upon it until he has ascertained its name. Why, then, should the fruit grower lag behind when, by paying attention to the flowers in the spring and the foliage in the autumn, all trees with false names can be detected the first year? Their true names may be a more difficult matter, but notes on size of flower, colour, character, and quality of fruit will soon enable him to correct many mistakes.

Peaches and Nectarines are divided into two classes by their flowers, which may be large, light coloured, and handsome, or small, darker in colour, and unattractive. The fruit may be rich, luscious, and melting, or tough, stringy, and adhesive. The first are called melting Peaches, the second clingstones. The leaves, a certain guide in all the old varieties and in most of Rivers' seedlings, will be found serrated on the edges and glandless, crenated with round glands, or crenated with kidney-shaped glands, three simple forms of structure which again divide themselves into sections. If the amateur wishes to ascertain whether his trees are true to name or not, he must obtain a small book and rule each page into four columns—the first for the number, the second for the name, the third for the size of the flowers, and the fourth for the formation of the leaves—thus—

No.	Name.	Flowers.	Leaves.	Remarks.
1	A Bec.	Large.	Round glands.	
2	Royal George.	Small.	Glandless.	

The first notes when the trees are in flower will enable him to fill in the third column; the second, when the leaves are fully developed, will complete the fourth column; size, colour, shape, and quality of fruit will be entered under the head of remarks at the end of the season. Furnished with one of the many books now published in which all the Peaches and Nectarines are divided into sections, we will take No. 1, A Bec. The notes taken in March show the flowers to be large, which is quite right; but when we examine the next column we find the glands are reniform, and we at once know the tree is not A Bec. In No. 2 all the characteristics are correct; the remarks bear out the assumption that the tree is true to name, and Royal George is done with. No. 1 is not true, but we know it belongs to the section having large flowers and kidney-shaped glands. In this way the trees, be they old or new, having false names, can be picked out in one year, and all can be thrown into their proper classes for future comparison. Peaches this season being generally plentiful, the preceding remarks may draw attention to their nomenclature, which, all must admit, is in a very unsatisfactory state; and the annexed list of sorts, which I have tried and thoroughly tested, may be of use to planters, who should soon be selecting their trees. There are, it is needless to say, great numbers of new varieties most likely equally worthy of cultivation. Some of these I am now testing, but should like to see more of them before I express an opinion upon their merits.

Early Peaches.

Early York.—Fair size, marbled with red; flesh melting; flowers large; leaves with round glands.

Hale's Early.—Medium size; skin deep crimson; flesh pale yellow and melting; flowers large; leaves with round glands. A good Peach.

Early Grosse Mignonne.—Full size; skin pale red, thickly covered with bright crimson dots; flesh white, veined with red; flowers large; glands round. One of the best.

Large Early Mignonne.—Fruit large; skin pale lemon, with bright crimson cheek; flesh melting, tender, and very rich; flowers large; leaves with round glands. A great acquisition to our early forcing Peaches.

A Bec.—Fruit large, one side higher than the other; skin bright crimson next the sun, pale lemon, covered with crimson dots; flesh melting and delicious; leaves with round glands. This and the two preceding are the best forcing Peaches grown, and they also lead the van when grown on walls. Being rather tender, they should be gathered before they are quite ripe.

Doctor Hogg.—Medium size, with deep suture; skin deep crimson; flesh firm, but melting, with rich flavour; deep red at the stone; glands reniform. An excellent Peach; packs and travels well.

Mid-season Peaches.

Alexandra Noblesse.—Fruit large; skin pale, flushed with pink; flesh white, rich, and melting; flowers large; glands round. Free, very hardy, and not subject to mildew.

Grosse Mignonne.—Fruit large, melting, and delicious; skin mottled with red and covered with soft down; stone small and rough; flowers large; leaves with round glands. One of our finest old Peaches; good forcer, and does well on walls.

Belle Beauce.—Fruit large and flattened; skin thin, downy, and brilliant crimson; quality excellent; flowers very large and handsome; glands

round. Rather shy when forced hard, but one of our most telling exhibition Peaches.

Bellegarde.—Fruit very large, flattened or depressed; skin dark purple; flesh rich, vinous, and juicy; flowers small; leaves with round glands. A grand Peach; forces well, does equally well on walls, and is one of the best for exhibition.

Dymond.—Fruit large and extremely handsome; skin deep crimson; flesh rich and delicious; flowers large; glands round. This variety is very hardy, a sure cropper, and, taken at all points, is one of the finest Peaches grown.

Stirling Castle.—Fruit large, slightly depressed; skin deep crimson; flesh white, tinged with red at the stone; flowers small; leaves with round glands. Equal to, and by many preferred to, Royal George, which it resembles, but, unlike that fine old variety, the foliage is seldom attacked by mildew.

Violette Hâtive.—Fruit above medium size, round and flattened; skin dark red, almost purple; flesh melting; flowers small; leaves with round glands. One of our hardiest and best Peaches, not unfrequently substituted for Bellegarde.

Royal George.—Fruit very large, round, and depressed; skin pale in the shade, marbled with deep crimson next the sun; suture deep and broad; flesh yellowish white, red at the stone; flowers small; leaves glandless. Too well known to require recommendation.

Crimson Galande.—Fruit large, round, and very handsome; skin pale straw colour in the shade, bright crimson next the sun; flesh white, tender, melting, and red at the stone; flowers small; leaves with round glands. A beautiful Peach, worthy of extended cultivation.

Magdala.—Fruit medium sized; skin smooth, almost like that of a Nectarine; white blotched with crimson, deep crimson next the sun; flesh greenish, melting, and very rich; flowers large, handsome, deeply coloured; leaves with kidney-shaped glands. One of Rivers' best Peaches.

Noblesse.—Although the off-spring, Alexandra Noblesse, is considered hardier, no selection can be complete without the parent. Fruit large, round, with small nipple at the apex; skin pale yellow, mottled with crimson when highly finished under glass; flesh white, slightly red next the stone, and very rich; flowers very large; leaves without glands.

Belle de Doué.—Fruit large, roundish, or oblate; skin covered with dark red; flesh melting, rich, and vinous; flowers small; leaves with round glands. A good Peach, not unlike Stirling Castle, but perhaps a few days earlier.

LATE PEACHES.

Barrington.—Fruit very large, round, with prominent nipple; skin downy, marbled with red next the sun; flesh firm, tinged with red next the stone, rich, and good; flowers large; glands round. A fine hardy Peach.

Walburton Late Admirable.—Fruit very large and round; skin yellowish green, mottled with crimson next the sun; flesh yellowish white, firm, juicy, and rich; flowers very small; leaves with round glands. One of our best late Peaches.

Sea Eagle.—Fruit very large, rather pale; succeeds Barrington, and keeps a long time after being gathered; flowers large; leaves with round glands. This and the two preceding occupy the front rank amongst late Peaches.

Nectarine Peach.—Fruit large and pointed at the apex, nearly smooth like a Nectarine; flesh firm, rich, and melting; colour pale unless fully exposed to the sun; flowers large; glands reniform. A very useful Peach, and keeps well after being gathered.

EARLY NECTARINES.

Advance.—Fruit medium sized, round, with a deep suture; skin dark bronzy green, deep crimson next the sun; flesh greenish white, rich, with Stanwick flavour; flowers large and handsome; leaves without glands. A very good Nectarine and a few days earlier than Napier.

Lord Napier.—This Nectarine is a host in itself, and should be planted wherever Nectarines are grown. Fruit very large, sometimes 9 ounces, pale cream, mottled with red next the sun when grown under glass, full crimson against a wall; flesh white, tender, juicy, and very rich, with Stanwick flavour; flowers large, glands reniform. A grand Nectarine, but rather tender in the flesh, and should be gathered before it softens for travelling.

Hardwicke.—Fruit large; skin pale purple next the sun; flesh greenish white, red next the stone; flowers large; leaves without glands. A good, but now neglected Nectarine.

Murrey.—Fruit medium-sized, round, one side higher than the other; skin pale green, dark red next the sun; flesh white, rich, and melting; flowers small; leaves with reniform glands. An excellent old variety, and forces well.

MID-SEASON NECTARINES.

Recent additions have made this section very rich indeed, all the varieties added by the late Mr. Rivers being well worthy of cultivation. Elruge, Violette Hâtive, Pitmaston Orange, Pine-apple, Balgowan, and Downton Improved will always be front-row sorts, and may be duplicated to any extent either under glass or against walls.

Stanwick Elruge I always associate with Napier, as I look upon these as the cream of the cream in the two sections. The fruit of this variety is very large; I have grown it 9 ozs.; skin suffused with crimson down to the stalk, bright crimson in the sun and almost black against a wall; flesh rich and melting, with high Stanwick flavour; flowers small; leaves with round glands.

Byron.—Fruit large, ovate, resembling Pine-apple; skin rich orange, marked with crimson; flesh orange, rich and red at the stone; flowers very large; leaves with reniform glands.

Milton.—Fruit very large and handsome; skin deep red under glass; purple-black against a wall; very juicy, rich, and finely flavoured. A grand exhibition Nectarine.

Spenser.—Fruit very large; skin deeply coloured even in the shade; colour peculiar, a kind of crimson overlaid with brick-red. One side of fruit a little higher than the other, still handsome, and promises to make a fine exhibition Nectarine.

LATE NECTARINES.

Albert Victor.—Fruit very large, flattened at the apex; skin pale green in shade, mottled with red when exposed to strong sun; flesh greenish yellow, tender rich, red next the stone; flowers small; glands round. A delicious Nectarine richly imbued with Stanwick flavour, but its pale green colour is rather against it.

Victoria.—Very large, roundish oval, flattened at the apex; yellowish in the shade, crimson on the sunny side; very rich, with Stanwick flavour. One of the best when grown under glass, but rarely succeeds in the open air unless the climate is extra good.

Humboldt.—Fruit very large, a seedling from Pine-apple; skin deep crimson, almost black against a wall; flesh orange, rich and excellent; flowers large; glands kidney shaped. Although earlier than Victoria, this will take a prominent place amongst late September Nectarines.

Eastnor Castle, Ledbury. W. COLEMAN.

Cox's Emperor Plum.—"G." does not overrate the usefulness of this Plum, the recognised name of which is Denbigh, formerly Denbigh Seedling. We have grown it for upwards of half a century, and as a Plum for preserving we consider it unequalled, and, moreover, it is excellent for dessert. The late Mr. Cox, of Ludlow, re-named it Cox's Emperor, and sent it out as a new variety about twenty years ago. Long ago it was cultivated at Denbigh, in the Vale of Clwyd, by a local celebrity, one Fulk Phrys (*Anglice*, Foulkes Price), whose name it now bears in that locality and surrounding country. Now, as Fulk Phrys is undoubtedly the original name in this country, should it not have the preference, unless the variety could be shown to be similar to any existing older variety?—JAMES DICKSON AND SONS, *Chester.*

Pyramid Gooseberry bushes.—Although the naturally low-spreading and spine-guarded Gooseberry is rarely seen as a tapering pyramid, it may be grown in that way so as to look much more attractive than in its ordinary state, and its fruit may be gathered, without stooping, as conveniently as that of an espalier Pear or Apple tree. We have recently seen a garden with several of its walks bordered by very pretty specimens of erect Gooseberries and standard Red Currant trees alternated, the Gooseberries simply tied to a slender iron stake rising about 7 feet above the surface of the ground, and pruned so as to gradually diminish from base to top to a mere point. The base of each cone was about 15 inches in diameter, and the whole perfectly furnished with fruiting spurs. Summer pinching of the shoots is practised to prevent the plants getting out of shape, and also to induce fruitfulness, and they are neatly pruned in winter. The kind best suited for this work is the rough red; it seems to make the handsomest pyramids, and is also a very desirable kind for eating or preserving.—R. T.

Diseased Grapes.—What is the cause of the disease on the Grapes which I send? It has done a great deal of damage in the case of Black Hamburghs. About five weeks after they are ripe, a slight indentation appears on the berry, followed by a red fungoid growth, which has destroyed one-third of the crop. I have now seen thirty-six crops on the Vines and never, until last year, have I seen this disease. I intend to keep our Grapes back another season, as they are not wanted till the end of August, when they might be used before the disease overtakes them.—D. LESLIE, *Appleby Castle, Westmoreland.*

*** As far as we can see, your Grapes have been badly spotted; that is, injured by sudden chills of cold air when the house is hot. The sudden opening of doors and sashes will often cause a depression or indentation on the berries, as described by you. The fungoid growth is an after result. The disease is said to be constitutional in the case of some varieties. The affected berries should be cut out.—W. G. S.

American Blackberries.—I send you a branch from my American Blackberries to show to what size they grow here in Surrey. I have also seen them do well in the garden of a friend some eight miles from Sheffield. Our American Blackberries have been planted about five years, and for the last three they have borne very large crops. They were at first very small plants, and were put in rather late in the spring. They are planted in a row just in front of our Raspberries, and are mulched with manure in winter at the same time as the Raspberries. The Blackberries are supported by wires, about 4 feet high, stretched between posts, but are not trained in any way. They are pruned in spring, and some of the growth is cut off after flowering to make it possible to get along the row. This summer they were watered once, just as the fruit was beginning to ripen, as we were afraid the drought might make the fruit drop. I suspect people who fail with American Blackberries do so from coddling; ours are fully exposed to the east and a good deal to the north.—T., *New Egham.*

*** The berries on the branch sent were plentiful, large in size, and in flavour excellent.—ED.

Strawberries degenerating. — Strawberries, like all other cultivated plants, do degenerate by incessant propagation from one and the same stock and by perpetual growth upon the same plot of soil, some varieties being more prone to this than others. Equally certain it is that change of soil will in a great measure renew their fertility, but I imagine that the addition of manure to such permanently used soil tends to give increased leaf vigour only. I draw this inference from experience in my garden. I have here a very old one; it possessed a Strawberry bed in evident vigour when I took possession in the month of September some years since. This I had cleansed and well manured, but was disappointed in the results the following season. I again, however, fed and grew the plants well, but the result was less

fruitfulness and greater vigour. Meantime I had given rooted runners from these plants to a neighbour not far distant which produced a good crop, and I have since learned that my old stock had been growing in this garden for very many years. I have obtained a change of plants, and have grown them on the same bed; being a convenient one, I elected to again employ it for this crop, and the result has been most satisfactory.—W. Earley.

Madresfield Court Grape.—All that "Cambrian" says (p. 234) of this fine Grape is true. But he should have added, beware of cracking, or given an antidote for this before advising amateurs generally to plant it. Perhaps no Grape Vine in cultivation has caused more disappointment among amateurs than this, and it is almost cruel to advise this class of cultivators to grow Madresfield Court without providing them with an anti-crack berry recipe.—Hortus.

Ripening the wood of fruit trees.—Mr. Hobday's timely remarks on this subject (p. 192) are as valuable as they are practical. There is one other radical aid to maturity, however, which he does not mention, that is, root-lifting or pruning. This arrests the supplies instanter, and so enables the sun to deal more effectually with the fluids sent to the front as to very materially hasten and heighten the fertility of the wood. After September every available means should be adopted to plump up flower-buds and harden the growth made for next year, and, unless under very exceptional circumstances, no more water should be given to fruit trees in the open air.—D. T. F.

The Magnum Bonum Plum—There is no accounting for tastes, but "J. G. H." will not get many to agree with him that the flavour of this Plum, grow it how we may, "is very good indeed—little short of that of the Green Gage." With the flavour of the latter, or such Plums as the Jefferson and Golden Drop, in one's mouth or memory, the Magnum Bonum must retire to the kitchen or culinary department, for which it is very well adapted. As a rule, however, it is rather a shy bearer compared with other excellent kitchen Plums, and hence it is now comparatively little grown, though in size and appearance and flesh, and even quality for culinary purposes, it is excellent.—Hortus.

Apple Beauty of Bath.—This valuable early Apple does not appear to be so widely known or grown as it deserves to be, and as far as I have seen it at exhibitions held this year it seems to be largely confined to the west of England. It is by no means a new variety, for I am informed that it was raised some twenty years since, and came from a pip of the Juneating raised by a market gardener in the neighbourhood of Bath, hence its name. I saw it this season at two or three west of England shows, and it was at the head of dessert Apples for flavour, and was represented by medium-sized handsome fruits, rather flattish, a good deal in the way of Fearn's Pippin, and with handsome crimson markings on a brownish yellow skin. As there is not a great number of good early dessert Apples, I think that Beauty of Bath deserves the attention of fruit growers. It comes in with the first earlies, such as Early Julien, Juneating and Mr. Gladstone. That it is a good and constant cropper there can be no doubt, bearing on trees of small as well as of large size. As many as four and a-half bushels have been gathered from eight small trees planted a year ago, and this year they have also produced a good crop. The fact that it invariably takes the first prize offered for dessert Apples ripe and fit for table at shows held during August is one of the best proofs of its earliness and quality, and it is all the more useful at that period for dessert; it comes in along with Jargonelle Pears, and makes side dishes for a large dessert when Strawberries are over. Apple Beauty of Bath therefore deserves the attention of fruit cultivators.—R. D.

* **Fruit trees with wet feet.**—The essential element of success in a case in which extra fine Apples were produced, says the *Country Gentleman*, was water—an abundance of water and wet feet from April to October. Alongside the handsomest show of Ben Davis Apples ever seen was a generous flow of water coursing down—not suffered to flow constantly, but as often as the soil seemed to need it. The same was true of the small fruits, and the result was Kittatinny, Lawton, and Wilson Blackberries, averaging in size well grown Siberian Crabs, and Black and Red Raspberries (of the finer kinds) rivalling Strawberries in solidity and form.

Trees and Shrubs.

THE UPRIGHT INDIAN SILVER FIR.

(ABIES PINDROW.)

In this country well-furnished and well-grown specimens of this interesting Fir are certainly few and far between, and for which the planter alone is responsible, for as the tree is perfectly hardy, there is no reason why special situations suiting its peculiar wants may not be chosen. Being somewhat predisposed to early spring growth, and in consequence liable to injury from what is termed late or unseasonable spring frosts, which occasionally nip hard even during the first weeks of May, this fine tree, when improperly placed, not unfrequently suffers rather severely from loss of the newly formed shoots, which gives it anything but a desirable appearance. By careful choice of soil and site, the latter in particular, the above evils may, however, be greatly obviated, and indeed entirely removed, and stately, well-furnished specimens produced, the only conditions being that a northern or eastern aspect be chosen, and a cool, late soil and sheltered situation—conditions that are readily enough procured on most estates.

In its native country this Fir is a noble tree, attaining heights of from 60 feet to 150 feet, with a densely clothed stem, the habit of growth being broadly conical, or the lower branches short in proportion to the tree's height. The stem is tall and straight, with a gradual taper from base to apex. Branches disposed in horizontal whorls, short and spreading. Leaves very variable in size and arrangement, those on young trees being thickly and regularly disposed on all the branches, 1 inch long on the under side by half that on the upper, the greater number bifid, and with two rather indistinct silvery lines beneath. In adult trees the leaves are 2 inches to 2½ inches long, and arranged in two rows horizontally. The colour is of a deep green, or if one might use the term blackish green, it would be far more descriptive. Cones oval, 4½ inches long by 2½ inches diameter, and produced singly (sometimes I have noticed them in pairs) on the upper sides of the three topmost tiers of branches. When they have attained full dimensions they are of a deep purple colour, and highly ornamental to the tree.

I have examined several thriving specimens here, and in all cases the leading shoot is welted or thickly covered with longitudinally arranged raised surfaces like whipcord. To the touch the whole shoot appears as if composed of india-rubber, and readily yields to finger pressure. The buds are remarkably large and prominent, oval in form, resinous and scaly. In young trees, after they have attained, say, 4 feet or 5 feet, the growth is very rapid, frequently as much as 16 inches of a leading shoot, and from half an inch to three-quarters of an inch in diameter, being produced in one season.

We have been fairly successful here at Penrhyn in the cultivation of this handsome Fir, and several well-branched, vigorous-growing specimens are the result. The average annual rate of growth is nearly 18 inches, and it is not at all unlikely that after the trees have attained to a certain size and age their growth rate will be increased, although I can hardly say that this is the case with a 40-feet specimen growing in the park; but it is also but fair to add, in this particular instance, neither soil nor situation received the amount of consideration that is necessary for the successful development of this particular tree in the climate of Britain.

Our finest specimen of Abies Pindrow is growing on a rocky eminence midway between the castle and the kitchen garden, but is well sheltered from the prevailing winds of the district by taller growing trees, the soil being loam freely mixed with broken rock fragments, and deeply top-dressed by leaf-mould in all stages of decomposition. Its present height is between 40 feet and 50 feet, with a trunk girth, at a yard up, of 44 inches. Cones have for years been produced abundantly, but always on the upper part of the tree, but no attempt at raising seedlings has yet been resorted to. The branches are rather irregularly produced and of uniform length, but reveal in a marked degree the peculiarities of the tree in its native wilds. This tree cones at a very early age, specimens of not 5 feet in height bearing these whilst still in the nursery borders. The strong, robust leading shoot formed by the tree is particularly noticeable, more especially when grown, as they are here, alongside numerous other members of the same family, including Pinsapo, nobilis, Nordmanniana, &c. I measured the diameter of leaders on six different plants growing in the park and nursery grounds, and found the average to be fully 1¼ inches, there being but little taper from the

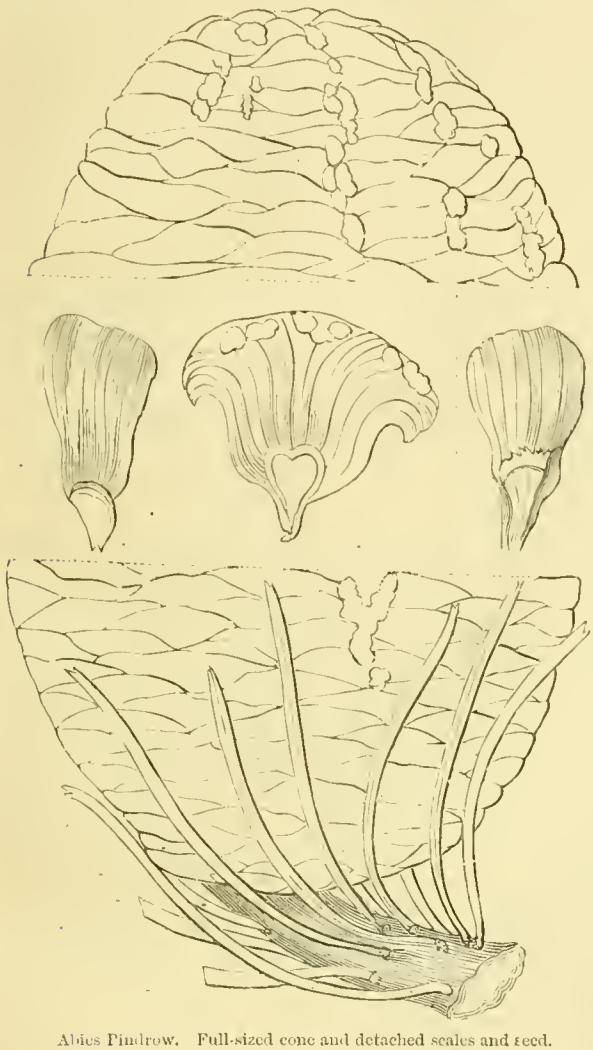
Abies Pindrow; coning branch and cone (reduced).

last year's start to the top of the shoot. Young trees of this Fir especially present a remarkably stiff, sturdy, and unyielding habit of growth. As regards quality of British-grown timber I know nothing, but Gordon tells us that it is "good, but soon warps and rots if exposed to rain and sun." It was sent to us in 1837, and is found more or less plentiful on the alpine heights of North-western India, at altitudes ranging from about 7000 feet to 13,000 feet.

The nursery management of Abies Pindrow requires more care than is usually bestowed on the generality of Conifers, as for the first half-dozen years we have, here at least, found it more susceptible to injury from unseasonable frosts than at any other stage in the tree's existence. To obviate this, choose a well sheltered—sheltered from the sun, but not wind—piece of ground facing north or east, in which to place the plants, and let the soil be free, but heavy, so as to prevent as much as possible an early start to growth. By this means the young trees will become gradually inured to our climate, and may be planted out with safety in similar situations when 6 feet in height. Although the leading shoot and tips of the branches may be cut back by frost during severe seasons, still no Conifer would seem to suffer less or pass through the ordeal with greater success than the one in question, and we have here more than one fine, healthy, well-furnished

specimen that at a certain stage of their existence certainly looked far more fitted for the rubbish-heap than ever to become suited for gracing the conspicuous positions they now so nobly fill. A. D. Webster.

Seaside Pines.—It may not be generally known that the Black Austrian Pine is an excellent seacoast tree. The rich massive foliage preserves its somewhat sombre, but healthy green in all situations. It should be planted in masses, as when isolated as a specimen, or standing singly among deciduous trees, it is rather apt to be overturned by storms, because the roots are rather spreading than descending, and the head of the tree becomes very heavy and branching. The Corsican Pine, also a capital seaside tree, is of more rapid growth than the Austrian. It is a good tree to plant in exposure, and is not particular about soil, appearing to thrive equally well in heavy clay and in thin poor soils. It is the last of the Fir tribe that rabbits will attack, no mean point in its favour. Pinus insignis is a real seaside beauty, for of all the true Pines this is the greenest, and in mild districts the most rapid in growth, and is all that can be desired as an ornamental forest tree. In high cold districts it is not hardy, from its habit of making a second growth in autumn.—M.



Abies Pinsdrow. Full-sized cone and detached scales and seed.

Cut-leaved Alder (Alnus glutinosa laciniata).—One of the finest trees that exists in this country of this Alder grows near the margin of the lake at Syon. So fine was this tree even fifty years ago, that a drawing was made of it for Loudon's "Arboretum." It was then 63 feet high, and the head as many feet through, and with a trunk 3 feet in diameter. It is a grand specimen, and in summer, when its leafage is in perfection, it is one of the most beautiful trees in the place. It is excellent for planting by waterside, as it not only flourishes in such a situation more vigorously than elsewhere, but the low-spreading branches have a beautiful effect in such a position. It is, in common with all the Alders, a good subject for planting in swampy ground, provided the water is not excessive, at least for the greater part of the year.—G.

AN AMERICAN ARBORETUM.

The Arnold Arboretum of Harvard College, which contains 165 acres of land, quite varied in character, is yet in its infancy, having been commenced only in 1874, when the seeds of the first trees were planted; so that, excepting the older trees previously on the place, of which there are many, a great portion is only nursery plants. Along the roadways will be planted both native species and those of foreign introduction, including all the varieties, so that even one not possessing special botanical knowledge can at a glance comprehend the arrangement and see by comparison the plants which best endure our climate. The arboretum will thus be a living museum, where the nurseryman, gardener, and private landowner may come for trustworthy information regarding all trees or shrubs, which will save them the cost of personal experiments, and of delays caused by unfortunate selections.

The collection of living plants at the arboretum is richer in species than any other in the United States, numbering at the present time over 2000 species and varieties of woody plants. Many of these may prove failures; but it is the work of the arboretum to show by living illustrations what to select and what to avoid. Experiments are also being made with seeds of plants taken from widely different localities, with the hope that additions may be made to our lists of hardy trees. This has already been done in several instances, such as Abies concolor, Pseudotsuga Douglasi, and several others; the seeds of those plants brought from the warmer parts of the Pacific coast having proved of little use to us in our changeable climate, while seeds from plants of the same species growing in Colorado under conditions similar to those in New England have produced plants which, so far, stand our climate as well as our native trees.

A shrub garden has been made, comprising about two acres, laid out in beds 10 feet wide, by 275 feet long, sufficient in extent for 1157 species and 357 varieties. The shrubs are systematically arranged, and not only botanically, but, as far as possible, geographically, American plants coming first. Here anyone with even a limited knowledge of plants can take notes of these growing specimens, which will enable him to gain more knowledge than months or even years of study of books or catalogues could give, and will help him to make such selections as he would like to plant. All this is done at the expense of the arboretum, thus giving all who wish to avail themselves of its privileges and advantages a real school of instruction free of all cost; and this will go on from generation to generation.

Among the larger Orders planted are fifty species of Spiræas and thirty-two varieties; thirty-four species of Clematis; twelve species of Euonymus and nine varieties; fifteen species of Rhamnus; fourteen species of Caragana and three varieties; forty-four species of Prunus and nineteen varieties; fifty-two species of Roses and eighteen varieties; nineteen species of Blackberries and twenty-four varieties; twenty-eight species of Philadelphus; twenty species of Ribes; fourteen species and seven varieties of Cornus; twenty-one species of Snowballs and three varieties; thirty-one species and eleven varieties of Honeysuckles; twelve species and three varieties of Huckleberries and Blueberries; sixteen species and five varieties of Rhododendrons; nine species and thirteen varieties of Ericas; and fourteen species and thirteen varieties of Lilacs.

Coniferous trees, such as Picea, Abies, Larix, and Pinus, are planted in single specimens and groups. Those of the best known utility will be planted for permanent effect, while unknown varieties will be so distributed that, in case they fail or prove unsuitable, they can be removed without defacing or marring the permanent planting, the effect in the landscape being also carefully looked after. It is the intention to give the preference to American trees in large groups and single specimens, while native shrubs will be planted as an undergrowth of the larger trees. For this purpose over 62,000 plants were collected last autumn, comprising all the best native shrubs in the New England States. Many thousands were planted in the spring of 1885, the most noticeable perhaps being at a point on the right of the entrance to the arboretum, planted with White Pines to correspond with the magnificent Hemlock grove on the opposite side. Within the last five years miles of boundary belts have been planted, comprising all the native trees as far as possible; and a grove of Pinus resinosa (the Red Pine), to the number of fifty or sixty, which in ten years will make a fine appearance. This is one of the most beautiful of American Conifers, and is well deserving of more general cultivation both for ornament and timber.

Among the many promising trees, the following deciduous kinds—Betula papyracea, Catalpa Kæmpferi and speciosa, Cladrastis amurensis, Fraxinus americana (a remarkably fine form of this species, with beautiful foliage, bright and shining above and glaucous beneath)—were especially noticeable. Fraxinus mandschurica and potamophylla—these two are from Northern Asia and Japan. Juglans mandschurica.—This tree was raised from seed eleven years ago, and has borne several crops of fruit. Phellodendron amurense (the Amoor Cork tree).—One of the two original plants raised from seed being pistillate and the other staminate, seed was perfected. It is believed that this is the first seed that has been produced in this country. Prunus sibirica. Quercus Daimio, macrocarpa, palustris, and Prinos. Syringa japonica.—A very rare species of Lilac from Japan, flowering in the middle of July; the trusses are a foot or more in length and pure white. It is a small tree rather than a shrub. Pyrus.—There is a fine collection of species from Northern Asia and Japan, which are very beautiful in flower or fruit, such as spectabilis, Toringo, and baccata, and their varieties.

Of the Conifers may be mentioned Abies brachyphylla, from Japan. A. concolor, from Colorado, one of the finest specimens in the arboretum. A. Fraseri and balsamea var. Hudsonica. Chamæcyparis (Retinospora) obtusa and pisifera, and their varieties. There is no doubt that the many varieties of this plant in cultivation came from these two original species. Juniperus communis aurea. Picea alba, a variety known as Maxwell's Golden Spruce; P. alba cærulea, Engelmanni, excelsa and its many varieties, pungens and its varieties, many of which are very handsome, and being quite hardy promise to become very desirable for general ornamental planting. Pinus Buogeana, excelsa, flexilis, Jeffreyi, Murrayana, parviflora, ponderosa, resinosa, Strobus and its several forms. Pseudotsuga (Abies) Douglasi, the Douglas Fir or Red Fir of Oregon.—*Transactions of Massachusetts Horticultural Society.*

The Rest Harrow (Ononis fruticosa).—I was glad to see this little shrub noticed (p. 216). Growing under ordinary conditions it is looked upon as a pest, but it is really ornamental. Here it grows in rough pastures on the hillsides, as though it was an indigenous plant, but this I believe is not so. One place where it abounds was formerly forest, *i.e.*, within the last century or two. From this it would appear to be a shrub which would grow well under trees, or at any rate in odd corners of the shrubbery.

Judging from the persistent way in which it grows in spite of frequent cutting, it must be one of our hardiest shrubs. Perhaps some one who grows it would give their experience of it. I only know it wild.—Rustic.

Kitchen Garden.

ROTATION OF CROPS.

Experience has taught us that farmyard manure contains in some form or other the elements upon which most plants feed, and that that, in combination with deep tillage, suits the majority of plants and enables them to thrive fairly well for several years together on the same land. Potatoes, for instance, in small gardens occupy the same ground year after year without any visible deterioration, especially if the seed be changed frequently. Onions, again, are often in small gardens sown year after year on the same land. But both these and Potatoes occupy the ground but a short time in comparison with some other crops—Cabbages, for instance—and where the land is well manured with an occasional sprinkling of lime, combined with deep cultivation, the question of rotation is of but little moment. But where rotation is really important is in dealing with the Cabbage tribe. If we want to avert such evils as clubbing, rotation must be insisted on. No one should plant successional crops of Cabbages or Brussels Sprouts on the same land. Deep culture in combination with liberal manuring solves, as I have said, a good many difficulties, but under the most favourable conditions, as to depth of soil and manuring, it would not be wise to neglect rotation in the case of green crops generally. In a garden always fully under crop it is not possible to follow out strictly any system of rotation, but I always make it a rule never to plant any of the Cabbage tribe on the same land two seasons in succession. In the matter of Potatoes fresh land can be brought up from below, and artificial manures can be employed to supply the wants of the plants. Compost can be used in the drills with the same objects in view, and the same remarks apply to root crops generally. Of late years the tendency has been to move what was formerly regarded as permanent crops more frequently than was at one time done, and with advantage to the crops themselves. Asparagus, Globe Artichokes, Horseradish, Strawberries, and Raspberries are looked upon less as fixtures than they were formerly, and all such things are improved by frequent removal. E. Hobday.

Lettuces for spring planting.—If seed has not been sown some should be put in at once in finely worked ground and where the sun shines freely through the greater portion of the day. In the case of plants raised at such a late date, it is not safe to trust them in the open ground through the winter. They should enjoy the protection of a handlight or frame in severe weather. In the open ground worms are apt to draw them under, and what with melting snow, alternating with hard frosts and a continuance of heavy rains, the greater portions of the plants are apt to come to grief. Even when the plants are raised, as they should be, at an earlier date, their fate is always an uncertain one in the open ground. Transplanting and a warm position at the foot of a wall will do much to save them, but those who require an abundance of Lettuces at an early date should have two strings to their bow. By sowing quite early in September for the open air, and a fortnight later to keep over in frames, the risk of failure is obviated. The Brown Cos is, of course, the best for autumn sowing, but it is a good plan to sow some of the Paris White Cos about now, as these come in well to succeed the hardier kinds, and if planted out early on good ground they make fine heads at a comparatively early date.—J. C. B.

Tomato Blenheim Orange.—This variety is a decided acquisition; it is very early, prolific, handsome in shape, juicy, and of fine flavour. It was raised by Messrs. Carter, between the yellow Green Gage variety and a red one. It has been in fine condition at their nursery at Forest Hill.

PROGRESSIVE EARTHING OF CELERY.

I am glad to see "R. T." (p. 220) protesting against this practice, as a waste of time and labour and a means of depriving the roots of moisture. The earth against the stems is only useful for the purpose of blanching them, and can be of no use as a fosterer of growth. On the contrary, its mere mechanical weight must of necessity prove a physical hindrance to enlargement of size. Besides, the debilitating effects of blanching on vital vigour unduly handicaps the plants in their efforts after enlargement. All artificial blanching is a weakening process, and in this way it cannot fail to be injurious to the Celery. There is yet another reason against the practice. A perfect stick of Celery should be of uniform quality throughout. This it can hardly be, unless it is blanched simultaneously. Blanched piecemeal, it will vary in crispness, tenderness, and sweetness in the ratio of time its various parts have been blanched. There is no objection, but the reverse, to the progressive surface-mulchings of soil recommended by "R. T." These may husband moisture and stimulate growth. But the earthing up of Celery for blanching should be mainly performed all at once. The word "mainly" is used advisedly, for occasionally Celery is earthed up too high at one operation, to the serious injury and, at times, the decomposition of the plants. If only the tips of the leaves are left out and the plants are strong and in vigorous growth, they may receive a sudden shock from which they will hardly recover; but if about 6 inches of leaf be left out of the earth, and especially if the plants are prepared for earthing up by the removal of superfluous leaves and suckers a day or two beforehand, and especially if a dry day is chosen for the occasion, they may be earthed up at one operation, though it is good and safe practice to add a little more earth a fortnight or three weeks after the main earthing. But this one earthing and a little afterwards is as different as can well be from the progressive earthing that so many cultivators still indulge in—a practice which deprives the roots of this semi-aquatic plant of moisture and places the stems of a free and loose marsh plant in a vice of hard soil during the most important period of its growth. Hortus.

Pipy Celery.—Mr. Peter Henderson writing on this subject in the *Gardeners' Monthly* in allusion to an article which appeared in The Garden says: The writer takes the ground that hollow or pipy Celery is always the consequence of using seed of some worthless kind. That this is true in general there can be no question, as a most extensive practice in growing and testing the different kinds of Celeries well proves; but our experience also has proved that on stiff heavy soils the same variety of Celery will be specifically heavier than on boggy soils formed mainly from leafy deposits. I first discovered this some twenty years ago. We had two places in which we grew Celery, one, leafy deposit and the other heavy clay loam, and in marketing the crop, we found, which was nearly of the same bulk, that that on the clayey loam was nearly one-third heavier than that grown on the leaf-mould soil. All giant or tall-growing Celeries should be avoided; as a rule they are always more hollow than dwarf-growing sorts, give twice the labour to work, are inferior in flavour, and under the same conditions rarely give as much weight of crop. No market gardener who knows his business ever grows the "giant" Celeries here now.

Tobacco in Wales.—In April last I received a packet of Tobacco seed from Messrs. Carter for trial. It was sown in a cutting box, germinated in a gentle heat, and the plants were hardened off by the middle of May. When they became too close in the seed box they were transplanted to other boxes, and thus given more room. By the end of May they were 6 inches in height, and then they were planted out. The spot selected for them was an east border that had been previously cropped with early Peas. The surface was hoed over and the plants were dibbled in like Cabbages. For many weeks after being planted no rain fell, and they only made slow progress during June and July, but when rain came in August, they grew rapidly, and they are now 5 feet in height, a perfect thicket of huge luxuriant leaves. Judging, therefore, from the way in which Tobacco has succeeded here under somewhat rough and inexpensive treatment, I feel sure that it would succeed as a field crop.—J. Muir.

Tar paint.—I am about to tar some outbuildings, and am told that if paraffin oil is mixed with the tar it will be an improvement. Is that so, and in what proportion should it be applied?—M.

*** Take of gas tar a given quantity and place it while cold in an iron furnace or three-legged pot. Make a slow fire beneath it, and when the tar nearly boils add half a pint of turpentine to every gallon. Stir well, and when it has boiled or been kept at boiling point for half an hour it will be ready for use. It can be applied to ironwork or wood when hot, but we always prepare a quantity and keep it in casks for use cold, as it works as freely as oil paint and lasts several years. New work, if wood, should be thoroughly dry, and iron free from rust, when the first coat is applied; hence the importance of having the varnish ready for use as soon as the building or fence is finished. A second coat should follow as soon as the first is well set, when a single coat every two or three years will suffice. We have not tried paraffin, a cheaper article which may answer equally well, but the cost of the turpentine varnish is a mere trifle compared with its excellent quality, viz., 2d. a gallon for gas tar and 4s. 2d. per gallon for turpentine. It may be well to remind the inexperienced that some little tact must be brought to bear on the incorporation and boiling, otherwise the mixture will prove unmanageable. This difficulty we get over by using a nine-gallon pot for four gallons of the varnish, and suspend the pot on a horizontal rack or arm by means of which it can be moved quickly from the fire.—W. Coleman, *Eastnor Castle, Ledbury.*

Obituary.

John Cox, long gardener at Redleaf, died at The Firs, Marlborough Road, Ryde, on the 30th ult., aged 71. Mr. Cox some years ago resigned his situation at Redleaf, and retired to the Isle of Wight. His health began to fail as long ago as the summer of 1881, when he had a sunstroke, and gradual softening of the brain has been going on since then; but he retained his mental faculties in some measure until two or three days before his death, although his speech and hearing were very imperfect. About three weeks ago he had an apoplectic seizure and then sank rapidly. He was interred, on the 2nd of September, in Brading Churchyard, a suitable resting-place for one who had lived all his life in a garden.

Nerium Oleander (*T. Barnes*).—A very fine specimen, but arrived too withered for our purpose. Oleander flowers do not travel well.

The "Garden Annual."—Gardeners should *at once* communicate any changes of address to the editor of this, or corrections cannot be made for the new edition.—Address, Editor, "Garden Annual," 37, Southampton Street, Strand, W.C.

Names of plants.—*Charles Harris*—1 and 2, varieties of Athyrium Filix-femina; 3, Lycopodium alpinum; 4, a Saxifrage, probably oppositifolia.——*W. S. B.*—The name of the berried shrub which grows in Glen Farg to a height of 8 feet or 10 feet is Berberis vulgaris.——*F. H. L.*—Abelia rupestris (shrub), Amaryllis Belladonna (bulb), Gongora portentosa (Orchid), Begonia Rex (variety).——*D. M. Russell.*—1, we do not name Roses; 2, Ragwort (Senecio Jacobæa); 3, Epilobium angustifolium; 4, Hypericum hirsutum.——*W. E.*—Yellow is Œnothera missouriensis; purple is Aster Amellus.——*G. F.*—Some species of Silphium, but as the lower leaves are not sent we cannot determine the species.——*B. Foster.*—Epidendrum macrochilum roseum.——*A. C. Bartholomew.*—Barnardia scilloides, Calceolaria chelidonioides, Campanula Hendersoni, Alstræmeria psittacina; 2, Sedum spurium; 3, Sedum oppositifolium; 4, Sedum album.——*J. H.*—Diplacus glutinosus.——*Blechnum.*—1, Asplenium Adiantum-nigrum var. acutum; 2, Lomaria alpina; 3, Cystopteris fragilis; 4, Polypodium vulgare var.; 5, a form of Athyrium Filix-femina.——*F. E.*—Chrysanthemum (Leucanthemum) maximum.——*O. B.*—We cannot undertake to name varieties of garden Peas.——*C. & Son.*—Very immature, probably Polyporus terrestris in an infant state.

Names of fruits.—*Pomme Poire.*—1, Warner's King; 2, Echlinville Seedling; 3, send when ripe; 4, Williams' Favourite.

WOODS & FORESTS.

TREES FOR CLAY SOILS.

To the casual observer there may not be much difference between the trees of different districts, and to a certain extent the species upon one kind of soil insensibly blend with others growing upon lands very diverse in character. Even botanically there may be little to indicate the varying conditions, but practically they are plainly enough marked. In clay itself there is, of course, a great deal of difference. These remarks apply to what is known as the Oxford clay—a bed whose depth has not been ascertained. The Oak has, I suppose, an affinity for most clays; at any rate, it is a tree which thrives on clays of quite a different nature in some parts of Sussex I am acquainted with, and there the timber is spoken of as being of especially good quality. After all, quality is the end and aim of tree culture, as an apparently fine lot of trees may turn out to be of little timber value. In this respect planting the Oak upon the Oxford clay is perfectly safe, because for soundness of quality and durability there is no soil with which I am familiar where better Oak is grown. From an agricultural point of view, these soils are of but very doubtful value. Occasionally in an especially favourable season some fair crops are produced upon the arable portions, but the pasture is generally poor and indifferent. The Oaks on this class of land are relatively slow in growth, but this is compensated for in the worth of the timber when grown. There are other trees which I shall mention, and many of them produce good timber on clay, but the Oak is, *par excellence*, the tree. In many cases good Ash is grown either with Oak or on soils of a similar nature, and in the case under review this, to a great extent, holds good. Ash for the production of the best timber always requires to be grown in plantations in contradistinction to the field or the hedgerow; but on this clay I have found the greater proportion of Ash trees, when grown under the less favourable conditions, to be of fine texture, and, so far as the boles grew, were free from knots, and all which could be desired for the best work. Of Elm I cannot speak in quite the same terms, as although the wood produced is usually of good quality so far as soundness goes, it does not often grow to the size or with the clearness of grain which is essential in this wood for the best uses. Of Beech I cannot speak with any degree of certainty, as at the moment of writing I have not any data to judge by. On the whole, however, I do not look upon it as a tree especially suited to clay planting, as it generally succeeds best where the subsoil is free and rocky. In many cases where the soil is moist and otherwise suitable, the Poplar can be successfully grown upon this clay, and I also know of many Willows of good size growing under corresponding conditions.

With regard to Conifers generally, I do not look upon them as being well adapted to such soils. Plantations of Larch here are apparently doing very well, but, on the other hand, there are many young trees which are dying off. Of the smaller species which do not, as a rule, reach a timber size there are plenty which do well, a great number no doubt being indigenous. Perhaps after the trees which have been mentioned the Hazel in coppices is most abundant. This seems to do well upon the clay, but possibly does not grow so rapidly as it does upon some other soils. Of Thorn and Elder there are always large quantities, and the common field Maple does well. While speaking of this, it may be well to note that where the Maple thrives the Sycamore should succeed, and by analogy in other respects it is a tree which seems suited to the Oxford clay. These notes as far as they go are the result of observation and experience in dealing with the woods here, and I have no doubt there are others who have remarked many circumstances connected with trees upon this class of soil which have escaped the writer's attention. I take it to be an important point in forestry literature that more information should be diffused upon this subject of trees and soils; therefore any notes upon it would, I have no doubt, be appreciated. D. J. Yeo.

HARVESTING TREE SEEDS.

The best tree seeds are those produced by fully fertile, healthy, vigorous trees, growing not too closely together in a favourable soil and situation. Very young trees usually furnish a large proportion of barren seed, while very old or weakly trees yield seeds which are not only difficult to keep, but also produce weak plants. Seeds ought to be collected only when they are ripe; such as are not fully ripe when taken off the tree do not possess the germinative faculty in the same degree as ripe seeds, and, moreover, lose that faculty much sooner. The ripe fruits of some species hang on the trees for a considerable time, and such one need be in no hurry to harvest; but there are other species, the majority of the seeds of which, with or without the rest of the fruit, are shed as soon as, or soon after, ripening. Among these are several kinds of deciduous Oaks, Silver Firs, Birch, &c. The collection of such seeds evidently admits of no delay. Rainy weather ought, whenever possible, to be avoided for the collection of seeds, especially of such as are small; but this prohibition, as a matter of course, does not extend to such seeds as are to be sown at once, or, which comes to the same thing, as cannot under any circumstances be preserved.

Hand-gathering from the trees is the most costly method, but is the only one applicable in the case of small or light fruit, such, for example, as Elm, Maple, Ash, &c., or of small light seeds that escape from the ripe fruit still hanging on the tree, as those of the Deodar, Silver Fir, Birch, &c. The seed-collector must climb to the crown of the tree, with or without the help of a ladder, as he can best manage, and with a sack slung over his shoulder. What he cannot reach directly with his hand he must draw to within arm's length of himself by means of a hook attached to the end of a light, but strong sapling of sufficient length. Branches and branchlets break off less easily when drawn upwards than if pulled downwards; hence it is always advisable for the collector to climb up to the highest point he can attain and begin by plucking off the fruit hanging at the summit of the tree. Gathering seeds or fruits from the ground after they have fallen from the trees is economical, and applies especially to large, heavy fruit which fall more or less perpendicularly, and which do not break up and allow the enclosed seed or seeds to disperse. To facilitate the fall of the seed or fruit, the branches of the trees may be shaken.

When trees marked to fall within a year or so are chosen as the seed-bearers, it may be found inconvenient or impossible to fell the trees as soon as the fruit ripens. On account of the nature and small size of the fruit and seed, shaking the trees and picking the seeds from the ground may also be inapplicable, while hand-picking would be unnecessarily expensive, since there is no reason for sparing the fruit-bearing branchlets and twigs of such trees. The fruit may then be broken off singly or in bunches with the aid of a strong hook forming a sharp angle of about 30° firmly attached to one end of a long sapling. The inside edge of the hook should be sharp and serrated and slightly curved inwards. The hook should be passed over the fruit-bearing branchlet or twig at the point at which it is to be broken off, and jerked downwards; or, if that does not suffice, it should be twisted round once or twice, by which means the branchlet or twig, as the case may be, will be firmly caught in it and a single jerk will then suffice to cut the former through. Where small wood has no value, and there is no objection to thinning out the crowns of the trees, branchlets of a certain thickness may be cut off with a bill-hook, and the fruit then hand-plucked from them. Some trees produce bunches of fruit, the common stalk of which dries up at maturity and early disarticulates from the rest of the branchlet.

In the case of seeds having a thick and fibrous covering the rind must be torn off with the aid of special shears, and in the case of seeds included in a capsule or pod or between scales, the quickest method, when practicable, is the application of heat, under the action of which the valves of the capsules or pods and the scales of cones open out or disarticulate, and allow the enclosed seeds to escape. In many cases simple exposure to the sun suffices; in others, however, a higher and more sustained temperature is required in order to bring about the full expansion of the seed vessel.

With seeds having leafy appendages, the wholesale removal of the appendages, except one by one with the hand, is not always possible without injury to the germinative power of the seeds; but whenever practicable, it should be effected. If the seeds are hard or tough, friction, more or less rough, suffices to detach these appendages. When this is the case, a very expeditious method is to nearly fill a large stout sack with the seeds, and to thresh these or work them violently backwards and forwards, according to the toughness of the seed, until the appendages are detached or crushed, when they can be easily separated by the ordinary process of winnowing.

The seeds of many trees have to be plucked before they are quite dry, in order to prevent their being disseminated and scattered far and wide. Other kinds of seeds contain a great deal of moisture even when they fall off naturally. Such seeds should be spread out not more than from 2 inches to 3 inches high in a dry, airy, sunny place, and turned over with a rake twice or thrice daily for a period varying with the kind of seed and the dryness and temperature of the weather. After this they should be piled up higher, the raking being continued as before, but being limited to only once a day. This latter process should go on until the seeds are sufficiently dry. Experience alone can tell when this is the case. It is needless to say that in cold weather the seeds should be removed under shelter while dew is being deposited. As regards seeds that are moist even when they are shed naturally, this drying is really the completion of the ripening process. W.

Foreign seed-collecting.—As in the case of collecting native tree seeds, it is a well-known fact that seed collectors abroad as a rule pay very little attention to gathering the best seeds they can find. Seeds are not unfrequently procured from medium-sized trees growing along the outskirts of Pine forests. In such situations it is often impossible to depend on the progeny. The pollen of most coniferous trees is produced in very large quantities, and is often blown about to a considerable distance. To this cause may be attributed the sickly condition of the plants raised from much of our home-ripened seeds, as is observable in Abies Menziesi, A. Douglasi, A. nobilis, Pinus monticola, P. Laricio, and others. Such examples prove the necessity of foreign seed collectors penetrating the Pine forests in order to secure seeds in a pure and perfect state. The rarer species of Conifers now cultivated in this country are not yet to be had in such quantities as to be grown as forest trees. The chances, therefore, of impure seed are very great.—J. M.

Larch seed—native *v.* foreign. — "Yorkshireman's" criticism of my remarks on this subject has not added much new information or brought forward any new facts. He seems to pervert facts and impute nefarious motives to me. I did not impute any base motives to nurserymen, such as "Yorkshireman" says; nor do I think that seedsmen seek to "deceive their customers by selling spurious foreign seed for home-raised seed." The truth is, nurserymen have to take the seed, whether it be foreign or native, whatever its quality may be, from the seller, seeing that they must have seed of some sort so as to supply their customers. Seedsmen have, in fact, very little control over the parties used to gather tree-seeds at home. "Yorkshireman" says, "There is really no

occasion for nurserymen to sell foreign seed for home-grown." Certainly not, since home-grown seed is preferable in every way to foreign, only it is not so abundant nor so easily procurable as the foreign. But, he adds, "home-grown seed is plentiful, and can be had by those who want it." It must be in Yorkshire that home-grown Larch seed is plentiful, and if that be so, it is strangely odd why Yorkshire seedsmen do not endeavour to supply the demand. Good home-grown Larch seed is never abundant any season, or, if it is, it is very curious how it cannot be got. "Yorkshireman" says there is no difference between that which is fit and that which is not.—J. F.

PREPARING GROUND FOR TREE-PLANTING.*

On the greater part of land which has not been used for agricultural purposes there will be much growth detrimental to the health of young trees if left untouched. Heath, Broom, Furze, Brambles, and other course woody plants must be removed, that there may be nothing to impede the full development of the trees. We would prefer burning, as the surest and most expeditious mode of checking the growth of Heath, where such an operation can be performed with safety, and where danger is apprehended, the flame can be stopped by turning over a line of sods across the direction of the flame. Even burning will not eradicate Heath, but will so check its growth that, by the time it recovers, the trees will be beyond all danger of injury from it. Were it not that, where the Heath is rank, the young trees might be choked by it, we do not consider it otherwise detrimental. Broom, if old, can easily be destroyed by cutting over above ground; but, if young, the stems will be covered with eyes, and such cutting will only induce a more rapid growth; therefore, it will be necessary to take such up by the roots. Whins are in this quarter more detrimental to the growth of plantations than other underwood plants, as well as more difficult to eradicate, and, where they grow close, simply cutting over above ground is altogether lost labour. The greatest care should, therefore, be taken to remove them by the roots, and any necessary expense incurred by this operation will be amply repaid in the smaller amount of labour required in the future management of the plantation. Raspberries and Brambles will sometimes, especially on gravelly soils, be found a great nuisance. It is next to impossible to eradicate these; perhaps the best plan is to cut the canes successively till the young trees are beyond reach of injury from them. All other growth, such as Birch, Hazel, &c., which, in almost all cases, will be entirely unworthy of a place in the new plantation, should be cleaned off, so that not only the growth of the young trees may not be impeded, but also that subsequent operations on the ground may have as little interruption as possible. In certain localities the clearings may be of value as firewood, and may somewhat lessen the expense of preparation. If such is not the case, let them be collected into heaps and burned, and the ashes blended with the soil.

Fencing.

Fencing is an indispensable operation in the preparation of ground for planting. It ought never to be considered a point of minor importance, but ought to be attended to immediately after the clearing of the ground, lest the future operations of making roads, drainage, and pitting might suffer damage from stray cattle or other causes. In selecting a fence for a plantation the first object to be aimed at is durability; next, the least possible ultimate expense. In some cases a necessity for ornament may guide the selection, but in all other cases, and where the requisite material can be obtained, we would prefer a stone dike, both for durability and ultimate cheapness. In many situations, however, it may be difficult, or altogether impossible, to obtain stones; in such cases a wire railing with Larch posts offers a good substitute; and, if economical considerations extend beyond the present, a little extra labour and expense in charring the ends of the posts or dipping them into some solution to resist the decomposition which inevitably ensues from contact with the soil, and coating the part exposed to the atmosphere with boiling coal tar, or other solution suitable for the purpose, will eventually remunerate, by increasing the durability of the paling; but, where cheapness guides the choice, a dike and ditch, with a hedge of Whins on the top—the materials of which the dike is built being taken from the outside—will form a fence of considerable efficiency, although this is, at best, but a clumsy and not very certain protection to the plantation, especially for the first three or four years, when the trees are young. In such places as require an ornamental fence, a hedge is, no doubt, the most suitable; Beech, Hornbeam, Holly, and Thorn are the more common materials, but the two former do not offer such resistance to animals as may, in many instances, be desirable; the two latter will, in time, make an excellent fence, especially Thorn, which offers greater resistance to animals than Holly, and is also much cheaper. Holly, being evergreen, may be preferred in some instances; still, as a general rule, we would prefer Thorn. Hedges, however, require to be protected for a number of years by a paling. Care should be taken to select such material, and give it such treatment as will make the paling last till the hedge is a sufficient fence. Hedges also entail considerable expense, not in the original laying down merely, but on account of the continued yearly attention which must be paid to them, but they amply repay it.

Making Roads.

It ought to be the object of the tree planter to provide the greatest possible facilities for the removal of felled timber, as such facilities will greatly enhance its value. In former times this was never thought of till the trees were of large growth, when gaps were made in the fences, if any fences existed, and avenues cut through the wood. This must often have been at haphazard, and the soil was in all cases unfit for bearing the conveyance of heavy loads, added to which, the stumps and roots of the cut trees combined to form a road as execrable as any in the backwoods of Canada. Nor are roads needful for the removal of felled timber only, but for the protection of the plantation when, in a growing state, they are highly advantageous, and also for preventing the necessity of removing prunings or thinnings over the fences. All these considerations enforce the necessity of forming roads at the commencement of operations for planting. The particular distances at which they should be made must be regulated by the extent, plan, and situation of the plantation, keeping always in view the economy of labour in conveying timber of large growth to the roads, taking advantage also of level tracts or gentle declivities leading to the outside of the plantation, and avoiding, if possible, ascents, thus lessening, as far as possible, the amount of animal labour required. In forming the roads, particular attention must be paid to drainage, especially where the soil is not hard. In most cases a drain on each side, with the material taken from them laid over the centre of the road, so as to give it a convex form and throw the surface water into the ditches, will be sufficient. When the inclination of the ground renders it necessary to provide cross drains, they should be built with stone, and have very strong stone covers. A road should not be less than 7 yards in width, so that loaded carts might pass with ease without injuring the edges of the ditches, and also to give room for loading and turning carts. A road made in this manner, when a plantation is laid down, will, by the time the timber is fit for cutting, be in a state to bear any ordinary load.

Drainage.

The next operation is drainage, which, except on very dry soil, is all but indispensable. In proceeding with this, it is necessary to examine the inclination of the ground that the main drains may have the advantage of all the fall possible. The distance of the main drains from each other must be regulated by the nature of the ground. If level, or nearly so, the small drains cannot be expected to be effective farther than from 150 yards to 200 yards; but, where considerable declivities exist they will act farther, and the mains should be carried along the natural hollows. As a general rule, small drains should not be less than 2 feet deep, and, if the fall permit, an additional 6 inches would make them much more effective. If the ground is very wet, we would not be inclined to place them farther apart than from 24 feet to 30 feet. Where the ground is not so wet, the distance may be increased by 6 feet or 9 feet. To keep the drains clear, the mains require to be from 4 inches to 6 inches deeper, and where a natural fall does not exist to carry off the water from the mains, no labour must be spared to secure it. It sometimes happens that very steep ground requires to be drained—in such cases, instead of leading the drains directly down the declivity, we would carry them obliquely across, taking care that sufficient fall is secured to carry off the water speedily. The propriety of this mode will be apparent when we consider that the particles of water in the soil of a deep declivity will have a greater tendency to settle down the declivity than sideways into a drain running straight to the bottom. A drain carried obliquely across the face of the declivity catches all the moisture as it percolates downwards, and, if a quick fall is secured, the water will have no inducement to penetrate into the soil below the drain, but will run off and secure a perfect drainage; whereas drains cut straight down the declivity would do little more than carry off the rain water which might fall into them. The advantage of judicious draining must be apparent to even the most casual observer. Stagnant water about the roots of the young trees prevents that development of the roots necessary for their healthy growth; hence, on undrained ground, young trees have a stunted, unhealthy appearance, make little progress, and in many cases die out altogether. It may also frequently be noticed on ground where the drains are too far separated, or too shallow, that the trees by the sides of the drains are thriving and growing rapidly, while in the centre between the drains they have the stunted appearance peculiar to undrained ground.

Making Pits for the Trees.

This is necessary for all hardwood trees. In ordinary cases slit planting is sufficient for trees of the Fir tribe, but hardwood trees will not succeed so well unless better pulverised soil is provided than can be got by slit planting. For trees of the size ordinarily got from the nursery, pits 2 feet in width, and depth regulated by the nature of soil, will be sufficient. The pits should be dug some months previous to the time of planting, that the action of the weather may pulverise the soil and make it more congenial to the tender roots of the young plants. Ordinary-sized hardwood plants, on gravelly soil especially, with a southern exposure, will require pits of much larger dimensions. In such situations pits of the ordinary size will retain too little moisture to sustain the young trees; whereas if a greater area and depth of the soil is loosened and the stones removed, the original channels through which the water percolated are disturbed, and far greater power given to retain moisture. In such situations, Firs, especially if intended for standards, would require to be treated similarly, and even in ordinary soil, if Firs are of larger size than common, they will require pits prepared for them.

* Communicated to the Transactions of the Scottish Arboricultural Society by Mr. John Darling.

Cryptomeria japonica.—A rapidly growing hardy tree, but one that will not bear exposure to high winds. It is very ornamental, the foliage being of a rich green, and somewhat Fern-like or Moss-like in character. Although planted in quantities in the Azores and elsewhere for light packing-case timber, it is not likely to be sought after in this country as a timber tree. The wood is very light and soft. It likes a somewhat damp soil. Of the other species, C. elegans, I cannot speak except in the character of a shrub. It is a very beautiful plant, and should it grow to the dimensions of a forest tree in this country, will be a very striking object in the landscape, from the coppery tint assumed by the foliage in winter. In its native country, Japan, it grows to the same size as C. japonica.—H.

Osier planting.—I am seeking information respecting the planting of Osier beds. Can you give me the name of a firm to whom I could apply?—L. J. L.

No. 775. SATURDAY, Sept. 25, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

TEA ROSES IN SEPTEMBER.

I do not remember ever seeing these so plentiful as this year. With us standards and dwarfs in the open and strong bushes against walls have all yielded abundance of good late blooms, and there will be daily supplies till severe frosts cripple them. Madame Lambard is remarkably free, and in the bud state very beautiful. Souvenir d'Elise in a warm position is also very free, and one of the best. Souvenir de Paul Neyron, both as a standard and on an exposed wall, is very serviceable, and one of the strongest of growers. Catherine Mermet on its own roots and planted against a south-east wall is in flower many months in the year, and this day (Sept. 18) I have cut a handful of really fine blooms off it. Altogether this is one of the finest Teas in cultivation. Safrano on a south wall is usually the first and last in bloom, and the buds of this variety are frequently in demand. Homer in the open is rather small, but wonderfully free, and its blooms find plenty of admirers, as do also those of the very free blooming alba rosea. Comtesse de Nadaillac is a general favourite and one of the best of Roses. Etoile de Lyon grows strongly and is fairly free blooming, but with us not good so late as other varieties. Anna Ollivier is of good habit and produces abundance of beautiful blooms, and the same may be said of Innocente Pirola. Climbing Devoniensis is now giving us several lovely blooms, and mixed with this we have Madame Berard, a variety much resembling the good old Gloire de Dijon. The latter is good everywhere this autumn, and succeeds in a much cooler position than the majority of Teas. Noisette Céline Forestier is one of the best for sunny walls, and a capital variety for cutting from. Even Maréchal Niel is giving us good late blooms, and a newer Noisette, W. A. Richardson, is just now very charming in the bud state. Perhaps the most useful Rose we have is the Bourbon Souvenir de la Malmaison. It is planted in various positions, and in each instance on its own roots. The finest blooms are cut from a large plant growing against a sheltered wall, which the sun reaches only late in the afternoon. Dwarfs of it in the open are usually in bloom before any of the hybrids, and flower almost continuously till severe frosts set in. Cuttings of ripened wood put in the open ground next month or not later than November strike readily, or the old stools may be divided. When growing strongly the plants push up extra strong branching suckers, much the same as some Teas do, and it is these that yield so many good blooms in succession. It does not do so well on light soils, and Somerset would really appear to be the favourite locality for this Rose. W. I. M.

Æschynanthuses.—We have few better stove-flowering plants for basket culture than the several species of Æschynanthus to be found in gardens. In a moist tropical temperature they soon grow into pretty specimens, and if the shoots are allowed to hang downwards they are, when in flower, much more effective than if trained up sticks. In pockets against fernery walls, or in that kind of rustic stove furniture made of cork and tree trunks, they are quite at home, looking neat and pretty even when not in flower. They want peat and Sphagnum, as they are mostly epiphytal under natural conditions, and they must be kept well watered all the year round. The best kinds are Æ. fulgens, with lanceolate succulent leaves and terminal clusters of bright scarlet flowers 2 inches long; Æ. Lobbianus, which has small ovate leaves, and purple cup-like calyx holding the upright scarlet and yellow corolla tube; Æ. pulcher, like the last, but with a green instead of purple calyx; Æ. speciosus and Æ. grandiflorus, which are stiffer in habit than the others, and may be grown as upright pot plants; they bear large clusters of brilliant scarlet and yellow flowers. All of them bloom during the greater part of the summer, and the flowers remain fresh about a fortnight. In a high temperature these plants are very easily kept in health. They are worth growing amongst tropical East Indian Orchids.

MASSING HARDY BULBS.

A SHELVING, shaded bank thickly covered with winter Aconites in January is a sight ever to be remembered. Snowdrops and common trumpet Daffodils are only seen to advantage in large bold clusters against a background of trees and shrubs. A large mass of the blue-flowered Squill (S. sibirica) in March makes a deep impression, though inferior in effect to that of the acres of Bluebells which I have seen in woods in Norfolk and elsewhere in June. Large clumps of white Lilies (L. candidum) springing out of a base of greenery against a background of large-leaved shrubs (Rhododendrons, for instance) never fail to attract attention. The Alstrœmerias when left undisturbed for years and allowed space for development form an interesting group that can scarcely become too large. Grandeur and importance are imparted by gathering things into masses. The Wood Anemone, one of the prettiest of British shade-loving plants, is always interesting, but plant a partially shaded bank with it and the effect is very striking. Lily of the Valley and the hardy Cyclamens, however beautiful they may be in isolated clusters in the border or on the rockery, are more effective when gathered into groups in sheltered recesses. The season for bulb planting is at hand, and those who intend to plant should purchase their bulbs and thoroughly prepare the site for them. Leaf-mould is always an excellent dressing to work into the soil where bulbs are to be planted. Daffodils of the common types if planted thinly will annually form new bulbs, and soon become a mass. The same thing happens in the case of Snowdrops and other things which I have named. Common Bluebells will be at home in partially shaded shrubberies. They should be planted in the open spots, not in dense shade. They will transplant very well any time before their growth gets above ground. I have moved quantities of them when even further advanced, but the best and the natural time to move all bulbs is when they are at rest. E. HOBDAY.

EARLY FLOWERING PAMPAS GRASS.

IF an early flowering strain of this highly ornamental Grass could really be obtained, it would prove a most valuable acquisition. The one great fault of the normal type is its lateness, and this season it is so much later than usual, that thousands of spikes will probably never get out of their sheaths till frost is down upon them. Something has been done to forward the flowering of Pampas Grass of limited size by storing the plants in pots in cold pits or frames, starting them freely into growth before planting out towards the middle or end of May. But then such plants seldom throw up more than from one to five spikes; whereas to have this plant in perfection, huge specimens with from fifty to a hundred plumes, such as the early plant noted at Kew (p. 261), are desiderated. By fostering the plants in pots in their earlier stages, and choosing warm, cosy nooks and corners for their permanent quarters, the flowering may be hastened by several weeks. But, unfortunately, a late season like the present has a tendency to keep all the flowers back to the middle or end of October or later, and, as already stated, to destroy them in a half developed state. Has anyone succeeded in forwarding the season of blooming by raising the plants at different times? Should, however, the precocious plant at Kew ripen seeds, it may give us the early strain so much needed, and develop to the full the rich ornamental effects of the Pampas Grass. Other points are also well worthy of the attention of improvers of this fine plant, such, for instance, as length, size, and whiteness of plume. Of course, in regard to the latter, very much depends on the time of cutting and after-treatment. Yet, apart from this, there are great diversities in the build, colour, and size of the spikes. A very fine variegated strain once not uncommon seems also to have been nearly lost. So far as my experience goes, this has never been reproduced from seeds; it had to be propagated by division, and has seldom been reproduced as a chance sport. HORTUS.

NOTES OF THE WEEK.

Anomatheca grandiflora.—This is a newly introduced species of a genus hitherto known in gardens only by the small, though pretty flowered, kind named A. cruenta, which grows and flowers freely in a warm sunny border out of doors, and is easily raised from seeds. The new kind is not unlike the common Tritonia aurea in habit, the leaves being 18 inches long and the spike about the same length, whilst the flowers are arranged in a cyme which springs from a large bract; each flower is composed of a narrow tube 1½ inches long, a spreading limb of six segments, three of which are narrow and 1 inch long, the others being nearly half an inch wide, narrowed above and below, and a little longer than the others. Colour bright scarlet, with a crimson blotch on two of the larger segments. This distinct and pretty plant is now in flower at Kew. It was raised from seeds obtained from Delagoa Bay, in South Africa.

Epidendrum Mathewsi.—This is a small and modest-looking little species of a large and very variable genus, the members of which are not, as a rule, of much value for garden purposes, though many are of interest, owing to some peculiarity of structure or delicious fragrance in their flowers. The above kind is a small edition of E. Medusæ, generally known as Nanodes, and remarkable for the size and leathery substance of its dark brown flowers, the lip of which bears a fringe of hair-like filaments. The habit of E. Mathewsi and the arrangement of its succulent foliage, as well as the form of its flowers, are just those of the Nanodes, except that the lip is without fringe, and the whole plant is about half as large in all its parts. It may now be seen in flower at Kew, where it is grown in a warm house, and fastened on to a soft piece of Fern stem. Unless we are mistaken, this curious little Orchid is in several other Orchid collections in the neighbourhood of London.

Sternbergia sicula and lutea.—Some little time ago M. Dammann asserted in THE GARDEN that Sternbergia sicula is by far the best of its kind. It seemed to me difficult to follow him then, because Sternbergia sicula did not come up to the mark. I had the bulbs from him, and I thought the encomium too great for them. But since then, as you probably know, the names have been revised, and this, one of the most glorious of autumn flowers, bears out everything that was said about it. I send with this a blossom of Sternbergia sicula which I had from M. Dammann, and it is unmistakably better than S. lutea in more respects than one. You should see a good clump of it at twelve o'clock when every petal is thrown back to the sun in an abandoned sort of way, and you could not fail to be pleased with it. Sternbergia lutea must be dethroned at once, and give way before its more imposing rival. Why is it, I wonder, that S. lutea has had possession of the field for so long? There is no such very great difference of price between the two as to indicate that Sternbergia sicula is difficult to get hold of in the proper places. What Vallota purpurea is for dazzling scarlet in the autumn, Sternbergia sicula is for yellow of the most clear and bright description that can be imagined.—H. EWBANK.

*** The flower of S. sicula sent is twice the size of that of the typical S. lutea.—ED.

Phalænopsis Lowi.—The finest example we have ever seen of this beautiful little Moth Orchid is now in flower at Kew, an unusually healthy specimen, with large, leathery, dark green leaves and long branching spikes of bloom, more like what one finds in P. Schilleriana than in this small kind. Possibly

the Kew plant is a superior variety to that generally met with, for we learn that it holds its foliage from year to year, and has produced large branching flower-spikes every year since it was first imported from Moulmein. Altogether, there are at present fifty-three flowers and buds borne by five individual plants, one bearing a spike 3 feet long, with three branches each 1 foot long, and there are fifteen flowers on this one spike. Four flowers on each branch or small spike is the average. The leaves are 5 inches long, and there are two or three leaves on each plant. A photograph of this specimen was taken by us last year, which we intend publishing shortly. The conduct of this species at Kew seems to prove either that there is an evergreen as well as a deciduous form of it, or that it has got the character of casting the whole of its foliage annually, from having been compelled to do so by the conditions of its natural habitat, while under more favourable conditions it is as evergreen as the other kinds.

COOMBE WARREN.

A highly elaborate style of gardening is represented in the beautiful garden surrounding Mr. Currie's Surrey residence at Coombe Wood. Art and Nature are here intermingled in such a way as to produce not only a pleasing, but a most charming home landscape, such as it would be difficult to match, even among the multitude of beautiful gardens to be found in the neighbourhood of London. The happy blending of formal objects, such as statuary, with Nature's uncultured growth must indeed be a most difficult art, or success in that direction would not be so rare. To do it successfully the designer must feel what he is doing; he must know how much formality to introduce, and, above all, how little. At Coombe Warren there is just enough formality immediately surrounding the house to enhance the beautiful scene beyond where the true natural style of garden landscape merges imperceptibly in the natural wood, where great trees, the growth of centuries, rise from a carpet of Fern and Bramble never molested by scythe or broom. It is this gradation of styles, this association of highly-polished Art with wild Nature, that makes the garden at Coombe Warren so enjoyable to all who can appreciate such arrangements.

For illustrating we have chosen a portion of the connecting link—the lawn between the formal garden and the wild garden. There is no need for us to say that this glade is beautiful; that is shown by the illustration, but it is even more charming when seen from the house, for then the Ha-ha which somewhat mars the upward view is not seen. Here the gently undulating slope, with its great Oaks and Elms and Chestnuts sweeping the turf, and with here and there a choice exotic, such as the deciduous Cypress or a Silver Fir, reminds us that we are still in the garden. From all sides of the house except the north one sees these delightful glades and vistas with the lawns kept faultlessly smooth, and upon the west side there is a broad expanse of lawn upon which are planted the rudiments of a pinetum. There are three or four groups of Conifers on this lawn which anyone who understands artistic tree grouping cannot but admire. The trees are chiefly common kinds, such as Douglas Fir, Austrian Pine, and Spruce, with a few of the rarer species of Abies; they are not huddled together in the usual way, but planted sufficiently far apart to allow each elbow room. The different rates of growth of the various trees have produced a beautiful skyline; in short, the groups look as if they had sprung from Nature's sowing. This is really the best way of grouping ornamental Conifers or other trees, for they not only produce a better effect than when scattered, but they thrive so much better on account of the shelter which they afford each other. These thriving and admirably planted groups form a contrast to the wretched isolated specimens of Conifers one often sees on lawns, which seem to have no connection with other trees or anything else. On the same lawn as the Conifer groups are there is a Heathery on a dry sloping bank, capitally adapted for sun-loving Heaths. There seems to be every variety of hardy Heath in the collection, and when in flower they have a beautiful effect.

The Conifer-planted lawn is connected with the adjoining terrace garden by a covered pathway, arched over with clipped Lime trees, which afford a delightful shady walk in summer. The foliage on the shoots of these Limes is still green—so different from that of unpruned Limes in the open. The subdued light of this shaded walk serves to intensify the brilliancy of the mosaic-work garden to which it leads. This garden is a small quadrangle, severely formal in design, the beds being in a geometrical pattern, and the whole enclosed by a stone balustrading. This little garden is quite separate from the rest of the terrace garden, and, while not obtrusive, can be seen when looked for. It terminates the broad-gravelled terrace, and is the best spot that could be chosen for it, as it is not in violent contrast to the more natural-looking part of the grounds. The brightness of the "carpet" beds at this season, when flower-beds are looking shabby, quite lights up the whole place. The mosaic garden is enclosed on one side by a high retaining wall, every part of which is densely clothed with a growth of Ivy-leaved Pelargoniums of a bright cherry-rose colour. These are blooming profusely at the present time, and have been doing so ever since June. They are planted yearly at the end of May, and they soon cover the wall and make what must be regarded as one of the most beautiful displays about the place.

The terrace garden, of noble breadth, is adorned with a profusion of pyramidal plants in tubs—Pelargoniums, Heliotropes, and beautiful-leaved shrubs, such as Golden Euonymuses, Bays, Eurya latifolia, Ivies, and the like, some of which are over 11 feet high. These pyramids may be said to be the peculiar feature of Coombe Warren, and certainly the prodigious Pelargoniums and Heliotropes and Fuchsias are the glory of it throughout the summer, for in few other gardens can they be found grown and flowered to such perfection. You meet them at every turn in the parts that are avowedly formal, but there they stop, and do not obtrude themselves in the natural parts. The Pelargoniums are mostly single-flowered Ivy-leaved kinds, of a bright carmine colour. One plant we measured was over 8 feet high and nearly 6 feet through. The Heliotropes are equally remarkable, and the shrubs, particularly the Golden Euonymuses, are at this season pyramids of gold.

The mansion is a modern building, irregular in outline, much attenuated in consequence of its having been added to. The style of house suits the surrounding scenery admirably, for it nestles among the trees very snugly, and this homely effect is enhanced by the creepers with which every wall is covered. Indeed, the creeper-clad walls of the house are one of the most charming features of the place, particularly at the oldest part of the house, where the Wistaria and other ramblers festoon the gables in a beautiful way. On the lawn side of the house may be seen a great variety of climbers, the most prominent being Magnolia grandiflora, white Jasmine, Ceanothus dentatus, Berberis stenophylla and B. fascicularis (the latter extremely fine), Cotoneaster microphylla, various kinds of Clematis, and Ivies in profusion. Climbing, creeping, and rambling plants are evidently great favourites with Mr. Currie, for there is not a wall, statue or pedestal against which he has not planted some kind of plant, and the delicate tracery which these make against the stone pedestals renders the statuary strikingly effective.

The opposite of the house to the lawn is treated in an entirely different manner from the front, the space being occupied by enclosed gardens containing bright effects from masses of coloured foliaged plants, while the surrounding walls are clothed with the favourite Pelargoniums and Heliotropes. In this part there is also a walled-in fruit garden, with the sunny walls at the present time covered with Peaches and other wall fruits, while the centre is occupied by pyramid-trained hardy fruits, Apples, Pears, Plums, and the like, which yield abundant crops. The whole of this portion of the place is treated in a most elaborate way, the paths, the dividing palings, gates, &c., being highly ornamental, yet in strictly good taste. There is a large number of houses for fruit and plant culture, though as the place is used mostly as a summer resort, the open-air garden has evidently received the most studied care of its owner. W. Goldring.

Anagallis cærulea.—I met with flowers of this lovely Pimpernel, together with carnea, the ordinary A. arvensis, growing side by side in the same field, the three colours, blue, pink, and red, blending and contrasting happily in their several hues. A. cærulea was the smallest of the three, and at first sight it seemed to be specifically distinct, but a closer examination with the lens failed to prove its distinctness. Dr. Arnold Bromfield states that he saw, in a garden in the Isle of Wight, the cultivated Anagallis bearing flowers of a bright blue on the same stem with the flesh-coloured variety. He records, moreover, that Professor Henslow established the question of identity beyond all controversy by cultivating the plants from seed. This is all the more likely, as the Pimpernel is primulaceous in its grouping. I am aware that it has been described by Persoon as a distinct species, as also by others who have followed him in later years. Even Babington says of it that it is "probably distinct," but practical acquaintance does not bear out his suggestion. Gaudin, in his "Flora Helvetica," vol. ii., p. 67, says that the seeds of arvensis are fatal to small birds, which eat those of the blue variety with impunity. It may be so, or he may have had an eye to the Continental A. Bonelli, a lover of chalk—mountain limestone. I would remark, in conclusion, that identity between arvensis and carnea was more apparent than between arvensis and cærulea as they grew together. The leaves were smaller and narrower in cærulea and the stems less procumbent; the flowers also were decidedly smaller. The purple eye at the base of the corolla was conspicuous alike in carnea and cærulea, and enhanced the beauty of the colours of each.—Peter Inchbald, F.L.S., *Fulwith Grange, near Harrogate.*

The provincial show of the National Rose Society will, we are informed, be held in 1887 at Edinburgh, in connection with the summer exhibition of the Royal Caledonian Horticultural Society.

Bouquet-holders (*G. L., Portugal*).—Holders for buttonhole bouquets may be obtained of any of the horticultural sundriesmen in London. (See p. vii. of last week's Garden.)

Heliotrope (*H. R.*).—Appears to be a first-rate dark sort, but we cannot say how far it is different from other sorts. —Ed.

Anæctochili. — These plants are seldom seen in a thriving condition, but we noticed lately some exceptionally healthy potfuls in the Phalænopsis house in the nurseries of Messrs. Veitch at Chelsea; they were not covered over by bell-glasses, or treated in any way different from the rest of the plants in the house.

New Figs in Smyrna.—During the last days of August the first dried Figs of this season were brought from the country districts into Smyrna for storage, packing, and exportation. The locomotive and the wagons carrying the fruit were, as in former years, decorated with flags and garlands of flowers. Thousands of persons were waiting at the railway station to greet the first arrival of Smyrna's principal staple. The casks and boxes containing the Figs were transferred to richly caparisoned camels adorned with flowers and ribands, and so carried to the bazaar, escorted by a great crowd.

Indoor Garden.

AMARYLLISES AT REST.

This is, or at least ought to be, the resting period in the case of Amaryllises, and I would recommend growers of them not to be too hasty in repotting and starting them into growth. While at rest, we give established flowering bulbs no water until February; as the leaves decay they are removed. Thrips are destroyed by tobacco fumigation, and when the plants are in good health they are not much troubled with red spider. We now leave all ventilators open night and day, and will do so until very cold weather sets in. Bright sunshiny days and warm nights have materially aided the ripening of the bulbs, which are this year large in size and very solid. Young plants raised from seed sown as soon as ripe in July should now be grown on freely, as should also young plants raised from seeds sown last year. The youngest plants do not lose any of their leaves, but continue to make growth all winter; consequently they must not be allowed to become so dry at the roots as old plants. Seedling plants are pricked out when ten days old, a dozen of them being put into a 5-inch pot. They will grow on freely if the pots are plunged in a gentle bottom heat and a hothouse temperature is kept up. In November and December they require but little water, and about the middle of January they should be shaken out of their pots, replacing them in others of the same size, but this time putting only three plants in a pot. Thus arranged, they will grow for another season without removal. Next year they should be repotted in January, one bulb being placed in a 5-inch pot. Established plants, both of named varieties and seedlings, ought all to be repotted between the middle and the end of January. As to compost, some difference of opinion exists. One grower with whom I was acquainted used heavy loam, to which was added a little manure. He had a notion that they succeeded best in it. They certainly grew and flowered well in it, but by the end of the season the roots used to be dead. I use two parts good turfy loam, one part peat, a fair proportion of sand, and one barrowload of manure to six of the loam and peat. Some, I know, say, "Why give minute instructions as to mixing up potting soils? These are mere trifles; one compost is as good as another," &c. The character of a compost is certainly not so important as old cultivators led people to believe, and therefore I do not think it necessary to mix its component parts up with precision; but we must not forget that perfection is generally attained by paying attention to minute details. We grow our flowering bulbs in pots from 4½ inches in diameter to 8½ inches, only a few of the larger sizes being used for very large bulbs. When repotted, the whole collection should be plunged in a tan bed, but it should not get any water until it is seen that the plants have started into growth. Giving water to the roots before they are in a state to avail themselves of it would cause some of the bulbs to rot. Nor is a high temperature at first desirable, as this causes them to rush into flower before the leaves appear, a circumstance which is not desirable. Even under the best of management many of the bulbs will produce flowers before leaves are developed, but without foliage Amaryllises are not nearly so effective as with it.

Amaryllis bulbs do best in bottom heat during the growing season, but very good results can be obtained without it. I have flowered them well in a vinery, and the bulbs have matured their growth both under the shade of Vines and Peach trees. The bloom is prolonged if the plants are removed when in flower to a greenhouse. Last spring was unfavourable to the perfect development of Amaryllis flowers. The weather, owing to lack of sunshine, was all against them, and near London the fogs, which were prevalent, further checked the expansion of the petals. Both the summer and autumn have, however, been favourable for the plants, which have done better than usual, a circumstance which promises well for next season's bloom.

New varieties have been quite as numerous this year as usual, and the result is that we have now an endless variety both of form and colour. Those with broad petals and such as produce six flowers on a scape are thought most of, and now that such breadth of petal and perfection in form have been attained, improvement makes slower progress than it used to do, and seeds are also more difficult to obtain. I tried this year to hybridise several of our seedlings with the best formed flowers raised by others, and though all of them seemed to take well at first and the pods swelled freely, yet before any seeds ripened every one of the stems died off, although ordinary varieties bore seeds well. The best amongst new forms are Colonel Burnaby, vermilion-red, the petals of which are 4 inches in width and well formed; Basilisk, light red, a very large variety with petals 4 inches in width—this has a pale green centre; John Heal, one of the largest and best of the lighter coloured flowers; Madonna, also very beautiful, creamy white with crimson flakes; Clarinda, likewise very fine in form; Lady of the Lake, almost white, unsurpassed as regards size, good in form and nearly white. Perfection is one of the more recently raised varieties and a stride in advance of anything produced last year. I am unacquainted with the parentage of these varieties, but Hippeastrum Leopoldi and H. pardinum were the species from which the pollen was taken which has effected such a revolution amongst Amaryllises. H. pardinum has no tube, nor has H. Leopoldi much tube; therefore by crossing forms with long tubes with these two kinds, the flowers have been altered in formation. I like the broad-petalled varieties best, but there are some who like flowers with long tubes and narrow petals. Hippeastrum vittatum, a coloured plate of which is given in the *Botanical Magazine* so long ago as 1791, though long-tubed and narrow-petalled, is unquestionably handsome, and from it several improved

Lawn view at Coombe Warren, Surrey. Engraved from a photograph taken last autumn for The Garden.

varieties have been produced, one of the best of which is one named superbum. H. solandriflorum is, however, the best type of the long-tubed varieties. Its flowers, which are 8½ inches long, are sulphur coloured inside and greenish yellow outside. The variety H. solandriflorum conspicuum has flowers 10½ inches long, and the flowers are faintly striped outside with red. Dean Herbert raised many interesting cross-breds in this section of Amaryllids, but they seem to have been lost. In "Amaryllidaceæ" (p. 142) Herbert describes no fewer than thirty-one distinct crosses, those of H. reticulatum and H. solandriflorum being the best. Herbert adopted a system of naming which answered admirably in the case of mules. Thus a hybrid between Johnsoni and solandriflorum was named H. solandriflorum Johnsoni. H. solandriflorumstylosum, raised at Spofforth and named by Sweet, had pale orange-coloured flowers, the largest seen in the genus, though the flowers of stylosum are small. The crosses from H. reticulatum were numerous at that time, as Sweet also raised some at Colville's nursery.

J. Douglas.

TREATMENT OF SHRUBS FOR FORCING.

Many shrubs intended for forcing are kept in pots, but some are lifted from the open ground for this purpose. Where this latter system is practised, the plants should be lifted in the autumn before the fall of the leaf, in order that they may establish themselves to some extent before winter sets in, as the blooms borne by plants treated in this way last longer in perfection than those that are potted just previous to being taken into the forcing house. The majority of the shrubs usually grown for forcing consists of Deutzias, Lilacs, Rhododendrons, and Azaleas; but this by no means exhausts the list, as great numbers of others are available for the purpose. A selection of shrubs for forcing should include the following: Deutzia gracilis.—This is so well known, that nothing need be said about its beauty when in flower, and it is, besides, one of the easiest shrubs to force; it can be had in bloom without difficulty soon after Christmas. It should be grown in an open, sunny spot, in order that its wood may get thoroughly well ripened; indeed, this rule applies to all shrubs grown for forcing. Lilacs, again, are used largely for forcing, the best for small bushes being the Persian, of which there is a white as well as a pink kind. The common Lilac is better fitted for larger bushes, and as such it makes a goodly show in the conservatory, and, besides, it is very valuable for use in a cut state. The double-flowered Peaches, blooming as they do so early in the season under natural conditions, soon open their blossoms when subjected to artificial heat, a remark which also applies to the double-blossomed Cherries, all the forms of which are valuable for forcing. A gem in the shape of small bushes is Cerasus or Prunus sinensis, a little, much-branched, rather upright-habited shrub, the slender twigs of which are closely packed with double rosette-like blooms. In one variety they are pure white, and in another tinged with pink. Azalea mollis is now largely grown for forcing, and very beautiful it is when in bloom. It will flower well either grown in pots or lifted from the open ground, for the delicate hair-like roots form a dense mass; therefore they can be lifted at almost any season without injury. The various Ghent Azaleas afford a pleasing variety, and the pretty little evergreen Azalea amœna makes a goodly show. Rhododendrons, too, must not be passed over, and among others of this class may be mentioned Andromeda floribunda, a compact-habited shrub, with dark green Myrtle-like leaves and spikes of pure white bell-shaped blooms, like those of Lily of the Valley. The Japanese Andromeda or Pieris japonica is a recent addition to this class of shrubs, and differs from the preceding in the greater length of the flower-spikes, and in their being pendulous instead of nearly erect. The bright crimson tints of the young leaves are also another distinctive feature of this species. The Kalmias flower well under glass, but they cannot be had in bloom so early as some of the other shrubs mentioned. Another subject to which the same remarks may be applied is Zenobia speciosa, the best form of which for growing under glass is the variety pulverulenta. The different varieties of the common Hawthorn may be readily forced, and if grown in the shape of small standards are very useful for grouping purposes. Forsythia viridissima flowers naturally very early in the season, yet when sheltered under glass its blooming period is hastened, and besides the flowers are not disfigured by bad weather, as is sometimes the case when grown out of doors. Spiræa Thunbergi is a little shrub with slender arching shoots and delicate green lanceolate leaves. The flowers, which individually resemble those of the Hawthorn, but are smaller, are borne in such numbers that the shoots are quite wreathed with them. It is a very easy plant to force into bloom, but the flowers do not remain long in perfection. Staphylea colchica has had a good deal of attention directed towards it within the last few years as a subject for early forcing, and very pretty and distinct it is when treated in this way. The flowers, which are white when grown under glass, are borne in large compact clusters. Magnolia stellata, or Halleana, a small growing white-flowered kind, blooms naturally in the spring before the expansion of the foliage, and can be readily forced even earlier into bloom, a remark which applies to the more vigorous conspicua and Soulangeana, but as a rule they are too large for glass shelter. The Guelder Rose cannot be had in bloom so early as many shrubs, but it is very amenable to forcing, and the large clusters of pure white blooms render it a prominent feature at any time. In the case of plants that are intended for forcing they should be grown in a well-exposed spot.

Fruit Garden.

DRY VINE AND PEACH ROOTS.

The annual amount of growth and the quantity and character of the foliage that it is natural for a plant to make determine the quantity of water that it requires. Slow-growing plants that produce few leaves, and these hard in texture, and that consequently throw off little moisture by evaporation, naturally need much less water than those which each year form quantities of big sappy shoots with leaves of a like character, such as Vines and Peaches. Yet it is more than doubtful if the majority of cultivators reflect on the vast difference there is in the quantity of water which these fruits need as compared with slow-growing things, or, still further, consider the widely different conditions under which the fruits in question exist in parts of the kingdom where the rainfall is heavy compared with that which they experience where it is light. These remarks apply to Vines and Peaches that have their roots all or part in outside borders; respecting such one thing is clear: if they do not get too much water in the wetter districts, to a certainty they must be short of it in the drier ones so far as the rainfall is concerned. This being so, it follows that the difference needs to be made up by watering. In Lancashire and Westmoreland, where the rainfall is heavy, Black Hamburgh Grapes wanting in colour are much less frequently met with than where the annual rainfall is less, a circumstance that can only be accounted for by concluding that the roots in the drier districts do not get enough in the shape of rain, and that the deficiency is not made up by watering. Much of the disposition which the roots of Vines so often show to go down too deep is the result of insufficient surface water. In striking down in search of moisture they are only following the law of self-preservation, which, if we only look for it, is as apparent in plants as it is in animals. Where the natural soil is such as will answer for Vines, and the roots get out of the prepared border, stretching away far and wide into what is often a vegetable garden, where they have an unrestricted space from which to draw moisture, although at times the whole may be drier than they like, still they are able to make shift better than when the roots are confined within a limited border, or where there is nothing outside it suitable for them. Under the former condition Vines are frequently able for years to produce fairly good crops, but if allowed to carry anything like the weight of fruit that they should do, a breakdown is the result; the crop either fails to colour properly or shanks, and oftener than not both. So far as inside Vine borders are concerned, there is little doubt that there are many which, though they appear fairly moist on the top and for some distance down, are much too dry below for healthy root action; and when once they get into that state they remain so owing to the difficulty there is in again getting the soil wet enough. In proof of this it is only necessary to notice the immense quantity of water that it takes to moisten a body of soil even in the open air when once it has got dry. Take, for instance, the old trees in the drier parts of the country; in the case of the greater portion of these the soil underneath the bole and for some distance round remains from one end of the year to the other dust-dry, and it has most likely been in that condition for a generation. This anyone may see who has an opportunity of noticing the state of trees that are grubbed up or who examines such as happen to get blown over, Elms especially. I have examined numbers of these in the southern counties that have been blown over after the winter rains have fallen, and all but invariably found the soil as dry as it could be. This would scarcely appear to be possible when one notices the quantity of water that runs down the trunk during heavy rain when the leaves are off. A case in point came under my notice lately that shows how easily it may happen for a Vine border that looks wet enough on the top to be so dry below as to render it impossible for the Vines to succeed. In a span-roofed house standing north and south, filled with Lady Downes Vines planted inside on each side of the house in borders divided in the middle, the crop suffered severely from scalding on one side, whilst that on the other was quite free. The cause of this difference seemed unaccountable, as it was the Vines on the western side that were affected, while those on the eastern side, the most likely to have been caught by the sun with moisture on them, escaped. The borders were examined, when that in which the roots of the Vines that had suffered were growing was found to be as dry as a board, except about a foot from the surface, whilst the opposite border where the crop was right was sufficiently wet. This threw light on the subject at once, for it is not easy to come to any other conclusion than that to the over-dry state of the roots the scalding was due, although this kind of mischief has usually been attributed to other causes. The case in question, I may say, did not happen in a place where there was any scarcity of water or any want of experience, as the individual in charge of the Vines was an old and successful hand at Grape growing. The mischief was no doubt brought about by the border being kept dry in winter with the object of having the atmosphere dry, so as to preserve the fruit from moulding, and not taking the precaution to see that it was thoroughly moistened to the bottom before the Vines were again started. In this way inside borders in houses where the Grapes are kept hanging far into winter are much more likely to get into the condition just alluded to than where the crop is cleared earlier. As already stated, when once a border has reached this unhealthy state of dryness it takes more water to moisten it effectually than those who have not looked closely into such matters are aware of, especially when the soil is of a strong holding character such as Vines like, as although water enough may be applied to moisten the whole if it settled down equally, still, this is just the reverse of what occurs, as it finds its way in odd places down to the drainage, often leaving the greater part a little below the top almost as dry as ever. In either vineries or Peach houses, where there is any possibility of the borders being dry below, there is only one safe course to pursue, that is, to examine them down to the bottom. From the frequent cases that I have seen where Vines and Peaches in inside borders were not doing satisfactorily, and where on examination the cause was found to be drought underneath, though apparently moist enough

above, I am convinced that drought is a much more common occurrence than is often supposed.

As regards keeping inside borders in vineries where late Grapes are hanging so dry, as is often done, I am satisfied that it is frequently carried so far as to injure the roots, and it is only part of the means to effect the preservation of the fruit, for, when damp foggy weather comes, the saturated air gets into the house, and unless fire-heat is used to correct its effects, it will bring about decay, even if the borders were dried until there was not a particle of moisture in them. Respecting outside Vine and Peach borders in the drier parts of the country, although the winter rains moisten the soil sufficiently to admit of the roots moving freely for a time in spring, it often happens that they run short of water later on, when the crop is taxing their energies most, and when little or nothing is done to supply the want. So far as Vines are concerned, it used to be the fashion to attribute shanking, and other ills from which they suffer, to the roots being too wet, but I venture to assert that for one case where evil comes from this cause, there are twenty where it happens through drought. Where borders are sufficiently drained, it is not an easy matter to give either Vines or Peaches too much water while they are growing.

T. B.

Watering fruit trees.—There can be no doubt that fruit trees suffer from drought far more than is generally supposed, and especially wall trees on sloping borders. The amount of rain it takes to wet soil to a depth sufficient to benefit root-feeders is surprising, and when a tree is heavily cropped, if it cannot find soluble food, either the crop or the tree must fail. I have at the present time some Pear trees heavily cropped, and since the fruit began to swell they have had a few gallons of water or some kind of liquid nearly every day; the result is that the fruit has swelled up to such a large size that the branches have had to be upheld by stakes, yet the foliage is healthy and the buds for next year's crop looking full and plump. I feel sure that if fruit trees received more attention in the way of root-moisture there would be fewer failures than we now experience. When grubbing up wall trees, I have been frequently surprised to find the soil under them dust-dry in winter, even when the surface has been saturated with heavy rain; and the same thing occurs under heavy-topped orchard trees. Unless more water than that supplied by the annual rainfall is given, there can be no doubt that many of the roots are rendered to a great extent useless through the soil surrounding them being too dry to afford them food.—J. G. H.

Late Peaches.—Three years back I planted two south walls with the following late Peaches, viz.: Princess of Wales, Late Admirable, and Walburton Admirable. The two former varieties have borne two good crops, but the latter, although studded with good healthy blossoms, has only borne one Peach. All have been treated in the same manner, viz., protected in spring with a slight covering of Bracken. Speaking of early Peaches, Mr. Douglas tells us if Peaches do not bear they should be made to do so, and this, I should presume, is by fertilising the blossoms of non-setters. In the case in question all set their fruit well, but Walburton Admirable does not swell its fruits after setting; they grow to the size of marbles and then wither and die. I am aware that the parent of this variety is Noblesse, one of our best Peaches, but a ticklish subject to deal with, and I should suppose that Walburton Admirable is similar in character. I know the seedling tree well and have seen fairly good crops of Peaches on it. It was raised by a friend of mine, who, I believe, is still amongst us, viz., Mr. Morton, then gardener at Walburton, near Arundel. I shall feel greatly obliged for a hint from any of your correspondents as to the best way by which this Peach may be induced to mature its fruit. —R. Gilbert, *Burghley.*

Peaches on open walls.—The whole secret as regards securing a crop of Peaches lies in successfully protecting the blossoms in spring. I have seen many trees quite destitute of fruit year after year. Great attention was given to thinning and training the shoots in summer, but they were never covered up with any special care when in bloom, the result being finely formed trees, but no fruit. Few fruit trees bloom more freely than Peaches. In fact, they hardly ever fail to produce abundance of bloom, and, therefore, many cannot understand why they produce no fruit. The failure to do so in the majority of cases arises entirely from deficient protection. I know where there are many good Peach crops this season, but every one of them was secured by covering the trees with nets and canvas until the fruit was formed; whereas fruitless trees are those which were unprotected. When once formed, the fruit is sure to swell well and prove satisfactory. I do not approve of thick coverings, which exclude light, but a double thickness of ordinary garden netting will always break the wind and protect the blossom. Open-air Peaches have been exceedingly good this season. They have been ripening freely since the middle of July, or thereabouts, and quantities of them are ripe now, but very late varieties, I fear, especially the Salwey, will never ripen. This variety bears freely here, but its fruits have not ripened for two seasons, and I do not think they will mature now. It is a mistake to plant this variety in the open air, unless there be some special means of assisting it to ripen its fruit. Fortunately, we have only one tree of it in the open air, and were I planting late Peaches out of doors again, it would be excluded.—J. Muir, *Margam.*

THE COLOUR OF GRAPES.

"Chef" says (p. 216) "if Grapes are ripe, colour is sure to be found in conjunction with high flavour and other good qualities, for it must be borne in mind that black Grapes get black before they are fully ripe." This sentence is by no means so clear as the valuable practical instructions that follow, for though colour usually precedes ripeness, it does not always accompany it, and in the case of black Grapes it frequently happens that they lose colour in the completion of maturity. A writer of "Chef's" obvious experience must surely have seen black Grapes, especially Hamburghs, lose colour at or after the finish. All this is rather opposed to the sweeping assertion that if Grapes are ripe, colour is sure to be found in conjunction with high flavour, &c., and this is perhaps less true in the case of white Grapes than black; colour has, in fact, less to do with flavour than is generally supposed. It may seem rank heresy to add that it holds an exaggerated importance in the estimation of most gardeners. This is easily accounted for, as colour, bloom, and finish are looked upon as the highest proofs of skill in Grape growing—and perhaps they are—though a good all-round crop and perfect flavour should be held of still more importance in fruit grown to be eaten. But little importance is attached to the colour of Melons, Apples, Pears, Plums, or even Peaches or Nectarines, provided the quality is good and the supply equal or rather in excess of the demand. But Grapes with little or with unpopular colours, such as green, red, or purple instead of black or golden, are generally decried or tabooed. This may be horticulturally orthodox, but it does not seem profoundly wise; and at the risk of raising a very tempest of horticultural wrath I venture to assert that I have eaten so-called red Hamburghs that were far more luscious than jet-black ones, and green Muscats more richly vinous than golden ones. I have also known epicures in Grape-eating who preferred the Grizzly Frontignan to all the jet-black Grapes grown, and chose green Muscats to golden, as the latter were far too fleshy for them.

As even "Chef" recommends the full exposure of Muscats to direct sunshine to lay on their amber brightness, it might be an interesting investigation to endeavour to find out how much Grape juice was absorbed by the sun and lost to the Grape in the process of its conversion from green to golden. Moreover, in investigating the correlation of colour to quality, it would be useful to determine how far the colour of Grapes depends on mere tension, thickness, or thinness of skin and other mere mechanical conditions. It might surprise a good many to find how largely these, playing as it were hide and seek on the outer surface of the berries with external sunbeams, were responsible for their colouring. In a word, is not colour more a mechanical than a chemical phenomenon? and if so, it can have little or any essential relation to quality. Further, is there, can there be any reason in the nature of things why a black Grape should be more luscious than a red one, a golden than a green? If so, Plums, Peaches, Cherries, Apples, and Pears seem all labouring under a mistake, or working out the problem of quality under different principles and laws from Grapes. Still, I am by no means wishful to decry colour. Either from prejudice, popularity, or from running in the beaten track, we are all attracted, not to say fascinated, by it. But it is a serious practical error to make it the be-all and end-all in Grape growing, and for this reason, that the blackest and yellowest of Grapes are by no means always the best. To graft such exquisitely flavoured varieties as the Muscat Hamburgh and Mrs. Pince on such turnipy-flavoured stocks as the Alicante and Lady Downes, merely to make them blacker, while the foreign stocks lower or rob them of their exquisite vinous luscionsness, is a cultural freak of folly far too expensive to be commended. These two Grapes on their own roots are equal or superior in flavour to the Muscat of Alexandria; some even prefer them to this prince of Grapes for flavour. Is the making of them black at the expense of their piquant Muscat flavour, the only quality that gives them value, to be commended or approved? We have Grapes black as jet enough and to spare without spoiling our all too sparse collection of Muscat-flavoured ones in the attempt to make them equally black and almost equally flavourless. In some places there are local or cultural reasons sufficiently potent to render it needful to work both these Grapes on other stocks. In plain terms, they will not otherwise grow, thrive, nor finish their crops without shanking. But, as I understand "Chef," he grafts for colour alone and sacrifices quality, which is surely a great mistake. In venturing thus to designate the practice of such a clever authority, my object is not to disparage "Chef" or his views. I freely admit they are almost universally prevalent among our best Grape growers. Still, whatever is, is not of necessity and in consequence of its existence always right. On the contrary, wrong-doing and wrong-thinking often seem endowed with a vitality at least equal to right, and I venture to think that the exaggerated importance attributed to certain colours in or on Grapes by my brethren of the knife and spade is pregnant with practical evils of great importance. For example, it has led to the discarding of not a few of the most luscious Grapes and the flooding of our gardens and markets with dense coloured varieties with the bloom of sour Sloes and flavour to match.

Hortus.

Hautbois Strawberries.—It is to be regretted that a Strawberry of such peculiar flavour as the Hautbois should be neglected in favour of finer-looking fruit. The genuine Hautbois is, no doubt, still to be found in old gardens, and would repay any attention bestowed upon it. The neglect into which the Hautbois has fallen is doubtless due, in a great measure, to the fact that size has more weight than it formerly had. Fruit is grown now almost as much for fine appearance as for quality; but I have no doubt the time will come when the Hautbois will again come into favour, and, probably, improved both in point of size and productiveness. This may reasonably be anticipated, as, in both points, Rivers' Royal Hautbois is far superior to the old Hautbois that used to be grown thirty years ago. With the exception of the two Alpines, the Hautbois Strawberry is less particular as to soil than most of the English and Continental Strawberries, now so generally grown. Of course, as a rule, the best result will be obtained on the best soil, but I have seen fine crops of Hautbois grown on land too light to be profitably occupied with other kinds. Light land, if it is well manured

and made thoroughly firm before planting, will do very well for the Hautbois, but mulching and watering in dry seasons must not be neglected. A very good way of growing them is to plant them in beds, say three rows in a 4-foot bed, and the plants about a foot apart in the rows, with alleys 2 feet wide between the beds. This will give room for gathering the fruit, and also allow space for the production of strong runners for making new plantations. It is not advisable to allow the beds to continue in the same place longer than three years. Early in August is the best time to plant; although, when the beds cannot be properly made then, the runners may be planted 3 inches or 4 inches apart in nursery beds, lifted with balls, and planted out finally the following March. I should recommend this course in preference to planting in ground ill-prepared or not properly consolidated. Planting in very rich soil or highly-manured land, especially if recently trenched and not allowed time to settle and become firm, will, by inducing over-luxuriance, often produce "blindness" in the flowers, or, in some cases, prevent flower-buds being formed at all, the whole efforts of the plants being confined to the production of foliage only. This, however, is usually the result of some error in management.—H.

NOTES ON PEACHES AND NECTARINES.

On all sides we hear that the season of 1886 has been one of the best known for Peaches and Nectarines both under glass and on open walls, much of this fruitfulness being due to the thorough ripening of the wood in the former case, while that in the open, though not generally fully ripened, was yet sufficiently so to both withstand frosts and also to furnish blooms in abundance. As is usually the case, some sorts stand out pre-eminently good, while second-rate varieties have also been better than I have known them to be before. As far as we are concerned, we have no very inferior sorts, but in spite of that we shall have to replace two or more trees that have partially failed with more healthy ones brought forward for that purpose. This failure is entirely due to the treatment which the trees received at the nurseries when in a young state, the severe cutting back twice repeated resulting in the premature decay of some of the principal branches. The wounds apparently heal over, and a strong well-formed tree is the result, but the mischief is only partially staved off, and the cultivator is disconcerted at seeing his fine trees collapsing slowly, but surely, and all owing, I believe, to the dead wood inclosed by the bark. Those who have trees, some of the branches of which either prematurely cast their fruits, or do not swell them to nearly the size of those on the remainder of the tree, will find, if they examine the lower portion of such limbs, that they are contracting rather than swelling healthily, and in all probability one-half of the bark and wood is already dead, the remainder following in due course; a much disfigured tree is the consequence. Two comparatively young and fine trees of Royal George Peach, one in a heated and the other in an unheated house, both failed this season to ripen their fruit properly on at least one-third of the wood, and in both instances the stems are dying near where they were last pruned to in the nursery. They were bought as trained trees, and at the same time we had several maidens; the latter are now perfectly sound and very profitable, and are producing some of the best fruit in this neighbourhood. No more trained trees, fortunately, have since been purchased, nor would I have them as a gift. Very little time, if any, is gained by planting trained trees, and to all intents and purposes maidens are the best. Now is the time to obtain them, and if there are no spaces on the walls requiring to be covered, there may soon be some, and it is always the wisest course to have young trees in preparation for any vacancy that may occur. These transplanted when in full leaf, or as soon as the wood is well matured, become established in their new quarters the same season, and are fit to bear fruit next year in quantity according to their size and vigour. This is old advice, but it will bear repetition. Then, again, it is sometimes advisable to replace an old and inferior tree by a newer variety, or one that is better suited to the position or the needs of the owner. I have taken particular notice of the various sorts of Peaches and Nectarines this season, and am in a position to discuss their merits.

Selections for culture under glass.—The small early English raised Peaches do not gain favour; in fact, they are fast being replaced by the larger American sorts, of which, perhaps, the earliest is Early Alexander. This is a good cropper, rich in colour and good in quality. It is about a week or ten days earlier than Hale's Early, but of the two the latter is much the finer, and is altogether a more desirable sort. We had it very good, it was still better at Longleat, and at Ashton Court it was finer than I have ever seen it, and that, too, early in the season, when Peaches were worth at least 30s. per dozen. It should be grown in quantity by those who supply the markets, as it is a good cropper and invariably sells well, owing to its handsome shape, size, and rich colour. The quality, too, is not to be despised, especially if eaten before the fruits have been long gathered. Waterloo I have had no experience with, but intend to give it a good trial. It is said to be earlier than Hale's Early, and from what I saw of it at Yeovil I should say it is one of the finest of all the early sorts. The constitution is good, it crops freely, and the fruits are very highly coloured and good in quality. As a show variety it will be hard to beat. A Bec, again, did remarkably well with us, and forms an admirable succession to Hale's Early. The fruit is large, handsome, and good in quality, though if gathered or packed when fully ripe it does not travel so well as could be wished. Early Grosse Mignonne is not wanted, as we prefer Bellegarde in the early house for affording a succession to A Bec; indeed, a tree of this valuable and most handsome variety ought to be grown in every house. Alexandra Noblesse is a great improvement on the old Noblesse; the tree possesses a stronger constitution, producing a heavy crop of fine fruit of a pale yellow colour, but very luscious—none more so, in fact. Where a high-class Peach is required, Alexandra Noblesse should be grown. Grosse Mignonne grows strongly with us, and never fails to bloom abundantly, but it is generally the most difficult to set. This, again, is not often highly coloured, but it is a most delicious sort, and is here preferred to any other. Royal George is not so extensively cultivated as at one time, owing to its liability to mildew, but where it can be managed it is yet one of the best second earlies we have. Crimson Galande appears to have been largely planted of late, and I have seen several very handsome dishes at local shows. We only have it in a cool house, where it is the first to ripen. It is a vigorous grower, sets freely, and matures a heavy crop of fine fruit, those getting most light being of a very dark crimson colour. The quality is fairly good, and I would also strongly recommend this second early sort to market growers. Barrington is our favourite late sort, and it is also well adapted for affording a good succession in any of the forcing houses. This well-known and very popular Peach is usually of excellent quality, and if gathered before it is very ripe will keep and travel better than any other variety I am acquainted with. Dr. Hogg and Dymond are now cultivated in several gardens in this locality, the former being esteemed as a good second early variety, while the Dymond is rather late and is very handsome, rendering it a favourite with exhibitors. I have had no experience with either of them.

Nectarines, though plentiful enough, have not been so good as usual. It is difficult to account for this, unless the dull, sunless weather experienced early in the summer injuriously affected them. I find it advisable to cease syringing Nectarines in dull weather, as too much moisture, especially when it lodges on the fruits, is apt to injure their smooth delicate skins, and scarred fruits find but little favour. Lord Napier appears to improve with age, as each season we and other cultivators have it both larger and richer in colour than previously. It is a thoroughly useful sort, and ought to have a place in every Peach house in the country. We now have a tree of it in all three houses, and in every case the fruit appears to ripen most opportunely. The most highly coloured fruits of it I have seen this season were exhibited at Trowbridge, where they resembled very highly coloured Victorias. Humboldt, also a comparatively new sort, proves to be an acquisition, and may well be planted to afford a succession to Lord Napier. It grows strongly, is remarkably prolific, whilst the fruits are of good size, colour, and quality. I can strongly recommend it. Impératrice succeeds remarkably well at Hill House, Langport, and is much liked for forcing. It resembles Violette Hâtive in appearance, but is superior to it in every respect. It keeps remarkably well. Downton is still grown by us, but each season it is reduced in size in order to give more room to better sorts. It is a showy, free-bearing kind, and just suits the markets. Elruge everybody is acquainted with, but that is no reason why so many should still cultivate it. Stanwick Elruge is as easily grown and is quite as prolific; the fruits colour beautifully, and are decidedly superior in point of colour to the Elruge; therefore, should replace it. Pitmaston Orange is a good successional sort; but Pine-apple is more highly coloured and quite as good in quality, and ought to have preference. The latter is one of the richest flavoured varieties in cultivation, and the fruits keep and travel well. At one time Victoria did not do well with us, but since we have discovered the cause and applied the remedy, a great improvement has taken place, and it is now the most profitable sort we have. It must be classed as a late variety, but we have it in both early and successional houses, and the fire-heat appears to improve it in every way. Our strongest tree perfected large beautifully coloured fruits, about 5 inches apart each way, all over the trellis, and it appears none the worse for this severe trial. In order to colour it properly, the fruit must be well exposed to the full sunshine. This variety also keeps well, and the quality is decidedly good.

Peaches on open walls for the second year in succession have been and are still exceptionally good. I am informed by my employer that they have not been so good here, as far as he can recollect, for about twenty years. Our trees are by no means handsome, but they answer their purpose, and that with me is the primary consideration. This success is pretty general—at least, wherever the trees receive fair treatment, and in all probability this will lead to a revival of more general outdoor culture. By means of our houses and open wall we shall have been enabled to supply the table with abundance of the most luscious of all fruits from the middle of May till well into October. Hale's Early is simply invaluable for open-wall culture, and as evidence of its popularity I may mention that at the Yeovil and Sherborne shows the classes for open-air Peaches were as well filled as those for indoor fruits, and in nearly every instance Hale's Early was shown and in fine condition. This was about the middle of August, at which time it was also plentiful with us. Those especially who derive their sole supplies from the open walls ought to plant Hale's Early. In succession to this we had a good crop on the trees of Acton Scott, and although the fruits of this good old sort are small, they are much appreciated on account of their rich colour and high flavour. Bellegarde has done splendidly in the open. We have two trees of it, and we commenced gathering from them late in August, and there are still many ripening at the present time, September 13. One tree, occupying a wall space 15 feet by 12 feet, has perfected seventeen dozen handsome fruits, the bulk of them weighing 8 ozs.—a good useful size. Barrington also does well on the open walls and the fruits promise to ripen well this season. The latest with us is Sea Eagle, and this gives promise

of being a serviceable variety. The fruits are large and are colouring well, but as this is the first time it has fruited here I cannot speak of its flavour. Nectarines have so often failed to ripen satisfactorily, that we have discontinued their culture in the open, and I believe there are few gardens where they pay for the trouble taken with them. Hunt's Tawny is one of the best for open-air culture that I am acquainted with.

Somerset. W. I. M.

Early and late Plums.—Plums have been a heavy crop in many parts this year; therefore our markets have been glutted and the Plum trade unprofitable. It will be found, however, that it is only midseason kinds that have been unremunerative, for both early and late sorts sold well; therefore anyone who has got a crop of even the commonest Plums, such as the Bullaces, that will hang until the bulk of the crop is over, will readily dispose of them at higher prices than those obtainable a short time back for the finest samples. The following is a brief list of sorts that would supply fruit that nearly always sell well; viz., Early Orleans, one of the most popular of all Plums, and good for any purpose; Blue Prolific, a valuable early Plum, very dark blue with bloom like that of a Damson; Rivers' Early Prolific, fruit medium sized, purple, tree good as a bush; Pond's Seedling, a very large fruit which hangs until the bulk of the Plum crop is over, tree a strong grower; Grand Duke, a very dark blue Plum that hangs well into October, one of the best new late sorts; Cox's Emperor, a large red Plum which hangs well on the tree. The above ought to be grown by all who want to prolong the Plum season either for private use or for market.—J. G., *Hants.*

Peaches by the million.—From Kent County, Maryland, U.S., which is the greatest Peach-producing territory of its size, it is reported that, while this has been a bad year for Peaches generally, there has been an extraordinary yield in Maryland. The estimated output of the Maryland peninsula section is 3,000,000 baskets. Of this amount, which does not appear to be exaggerated, Kent County alone will furnish 1,500,000 baskets; while the contribution of Still Pond Neck alone is 450,000 baskets. Within a tract six miles long and three miles wide, forming Still Pond Neck, fourteen crops of over 10,000 baskets each were gathered, while on all sides of them can be found men who will market from 1000 to 5000 baskets of excellent fruit. The inquiry naturally follows, what is there in Kent County that guarantees such remarkable crops of a fruit that fails in almost every climate and section? To this question the only answer received by a *Philadelphia Times* commissioner was: "The climate is not so mild, for the thermometer went below zero here last winter, but the orchards facing the Chesapeake Bay did not suffer from frost. We believe that the high bluffs and deep water protect the tracts near the bay from the severe frosts of the winter and the late frosts in the spring, and thus make this a favoured section for Peach raising. Experience has taught us this, and it is a good teacher in the fruit business. The soil is a sandy loam, with a clay bottom, which is also favourable for successful Peach-raising. But the secret of our great crops has been that, in addition to soil and location, we have thoroughgoing fruit-growers, who have made the Peach a study and have cultivated it with the same care and industry as the thoughtful and thrifty farmer looks after his Wheat or Corn. Our orchards are fertilised and tilled as a model gardener attends to his most delicate plants, and we are handsomely remunerated for the expense and trouble at the end of the season. This year the crop is extraordinarily large, the prices high, and we shall be rewarded accordingly. But it always pays to raise Peaches in this section. We seldom fail to get an average crop and a fair price."

Trees and Shrubs.

THE TREE LUPINE.

(LUPINUS ARBOREUS.)

This most useful plant is a good deal neglected in gardens, perhaps because of its short-lived character. It may be said to have a life of three years; one year in which to grow to flowering size, and two years when it may be enjoyed in its prime, as one of the finest bush-like plants that can be placed among large rockwork or on rough banks. It should not be staked up, but allowed to spread about in arching branches, when it takes forms that are highly picturesque and rather peculiar to itself. One such branch, perhaps the eighth part of the whole plant, is shown in the engraving. The yellow kind is by far the best,

The tree Lupine (Lupinus arboreus). Engraved from a photograph for The Garden.

the others being of dull pale purple colours. It is easily propagated by seed or cuttings. The scent is delicious, of a sweeter quality than that of the perennial garden Lupines, rather more like that of some of the annual kinds. It grows plentifully on the Algerian coast, about 200 feet above the sea, where bushes of it growing out of the rocky soil, seen from above against a background of blue water of that wonderful quality of colour that a southern sea assumes close to the shore, form a picture that can never be forgotten.

Escallonia montevidensis.—In the milder parts of England this is a handsome flowering shrub, and one that will keep in bloom till autumn is well advanced; but, except in the south and west, it is liable to be injured in winter—indeed, against all the Escallonias this charge can be brought. The Monte Video Escallonia is a free, vigorous-growing shrub, that pushes up long flexible shoots from its base, after the manner of some of the Spiræas. On the points of these shoots the flowers are borne in good-sized clusters. The blooms are white, and remind one to some extent of those of the Hawthorn. This Escallonia will survive most winters against a wall; but its habit of growth scarcely fits it for this treatment, some of the others being better adapted for this purpose, and notably E. macrantha, a kind with red Fuchsia-like blooms and deep green glossy leaves. E. macrantha is a summer-flowering kind, but it often keeps in bloom till autumn sets in; while another pretty little species is earlier still in flower. I allude to E. Phillipiana, a sort with slender arching shoots, studded a good part of their length with small white blossoms. This was only introduced within the last few years, but it is quickly becoming popular. Another kind still in flower is E. rubra, the individual blooms of which are smaller than those of E. macrantha; but the plant is more hardy, and the flowering season spreads over a longer period.—H. P.

Propagating the Wellingtonia.—Cuttings of the Wellingtonia will strike root more readily than those of many coniferous trees if put in a frame and treated as cuttings of this class usually are. The end of the summer or early in autumn is a good time for the cuttings to be taken, as the young growth is then sufficiently firm to resist decay, and not so hard as to arrest the formation of roots. One point relative to the propagation of the Wellingtonia by means of cuttings is, that unless very unpromising shoots are taken they form good symmetrical plants, and in no way retain their branch-like character as some Conifers do. Of course, if the weak unripened shoots from the interior of the plants are taken they will seldom grow into a good specimen, but such a result could only be anticipated. The best cuttings of this, and, in fact, most Conifers, are good clean shoots from the outside of the plant not too much surcharged with sap. Shoots that have grown entirely in the shade are more liable to decay than those grown in sunshine, these latter being altogether of a firmer texture. It matters little whether the cuttings are put in pots or dibbled into a bed of soil provided they are sheltered by a close frame. The advantage of using pots is, the readiness with which they can be removed or shifted in any way, but if dibbled into a bed of soil there is not so much attention required in the matter of watering. In any case good drainage must be provided, and the soil made very firm before inserting the cuttings, which in their turn must be securely fixed.—W.

Pyrus Maulei.—Among ornamental shrubs this should occupy a more prominent position than it does; its bright golden fruits, prettily flushed with red on the sunny side, are just now most attractive. They somewhat resemble small Apples, and are borne with such freedom that even slender twigs are densely packed with them. In spring, too, this Pyrus is equally showy by reason of its orange-red blossoms. A succession of blooms is also often kept up for a considerable time; indeed, I have had it in flower continuously for three months. It is a plant of the easiest possible culture, doing well under the same treatment as its near ally, the Japanese Quince, and, like that, it may be either trained to a wall, or grown as a bush in the open ground. One thing to bear in mind, when employing Maule's Pyrus for wall covering, is that it will not attain the height of the older and better-known kind, so that it must only be used for spots where low growing plants are desired. The propagation of Pyrus Maulei is a simple matter; seeds are readily ripened, and suckers, which push up in profusion from the base of the plant, can be detached either with a few roots, or in such a condition that they strike quickly when inserted as cuttings in the open ground.—Alpha.

The Bhotan Pine (Pinus excelsa).—This noble Pine was introduced into this country from Northern India about the year 1823, and has proved to be quite hardy, or nearly so. I have never had it killed by frost, but when planted on flat boggy ground, subject to late spring frosts. I have had it frost-bitten even after it had attained a height of 20 feet. When

planted on good soil it is of rapid growth, and often adds to its height from 20 inches to 30 inches in one season. Its habit of growth is strictly conical; the branches are long and spreading, and produced in regular whorls, clothed with soft silvery-looking leaves from 5 inches to 6 inches in length. The wood of young trees is of a close, compact texture, but rather soft and white in colour, and as the trees advance in size and years, there can be no doubt that the quality of the timber will improve in like proportion, and from what I have seen of it I have every reason to believe that it will yet rank as a first-class timber tree. As an ornamental tree it is singularly well adapted for planting as a standard in a park where the grounds are extensive and not in the least cramped for space. In such places its long graceful drooping side branches have room to extend, and it has few equals, more especially when associated with water scenery, as from its neat habit of growth and peculiar colour it imparts a charm to the landscape that cannot be excelled by any other tree with which I am acquainted.—J. B. W.

ORNAMENTAL TREES IN GROUPS.

Now that so much is being done in the embellishment of parks and pleasure grounds by the use of hardy trees instead of such as are tender, attention should be directed to a few of the most striking among the variegated and ornamental-leaved section, with which, by judicious grouping, fine and durable effects may be produced. If for park or woodland scenery, nothing can be more effective in certain situations than the Copper Beech and Abele or white Poplar, the contrast of the rich dark leaf of the one with the light silvery grey of the other being most striking when seen with the wind acting on them, and a full play of light and sun on the foliage. Then, again, there are other deciduous trees that colour off exceedingly rich and warm-looking in the autumn, giving tints of a most lovely hue, which, although fleeting, make the landscape while they last a picture such as gladdens an artist's eye to behold. Among the most noteworthy of these may be mentioned the Tulip Tree, which is not half so much grown as it should be, and yet where the soil suits it, it is one of the best of ornamental trees, the leaves being large and singularly cut; these, too, in favourable seasons die off in such a manner as to attract the notice of even the most casual observer. Another tree of noble aspect, and having very fine foliage, is the Ailantus glandulosa, the only drawback to which is that its wood is somewhat brittle, and the branches are therefore liable to snap off; but if planted in favourable situations, where it can have shelter, it generally escapes that disfigurement. As a companion plant to this latter, to grow under or around it to form a group, the Sumach answers well, on account of its being of a somewhat similar character. For using in the same way with the Plane, Liriodendron, or Acer, the Liquidambar comes in well, but with most of the Acers this should be used in the background, that it may there show up above them. Another very ornamental tree seldom seen is the Salisburia adiantifolia, or Maiden-hair tree, which, as its specific name implies, has leaves that resemble those of the Maiden-hair Fern. The Salisburia makes a most interesting and beautiful object on a lawn, a position for which it is well adapted, and where it shows itself to advantage.

The purple Birch.—The comparatively new purple-leaved Birch may be classed amongst, and in the first rank of, gay autumn-coloured trees. A fine specimen growing here is just now clad in foliage varying from bright chestnut to vermilion. This Birch is a very free and fast grower; indeed, my experience of it is that it seems to over-grow its strength. The stem and branches become so long and slender, that it can rarely withstand rough winds without suffering breakages. I intend in future when planting this particular tree to be sparing with rich soil, so as to check its over-luxuriant growth. It is a real acquisition as a landscape tree, and can hardly be too extensively grown.—B. G.

JUNIPERUS RIGIDA.

This is a very pretty and distinct Juniper especially suited for planting as a single specimen in gardens where space is limited, as it is of rather slow growth, and even if likely to get too large it can be kept within bounds by a judicious use of the knife without in any way destroying its beauty. It forms a low tree, the habit of which is broadly pyramidal, but it is in no way formal in appearance, as the branches vary a good deal in length, and thus, as it were, break up the outline of the specimen. The branches are slender and rather upright in growth, but the branchlets and the whole of the young shoots are pendulous, thus imparting a graceful character to the tree. The leaves, from whence the name of rigida is derived, are about half an inch long, very narrow, stiff, and terminated by so sharp a point as to need careful handling, otherwise they will prick severely. The young foliage is of a pale green colour, but becomes darker when mature, and in winter is usually slightly browned. It is a native of Japan, and is quite hardy in this country. The soil most suited for it is a good but rather light open loam, so situated that it does not get roasted up during the summer, but such conditions are by no means indispensable to its well-doing. Like most of the Junipers, this species is not difficult to increase by means of cuttings, the present being a very good time for the purpose. They should be about 4 inches or 5 inches long, formed of the current season's growth, inserted firmly in well-drained pots of sandy soil, and kept in a close frame till rooted. T.

Another word for the Liquidambar styraciflua.—Mr. Leach has done well to call attention to the great beauty of this tree, which is so seldom grown and yet deserves a place in every garden. A group of it against the Silver Ash-leaved Maple would be a sight to go many miles to see. The Liquidambar is a brittle tree easily destroyed by wind, and should therefore be grown in partially sheltered places fully exposed to the sun on the southern or western sides. Unless thus freely exposed to the light the leaves will be coloured less brilliantly. We have no tree, on the whole, to come up to the grandeur of the Liquidambar, the leaves of which are also striking in form as well as possessed of the most brilliant shades of colour.—D. T. F.

How to flower Pomegranates.—There are plenty of large plants of Pomegranates in the country, especially in the more southern counties, but in every instance that has come under my notice the owners would have been only too glad to learn what would induce them to flower freely. I have known large bushes, as well as trees, loosely trained against sunny walls produce a few flowers annually, but only enough to cause those who saw them to wish they could be made to flower more freely. Pomegranate blooms are very uncommon in form and very bright in colour. At Mells Rectory, near Frome, many rarities are cultivated successfully, and among these may be included the Pomegranate. It is trained thinly against a south wall and kept closely spurred back, and this would appear to be the only method by which it can be induced to flower freely. It is only the strongest lateral growths that are shortened back, much as we would those of Pears or Plums; the short leafy spurs, which vary from 3 inches to 5 inches in length, are not interfered with, and it is these which the following season produce the blooms. It can be told a long time in advance which spurs will bloom, from the fact that these assume a much darker green than the others, and plenty of them may now be seen all over the tree, as well as the last of this season's blooms. One year's neglect in the matter of freely shortening the longer growths invariably results in the loss of the principal portion of bloom. It thus appears that nearly the whole of the tree's energies has to be directed into the formation and development of flowering spurs. A few fruits generally set on the tree under notice, but they do not ripen.—W. I.

AUTUMN WORK AMONG TREES.

Many are apt to plant thickly in the neighbourhood of their houses, in order to produce early shelter. This is often a mistake, as I have frequently observed that trees, both for avenue and plantation purposes, when not too thickly planted, but judiciously topped and branch-pruned when young, so as to secure a proper shape, stand the wind better than trees which have been allowed to go on unpruned till they have acquired a large size. This particularly applies to the Norway Maple, Plane, and Elm. If ornamental trees are to stand amongst evergreen shrubs, their stems ought to be pruned; but if to stand singly on Grass, the natural outline of such trees should be carefully preserved. When the site of a new mansion is first determined on, the distant landscape effects to be obtained from it are often a source of much discussion. When finally settled the building goes on, and the ground is laid out with trees, at the time in all probability small. The planting and choice of the trees are generally conducted without much reference to vistas or views to be afterwards obtained; on the contrary, they are left to be thinned out as may be needed.

If openings were originally left and filled up, such openings can be restored by pruning and thinning the branches, and these can be annually gone over and dressed; but where a dense, close mass has been allowed to grow up, the removal of certain trees will be absolutely necessary. In some cases stem-pruning may be safely performed so as to allow vistas to be opened up below the upper spreading branches. It may happen, too, that a distant tree may interfere with the carrying out of such views, and in such a case it may be removed; but should the removal happen to introduce any unpleasant object, the top only need be taken off and the remaining portion rounded over so as to give a clothed appearance to the landscape.

Forming vistas or views is, perhaps, one of the most interesting works with which a landscape gardener has to deal, and it is amusing to observe the amount of zeal shown by some proprietors when one or two vistas have been successfully opened up. When once infected with picture-making of this kind they become constantly on the outlook for subjects on which to experiment, and when this is the case, neither shrub, tree, nor branch will stand in their way, notwithstanding the doubtful feeling which was exhibited when the first branch came down. After the *débris* attending the removals, and the requisite dressing given to the trees and shrubs have received attention, such places become the chief resort of visitors. When mansions stand within wooded grounds a mile or so from the sea, the judicious formation of vistas and views is absolutely necessary. When arranging vistas, which are to be opened through plantations, it is desirable to have such openings made along carriage drives or roads; but instead of a narrow cut, they should be made of ample width. Should a good tree happen to stand in the foreground, branch-pruning the stem may be resorted to, so as to have the views below the upper branches; a few evergreen shrubs may be planted on each side, and the surface of the ground between the drive and the fence should be grass. All such finishings, together with numerous others, will readily suggest themselves to the operator while such works are in progress.

Poplars in the neighbourhood of houses are often positively dangerous, their large limbs being frequently blown down; and if it should be found necessary to remove them, great difficulty often attends the operation. The branches in such cases must be lowered down piecemeal by ropes, in order to prevent them injuring buildings, fences, or neighbouring ornamental trees. Lombardy Poplars are often employed extensively in small places, owing to their occupying but little space in comparison with

other trees, but when they become 8 feet or 10 feet high, they are apt to become bare at the bottom and leafy towards the top. Where this is the case, it becomes necessary to reduce the height of each intermediate tree to about 6 feet, giving each cut specimen a good surface-dressing at the same time. The pollarded trees soon become furnished below, while the unpollarded ones fill up above. After the specimens that were cut down begin to grow freely, those uncut in a few years may be treated in the same way. By this successful way of cutting the tops off Lombardy Poplars they assume an irregular outline in the landscape, which is infinitely better than all being of an uniform height. Large branches of Poplars, say from 10 feet to 12 feet in length, and 18 inches or so in circumference, may be inserted in the ground as cuttings, and it matters but little which end is inserted. I have seen some put in upside down, and grow as well as if they had been inserted in the right way. Numerous shoots will always be produced from the stems; the under ones should be removed and the upper ones shortened. If this shortening be carried out every three or four years, they will ultimately make good trees for shelter, and will often be more pleasing in appearance than unpruned trees, the branches of which extend in all directions. G.

The Golden Yew.—Those who have any doubt about the wonderful effects in the landscape produced by variegated plants should see what is done by means of the variegated Yew (Taxus baccata aurea) at Elvaston, where it is extensively and most successfully used to light up and relieve the darker evergreen masses with which it is associated. At midsummer it is remarkably fine, and especially if it be a wet season. —G.

Thujopsis borealis.—For avenues, few Conifers can exceed in beauty Thujopsis borealis. It is a plant of free growth, perfect in symmetry, graceful in habit, excellent in colour, thoroughly hardy, and very cheap. Yet how rarely do we meet with it. Another plant almost equally good, though of a different habit of growth, is Thuja Lobbi, which being more conical in habit, might suit some tastes better than the Thujopsis.—W. H.

The Wild Cherry (Cerasus vulgaris).—Before the planting season is past, I should like to direct attention to this tree, as it is so beautiful in autumn, being then one of the brightest of timber trees. Some specimens of it here are very conspicuous and beautiful in the landscape; it is a fine pictorial tree for parks and pleasure grounds, yet how scarce it is, generally, in parks, and how seldom planted in situations which are so well suited for such a charming tree to occupy prominent sites for displaying its sheet of white blossom in spring and brilliant autumn foliage to advantage.—B. G.

Fuchsias at Culford Hall.—"E. H. W.'s" remarks on Fuchsias in the open air at Hackness Hall, Scarborough, remind me of a very fine row that fringes the base of the retaining wall of the glass houses by the side of the main walk across these fine gardens. They were planted by Mr. Grieve many years ago, and still grow vigorously and bloom profusely. The variety is Madame or Marie Corneilisson, a so-called white Fuchsia admirably adapted for the purpose. It must not be supposed, however, from this example and others on walls in this county that might be given, that Fuchsias are generally hardy in Suffolk. Even Riccartoni, gracilis, and virgata will not stand in open beds without protection; and it will be a surprise to many to find this white-corolla'd variety so hardy at the base of a wall.—Hortus.

Pinus contorta.—This is one of the most distinct and beautiful of the medium-sized Pines, and particularly suitable for planting in limited areas. The foliage is short, of a bright green colour, and arranged thickly on the branches. It belongs to a section of the genus, having its leaves in pairs, which includes nearly the whole of the European as well as some American and Japanese kinds. The specific name is derived from the peculiarly contorted branches, which twist in such a manner that the diameter of their spread is less than that of most other kinds. When from 15 feet to 20 feet high, it forms a dense tree of narrow pyramidal habit and of a very effective shade of green. This tree is a native of the western part of North America, and appears to be perfectly hardy in England. It bears cones freely, even in a small state, which are about the size of those of the Scotch Fir.—W. T.

Gorse hedges.—In the neighbourhood of Ockham, in Surrey, there is a great deal of unenclosed land covered with Gorse, or Furze as it is more commonly called, and Heath. The cottage gardens which border the common land are mostly large, and are enclosed with thick Furze hedges. These are neatly kept, being clipped in regularly, and are so dense and strong as to be completely cattle and chicken-proof. This is the only locality in which I have seen the Gorse used as a hedge plant, but my impression is that it is second to none for that purpose. It is perfectly hardy and always green, and becomes so thick at the base that I doubt if even a rat could pass through it. The gardens which these hedges enclose belong to old-fashioned brick-and-timber erections, several hundred years old, and at the time they were built there was probably no other material available for forming a fence. A ditch seems to have been dug, the soil therefrom forming a mound on which the Gorse was set. Whether seed was sown or young plants used I cannot say, and I doubt if the oldest inhabitant could impart any information on the subject. The soil in this particular locality is very light and sandy, and it is possible that the Furze might not last out in heavy land. It is evident, however, that on warm dry soils, hedges of Furze are a success, and they can undoubtedly be formed in a cheaper way than by the use of any other material.—J. C., *Byfleet*.

NOTES.

The common Asparagus.—"What sort of Asparagus is that leaning out of that Yucca?" asked a friend who has a better knowledge of plants generally than most gardeners have even in these enlightened days. "Common Asparagus," I replied, but it took a little time to convince him, so lovely did its sprays appear, as fresh and feathery they were seen in contrast with the hard Yucca leaves. Now that a crusade has been begun in favour of fruit trees in pleasure grounds, one may the more boldly venture to proclaim the infinite beauty of common things, and especially of that possessed by this feathery native of our own seashore. A lady who is noted for a well-planted garden came to me two years ago. "Oh! I do not wish to trouble you much," she said, "but you know the bed under my window at the shooting lodge; we are only there in September, and I want a really nice arrangement to be at its best when we are there." "I will consider and write to you," I replied, being busy, but I thought what would have been the reply of any *cordon bleu* if she had asked for a new arrangement in the *menu* all at once. What I wrote was this: "In the centre of your bed put one big clump of Tritoma Saundersi, around it a belt 2 feet wide of common Asparagus, a band 3 feet wide of white Japan Anemone, and a broad edging of Viola Mrs. Clarke (Flag of Truce)." Nothing more was said; I was not pestered with thanks, but this year I was asked to see the bed itself, and the sight of it repaid me. All who disbelieve this history must pay a crown, as the Brothers Grimm used to say.

Time and place.—In gardening, more than in most other pursuits, everything hinges on operations being done in the nick of time, since it not unfrequently happens that one must wait a year if any needful operation be forgotten at the right moment. There is no royal road, no general rule, for nearly every set of plants have their own peculiarities, and the safest guides in gardening are observation and experience. Now and then we hear of elections, or selections, being made of the best fruits, vegetables, or flowers, but after all so much depends on soil, aspect, and elevation, and the vagaries of climate generally, that what is the best variety to cultivate in one locality may be the very worst in another. In a word, the variations in soils and in climate are as numerous as are those in the plants themselves; hence local knowledge of a simple practical kind is a *sine qua non* in all horticultural operations. Quibbler says there is nothing new in this, and that it has often been said before, and I cordially agree with him, but the matter is so important that one may be excused for saying it over again.

Tiger Iris.—A gorgeous blossom of scarlet and gold of only one day's duration, but a well established clump, is so floriferous, that flowers succeed flowers for weeks together. There are three or four varieties. Tigridia Pavonia, or grandiflora, the Tigris flos of the early South American travellers of two or three centuries ago; then there is the buff, or orange-yellow T. conchiflora; and last of all, and as some think the loveliest, T. alba, a milk-white blossom, blotched in the centre with purplish red. Beautiful as it is, it is unfortunately the least robust of the whole group; its flower-scapes, indeed, are so limp, that some support becomes actually essential. We find all the Tiger flowers perfectly hardy if planted in deep sandy soil at the foot of a south wall. Like the lovely Belladonna Lilies, these Mexican corms are grateful for the little extra warmth afforded by the walls of heated plant houses, and in very cold and wet localities such choice positions should be reserved for such beautiful half-hardy things. The Tigridias are by no means ill-favoured substitutes for the Cape Disa when the latter cannot be grown.

Magnolia grandiflora.—Again it is fruity autumn time, and the bees and the butterflies are happy honey-hunting on the rosy heads of the Sedum. The Wistaria is changing from green to gold; Sunflowers and Torch Lilies glow here and there amongst the dark Holly trees, and the music of the redbreast is mingled with the first rustle of falling leaves. But just as the chilly nights, thick with white mist and illumined by the harvest moon, are beginning, the old Magnolias bear their great ivory-white blossoms, nestlingcosily among their great glossy leaves. The buds are like the milk-white eggs of a swan, and the open bowl-like blossoms with their soft thick segments exhale a fragrance fit for the gods as one breathes it in the open air. A big bowl of its flowers and leaves forms an exquisite picture, but their fragrance is quite overpowering in a small room unless placed near an open window, and even then some find the spicy odour too overpowering. But, after all, the buds and blossoms are never seen to better advantage than as Nature arranges them among their own foliage in the open air, and on still, warm, sunny days their presence is satisfying, their fragrance being exquisite.

Giant Polygonums.—Wherever there is room for them on the sheltered portions of the lawn these great Japanese Knotweeds deserve a place, and a good depth of rich, moist soil. Polygonum sachalinense is by far the most robust and stately, while P. Sieboldi is more elegant in habit—smaller in leafage, it is true, but this apparent drawback is more than compensated for by the profusion of its white Spiræa-like flowers. On all good herbaceous borders these plants are a dreadful nuisance, as they creep about for many yards and soon reduce anything like order into a very wilderness of rank growth; but as planted on the Grass in isolated clumps or groups there

is no trouble, as the constant use of either scythe or mowing machine keeps them within respectable bounds, and the plants possess when thus restricted a much more shapely and well-kempt appearance. Once well planted they give no further trouble, but if watered with manure water, or top-dressed now and then, there is a proportionate increase of luxuriant health and vigour in leaf and stem alike. Veronica.

Orchids.

SLENDER-STEMMED EPIDENDRUMS.

Amongst the slender-stemmed or paniculate Epidendrums, though not general favourites, are many pretty kinds that might well occupy a foremost place amongst cool Orchids. Cool treatment was not so well understood as it is now when these Epidendrums were first introduced; they were therefore subjected to a temperature quite unsuitable for them, and the result was they did not thrive; they also had the character of being tall and ungainly in appearance, and therefore, to some extent, they have slipped out of cultivation. The late Mr. Skinner laboured hard and long to bring this class of Epidendrums into favour; his success was, however, but limited. It cannot be denied that they are somewhat difficult to establish when first imported, but so also are many other Orchids (especially those with thick fleshy roots) upon which much trouble and pains are expended. In commencing the culture of slender-stemmed Epidendrums carefully avoid that great stumbling block, high temperature; all of them revel in a cool, moist atmosphere—some in a very cool one, and in this lies the whole secret of success. In houses of low elevation they might be grown as rafter plants, and treated in that way when in flower they would be very effective. The pots for their reception must be thoroughly well drained, and the best material in which to pot them is good rough fibrous peat and living Sphagnum Moss, intermixed with some nodules of charcoal. They enjoy an abundant supply of water all the year round, but, of course, less will suffice during winter than in summer. The plants in this section of the genus have no pseudo-bulbs, but tall Reed-like stems, furnished with two-ranked (distichous) leaves, and terminated by large panicles of flowers, which retain their beauty for a very long period.

The following list contains all the best species at present in cultivation, viz.:—

E. paniculatum.—This attains a height of about 5 feet or more. Its stems are furnished with narrowly lanceolate leaves, which are slightly recurved, pointed, and deep green. The panicle, which is upwards of a foot in length, is much branched, and bears between 200 and 300 flowers, which are deliciously fragrant. The sepals and petals and long slender tubular ovary are of a beautiful deep rosy lilac. The lip is spreading, lilac-mauve, and bears two small yellow lines on the disc. The flowers are produced during March and April. It appears to be widely distributed, having been collected in Peru, Bolivia, and New Grenada at elevations of from 7000 feet to 8000 feet.

E. Catillus.—The Reed-like stems of this species bear oblong-acute leaves, sheathing at the base, and dark green. The panicle, which is unbranched, bears from thirty to fifty flowers. The sepals, petals, and long tubular ovary are bright cinnabar-red, while the front lobe of lip, which is dentate, is white. The flowers appear in April and May. It is found at considerable elevations in New Grenada.

E. myrianthum.—The leaves of this species are long and narrowly lanceolate, acute, recurved, and bright green. The panicle, which is large and much branched, bears several hundred rich magenta-coloured flowers, the lip being tinged with yellow. The flowers are produced in spring and early in the summer. It comes from the mountain regions of Guatemala.

E. rhizophorum.—This attains a height of from 9 feet to 10 feet, and its stem is furnished with oblong-lanceolate, sheathing, pale green leaves. The panicles, which are unbranched, bear numerous large, orange-scarlet flowers, the centre of the lip of which is orange-yellow. It blooms in spring and summer, and lasts a very long time in perfection. It comes from the mountain regions of Mexico and Guatemala.

E. syringothyrsis.—The stems of this bear numerous broad, elliptic-lanceolate leaves, which are leathery in texture, and dark green above, but paler below. The panicle, which is unbranched, bears half a hundred or more flowers, the sepals and petals and also the long tubular ovary are rich deep purplish lilac. The lip is stained on the disc with yellow. It blooms in early spring, and comes from the mountain regions of Bolivia, where it is found at elevations of from 7000 feet to 8000 feet.

E. cnemidophorum.—A somewhat slow-growing, but extremely handsome species, the stems of which are clothed with leaves about 9 inches long, sheathing at the base, and deep green. The panicle is nodding and many-flowered. The sepals and petals are white at the back (as are also the long pedicels); in front they are pale yellow, broadly mottled, and streaked with reddish brown. The lip is creamy white, suffused with rosy lilac. It blooms in winter and spring, and comes from the mountains of Guatemala, where it is found at elevations of from 7000 feet.

E. ibaguense.—The slender stems of this species are often branched and clothed with broad, oblong, sessile, bright green leaves. The panicle is many-flowered, and the flowers wholly rich, deep orange-scarlet. It blooms during spring and early summer. It comes from the mountain regions of Ibague and New Grenada, where it is found at elevations of from 4000 feet.

E. Wallisi.—The stems of this kind are both stout and tall, and conspicuously spotted with brown. They are furnished with large leathery leaves, and bear lateral as well as terminal clusters of fragrant flowers. The sepals and petals are yellow freckled with carmine. The lip is white, variously streaked and lined with purple. Its flowers are produced late in autumn and winter. It comes from New Grenada.

E. evectum.—The stems of this, which are tall and slender, bear distichous leaves some 6 inches long, notched at the points, and clasping the stems at their base. They are leathery in texture, and deep green. The flowers, which are borne upon pale red footstalks, are rich magenta, shaded with purple. It comes from New Grenada.

E. Friderici Guilielmi.—This is a very tall and robust plant, the stems of which are clothed with broad, leathery leaves nearly a foot in length. The flowers, which are borne in dense racemes, are deep crimson, with the exception of the base of the lip and the tip of the column, which are white, whilst the long footstalks are purple. It blooms in spring and early in summer. It comes from Northern Peru, at an elevation of from 7000 feet to 8000 feet. W. H. G.

Moss litter for Orchids.—Mr. Buchan inquires (p. 262) if anyone has had experience of the growth of Orchids in Moss litter. When this article was first imported I tried it, and found it soured and fell to powder or else became slimy, and the darker the colour the quicker it decayed; but, seeing the large amount of moisture which it held in suspense, I made a number of experiments with it, and found that, by treating fresh Sphagnum Moss with sulphate of ammonia, borax, &c., and pressing it afterwards into a solid block, it retained the moisture and kept good for two years. While travelling in Germany and Bavaria shortly after I had made these experiments, I found Sphagnum growing most luxuriantly with several inches of green growth. I therefore determined to get a quantity chemically treated as above and pressed into blocks, as I have found it excellent for the growth of Odontoglossums, Cattleyas, &c., and more particularly for Sophronitis, which I had hitherto found difficult to grow, and for your inspection I send herewith a pan on which the plants were placed in December, 1884. I shall be glad if you will carefully examine and report on the specimen sent—now nearly two years in the pan. I have been for years trying to find a material in which to grow Orchids, good peat becoming every day more difficult to obtain.—Marcus H. Voss, *Streatham*.

*** Nothing could surpass in vigorous growth the specimen of Sophronitis grandiflora sent by Mr. Voss. The plant is in a pan, measures 6 inches across, and is crowded with bulbs, the roots forming quite a network amongst the potting material, which has the appearance of being sweet and durable.—Ed.

Garden Flora.

PLATE 563.

THUNBERGIAS.

(with a plate of T. laurifolia.*)

Of the thirty known species of Thunbergia we have about a dozen kinds in cultivation as garden plants, some of them being characterised by a strong, vigorous, scandent habit, whilst others are shrubby and more or less compact, all of them being easily managed and flowered except one, viz., T. coccinea. The genus is now made to include Hexacentris and Meyenia, but we have omitted the latter here, because, for garden purposes, Meyenia is distinct enough to be kept separate from Thunbergia. All the species cultivated in gardens, and of which descriptions are here given, are happiest when treated liberally in respect of watering and soil, though some, to induce them to flower freely, should be kept rather dry and well aired after they have made good growth. The free-growing kinds should be planted out, and their shoots trained against pillars or made to grow in festoons along the roof of the stove. For details as to cultivation, our readers cannot do better than consult the articles on Thunbergias and Hexacentris in Baines' "Greenhouse and Stove Plants," previously published in The Garden, Vol. XXIV., p. 314.

T. affinis.—This is a recent introduction from East Africa, having been sent home by the German collector Hildebrandt. A plant of it has been flowering all summer in the Palm house at Kew, as already noted in The Garden. It is a slender-stemmed scandent shrub, with thin, smooth Privet-like foliage, which is almost stalkless; the flowers are exactly similar to those of Meyenia erecta in shape and colour, but larger than these usually are. The neat habit, freedom of growth, and beautiful deep blue of its large flowers should secure for this species a favoured position among stove climbers. It may be grown in much smaller space than is necessary for the larger kinds, such as T. laurifolia.

T. alata.—Although usually treated as an annual, this plant is really a perennial. It is one of the prettiest of quick-growing climbing plants for the greenhouse or cool stove, and it seems to thrive either in shade or in full sunlight. We have seen it used as a screen-plant for covering bare stems of old plants in stoves, and we have grown it in baskets in the conservatory with very pretty effect. It is a twiner with hastate leaves and winged stalks, and bears in abundance its axillary flowers, which are 1 inch long and wide, with a flat, spreading limb. There is considerable variety of colour in the flowers—white, buff, pale yellow, orange with purplish eye-like centres, or uniformly orange or white. A variegated-leaved form, known as Doddsi, is also in cultivation. Not only in this country, but also in all tropical countries where gardening is practised, this pretty little climber is a universal favourite. It is a native of Africa, but is now naturalised in India and elsewhere. T. aurantiaca is a form of this

* Drawn in the Royal Gardens, Kew, September 10, 1885.

species, whilst T. fragrans is often confounded with it. The latter, however, has not a winged petiole, and bears pure white fragrant flowers. It is not as useful a garden plant as T. alata, although spoken of by Indian botanists as the most charming of plants.

T. chrysops.—A very beautiful Meyenia-like plant with a scandent habit, hastate, toothed foliage, and large axillary, deep blue flowers; it was figured under this name in several magazines about forty years ago; but we do not know of its existence in English collections of to-day. It was found in Sierra Leone by Whitfield, a collector employed by the late Earl of Derby, to whose enthusiastic love of horticulture we are indebted for some fine African plants. The flowers in T. chrysops are larger than in Meyenia, and they have a very brilliant effect, owing to the golden yellow eye being surrounded by a deep indigo-blue, changing to violet towards the margin of the lobes. It is a stove plant which, if lost to English horticulture, is worth re introducing.

T. coccinea (Hexacentris).—This is very remarkable in the form of its flowers; it is also usually disappointing as a garden plant, because of its rarely flowering satisfactorily. It is a rampant grower, covering a very large area if allowed to grow unchecked, and developing hundreds of racemes in autumn, the flower-buds on which, however, usually fall long before they are fit to open. The stems are four-angled, and the leaves vary in form from hastate to cordate, and are variously toothed or lobed. The racemes are axillary or on the ends of short branches, and they hang down sometimes to a length of 3 feet, the flowers being arranged in pairs set at intervals of about 2 inches apart. Each flower is on a stalk 2 inches long, and has its tubular part hidden by two large brown bracts, which fold round the flower and give it an urn-like appearance; the corolla lobes are short, reflexed, bright scarlet, yellow in the throat, and these colours, with the chocolate-brown of the bracts, produce a brilliant effect. We have seen this plant in flower several times, but the art of growing it so as to make it mature flowers annually is apparently not yet discovered. It is said to be a very common inhabitant of the tropical jungles of India. Possibly the absence of sunlight and warmth in early winter when this species tries to flower is the cause of its usually failing with us.

T. grandiflora.—This is a large, quick-growing climber, with long, smooth-barked shoots bearing hastate leaves 5 inches long, deeply toothed or lobed, and rough almost as sand-paper on both surfaces. The flowers are on short, stout racemes developed in the leaf axils, strong shoots bearing as many as twelve flowers on each raceme of not more than 3 inches in length. The size of the flowers justifies the name of this species, as they measure 3 inches in length and width, the tube being short and wide, and the limb divided into five large spreading lobes; colour pale blue, becoming almost white in the throat, where there are usually a few deeper coloured streaks. Flowering season from midsummer till winter. When grown in a large house where plenty of space can be spared for its shoots to extend and festoon, this plant becomes a magnificent sight during its flowering period. The shoots should be allowed to hang downwards if the plant be trained against the glass, so that the flowers may be seen to the best advantage. As a pot plant this species makes but an indifferent display; it must be treated liberally and grown into a large size before its grand characters are fully developed. It is a native of India and China, the form cultivated in gardens here being that found in Bengal, and introduced in 1823.

T. Hawtayneana.—A climbing shrub from Nepaul, and a very handsome stove-flowering plant. The leaves are oval, smooth, dark green, and sessile, and the flowers, which spring from the axils of the leaves, have a yellow tube 1½ inches long, and a five-lobed spreading limb of a deep blue-purple colour. It is very free-flowering and belongs to the same group as the Meyenias, from which, however, it is quite distinct in having round instead of angular stems. We have not seen this plant for several years. Is it in cultivation now?

T. laurifolia.—This beautiful stove climber is known in gardens under the name of T. Harrisi as well as that here adopted, the two names having originally been given to two slightly different forms of what is now known to be a somewhat

Thunbergia laurifolia as a small pot plant.

variable plant. The form shown in our plate is what has been known as T. Harrisi, and is the better of the two, being brighter coloured and bearing larger racemes than that to which the name of laurifolia was once limited. It is a strong grower with long cord-like shoots, ovate, Laurel-like leaves, the margins slightly toothed or waved, and the surface smooth and shining. The flowers are borne on a short raceme springing from the leaf-axils, as many as two dozen flowers being crowded on a raceme not more than 4 inches long. The size, form, and beautiful colour of the flowers are shown in the plate, which represents only a small cluster of flowers, a full-sized one being too large for our space. A large specimen of this plant may be seen now in flower at Kew, where it is trained against the roof of the Palm house, and festooned from one wire to another, the flowers hanging in profusion from all parts of the plant. Treated liberally and allowed to grow its own way against a large pillar, or as at Kew, this species makes as grand a show as the Allamandas do. It is a native of India, and was introduced in 1857.

T. mysorensis (Hexacentris).—One of the most gorgeous of stove climbers, and one of the very easiest to manage and flower. It has long scandent shoots, which hang down or form festoons if permitted, and bear elliptical or hastate leaves with toothed margins and short stalks. The flowers are borne on long pendent racemes, which terminate the short branches, and which are sometimes 2 feet or more in length; each flower has a rather long stalk with an upward curve, so that the flower itself is nearly erect. In shape the corolla suggests that of a large Snapdragon or Mimulus, the upper lobe forming a sort of hood and the two lateral ones standing out wing-like; while the bottom one points downwards like a lip. These lobes are yellow with broad margins of scarlet, the colour of the tube below being purplish. As each flower is 2 inches across and of good substance, the effect of the numerous long racemes borne by a large plant of this species is extremely fine. It is so very free-flowering, too, and thrives under such simple treatment, that no stove need be without its beautiful flowers for many months in the year. Planted out, it soon forms a large plant, and will certainly flower; whilst in pots it may be grown into handsome specimens. To induce it to bloom a drier atmosphere and plenty of air are all that is required. It is a native of Mysore and the Neilgherries, and was introduced about 1855. There is a yellow-flowered form of it which is named lutea.

T. natalensis.—A distinct shrubby plant, with ovate, sessile leaves, the veins in which are very prominent, and axillary flowers which are slightly drooping, and are composed of a tube 2 inches long, almost hidden by the two large green calyx-like bracts, and a large spreading five-lobed limb which is coloured pale purple. The flowers appear in July, and although not more than two flowers are open at one time on each branch, they make a nice display on specimens grown in pots, and made to branch freely by frequent stopping early in the year. It has been in cultivation since 1858, thriving in a warm greenhouse where the atmosphere is continually moist. B.

WORK DONE IN WEEK ENDING SEPT. 21.

September 15 to 21.

Brilliant sunshine by day and cold, nearly freezing, by night are phrases descriptive of the weather that has prevailed all the week. The cold nights have made us somewhat apprehensive as to the safety of tender bedding plants, for though all our cuttings of the same are taken, we do not yet wish to see the end of the old plants; hence protection with light tiffany sheeting and thick netting has been put over the most important beds to preserve them from frost, as the probability is that if we get safely over the first cold nights we shall have a second little summer, when the beauty of the flower garden will be very welcome as a sort of floral set-off to the autumnal tints of the trees that are now showing in every direction. Till frost has really cut down the plants we continue our work of keeping every bed and plant in perfect order by picking off seed-pods, bad flowers, and leaves, and take just as much pains to keep edgings and groundwork as neat and trim as we do in the early part of the season. Of course, when a sharp frost does come the collapse is sudden and complete. Well, and what then? Why, there is an end of gaiety; and winter dress is put on forthwith, shrubs and other hardy plants take the place of such plants as must be moved, but all that will winter without injury

remain as before. The present must surely have been a favourable season for Lilies of all kinds. The auratums have been, and still are, most magnificent, and the double-flowered Tiger Lily is equally good. Our bulbs of both are constantly left in the ground and winter well, and shoot forth each year more strongly than the previous one. The soil is an open sandy loam resting on gravel, and therefore warmer and drier than most soils, and this, no doubt, prevents injury accruing to the bulbs in winter. It is questionable whether the auratum Lily would winter in a soil of a tenacious nature, even though it were well drained, and therefore a trial on a limited scale only should be made till this has been ascertained. Tied up spikes of Gladiolus, which are still flowering profusely; and so are Phloxes, which also have been freed of bad flowers. Asters (Michaelmas Daisies) are nearly in full beauty, and the tall varieties have been securely staked. The short crops of both Apples and Pears make us most anxious to harvest them in good condition, that the supply of each may hold out, and on most days we gather a few Pears—Marie Louise, Beurré Thouin, Comte de Lamy, Beurré de Capiaumont, Doyenné Gris, and Gansel's Bergamot have been gathered during the week, and about as many varieties of Apples; only the latest varieties, such as Ribston Pippin, Northern Greening, Court Pendu Plat, and Deux Ans, now remain to be gathered. Peaches and Nectarines ripen more slowly than usual, and are certainly of finer quality, and the colour of all is perfection, thanks to the unusual amount of sunshine that has lately prevailed. We water both these and Apricots as often as the non-neglect of other duties will admit of; this is necessary, as our rainfall up to this date is several inches below the average. Kitchen garden work has been earthing up Broccoli and hoeing between rows of winter Spinach and August-sown Onions, Lettuce, and Cabbage, and the completion of Potato digging and housing. Planting of Cabbages, &c., is deferred till rain comes. Work in and about the houses has mainly been propagation of flower garden plants, but all cuttings are now in, except those that it is desirable to put in later, such as Calceolarias, Leucophytons, and Gnaphaliums, which all do best in cold frames, where they remain till needed for planting out in the beds in spring. The second crop of Figs being about finished, the house is now kept cooler—no fire-heat, and ventilation will be gradually increased till it is safe to leave the house wide open night and day; the border—an inside one—will not be allowed to get dry, but, as a matter of course, the supply of water will be considerably reduced and syringing quite discontinued. Put inside our first lot of Chrysanthemums—the latest varieties only; the remainder are so forward, that they will be left out as long as it is safe to leave them without danger of injury by frost; meantime, every available place is being got ready for them, as also are stakes for tying them into position in the houses. A greater amount of fire-heat is now given to Melons, Cucumbers, and Tomatoes by night, 70° to 75° being the present average temperature, and a similar warmth is afforded to Pines in all stages of growth. Did final pruning to early Peaches; mulched the freshly top-dressed border, which is now available for standing plants on all the winter. HANTS.

HARDY FRUITS.

Apples.

This season a partial crop must be carefully watched and gathered as soon as the stalks of the fruit yield to the usual upward pressure. Although the season is generally considered late, we find but little, if any, difference in the period of ripening; indeed, many of the early varieties are forwarder than they have been for several years; moreover, the fruit is bright, clean, and exceptionally fine. We have during the past week gathered Worcester Pearmain and Echlinville, two of our most handsome and useful early autumn Apples, Lord Suffield, Lady Henniker, Stirling Castle, Keswick Codlin, and Devonshire Quarrenden, both from pyramids, bushes, and upright cordons, and the trees are now ready for root-lifting or top-dressing and watering. The crops from the above-named trees having required much thinning, we do not think it necessary to disturb the roots, as the growth is not too strong and the set of flower-buds is profuse; but close examination reveals the fact that the subsoil under many of them inclines to the dry side; hence the secret of early maturity. Having a good supply of water, basins will be formed round the boles of the trees, and after well washing the foliage the hose will be laid on until the lower roots are properly moistened. Mulching will then complete their requirements for the season. Late kinds are colouring fast, and no doubt, from the same cause, show a tendency to early maturity; but, unlike the fruit in the home and southern counties, the Apples are clean and free from grub.

Apricots.

These, as a rule, do not receive the care and attention they deserve and require after the fruit is gathered. Natives of a warmer clime, many people think they cannot have too much dry sunheat to ripen up the fruit-buds and wood; neither can they if the roots are freely supplied with water. This important element is not, however, always administered through the latter part of August and September. The lower stratum of deeply-drained south borders becomes dry, and the trees resent this treatment by shedding their buds and perhaps losing a few branches in the spring. Better late than never. Those who have neglected the roots should not lose a day in making an effort to restore the soil to a growing state by pointing up the hard-trodden surface of the wall path, mulching and watering heavily. An inch or two of rain or an occasional dash with the hose cannot reach the deeply placed roots, as those near the surface carry it off, and the rapidly perspiring leaves lack that fulness so essential to the forming and feeding of the buds. Once properly moistened and mulched to prevent the borders from again becoming dry, autumn watering must not be continued to an extent that will force fresh green growth that will never ripen; but this is an extreme which few people fall into, especially when well drained trees are growing against sheltered south walls. Apples and Pears in the open quarters may have too much wet in the autumn, but the roots of Peaches and Apricots, which commence swelling their buds soon after Christmas, must be kept progressing, and the proper time to commence cultivating next year's crop is immediately after the last of the fruit is gathered. Old trees which have become barren or gross through the roots descending into a dry or unsuitable subsoil may now be taken in hand with every chance of their speedy restoration to a fruitful condition. Careful lifting and replanting in fresh maiden loam, now so well understood, is the proper remedy, as it not only cuts off the supply of damaging food, but raises the main roots to a horizontal position within the influence of heat, water, and air. In course of time the spurs of old Apricots get very long and unsightly, when the flowers and fruit, if they produce any, lose the influence of heat absorbed and reflected by the wall. Close examination generally shows a number of buds clustering near the main stems, which one year's management will convert into close spurs. To these, then, all old spurs should be pruned as soon as the roots have thoroughly taken to the new compost, and where they are not visible all the old spurs, with the exception of one at the extremity of each branch, may be cut off, when latent buds will soon push into growth.

Peaches.

Of these the flush of midseason kinds will now be over, and many of the trees will be ready for pruning. Light, warmth, and air being such important factors, the earliest available opportunity should be devoted to the removal of all past-bearing shoots which have finished their work, and the trees before and afterwards must be well hosed to divest them of spider. When pruning is finished and the trees are clean, all summer mulching may be taken away to let warmth into the borders, but top-dressing laid on in the winter or early spring and now full of fibres will be best left until the time arrives for the annual root-pruning. The end of September and the month of October is the best time for this work, and so completely does this operation form the keystone of success, that I cannot forbear again directing attention to it. So many think root-lifting means a year's loss of fruit, but this is not the case, as I never allow the roots of a single tree to escape the annual shortening, and they always bear full crops. Indeed, so grateful are they for the usual supply of fresh loam and lime rubble, that I always secure the best wood and fruit when the work is most efficiently performed. Last October I had occasion to move a large tree of Dymond three times; the fruit, a full crop, is equal to the best on the wall, and the wood is perfect. Further, by way of experiment, a number of large trees which I had been testing in pots were shaken out and the roots washed free of every particle of soil preparatory to planting them against walls. Strong roots we could not uncoil were shortened, the others were spread out in pure calcareous loam, and most of them are now swelling off large Peaches. If by oversight, certainly not under good management, the roots of any of the trees have become dry the borders should be well watered before root-lifting is attempted. Then, during fine, dry weather, say early in October, the work may be taken in hand as the soil can be handled and worked without becoming pasty, and flooding with water will be found the best rammer.

Figs

must be kept thin of wood and closely nailed in to the walls to insure its being properly ripened. Mulching having done its work, crops, as a rule, being extremely light, it may be removed to let the sun into the borders. We are still gathering a few fine Figs from Brown Turkey, Brunswick, and a variety sent out under the name of Williams' Prolific, but, in my opinion, neither more nor less than Brunswick. Where Figs have failed, or so soon as the crop is over, all root-pruning must be taken in hand and completed. This process, while the leaves are yet on the trees, will hasten the ripening of the wood and check the swelling of the embryo Figs, which cannot be too small to pass safely through the winter. If not already done, all intermediate fruits larger than Hazel Nuts must at once be rubbed off, as they cannot possibly hang to ripen. Figs submit to very severe root-pruning and become gross, pithy, and unfruitful in nearly every garden where it is neglected. They like light, not over-rich, calcareous compost, and do best when the roots are confined to a small area. Unlike stone fruit trees, they may be kept dry through the winter, but water and surface-dressing must be supplied *ad lib.* when spring growth can no longer be retarded.

Strawberries.

The terrific thunderstorms by which the hot, dry weather was broken up have told upon our Strawberry beds in a way we did not wish or bargain for. What the outcome will be, a mild or severe winter alone can determine. The plants, in accordance with good practice, were trimmed as soon as the crop was cleared, and a heavy top-dressing of old Peach border loam put them right, as we thought, for the winter, but growth of foliage has set in with all the spring vigour Strawberries are capable of putting forth, and should the weather continue mild, I am afraid many of the crowns will throw up flower-scapes. A check now may prevent flowering, but it is to be feared this unwelcome precocity may tell unfavourably in the spring. It may be that Dame Nature is only laughing at our autumn Strawberry fruiters, and showing them how she can produce second crops without subjecting the plants to pot culture or sharp attacks of red spider. Although detrimental to old beds, this autumn growth may favour newly formed plantations, as the plants are now making good crowns

and throwing out strong wires, a sure sign that the roots are at work below the surface. These beds we generally about this time top-dress with old Mushroom manure, but under existing conditions the plants will be firmed with the foot and the manure will be withheld for the present, as the crowns are more in need of the hardening effect of exposure than the roots of nutriment. When August-planted beds are well established, all runners should be removed as they appear, and the Dutch hoe in careful hands on fine days will keep them clear of weeds and benefit the plants by letting in sun and air. If the late discussion on Strawberries has induced amateurs to invest in new sorts which may be weak or still in small pots, they may with advantage defer permanent planting until the spring. The plants must not, however, be kept standing about in these cramping and starving nutshells, as such treatment will greatly decrease their number before the winter is over, and those which escape will be weak and poor. Neither must they be pampered, for Strawberries worth growing resent coddling, but rejoice in full exposure to the elements. The proper course, then, is an early clearance from glass and shade, and temporary planting in a well-prepared nursery bed in an elevated airy part of the garden. The plants need not be placed more than 6 inches apart, but they should be divested of sour soil and firmly planted in a good layer of fresh heavy compost.

Bush Fruits.

Currants and Gooseberries, like all other fruit trees, seem inclined to ripen their wood and foliage early. It is as yet rather too early to commence pruning, although it is a good plan to get this work forward before we are overtaken by cold weather; but it is not a day too soon to commence planting. The ground just now is warm and in excellent condition, and young trees, especially those of home growth, can be transplanted in full leaf without their feeling the moving. A good start with trees which are not to be disturbed for some years being more than half the battle, the ground should be well trenched to a uniform depth, and enriched with rotten manure if poor, with burnt earth and old lime rubble if cold and heavy. Then on a dry day it must be levelled and made quite firm—two important operations which must precede workman-like planting. When bush trees are to be planted in lines near the margins of walks it is a good plan to throw out a trench 3 feet wide and 2 feet deep and put in a thick layer of trimmings, clippings, and other cumbersome refuse to form a tolerably rich foundation. Upon this the best of the soil recently taken out must be placed and made firm in consecutive layers until the bed is 6 inches above the surrounding level. When worked into proper form a line should be strained along the centre, and neat, but stout, durable sticks or stakes placed equidistant with a rod and driven down to the solid subsoil to indicate the stations, one tie to keep the trees upright and steady being all that is needed; these sticks should be cut off to one uniform height, a few inches above the level of the collar of bush trees, and 2 feet or more for pyramids and standards. When planted and mulched, a good watering will settle the soil home about the roots. This will prove to be the finest border in the garden for crops of winter Lettuce.

The Orchard.

The gathering of fruit this year in many orchards will be light, and for this reason the few trees bearing full or partial crops of Apples and Pears must receive extra care and timely attention. I have just stated that the fruit in gardens, owing to the dryness of the subsoil, is ripening earlier than usual, and find the crops in Grass orchards are equally forward. Fruit generally, even on old trees, is clean and fine, but it lacks colour, and, judging from the tendency to dropping and the ready way in which Apples part from the lowest branches, it is questionable if much will be gained by allowing this settled weather to pass before hand-picking is commenced in earnest. Midseason and late sorts should be allowed to hang until the kernels have changed colour and begin to shrink in their cells, but a sharp outlook must be kept on the weather, and all hands set to work on the eve of a change, as one sharp storm would nearly clear many of the trees. Assuming that the fruit room has been prepared for the reception of the fruit, the different varieties should be carefully put away, the thinner the better, as they are gathered, the latest most out of the way, the earliest where thay will be most in sight. Newly gathered Apples perspire freely, no matter how dry they may be when stored; hence the importance of keeping the fruit room dry, cool, and abundantly ventilated throughout the autumn. When the sweating process which glazes and fits them for keeping is over, each shelf should be examined for faulty fruits which are not sound, and gradually the ventilation may be reduced on the approach of cold, wet, or severe weather. W. Coleman.

Eastnor Castle, Ledbury.

Kitchen Garden.

Earthing up Celery.

More depends, I am disposed to maintain, upon the way in which this operation is performed than upon whether it is done piecemeal or all at one time. On light, well-drained soils it may be necessary to water the rows repeatedly up to the time when the plants are nearly full grown, and earthing them up, in that case, would have to be delayed, but on heavy lands, as in our case, about three good soakings, if the month of August is hot and dry, are all that are needed; at least, that is our experience, and we have as good Celery as most people. With us slugs are remarkably troublesome, and it is difficult to keep them in check, the Celery rows being their favourite winter quarters. We have tried several plans of preserving the plants from them with varying success. For two seasons we completely surrounded the stems with fine coal ashes, but this, though effective enough, does not improve the fertility of the soil for after crops; on the contrary, there is too much of it in one place, and we are not using it this season. At Longleat burnt clay is substituted for the ashes, and this, besides keeping the slugs off, preserves the Celery, and also improves naturally stiff soil. When any such material is employed, moulding up is done principally on the second occasion, and before severe frosts are anticipated. As we have no burnt clay and do not intend using any kind of ashes, our earthing up will be done in the ordinary manner—that is, at about three times, plenty of soot and lime being freely dusted about the stems each time for the benefit of the slugs. It might, too, be a saving of labour to mould up completely at one time, but I still prefer the good old plan of doing it piecemeal, always supposing that the operation is rationally carried out. Both "R. T." (p. 220) and "Hortus" (p. 281) appear to have overlooked the fact that Celery is naturally of a spreading habit, and unless something is done to check that tendency when the time arrives to earth up "all at once," the leaves cannot be induced to properly enclose the heart—the only part eaten, and what we have to study is how best to develop and preserve it. The cook may be prevailed upon to use some of the outer stalks for soups, but, as a rule, all Celery that reaches the pantry is very roughly used indeed, and very little—I may say nothing—is gained by growing large "sticks." Nor does any real advantage attend the practice of placing two rows of plants in one narrow trench, as the same number of plants may be grown in a single row with much less trouble. When these are growing strongly they should be moulded up. After being properly cleared of suckers and the small lower leaves, they should either be lightly tied up just above where the soil will reach, so as to allow the soil to be worked in amongst them expeditiously, or if a boy is available, he can be made to hold the stems together while the soil is being carefully and lightly disposed about them. For the first moulding 3 inches or 4 inches of soil will be ample; moisture is thus retained and the leaves are kept nearly erect. At the next moulding, if any protecting material is worked in, two boards will be necessary, and the plants should also be again loosely tied up, so that the stalks shall cover the heart all round. The boards being placed in position on each side of the rows, the next proceeding is to mould up against them from the ridges, while inside the ashes or burnt clay should be carefully placed, and the boards can then be withdrawn and be ready for another length. This would not be the final moulding; later on the earth should be banked up around in such a manner as to throw off superfluous rain and complete the blanching. At no time should the soil be heavily banked above the fast developing hearts, nor should it be tightly pressed about the stems, as some are fond of doing, for this causes bulging and splitting at the base; nor ought many of the leaves to be enclosed, as it is not these that require blanching, and the more healthy the foliage above the soil the better and larger will the heart be. The idea that piecemeal blanching varies the amount of crispness is fanciful, and will not have much weight with experienced cultivators. The longer Celery is allowed to remain exposed to full light and air the stronger the flavour becomes, and I very much doubt if after-blanching will entirely remove this objectionable taste. W. I.

Autumn Giant Cauliflower.—The extent to which this variety is now cultivated for market would hardly be credited without actually seeing the enormous breadths of it that are planted in the neighbourhood of large towns. Even when other vegetables are plentiful and cheap this Cauliflower finds a ready sale, owing to its heads being beautifully white and compact. They are now being sent into Portsmouth and other large south coast towns by wagon-loads, nearly every head being fit to set up in a prize collection of vegetables. The secret of success in the case of this Cauliflower is good rich soil, early planting, and plenty of room. It succeeds in open fields where sun and wind play freely around it, and in periods of drought plenty of sewage is applied to the land. The latter, too, is mostly dressed the preceding winter with town refuse, and great care is taken to have soil for it on which no other kind of Brassica crop had been grown for some time. The seed is sown by our market-growers very early in cold frames, and as soon as the weather is favourable and the plants large enough to handle, they are planted out 1 yard apart, which allows for the free use of a horse hoe between the rows. And at this time of year they entirely cover the ground with massive dark green leaves, betokening good cultivation. Another valuable characteristic belonging to the Autumn Giant is the length of time during which it is in season; by having successional batches a continuous supply can be secured from August until severe frost sets in.—J. G., *Hants.*

Thinning Asparagus.—The plants in my young Asparagus bed (two years old) are in bunches of some six or eight stems, and the bunches about 1 foot apart in the bed. May these be left in bunches, or ought they to be thinned to single stems? and if so, will simply pulling up the superfluous stems be sufficient, and can that be done without injury to the root?—H. S. M.

*** Well-grown Asparagus, two years from the seed, will produce several shoots from each crown. Why thin or destroy them when each shoot is forming and feeding a bud at its base? Better tie the young growths to sticks to prevent wind-waving, as future growth depends upon their preservation until they die down naturally, when their work will be done. These remarks apply to plants which were planted singly two years ago, but it is more than probable they do not meet your case, as we suspect your Asparagus was improperly sown—*i.e.*, a number of seeds were allowed to fall together, and thinning when 2 inches high was neglected. If so, and a

number of young plants are now clustered in bunches 1 foot apart, a different course must be pursued, as thinning is a simple impossibility. Leave the bed alone until the buds begin to move in April, then, the bunches being so terribly close together, lift every alternate row, divide the plants, carefully preserving the buds, and with the best make a new plantation. If early cutting is imperative, the other rows may remain; but they will never do much good, as the roots will strangle each other. When Asparagus seeds are sown where the plants are to remain, the seeds should be dropped, singly, say, 6 inches apart in the rows and 3 feet from row to row; the plants will then have fair room for development. Assuming that every seed grows, they will be much too close, but being 6 inches from each other, every alternate plant when twelve months old may be carefully lifted with a hand-fork and transferred to fresh ground, properly prepared through the winter.—W. Coleman, *Eastnor Castle, Ledbury.*

PEAS AND PEA CULTURE.

Little that is new can be said about Peas, and yet it is of importance to know how to keep up a supply of good green Peas from May to November. In order to do this a considerable amount of attention and forethought is necessary. Some, doubtless, fancy that Peas will grow anywhere and under all conditions, but that is a mistake. In order to have palatable green Peas during the period named there is no doubt that a rich deep loam is of the utmost importance. Without this they cannot resist the summer droughts. In our light soil, over a subsoil of dry gravel, there is no difficulty in obtaining good early Peas without taking any extra pains with them, except to prepare a piece of ground in a warm position. Our kitchen garden difficulties in light soil begin with the hot dry weather which sets in either in June or July. The only possible way to keep up a supply during July and later is to prepare the ground by trenching it the previous autumn or winter. Some good manure should be worked into it to a considerable depth. If placed near the surface, it leaves the soil too open to produce successional crops of good Peas. The nature of shallow light soil is (even if well manured) to rush in a good crop quickly, and it is soon over. Great quantities of Peas are grown in this neighbourhood for the London market. No sticks are used for their support, and during the Pea-picking season a surplus population of a peculiar character settles in our midst to aid in getting the crop ready for market. They pick the Peas at so much per bushel. The first gathering takes the cream of the crop, and seldom is more than two gatherings made, after which the ground is ploughed and planted with Coleworts, sprouting Broccoli, or any similar crop. Watering, or any special preparation of the ground, is out of the question. In good seasons the market for the earliest Peas is sure to be overstocked, and, as a rule, the later Peas pay much better. The crop may not be so large, and more is paid for gathering it; but during some part of August Peas were sold at seven shillings and sixpence per bushel. The ground, after later crops have been removed, may be planted with spring Cabbages.

In private gardens sticks are used to support Peas, and I would here like to urge the importance of leaving sufficient space between the rows. For tall varieties a space of 5 feet or 6 feet apart gives the best results. Some may fancy this too much, but they are wrong. As soon as dry weather sets in keep the hoe at work between the rows; there is no need to hoe deeply, but it will keep the ground from cracking and will destroy all weeds. It is quite necessary in some cases to water well at the roots. My plan for this is to draw drills on each side of the rows, and fill them up three or four times with water, or until the ground is well soaked. Level the ground, and spread a layer of light manure or short litter over the surface. We can obtain manure from stables in which peat-litter is used. This is light and answers admirably. Mildew and thrips are very troublesome in our garden. All late Pea crops have been much injured by it this year. It makes its appearance during dry weather. If it can be prevented at all, that can only be done by watering and mulching, aided by deep culture. Every successful cultivator knows the value of well-worked and deeply-trenched soil for vegetables. Its obvious advantages are well set forth in "The Manse Garden," a useful little book. In it (p. 104) the author says: "The great advantage of a deep soil is its aptitude for equalising the supplies of moisture. There subsists no sympathy between the surface and a hard subsoil. If the former is drenched with rain, the latter refuses to have anything to do with it, and if the former is parched, the latter will yield up none of its moisture; again, if the subsoil be pure gravel, it readily takes in the superabundant waters, but it soon squanders them, and then has nothing to give back to the surface during its greatest thirst. But when you acquire a sufficient depth of soil you have a large quantity of homogeneous matter sympathetic throughout, and all nearly alike wet, or alike dry; consequently not so liable to suffer injury by a too long continuance of rain or drought. This improvement, then, as it renders the elements of Nature more subservient to the purposes of vegetation, is permanent, and cannot wear out or lose its effect, while that of manuring, at whatever expense, must certainly do." It must not be inferred, however, that repeated trenching is unnecessary. It ought to be done, says the book just quoted, once in eight or ten years. We do it once in three or four years, and consider this system of trenching and manuring absolutely essential to the successful culture of late Pea crops.

What are the best varieties to cultivate is a question of as much importance as the method of culture. The varieties that have been introduced during the last few years, as far as mere names are concerned, have been plentiful enough, but in some cases they are not sufficiently distinct for garden purposes. We do not require a new Pea, which we have to purchase at a high price, unless it is sufficiently distinct and better in quality than others already in cultivation. Mr. Laxton has done good work in raising new varieties of Peas by cross-breeding, and has added many good and distinct varieties to our gardens. Mr. Culverwell and Mr. Eckford have also achieved some successful results in this direction. But what with new and old varieties we seem to be overwhelmed with numbers. I have been curious enough to count the number of varieties contained in the retail catalogue of one of our London houses, and find sixty-nine described. We grow in our garden six varieties, and would rather reduce this number than add to it. We, however, try one or two new kinds every year, and if after a fair trial they are likely to be superior to any we already have they are retained. For many years we grew as early varieties William the First and Alpha, the first a variety with round blue Peas, and the other a blue wrinkled marrow. We still grow them, but with the addition of Selected Extra Early. This variety is not so prolific as William the First, but is quite a week or two earlier. Dr. McLean is the best second early; it is a wrinkled marrow, and very prolific. It neither produces very large pods nor very large Peas, and as we do not require them, that is no loss. The pods are medium-sized; so are the Peas; and if there is a better variety for use in a first-class establishment I would like to know its name. Veitch's Perfection, or selections of it, we also grow, and this is too well known to need any comment. It is a grand marrow Pea, but larger than Dr. McLean. Of tall-growing sorts with large Peas and pods we have grown Telephone for several seasons, and this year Prodigy, said to be a cross between Culverwell's Giant Marrow and Stratagem. I could not discern any of the Stratagem parentage in it, nor did it differ materially from Telephone, grown side by side with it. We put it down as an improved form of Telephone. It had a first-class certificate from the Royal Horticultural Society, so it is doubtless distinct. Sturdy we have grown since it was sent out, and have been rather favourably impressed with it. It is a very late Pea—I believe one of Mr. Laxton's hybrids. Those named will give satisfaction in any garden.

J. Douglas.

LATE PLANTED POTATOES.

Having a quantity of good sets of Beauty of Hebron, Early Rose, and other popular Potatoes on hand, and not having ground vacant for them, they were spread out thinly on a hard border out of doors until crops could be cleared to make room for them. A good many of them were planted on June 1; they were fine sets, well furnished with sturdy shoots, and in planting we took care not to rub these off. We made good wide trenches with a spade and laid them in rows, carefully returning the soil, and in a very few days they were up and grew so vigorously, that little difference could be discerned between them and others planted in March and April. Most of them were lifted by August 1, or two months from the date of planting, and a capital even crop they proved to be. I do not say that such late planting should, as a rule, be followed, but I mention the fact to show that a really good crop can be produced thus late in the season. As regards earthing or moulding up the rows of Potatoes, I may state that we grow a good many of ours solely for seed, and they are not moulded up at all; nevertheless, I have not been able to detect any difference between the crop when moulded up and that grown on the flat. There is, however, one advantage belonging to earthing up, viz., in a season like the present, when copious rains are frequent, the ridges help to keep the tubers dry, as the rain runs down into the hollows between the rows and soaks away without wetting the tubers. Disease up to a late period this year has been absent, but the heavy rainfall which we have lately had has made it spread rapidly among late kinds, even after the earlies were all safely harvested. Nevertheless, I do not think the loss will be enough to greatly affect the crop. Magnum Bonum is still largely grown as a field Potato, and although it cannot be said to be disease proof, its strong constitution does not appear affected by it like that of many of the garden varieties of Potato. J. G. H.

Bone fertilisers.—There are two modes of preparing bones to apply to land as fertilisers. One is to grind them to meal and powder, and use them without further chemical change; the other is to change the phosphate to superphosphate with sulphuric acid. The last-mentioned mode requires some skill and experience and is attended with some difficulty by those not familiar with the process, as well as additional expense. "The following," says the *Country Gentleman*, "is perhaps the best way of converting refuse bones into manure: First break them into as small pieces as may be convenient; the smaller, the sooner the process will be completed. The bones should be worked down with ashes, and with liquid and solid manure. The ashes should be good, such as are obtained from hard wood grown on uplands, and which have not been so long exposed to the air as to lose their strength; or, if they have been long exposed, a small portion of fresh lime should be added. The operation may be performed in barrels or in large boxes of any convenient size. The bottom is first covered with a few inches of the ashes, then a thicker layer of bones, and so on till the box or barrel is full. The ashes should be moistened, but not quite enough to cause water to drain away from them. They should be kept wet by additions of liquid manure, or with soapsuds or hot water if nothing better is at hand. The time required for the completion of the process and the working down of the bones depends much on the freshness and strength of the ashes, and on the concentrated character of the liquid manure. The mass is rendered dry and friable by thorough intermixture with dry powdered loam or road dust. Hard or large bones, which do not work down easily, may be put with the ashes in a large boiler or kettle, lye or liquid manure being added, and the whole boiled till the bones are softened. The easiest way, however, by which to soften bones when they can be had ground or broken very small is to place them in alternate layers with strong fermenting manure, and leave them till fermentation ceases, adding enough

lye, liquid manure, or hot water to keep the mass well moistened while the process is going on. Manure thus manufactured will possess much strength.

Flower Garden.

FRENCH POPPIES.

(PAPAVER RHŒAS.)

The common red Poppy of cornfields has developed under cultivation into the widely varied colourings of the valuable annual that we know as the French Poppy. A small packet of seed will give a wide range of colouring from white to deepest blood-red, of which the best are the many shades of pink, rose, and scarlet. They are for the most part double, but there will be many single flowers of great beauty, such as the rosy pink with the white blotch at the base of each petal. French Poppies are best autumn sown, but once established in a garden they may be trusted to sow themselves, and to re-appear yearly in their many beautiful forms.

Narcissus viridiflorus.—I have just succeeded in flowering this species from bulbs I collected in the neighbourhood of Gibraltar in the autumn of 1883. I have been in doubt whether, like some other autumn-flowering bulbous plants, it has a double period of growth, an autumn growth of the flowering scape and a separate vernal growth of the leaves, but am now satisfied that there is but one growing period in which flowering scapes or leaves, or both together, are thrown up in the autumn, the leaves continuing to grow late into the spring; then with the hot weather comes the long period of rest from April or May to September. My bulbs potted in 1885 continued to produce a free growth of leaves up to the end of last May. I then dried them off and repotted them about the beginning of August, standing them for about a month under the conservatory stage and then removed them to a slightly heated pit, in which leaves are being rapidly produced with the flowering scape. I can detect no difference of character or structure between the leaf and the scape; indeed, it would seem that the Rush-like growths—call them leaves or scapes—are identical in their nature, the stronger growths only producing flowers. I believe the difficulty attending the flowering in cultivation of many autumn-flowering bulbous plants, *e.g.*, Narcissus viridiflorus, N. serotinus, N. elegans, &c., is that they are kept growing when they ought to be at rest, and that we often reverse and mix up their natural periods of growth and rest in cultivation.—George Maw, F.L.S., *Benthall, Kenley, Surrey.*

Clematis coccinea.—Those who have condemned this Clematis as being destitute of decorative value have surely only seen inferior varieties of it, or have grown it where its colour could not be properly developed. It is one of the brightest of climbers, but, like all that have small blooms, it requires time, suitable position and good food to enable it to attain large dimensions. The fragrant Flammula is nothing as a small specimen, but loaded with thousands of blooms it is a thing of beauty. The same remark applies to C. coccinea, which should get a fair chance; it should have a position where it can have plenty of air and sunshine with a liberal supply of nourishment. I have no doubt that when the blooms can be counted by the thousand instead of by the dozen, this Clematis will receive the acknowledgment of its merits to which it is entitled. I find that many have grown this Clematis under glass, but why I cannot conceive; it comes from a climate the rigour of which exceeds our own, and is therefore not thankful for the nursing that it has been favoured with. The free, open air is the place for it, and in the sunshine and breeze it is happier than in the confined precincts of a glass house. It would certainly never have occurred to me to grow it indoors, and those who have done so need not feel surprise that it has disappointed them.—J. C. B.

SINGLE DAHLIAS.

The autumnal exhibitions of 1886 have demonstrated pretty clearly that the single Dahlia must now be reckoned among the so-called florists' flowers. The champions of the double varieties, that have irreverently been described as "lumpy and inelegant," may sniff, and those who cannot recognise refinement outside a flower-pot or a cold frame may be scandalised at so rude an intrusion; but the admission must be made. A few years back, when a few single-flowered varieties were re-introduced, they were for a time regarded by many florists with some amusement, or at best with a slight amount of curiosity, as an odd relic of an early state of floricultural barbarism. The raising of seedlings which flowered the same season was found to be so easy, that several people advocated growing single Dahlias as annuals; and, owing to the great variability of the plant, numerous varieties were soon obtained with flowers of all sorts of shades, shapes, and sizes. Selection and rejection, however, quickly brought up the quality of the flowers, and in the course of two or three years pretty good varieties in each of the leading colours were secured. A mode of exhibiting them in the cut state, so as to make an effective display and at the same time to allow of each flower being individually criticised, was devised by the celebrated Slough firm, and has since been generally adopted; and from being at first exhibited in an apologetic sort of way "not for competition," these single Dahlias in continually improved varieties and with ever-increasing popularity are now found in classes specially devoted to them, the subjects of the keenest contest among all the leading growers. The extension of the competition lately has, of course, greatly augmented the difficulty of judging these classes, and there does not appear to have been any definite statement of the lines upon which judgment should proceed, or of what constitutes a first-rate single Dahlia. The good points of all other florists' flowers are pretty clearly defined, and it seems eminently desirable that the awarding of prizes should not be merely and entirely dependent upon such a very variable quantity as the taste of the judges. In attempting, therefore, to point out the good qualities of the single Dahlia, it may be premised that in the case of many single flowers mere size is not nearly so much a criterion as it is in the case of double flowers. In the latter, whether they be Roses, Dahlias, Zinnias, or what not, there is only one circular outline to consider, and as long as form and colour are maintained there is theoretically no limit to the size of the flower, and practically the larger the better. But in the case of single composite flowers there is a second circular outline, that of the central disc, whose proportion to the outer circle of ray-florets is of great importance to the effective beauty of the flower. The diameter of the disc of an immense number of Compositæ is from one-third to one-fifth of the diameter of the entire inflorescence, that is to say, the length of the outer ray-floret commonly varies from once to twice the diameter of the disc, and while many may be noted in which the disc is far greater in proportion to the ray-florets than this, species that illustrate the converse will hardly be found. Now in Dahlia species the length of the ray-floret is found to be about twice the diameter of the disc, and as the disc of the bulk of single Dahlias is three-quarters of an inch wide, the total diameter of the flower should never exceed 4 inches, in order that the natural proportions of the parts of the flower may be maintained. When single Dahlias about 5 inches across, with a disc of not more than five-eighths of an inch, are seen in gardens, as is unfortunately too often the case, the eye is offended, perhaps unconsciously, by the unnatural proportions of the disc to the ray-floret. In addition to this natural limitation of the diameter of these flowers, the desirability of their being of moderate size is especially observable when they are used as cut flowers, although this may seem a matter of taste—always the unsafest of guides. But it is in the cut state that single Dahlias are most used, and then over-large loose flowers are found to be very impracticable, as they seldom have substance enough to support their length and weight of petal.

Varieties of the Field Poppy (Papaver Rhæas). Engraved from a photograph for The Garden.

Submitting, then, that single Dahlia blooms should not exceed 4 inches in diameter, the next point to establish is perfection of form. The flower should approach as nearly as possible to a perfect circle composed of eight ray-florets, which for convenience may be referred to as petals, and which surround the compact golden central disc. While flowers more or less star-shaped, or having pointed petals, may be desirable for some special colouring or to give

variety, the handsomest flowers undoubtedly are those which have broad rounded petals lying perfectly flat (*i.e.*, at right angles to the stem) or slightly recurved. In any case the petals must overlap from the points of insertion to at least half their length, so that there be no interstices towards the centre of the flower between the petals, which, moreover, must be of good substance (not flimsy), and not in the least cupped or quilled.

For exhibition, single Dahlias are generally arranged in bunches of ten blooms each, with buds and foliage, the latter, of course, has to be added, as Dahlias do not grow foliage on the flower-stems in the decorative way that Roses do. It has been suggested that it might be well to allow the use of other kinds of foliage, as that of the Dahlia is often coarse for use in the cut state and quickly fades; and Asparagus has been found to be enduring as well as very effective for the purpose, but there is always something objectionable in the exhibition of any flowers with foreign foliage. In drawing up schedules, care should be taken to state in the classes for single Dahlias the exact number of blooms to be shown, as when some loose term, such as merely "twelve bunches," is used, the difficulty of judging is greatly increased, and the collective effect of the exhibits greatly impaired by the setting up of bunches of all sizes from three blooms each to twenty.

The flowers should always be cut before the disc is fully developed, as they will then travel without shattering or being disfigured by the shedding of the pollen over the petals. Blooms should be selected that match well in colour and size; fancy flowers especially should be similarly marked, and, if edged, each petal should be clearly margined with the lighter colour. There are now a good many striped and edged varieties, though some of them are not very perfectly formed flowers; but if framers of schedules could see their way to making a separate class for these popular fancy flowers, just as with the double Dahlias (the show and fancy flowers are always separated), no doubt the defect would soon be remedied. At present some of them have pointed or flimsy petals, and are hardly good enough to include amongst the best selfs; yet they are very attractive, and it would be a pity that they should not be seen, when probably a little encouragement would cause raisers to take the pains with them that would ensure improved form in a very short time; for it is well known that at first the double fancy Dahlias were inferior to the show varieties, but the former, through having been separately provided for and encouraged, have now been brought to a state of perfection equal to that of the latter.

In raising seedlings, just as much attention should be paid to the habit of the plant as to the flower. Sometimes among seedling single Dahlias a distinct flower is obtained on a plant with foliage like a Cabbage, or with a habit of growth to which an ordinary lamp-post might be favourably compared with regard to grace and elegance; but in such a case the raiser should not rest until he obtains a similar flower on a plant likely to be of real value in the decoration of the garden. There are many single Dahlias with coarse foliage and rough hairy stems that give the plant a most unrefined appearance, for which there is no excuse, as it is most easy to raise varieties with dark green compact leaves and bright smooth flower-stems. There is a well-known fancy at the present time which, beyond the fact that its flowers are distinct and pleasing in colour, has no claim to consideration as an ornamental garden plant; its flowers are over-large and very rough, and its leaves, which have a wretched half-developed appearance, are, with the flower-stems, of a uniform dyspeptic yellowish green colour. This sort of plant is of no help to the reputation of the single Dahlia, and had much better not be sent out; it is not enough that the flowers be distinct; they must also be of good form and substance, and produced upon plants of sturdy branching habit that have stiff, moderate-sized, deep green leaves and straight wiry flower-stems that are all the better if dark-coloured.

Another point vitally essential in single Dahlias, either as cut flowers or in garden decoration, is, that the flower-stems be stiff enough to maintain the blooms in an upright position either in the vase or on the plant. Weak-necked and pendulous flowers should be studiously guarded against. For instance, beautiful as is the individual blossom of White Queen, it is a most impracticable flower for vases, because without a wire it cannot hold its head up, and, for the same reason, it never makes half the display in the garden that from the size and purity of its flowers might be reasonably expected.

If care be taken to eliminate flowers with this weakness, and there are grown only varieties that are of good habit with elegant foliage, and that have moderate sized flowers of good form and substance, there is little likelihood of the single Dahlia being again allowed to drop out of cultivation. Managers of shows will continue to encourage the singles, as they constitute the most brilliantly decorative part of the cut-flower section at the autumn exhibitions, far eclipsing in their blaze of colour the general effect produced by the doubles, and when the competition in the amateur classes has been brought up to the high level of that witnessed among the nurserymen, framers of schedules who wish to provide an effective *coup d'œil* at their exhibitions will not readily let the singles die. The florists who had evolved from their inner consciousness the globular exhibition double Dahlia seemed inclined at first to regard the revival of the single flower as a mere passing whim of fashion; but there are not wanting indications that the awakened taste of recent years is inclined to look upon the "pure rotundity" as an artistic failure. Certainly for cut flowers the double show Dahlias are singularly ill-adapted, except it be for harvest decorations, when a nail can be driven through them and they can then conveniently be fastened up wherever wanted. Nor in the garden are they as decorative as might have been expected, owing to the coy way in which so many of them hang their heads; and they cannot be said to add much to the picturesqueness of the scene when they refuse to present themselves to view otherwise than upside down. Their cultivators do not seem to multiply, for the difficulty of maintaining the National Dahlia Show appears annually to increase, and but for the attraction of the singles and pompons the exhibition would probably hardly attract the general public.

In fact, the pursuit of form having resulted in the achievement of the most utter formality, a return has been made to the *sancta simplicitas* of the natural flower, which cannot be surpassed for the internal decoration of our houses, in order that if double varieties are to be had for the garden, an entirely fresh start may be made on a new line, to ensure flowers whose duplicity shall be carefully watched, so as to guard against the serious warping of that uprightness of character which should at least enable them boldly to hold their heads up, and, *coûte qui coûte*, look one full in the face. T. W. G.

Crinum giganteum.—I think that the correspondent who describes this handsome South African bulb (p. 260) of your last issue, and says it is not well named, cannot have seen the true C. giganteum, but rather its smaller variety, known as coucinnum, described by me in your current volume (p. 140). The real C. giganteum, as figured on plate 2505 of the 86th volume of the *Botanical Magazine*, is most accurately named, and is a stately plant, with very large flowers, borne on tall footstalks about 3 feet in height.—W. E. Gumbleton.

Persian Ranunculuses.—As the bulb season is now upon us, I should like to put in a plea for these most beautiful flowers, which have, alas! shared too much the neglect to which florists' flowers were exposed during the bedding-out mania. I am aware that they are somewhat capricious, that sometimes—as during the past season—drought is injurious to their well-being, and that great care has to be exercised in taking them up and drying them; but withal, as no flowers can be well cultivated without some trouble, I would try to persuade lovers of their gardens to plant a bed of them, and see whether when these beautifully-formed and variously-coloured flowers—ranging through almost all colours except blue, and having some colours which it is difficult to find in other flowers—are developed, they will not say that their trouble has been amply rewarded. The neglect under which they fell and the death of the only two nurserymen in the kingdom who really cultivated and improved them—Mr. George Lightbody, of Falkirk, and Mr. Tyso, of Wallingford—made it exceedingly difficult to obtain them, but some of the Dutch nurserymen, notably M. A. Roozen, of Haarlem, have given their attention to them and preserved them, and it is now possible to obtain really good and beautiful varieties. They are reasonable, too, in price; a small bed might be first tried, and if success attended the effort, it might be increased. With regard to sorts, probably the best plan would be to leave it in the grower's hands, and if a mixture be made of the Persian and Scotch, the latter of which are mostly edged flowers, a great treat may be looked for. I had such a lot from Haarlem, and they were a great delight.—Delta.

French Pompon Zinnias.—Your estimate (p. 270) of the value of these flowers is correct; they are invaluable for any garden in which annuals are grown. My belief, however, is that the double Zinnia is distinct from Z. elegans, and a native of India. The seed is distinct, and any single flowers that it may produce are distinguishable at once by the experienced eye from those of the usual single Z. elegans. Some thirty years ago I had seed of the double Zinnia sent to me from India, and I neglected to grow it, having no great opinion of it; but on testing it, in 1858, I found it to produce most beautiful flowers, equal to those of any small Dahlia both in form and colour. The same year, while travelling in the south of France, I found that a retired French officer had brought from Pondicherry a similar strain, but his flowers were flat, while mine were pyramidal, there being thus two varieties belonging to the same strain. In 1859 both these varieties were put into commerce, one by a French the other by an English house. For the intermingling that subsequently has occurred, of course, I cannot account. When the late M. F. A. Haage, of Erfurt, showed me the first plants that he had grown from seed received from Mexico of the sort called Zinnia Haageana, we both agreed that it was doubtful if it was a Zinnia at all. I am still of opinion that it is more of a Tagetes than a Zinnia, and that it should be called T. mexicana. For Zinnias, rich soil and free drainage are needed.—S. A.

SHORT NOTES.—FLOWER.

Chrysanthemums (*W. F.*).—Pretty; but not in a condition to enable us to speak with certainty as to their merits.

Seedling Dahlia (*J. Roberts*).—A pretty sort, different from any we have seen; the white ground flaked and striped with delicate pink is an unusual combination of colours. If good in habit, it will be an acquisition.

Crinum Powellii.—In connection with "Veronica's" note on this Crinum (p. 239), I may state that a bulb given me by a horticultural friend, planted last November in an open part of our wood garden at Oakwood, Wisley, and not having any protection, has lately bloomed beautifully.—George F. Wilson, *Heatherbank, Weybridge Heath.*

GOOD ANNUALS.

There is but little doubt that annuals, especially the hardy kinds, do not get all the attention they deserve. Under really good culture there are few things more showy than the best of them. Their comparatively fugacious nature is rather against their liberal employment, but this defect may be minimised by giving them what they need and allowing them plenty of space. I have found that no good results can accrue when the too common let-alone method of culture is adopted. Overcrowding, starvation, and drought are as fatal to them as to any other flowering plant. From the time they appear above the soil they need looking to. The common practice—and this is not bad in itself—is to sow thickly, but this safeguard against scarcity of material contains the germ of almost complete failure. Annuals grow away so quickly, that if they are not thinned out as soon as they get a couple of pairs of leaves they are sure to grow into one another, and be charged with an element of debility which declares itself later on in diminished robustness and lessened powers of endurance in a time of drought. Annuals do not want ground so rich as we give Cabbages, but they should have plenty of nourishment at command, and some of this should be down tolerably deep in the soil. Give a robust-growing annual, such as Godetia Lady Albemarle and Clarkia pulchella, a square foot or more of space with plenty of food, and you will get specimens 2½ feet high bearing hundreds of good blooms and clothed down to the soil with handsome leafage. However much an annual may run to leaf for a time, it will be sure to finish up well if it has room to extend, but cramped and with the roots in the enjoyment of an abundance of food the plants become choked. I have had Godetias with stems 3 feet high and as thick as a fishing-rod; nothing could be handsomer, and they grew in ground which was very rich in nitrogenous matter. Some kinds require timely support, and those of branching habit, such as Clarkia and Collinsia, are best sustained by twiggy Birch inserted among the branches before they are much developed. "Delta" has given in a recent number of The Garden a list of good annuals which I desire to supplement with the following:—

Sunflowers.—I mention these first because they stand at the present time in the very foremost rank of popularity. In this respect they have probably attained their zenith, and I never remember to have seen so many Sunflowers grown as this year. Their showy flowers are to be seen in almost every garden, and if they are somewhat coarse and gaudy, they are wonderfully effective and cheerful-looking. The finest of this family, beyond doubt, is that called Sutton's Double, which seems to be a selection from the better-known globulus fistulosus, itself very handsome. Sutton's Double is, however, in all respects a fine flower, surpassing it in colour, habit, and form. The flowers are semi-spherical, bright yellow, with a suspicion of crimson; the florets are very thickly set and are beautifully quilled. The habit is dwarfer, more spreading, and leafier than fistulosus, forming a broad-topped mass of leaves, from which a dozen or more large blooms are thrown out in a somewhat pendulous manner. The most beautiful phase in the blooming of this Sunflower is that which immediately precedes perfect expansion. The inner florets form a disc, having at a slight distance off the appearance of a crimson ring—a charming, but harmonious contrast. In this Sunflower the exceptional beauty and fine form of the blooms almost obliterate coarseness, and make one regard it as a choice garden flower. Everyone who sees it for the first time yields it an ungrudging and involuntary meed of admiration. Oscar Wilde is an acquisition, and is another step towards refinement. The description with it was "dwarf and distinct in colour;" it is neither one nor the other, its merits lying in other characteristics, none the less charming, however. I sowed the seed near some Currant bushes, in ground which has known no manure for years, and which was dust-dry for a month or two. In spite thereof Oscar has proved to be of grenadier dimensions. The flowers are, however, quite under the usual single Sunflower standard, but in form they are a great improvement. This consists in a reduction of the disc with a corresponding increase of length of floret, so the blooms have a lighter and more graceful appearance. It also seems a perpetual flowerer, as plants which are ripening seeds are still forming buds. It may be fitly described as a perpetual blooming annual Sunflower, the continuous flowering nature of which would doubtless be accentuated by liberal culture. For harvest festival decoration it ought to be welcome. The novelty of the Sunflower season is the Miniature, much lauded by leading seedsmen. It is to fill a void by supplying from seed a small-flowered kind for cutting similar to the perennial kinds which do not ripen seeds with us. I am disappointed with it. The flowers are not so very small and they are ragged looking, but I will not pronounce positively on its merits, as my seeds were sown in winter, and the tardy blooming nature of the Sunflower points to the necessity of sowing in warmth. The appearance of this miniature Sunflower puzzles me; the foliage is woolly, the plants branch to the ground, and this, in conjunction with the reluctance to bloom till the approach of autumn, would almost indicate hybrid origin. There is no mistake about its floriferousness, and it would probably impress more were it covered from the base upwards with bloom. With me in poor soil it has attained a height of 8 feet, so that its Lilliputian nature is confined to the flowers.

Erysimum Perofskianum.—Here we have an old inhabitant and the earliest, brightest, and one of the best of hardy annuals. In colour it is unique, and sown in September and allowed to remain in peace, it forms a glowing mass of chrome-orange, which glows in an April sun and lights up a garden with beauty. If you want a dazzling effect and wish to forestall the glories of summer, scatter a handful of seeds early in the harvest-moon month at the foot of a sunny wall. You may sow them as near to it as you like, for this annual is of Wallflower nature, and delighteth in the companionship of bricks and mortar. I never saw it on a wall, but I have no doubt as to its ability to crown such a place with a golden garland.

Dwarf Marigolds.—The French call the common Marigold (Calendula), which covers the fields in Normandy as the Corn Marigold does in many parts of this country, Sans Souci (without care), because it bears itself so bravely through climatal changes such as banish the brightness from so many flowers. Through parching heat and battering rains the Marigold retains its joyous look; it expands its first flowers in a March sun and witnesses Sol's dying gleam at the close of the autumn. No matter how dry and poor the soil, the Marigold will flourish there, and year after year it comes without aid from the seed-sower, the younger generation of seedlings hybernating in sheltered spots with buds in embryo ready to open as soon as the sun comes round again to visit them. It is, perhaps, in those dismal periods of wet weather, all the more depressing because we know that summer at its best is but short, that Marigolds distinguish themselves. I have been in gardens of tolerably pretentious character which at such a time owed their brightness principally to Marigolds. And this brings me to mention a dwarf strain of French Marigold that I have grown lately, and the merits of which are great, especially from the bedding-out standpoint. For a long time I have not seen a garden flower that pleased me so much. When finely grown the plants form compact tufty masses so charged with flowers that they look all bloom. The whole of the plant does not exceed 6 inches high, although the flowers are well thrown up above the foliage. They are not quite what the florist requires as regards form and symmetry, but they have that which is more delightful, *i.e.*, richness and brightness of colour. For bordering small beds on the Grass or forming rows where ribbon bordering is in vogue, this Marigold can scarcely be surpassed. There is a vast difference in strains of French Marigolds, the inferior ones being weedy-looking, whilst in the flowers the colours run together and the form is bad. In the best strains these defects, which cause many to regard this worthy flower with something akin to contempt, are replaced by symmetry, richness of colour, distinctness of marking, whilst the height does not exceed 1 foot. It therefore behoves all who wish to grow Marigolds to secure a good strain.

White Clarkia pulchella.—This is rarer in cultivation than the typical rosy form, differing from it in colour only. It is a good white flower and useful for cutting, having lightness and elegance of form to recommend it. Sown in September, and again at intervals through April and May, it is found of great service where white flowers are needed.

Double Sanvitalia procumbens.—This is a gem among annuals, its exceptional worth being most distinguishable at the tail end of the season. It is so entirely free from the charge of fugaciousness, that the season scarcely seems long enough for it; and I have often wondered how long it remains in bloom in a natural state. It is one of the freshest-looking plants imaginable, forming a spreading mass of rather pale green foliage, thickly studded with glowing little black-eyed, golden, button-like blooms, which hold on to life and freshness through heat, drought, and battering rains in a most remarkable manner. A curious feature of this plant is the way in which it retains the elasticity of youth. Whilst extending in the usual manner, new growths continually push up from the woody portion of the stems near the collar, thus guaranteeing against exhaustion. The height of this annual does not exceed 6 inches, so that it is an admirable subject for forming the borders to beds. This is either hardy or half-hardy as one likes to treat it. The seeds may be sown in the open ground early in April, or they may be sown in a cold frame or in warmth. The latter way is preferable, as the seeds do not germinate readily unless they get the stimulating influence of warmth. Heat at sowing time also gives precocity of bloom, the difference in the time of flowering between plants raised quite cool and those brought on in warmth being quite a month.

Malope grandiflora.—This is a true Mallow in habit, and although somewhat coarse in this respect, the rich brilliancy of the blooms compensates for this defect. It is not a plant for small beds, but has a fine appearance massed in the mixed border. It bears drought well, and is suitable for poor porous soils.

Leptosiphons.—There could not be a greater contrast than that between these and the foregoing. They are the neatest-habited of all annuals, and they are as distinct as they are beautiful. Whoever sows them in spring will, however, be disappointed; they seem to need the firmer root-hold that autumn sowing gives them. Sown early in September, they form neat little tufty masses of Heath-like foliage, from which the flowers project on long filament-like tubes. I do not know which is the prettiest, the golden-hued aureus or the bright coloured roseus, but both are worthy of good attention. To do them justice they should be grown in good sized patches, and if in a somewhat elevated situation, their distinctness and beauty will be better appreciated.

Portulacas.—As they glow in the bright sunshine, what can exceed Portulacas in brilliancy and beauty? They cover the ground with a dense cushion of foliage but a few inches in height, and are seen at their best when forming a tolerably broad, straight edging, where their beauty and brightness fall directly under the eye. The seeds may be sown outdoors, but they are worthy of more care, and if strong plants are put out in May, they soon yield a good measure of effectiveness. I recommend Portulacas to those who have parching soils to deal with, as they mind drought less than most plants. They rejoice in the sunshine, of which they never get too much.

Dwarf Nasturtiums.—There are now a goodly number of these, the merits of which cannot be too strongly emphasised. They are a host in themselves, and those who have comparatively little room for wintering bedding plants will find them of great service, as they flower so continuously and freely through the summer and early autumn if frost is merciful at that time. Sown outside, they will do well enough, but they should not be committed to the soil before mid-April, as the seeds are apt to rot in the cold, damp ground, and the nipping easterly blast and rhimy frost is apt to play havoc with the tender foliage if they appear above ground ere flowering May is with us.

Cosmidium Burridgianum is not much grown, and can scarcely be classed among showy annuals. The flowers are much in the way of those of the Coreopsis, but there is more reddish brown than yellow in them. I think those who need cut flowers would find this annual useful, as the flowers are poised on long, very slender, but strong footstalks, which give it a graceful appearance. It has much-divided, dark-hued foliage, and grows 1½ feet high.

Whitlavia grandiflora.—Quite a charming plant, lowly of growth and distinct, the flowers having a marked resemblance to those of the Gloxinia. It is not brilliant, but bears looking into, and is really meritorious as affording variety.

Byfleet. J. Cornhill.

TREE ROOTS IN FLOWER BORDERS.

"H. R. C." may rest assured that if he plants a Yew hedge as a back row to his herbaceous border 8 feet wide, the Yews will appropriate the best of the border to themselves, and will grow too strongly by far and thrive too luxuriantly at the expense of his herbaceous plants. Various expedients might be adopted to check the Yew and protect the border from its encroachment, that is, if it is really worth while to post a Yew hedge there at all. It seems hardly worth while to plant Yews to reach a height of only 3 feet, as there are plenty of herbaceous plants to reach or exceed that height. Dahlias or Hollyhocks, for example, will form a temporary hedge or shelter much higher than 3 feet. But it seems a pity to have any hedge or back at all for such a border. The lawn in front and the gravel walk behind are both admirably adapted for access to the border for cultural purposes or enjoyment. They suggest the desirability of forming the herbaceous border highest in the middle, and making it face the lawn on one side and the gravel walk on the other. This arrangement would get rid of the necessity for any Yew or other hedge at the back, and afford a ready access to the border from the gravel walk in wet weather. If a hedge is merely wanted for shelter, why not put it on the opposite side of the gravel walk from the border? This would interpose the entire width of the walk between the roots of the Yew and those of the herbaceous plants in the border, and if the walk were 4 feet, 6 feet, or 8 feet wide, practically the herbaceous plants would be safe from the intrusion of the Yew roots. Or if the Yew must be planted at the back of the border, then a concrete or brick wall should be run down to a depth of 2 feet or 3 feet to shut out the roots from the flowering plants. To plant Yews at the back, as proposed, would be to invite failure from the roots of the Yews. The injury from slugs, &c., would not be great, as the Yew is so dry at the roots, and its dead leaves are too sharp and by no means genial for slugs, snails, grubs, or worms. But why plant Yews when a hedge of Roses, Clematis, or a rich mixture of Sweet Peas and Canary Creeper would be so much more beautiful, and injure but little or not at all the choice herbaceous plants in the border? D. T. F.

—— "H. R. C." had better keep the Yew hedge a long way from his herbaceous border, or the Yew roots will soon monopolise the soil, and then flowers need scarcely be looked for. I have such a border myself close to a Holly hedge, and the Hollies luxuriate at the expense of the herbaceous plants. I have frequently pointed out in The Garden the danger of tree roots penetrating borders; such a hedge, too, harbours slugs, snails, and other vermin; even shell snails are in this part a perfect pest; to try to keep plants in a border by the side of a hedge is labour lost. I find that the common white Lily in such positions gets so often defoliated as to soon kill the bulbs. How these shell snails find any plant to which they are partial it is surprising, and the way in which they clear off the leaves of any plant which they attack would hardly be credited in places where they are scarce. Blackbirds and thrushes are the best snail destroyers; the way in which they hunt them out and crack their shells against a stone, needs to be seen to be realised. My advice is, don't have the Yew hedge at all; some climbing Roses on a trellis would be far better.—J. G., *Hants.*

Verbena venosa.—"J. G." (p. 243) does well to call attention anew to this valuable plant, which is one of the most useful for cutting as well as for decoration of beds or borders. It is hardy on warm sites and light soils and thrives best in such, left undisturbed, for years. It seldom thrives on heavy, wet, or cold soils, however much it may be coaxed or petted. As to pegging down, it looks best left to its natural habit of spreading and blooming at a height of a foot or so. When used alone it should be planted pretty thickly, and, in addition to the mode of propagation and culture described by "J. G.," it is raised freely from seeds sown in heat in February, and fostered into nice healthy plants for putting out about the middle or end of May. But one of the most effective modes of utilising to the full the colour and habit of this choice species of Verbena, quite unlike all the others now, alas! becoming so rare, is to plant it alternately, or pincushion style, with Mangles' pink variegated Pelargonium, and thus enjoy the shot-silk bed first invented and eulogised by the late Donald Beaton at Shrubland Park, near Ipswich, and still, I believe, repeated annually in those fine gardens. The Verbena venosa used to grow and run almost like Couch Grass in the warm soil at Shrubland, and took such full possession of the shot-silk beds at one time as almost to starve the Pelargoniums out of the beautiful combination. —D. T. F.

Crocus karduchorum (Kotschy).—I have at last obtained corms of this species—which has heretofore been only known by a few dried specimens scattered through European herbaria—collected by Theo. Kotschy, on the 27th of September, 1859, on a mountainous ridge between Mükûs and Scherwan, in Kurdistan. The corms I have recently flowered were sent me last autumn by the Rev. A. H. Hubbard, American missionary of Sivas, Asia Minor, but whether they were obtained near Sivas, or from the locality far to the east where Kotschy discovered the species, I have not yet been able to ascertain. The figure in my "Monograph of the Genus Crocus" (plate 5), which was drawn from Kotschy's herbarium specimens, fairly represents the plant, except that in colour the fresh flowers are a little bluer in tint, and each segment veined with about nine fine purple lines, extending half way up the segment, which were not visible in the faded dry specimen. C. karduchorum somewhat resembles C. zonatus of Gay, but the flowers are smaller, and instead of the bright golden zone at the base of the inner surface of the segments above the throat, two small orange spots occur, similar to those in C. vallicola of Herbert. In Kotschy's specimens preserved in the Vienna Herbarium the leaves pertaining to the previous vernal growth were preserved up to the flowering time in September, two years' sets of leaves, one dormant within the sheathing leaves, being present at the flowering time. This occurs in only one other species, C. Scharojani, of Ruprecht. —George Maw, F.L.S., *Benthall, Kenley, Surrey.*

FERNS.

FERNS FOR BRACKETS.

The majority of the plants included in this enumeration are epiphytal, and have stout creeping rhizomes. They grow naturally upon the branches of trees or in the crevices of almost perpendicular rocks, where shade and moisture abound. They therefore thrive best and display their beauties to the greatest advantage when their treatment under cultivation resembles as much as possible that which Nature provides for them. Positions to suit them can easily be found in a house built expressly for Ferns. But where rockwork and other conveniences do not exist, the next best course is to place them in pockets constructed with cork or some good durable material, and hang them upon a wall, or plant them in large shallow pots, and place these upon elevated brackets at such heights as will enable them to display their proper character in the most effective manner. As plants placed in the positions here indicated may be looked upon in the light of permanent fixtures, and are therefore not likely to be subjected to frequent repotting, the drainage should be so arranged as to obviate the necessity for readjustment. The compost for these plants should consist of rough fibrous peat, some chopped Sphagnum Moss, good turfy loam, and some sharp sand. This should be well incorporated, but by no means reduced to fine mould. The follow

Platycerium Willinckii.

ing selection will be found to contain some of the finest and most distinct kinds for brackets :—

Platycerium grande.—This is one of the best Ferns to use in the manner here recommended. The sterile fronds, or shields as they are popularly called, are erect and permanent, the lower edges being round and smooth, whilst the upper edge is deeply divided or forked. These shields are some 2 feet or more in height and as much in breadth ; they overlap each other, and tightly clasp whatever they are planted upon. Therefore, in order to produce the best effect, a broad surface should be placed behind the plant when in a young state. The fertile fronds rise from about the centre of the shields and stand out at right angles, their ends being pendent ; they are about 2 feet in length, much branched, and bear a large patch of dark brown sori on the under side just where the frond first begins to fork. The whole plant is pale green, but is densely clothed with white stellate scales, which give it a peculiar hoary appearance, a feature common more or less to all the species. It requires stove heat in winter, but will thrive without fire heat in summer. It is found throughout the Malay Islands and various parts of Australia.

P. alcicorne.—The shields of the normal form of this species are somewhat small, erect, and usually die annually, but are persistent, the young shields overlapping them. The fertile fronds are from 1 foot to 2 feet long, much forked at the ends, bearing large patches of brown sori on the extremities of the lobes. Of late years several distinct forms of this species have been introduced to our gardens which differ from others in cultivation, mostly in being of greater size ; the most desirable amongst them are P. alcicorne majus and P. Hilli. P. alcicorne is a cool house plant, with a wide range of habitat, being found in Java, the Malay Islands, and in various parts of Australia.

P. stemmaria.—This is a warm house plant, and one which produces large, erect shields, from 1 foot to 2 feet in height. These die annually, becoming chestnut-brown, and are overlapped by the young green fronds in spring. The fertile fronds are about twice divided, the sori being borne in large patches on the under-sides of the extreme tips of the last forkings of the lobes. These fronds do not die annually, but are more persistent than the shields. This species rapidly forms a large mass, throwing out suckers or young plants from its roots. It appears to be confined to Western Africa, where it occurs plentifully.

P. biforme.—The shields of this species are not persistent, but the long, much-branched fertile fronds are. The large mass of sori is borne upon stalked, somewhat kidney-shaped lobes—a distinctive trait in this species. The long, drooping fronds, with their narrow segments, are similar to those of the next species; but the peculiar manner in which the fructification is borne renders it not only distinct from that plant, but also from any other belonging to the genus. It comes from Borneo, and is a warm house plant.

P. Willinckii.—This very handsome plant is of somewhat recent introduction, and very distinct in character. It produces young plants from the roots, and thus rapidly forms a large mass. The sterile fronds are overlapping and erect, and deeply lobed on the upper edge. The fertile fronds, which are mostly in threes, grow from 2 feet to 3 feet, and, as will be seen, are much forked and divided into ribbon-like lobes, on the under-sides of the extremities of which are arranged the sori. It comes from Java, and requires a warm house.

P. Wallichi.—This is a majestic Fern, but one of the rarest of its family. In general outline it resembles P. grande, but differs from it in being much larger in all its parts, and also in the greater and more deeply ramified character of its shields, which arch gracefully. It comes from Borneo, and requires a warm house.

Drynaria coronans.—This and the next species have characters peculiarly their own. Their stout, hairy, creeping stems usually grow in circles, and the fronds, when well developed, form a beautiful crown, which on a projecting ledge of rock or on a large bracket has a fine appearance. The fronds of this plant are deeply pinnatifid, erect, and rigid in texture, their colour being a peculiar blue-green. They grow from 3 feet to 4 feet in height and 18 inches broad. It comes from Malacca, and is a warm house plant.

D. morrillosa.—The creeping roots of this plant are very stout and densely covered with large, deep brown, chaffy scales. The fronds are erect, stiff, and rigid in outline, some 4 feet or more in height and 2 feet in width, the upper portion being deeply divided, the lower part obtusely lobed and bright green. Its peculiar habit renders it very effective. It comes from the Malay Archipelago.

D. quercifolia.—This is a smaller plant than either of the preceding. The fronds are erect and rigid, the fertile ones about, 2 feet long and deeply divided ; the sterile ones stand in front of the others, and somewhat resemble an Oak leaf in appearance. It is widely distributed throughout the islands of the Indian Archipelago.

D. musæfolia.—This has plain, simple, erect fronds about 2 feet high and between 2 inches and 3 inches wide. The great charm of this species lies in the variegation of its fronds, as seen when above the eyes with the light shining through them. Their colour is a peculiar whitish green, and the numerous netted veins are blackish green. It comes from the Indian Archipelago.

D. diversifolia.—This is a grand plant for draping the face of a rock. As its name implies, the fronds differ amongst themselves in character. The fertile ones are pinnate and pendulous, from 2 feet to 4 feet long and bright green, with little membranes on the upper side. The shield-like barren fronds are about 4 inches high, erect, rounded at the base, and deeply incised on the upper edges. It is a native of the East Indian Islands.

Aglaomorpha Meyeniana.—This when infertile has much the habit and appearance of Drynaria coronans, but when in its fruiting condition, the pinnules of the upper portion of the fronds are contracted into linear segments bearing dark brown sori. It is a native of Luzon.

Tænitis blechnoides.—A rare plant, with pinnate fronds, which reach a height of from 1 foot to 18 inches. The pinnæ are arranged in from three to five pairs, with a terminal one. These pinnæ are from 6 inches to 9 inches long, narrow, and taper to a sharp point. The colour is deep green, and the under side is ornamented with two rows of dark brown sori, running parallel with and near to the mid-rib. In the plant called T. intramarginalis, and which is, perhaps, only a variety of T. blechnoides, the continuous rows of sori are near the margins of the fronds instead of close to the mid-rib. It comes from the Philippine and Fiji Islands, and requires stove heat.

Dicranoglossum furcatum.—This should occupy the crevice of a rock, or should be placed in a pocket about level with the eye, as it is not a large growing kind, and if removed far from the line of vision, its distinctive character is lost. The fronds range from 6 inches to 1 foot in length, and are much forked or divided into long, narrow, bright green segments, which are contracted near the upper half, where they bear a continuous line of nearly marginal sori. It is a native of Trinidad and various West Indian Islands, and requires a warm house.

Antrophyum lanceolatum. — This has simple fronds, from 6 inches to 18 inches long and from a quarter of an inch to half an inch wide, tapering at both ends. They are deep green above, and ornamented beneath with netted sori. It comes from the West Indian Islands.

A. coriaceum.—This has fronds from 12 inches to 18 inches long and nearly 2 inches wide, tapering at each end. They are bright green on the upper side, their bright red netted lines of sori being very conspicuous. It comes from Ceylon and various Indian Islands.

A. Mannianum.—This is a distinct and handsome plant, but, unfortunately, rare in cultivation. Its footstalks, which are slender and some 6 inches in length, bear fronds somewhat rhomboid in shape, lengthened out into tail-like points. These are about 6 inches long and 4 inches wide in their broadest part. In colour they are bright olive-green, the underside being netted with red veins. It is a mountain plant, having been found in Fernando Po at an elevation of 3000 feet.

Ophioglossum pendulum.—Those who know this genus only by the common Adder's-tongue of our meadows (O. vulgatum) will be surprised to find that this plant makes fronds from 1 foot to 6 feet or more long and about 1 inch wide, and that these fronds decorate trees as with strips of green ribbon. In our Fern houses it thrives well in pockets, its pendent, ribbon-like drapery contrasting strikingly with the finely-divided fronds of other Ferns. It is widely distributed, being found in Ceylon, Madagascar, Australia, and other places.

Polybotrya osmundacea.—The Polybotryas are large-growing Ferns with stout, woody, creeping stems and broad, much-divided fronds, the barren and fertile forms of which are dissimilar. The former have much the appearance of those of a large Polystichum, whilst the fertile ones have the divisions all much contracted and wholly covered with sporangia, which give them the appearance of elegant plumes. P. acuminata and P. caudata are also handsome Ferns of somewhat similar aspect, all of which display their beauties to the greatest advantage when placed on brackets. All are natives of Tropical America.

Phymatodes.—This family comprises many kinds of noble port. Their large and broad fronds are divided nearly to the midrib, the large impressed sori forming raised protuberances on the upper surface, a circumstance which adds much to their beauty. A few of the best are P. peltidea, P. nigrescens, P. longipes, P. incurvata, P. leiorhiza, P. glauca, and P. longissima. All these are natives of the tropics of the eastern hemisphere. W. H. G.

Garden Destroyers.

NO WASPS.

One envies your correspondents up and down the country who record the scarcity of wasps. A writer from near Tunbridge Wells asserts that he has not seen a wasp for some months, nor heard of a nest. Happy mortal ! We have any number here, and they have just cleared out our Warrington Gooseberries, leaving the empty husks as a present to us for our trouble in growing and netting them. They are now, and have been for some time, busy devouring Plums, Peaches, Grapes, Pears, and all other sweet morsels they can find, not omitting the sugar-basin, which we have had to cover up when enjoying the cup that cheers, but does not inebriate, a precaution I never remember to have been needful till this year. Our bottles on the fruit walls have also been filled with wasps, hornets, and bluebottles much as usual, and up to this date we have destroyed fifty wasps' nests, and shall probably find ten or a dozen more. Since north-east winds have set in, fewer wasps have been visible, but possibly a few warm days will bring our old enemies back again, as they mostly linger in the garden so long as there is anything to devour, and then adjourn to the vineries unless these are securely barricaded with wasp-proof netting or bunting. Plentiful as wasps have been, however, they have been nothing to the pest of bluebottle flies, which reached the dimensions of a practical plague this year. They have literally swarmed in the garden and in our homes, and have helped themselves in the most raveneus manner to every sweet and savoury morsel within their reach. We have caught pecks of them in bottles baited with beer; and it is to be hoped that their reign over the fruit is almost over, as the north-east wind renders them sluggish. —D. T. F.

—— In spring an unusual number of queen wasps made their appearance ; in fact, I killed as many as half-a-dozen in one forcing-house in one day, and I anticipated an unusually prolific wasp season. Whether they all perished through the winter being prolonged so far into spring or not I cannot say, but there has not up to the present

time been a single wasp seen in this neighbourhood, so far as I can hear. I cannot furnish any accurate returns respecting scarce or plentiful wasp years, but I think if a record could be kept it would be found that in seasons when they have put in such a plentiful appearance in spring they have been correspondingly scarce in summer, and *vice versâ*. My own impression is that when we get unusually fine, spring-like weather very early in the year, the wasps awake from their slumbers, and get killed by a return of wintry weather.—James Groom, *Gosport*.

*** Mr. Gumbleton, who writes from Belgrove, Queenstown, Co. Cork, says, "We have had, I am happy to say, no wasps at all here this summer."—Ed.

Societies.

ROYAL HORTICULTURAL.

September 21.

A bright gathering of autumn flowers filled the conservatory at South Kensington on Tuesday last, most conspicuous amongst them being Dahlias, Roses, and Gladioli. A few interesting new plants were placed before the committee, who were also liberal in bestowing certificates on Dahlias.

First-class certificates were awarded to—

Cypripedium Sanderianum.—A remarkable new Lady's Slipper belonging to what may be termed the long-tailed section. It comes from the eastern tropics, and has affinity with C. lævigatum and Robelini, although it is quite different from any other hitherto introduced. The flowers are about the same size as those of C. lævigatum, of a reddish brown colour, mottled with lighter and darker tints, while the sepals in well-developed specimens measure over a foot in length. The specimen shown was from Messrs. Veitch, of Chelsea, but it bore but one flower; whereas the first specimen flowered in this country bore three, and dried specimens show even half-a-dozen on a spike.

Cespedesia discolor.—A noble-leaved plant, reminding one of a Theophrasta. It has long and broad foliage of thick texture, the young leaves having a beautiful bronzy tinge. It is presumably a tropical shrub of new introduction. Shown by Mr. W. Bull, Chelsea.

Selaginella tessellata.—An elegant species with broad fronds finely divided, and of a cheerful green. From Mr. W. Bull.

Rhododendron Rose Perfection and Queen of the Yellows.—Both seedling varieties of the Javanese race. The former has flowers of a delicate rose, those of the latter being of a bright yellow. The flowers of both are large and of fine form. Shown by the raisers, Messrs. J. Veitch and Sons.

Selaginella gracilis.—A beautiful new species with long spreading fronds of a bright green. From Messrs. Veitch.

Ulmus Piteursi pendula.—A graceful variety of weeping Elm, having large leaves so deeply toothed as to appear lobed. It is presumably a form of U. montana, and if quite hardy will prove a great acquisition. Shown by Messrs. Paul and Son, Cheshunt.

Crataegus Pyracantha Lelandi.—A variety of the Pyracantha Thorn remarkable for its extreme fruitfulness, even when in a small state. Some half-dozen specimens, shown by Messrs. Veitch, of Chelsea, were literally covered with bright orange-scarlet berries.

Dahlia Empress of India.—A so-called decorative variety with double flowers, in form resembling the Cactus Dahlia. The colour is a rich claret-purple streaked with red. It appears to be a double form of the well-known Paragon, and is one of the most beautiful and distinct that have been shown. Exhibited by Mr. R. H. Munday.

Dahlia The Quair.—A single variety with large flowers having broad florets elegantly reflexed and of a deep crimson. From Messrs. Paul, Cheshunt.

Dahlia Queen of the Belgians.—A show variety reminding one of another called Mrs. Gladstone, but while it possesses the large size and perfect form of that sort, it is of a deep tinge of pink. Shown by Messrs. Rawlings, Romford.

Dahlia Mrs. Foster.—A fine show variety of a salmon-pink colour; size and shape perfect. From Mr. C. Turner, Slough.

Dahlia Cochineal.—A double decorative variety, of a vivid crimson. Said to be of good habit and very floriferous. From Mr. T. S. Ware, Tottenham.

Dahlia Charming Bride.—A single variety with large flowers perfectly shaped, and of a charming pale pink colour. From Messrs. Cannell, Swanley.

Dahlia Valentine Humphries.—A fancy variety with large perfectly shaped flowers of a salmon-pink ground, streaked and striped with crimson. Shown by Mr. G. Humphries, Chippenham.

Dahlia Lady Marsham.—A single variety of a pleasing bright scarlet colour, flowers large, florets broad and of firm texture. From Messrs. Cannell.

Dahlias (Pompon) Gazelle, magenta tipped; Iolanthe, fawn and yellow; Don Juan, deep blush-pink. All first-rate sorts. Shown by Mr. C. Turner, Slough.

Davallia solida major.—A large and vigorous growing form of one of the well-known Hare's-foot Ferns. It has broad, deep green fronds of thick texture and massive in appearance. Shown by Mr. Bull.

Cyrtanthus hybridus roseus.—A variety of a beautiful hybrid bulb, raised between Vallota purpurea and Gastronema sanguineum. The colour is a deep rose, much darker than that of the original. Shown by Sir Trevor Lawrence, Burford Lodge, Dorking.

There was again a large display of hardy flowers, and to these chiefly the show owed its brightness. Mr. Ware had a large collection, consisting chiefly of Dahlias, among which the old sort called picta formosissima was conspicuous. It is not a florist's flower, but the combination of colours, yellow and bright scarlet, renders it very attractive. There was a great gathering also of the crimson Cochineal and Mrs. Hawkins, the latter reminding one of Marie Van Houtte Rose. The Iceland Poppies were also shown well by Mr. Ware, as they have been every week since June. Messrs. Paul, of Cheshunt, had also a large show of hardy flowers, Dahlias, and specimens of hardy ornamental trees—Senecio pulcher, Kniphofia corallina, Veronica subsessilis, and the golden Montbretia crocosmæflora aurea being the most prominent. Viola Wellsiana, the new early-flowering Violet, was shown by Messrs. Paul. It is almost as large as The Czar and deliciously scented. Messrs. W. Paul, of Waltham Cross, showed a large gathering of autumn Roses, numbering many sorts, the most noteworthy for freshness being Marie Van Houtte, W. A. Richardson, Etendard de Jeanne d'Arc, Sunset, Mad. Cusin, Boule de Neige, Catherine Mermet, and the new Mad. de Watteville. Messrs. Kelway, of Langport, again sent a large collection of Gladioli, not, however, so fine as at previous exhibitions, but very good spikes, considering the late date. Dahlias were plentifully shown by the leading growers about London; Messrs. Rawlings, of Romford, had a large display of new sorts, chiefly show kinds, as did also Messrs. Cannell, of Swanley, whose Cactus varieties were much admired. Messrs. Turner's bouquet varieties and the singles from Messrs. Paul and Ware made a brilliant show. Among miscellaneous plants were the following: Cattleya Gaskelliana Sunray, from Dr. Duke, Lewisham. It is remarkable for the streak of magenta colour in the sepals, like as in C. Trianæ Backhousiana. Mr. Measures, of Cambridge Lodge, Camberwell, showed a finely flowered plant of Grammatophyllum Ellisi, and a cultural commendation was awarded to his gardener (Mr. Simpkins). Mr. Bull showed some new plants, including Pancratium guianense, Palicourea jugosa, Maranta eminens, and Aristolochia elegans. Among Messrs. Veitch's new plants were Curcuma sumatrana and Trevisia palmata, a plant resembling an Aralia, with palmate leaves. Mr. Ford, Leonardslee, sent specimens of the blue Hydrangea; and Mr. Boyce, Highgate, sent a new early bright yellow Chrysanthemum named Golden Fleece.

Fruit.—Two large collections of Apples were shown, one from Messrs. Paul, of Cheshunt, the other from Messrs. Paul, Waltham Cross. Both represented a selection of the best sorts, but the size and colour this season seem inferior. Messrs. Lane, Berkhampstead, had a group of pot Vines, Black Hamburgh, Alicante, Foster's Seedling, and Gros Colmar, all laden with bunches quite up to the usual standard of excellence. Mr. Laxton, Bedford, sent specimens of the Dartmouth Crab Apple, a small pretty fruit, also samples of his huge Czar Runner Beans and Sandy Prize Onions. Mr. Roupell showed some excellent examples of Madresfield Court Grape and Fertility Pear in pots. Clapp's Favourite Pear from a pyramid tree on Quince was shown by Messrs. Veitch, and Mr. Burnett, Deepdene, showed the Tyson Pear and Raspberry Belle de Fontenay. Mr. Smith, Yalding, sent some fine fruits of Peach Prince of Wales, and Mr. Baines showed some heavily laden fruit branches of the Parsley-leaved Blackberry. Mr. Gilbert, Burghley, again showed a fruit of Her Ladyship Melon, green fleshed, which was considered of good flavour. Some very fine Navel Oranges came from New South Wales, which were highly commended.

New Zealand edible fungi.—In addition to the information given by "W. G. S." (p. 260) perhaps "T. V." may like to have the following references to Hirneola polytricha, which is shipped in large quantities to China as an article of food. An interesting account from Consul Griffin's report is printed in the *Journal of the Society of Arts*, Feb. 24, 1882, p. 399, which has been reprinted in the *Pharmaceutical Journal* for April 22, 1882, p. 866.—John R. Jackson, Curator, *Museums, Royal Gardens, Kew*.

Bouvardias in summer.—Though Bouvardias are generally regarded as winter flowering plants, and, as such, are greatly valued, they will, if grown for the purpose, bloom during the summer; indeed, if required, they can be had anywhere throughout the year. Where cut flowers are a good deal in demand, their chaste and delicate blooms are very welcome, even in the summer, as they can be used in the more select arrangements, such as button-holes, sprays, and similar purposes. As some old stock plants are generally left on hand, a good way to utilise them, if it is not intended to grow them on another season, is, after the frosts are over, to plant them out of doors, when they will soon establish themselves, and grow and flower throughout the summer. By this means it is possible to gather a handful of their beautiful flowers at any time—a boon that is justly appreciated by those who carry out this practice. They succeed best where the soil is fairly light, and not dried up during the summer. All the kinds are available for the purpose, but perhaps the most floriferous under this mode of treatment is the vivid coloured triphylla, of which I recently saw some fifty plants arranged in a bed; and, though no trouble was bestowed upon them beyond planting and keeping them clear of weeds, they were completely covered with bloom, and formed such a conspicuous feature as to suggest their use for bedding purposes.—Alpha.

Plague of earwigs.—It is the custom in some parts to gather together a number of the larger or pincer claws of crabs and lobsters, and, placing them on the tops of short sticks about 1 foot high, to plant them wherever these insects are the most troublesome. Every morning the gardener goes round with a pail of boiling water, into which the claws are plunged; and, the little plagues being thus disposed of, the claws are re-set for next day's slaughter.—J. C. W., in *Field*.

Names of plants.—*A. D.*—The Gloxinia flower is not an unusual monstrosity; Fern, Cystopteris bulbifera.—*H. D.*—Scarlet flower, Sophronitis grandiflora; Oncidium pulvinatum.—*J. M.*—The Passiflora flower resembles somewhat P. racemosa cærulea, but the foliage is very distinct.—*W. C. R. T.*—2, Cistus roseus; 3, Diplopappus chrysophyllus; 3, double-flowered Pomegranate.—*C. A. N.*—Sedum altissimum, Polystichum angulare truncatum.—*A. Hoires.*—1, specimen insufficient, send flowers; 2, Origanum Dictamnus.—*W. G.*—Yellow flower, Chrysanthemum segetum; white, Anthemis Cotula.—*E. C. C. D.*—1, Harpalium rigidum; 2, Helianthus giganteus.—*C. P.*—1, Clematis Flammula; 3, Pelargonium quercifolium. We cannot name Fuchsias.—*L. King.*—Pepper Bush, Clethra alnifolia.—*Dr. D.*—1, Scrophularia nodosa variegata; 2, Bocconia cordata; 3, Physostegia imbricata; 4, Solidago Virgaurea; 5, Polygonum cuspidatum.—*A. Wallace.*—Ornithogalum thyrsoides. No name of sender received before this week.

Names of fruits.—*H. W.* (*Roscrea*).—Plum apparently Goliath.—*W. J.*—1, not recognised; 2, Marie Louise; 3, Ashton Town; 4, Duchesse d'Angoulême; 5, Josephine de Malines.—*A. M. A.* (*Batley*).—1, Lord Derby; 2, appears to be Catillac, but is not developed; 2, Hoary Morning; 4, Echlinville.—*G. H.*—1, Pitmaston Duchess; 2, apparently Beurré Diel; 3, Marie Louise; 4, Duchesse d'Angoulême.

WOODS & FORESTS.

SOILS AND SITUATIONS FOR TREES.

The Larch.—The forester, unlike the gardener, is very apt to be influenced in tree planting, solely by his limited experience and the information he may possess regarding the natural habitats of and conditions under which the tree thrives in its native country. He has, as a rule, little else to go by; but it is different with the gardener, who, while he, as far as he can, imitates natural conditions and circumstances of situation, yet deviates very far from both in the culture of many garden plants and trees and succeeds wonderfully. An example of the disadvantage under which the forester labours in this respect may be found in the forestry report in the evidence of one of the most important witnesses, who attributed the Larch disease to our attempting to grow it anywhere but on dry precipitous slopes or hills as nearly resembling the slopes of the Alps as possible. No doubt there are right and wrong situations for this tree, but it has been abundantly shown in this country that the Larch will grow and thrive on very different soils and situations, and both in the valley and on the mountain-side. In its native habitats it is found growing both on plains and mountains, and I doubt if in this country the best Larch timber is not found on the lowlands. There are not any hills in Lincolnshire on which to grow Larch, but it grows there and produces fine timber. I am in the habit of seeing trainloads of Lincolnshire Larch of excellent quality which is delivered at the collieries near here, and which, I understand, is grown, if not in the fens, at least on the level lands adjoining. The parliamentary witness referred to above spoke of the mistakes made by foresters in planting Larch near river banks and in valleys; but the tallest and best Larch for their age we have felled here grew at the very bottom of a valley and at the base of a steep hill close to the river-side. The soil is loam lying on rock, and is pretty well drained by the river, which has worn a rather deep channel close to the spot, but when it overflowed its banks the water inundated the Larch for the time being. They were a tall and very fine lot of trees, running about 90 feet or 100 feet high, and were all sold as "big Larch" for a special purpose. Just on the other side of the river grows the best group of Scotch Fir on the estate under similar conditions. Only the other day a gentleman told me that his new forester had made him very uncomfortable by reporting that his young Larch plantations had all been planted on the wrong kind of soil or subsoil, and that they would fail in consequence, but he left in a better frame of mind on being told that probably his new manager argued from preconceived notions, and did not yet know that some of the best Larch in England grew in the same and the next parish on the very soils he had condemned. I imagine it is the clay bottom above the coal hereabout that has frightened the man from the north; but it is a perfectly good bottom for Larch, provided it is hard clay and dry. If I am not mistaken, the three famous Dunkeld Larches are growing on good deep loam in a flat situation in the park, as unlike the slope of the Alps as well could be. Now that the subject of forestry is awakening attention among landowners, we must beware of rule-of-thumb foresters and their crotchets.

The Ash.—A general impression exists among people that the Ash loves a damp if not a wet soil, but how such an impression ever originated puzzles those who know better. The Ash loves a good, deep, rich soil, provided it is neither too wet nor too dry, but in a wet soil or situation it thrives worst and soonest dies. It goes off in the heart in wet soils and is worthless when felled, the heartwood being often black or as rotten as touchwood. No tree stands exposure better. One of the largest and oldest Ash trees on the estate is now the sole tenant of a spot in the park called The One Tree Hill by our farm folk—the Ash being, I presume, the remnant of some former plantation. It is in good health, has a good soil to grow in, but the position is one of the driest, as the coal has been got from under it up to within a few feet of its roots, from which cause the pasture near it simply disappears in a dry time. It pays to plant Ash in a good soil up to an altitude of about 1000 feet above the sea. It will do well if planted pretty thickly even in a thin soil, but rapid growth and bulk is everything in an Ash tree, and it pays best to grow it under these conditions. One of the finest Ash countries in England is on the North-Eastern Railway, between Northallerton and Hawes, and it is also one of the best drained and cultivated districts in Yorkshire. The hedgerow Ash there is the largest, cleanest, and finest I have ever seen.

The Beech.—A correspondent of *Woods and Forests* wrote a year or two ago stating that the Beech could not stand exposure, and hence was not a tree to plant on exposed sites. He wrote from the south, and evidently stated but a general belief. The Beech is, however, one of the best trees for planting on bleak upland spots in all our lists. On a lofty ridge here, about 1200 feet above the sea and very much exposed to gales from east-west, that was many years ago planted with Scotch Fir principally and some Beech, the Fir has all but disappeared and the Beech alone remains, and has done well, making good spreading trees, although the soil is poor and thin. They have surprised many visitors. We have plenty of Beeches also in other exposed places that resist cold gales better than almost any other species, making but short growth annually certainly, and the tops leaning away from the stormy side, but quite healthy and with sturdy trunks well furnished. Most of the trees form a portion of the outside belt of an exposed plantation. The Beech thrives in a great variety of soils, but does not do well in wet soil or above the clay; that, however, is, I think, the only exception.

The Oak.—This tree thrives under conditions that suit the Beech and Ash, and grows largest and strongest, of course, in good deep well-drained soils. Yet we have here some very ancient specimens of large size that, as the poet expresses it, have literally "cast anchor in the rifted rock," and it would be hard to explain how they have grown so large and lived so long. These trees grow on the very brink of the most exposed and lofty cliffs, and although they are broad rather than tall they have made good trunks, and the descending sap has been so obstructed in its descent on reaching the fissure out of which the tree originally sprung, that the tissue has extended over the stone in a flat layer many inches wide. Our finest Oaks are, however, in the valley where the soil is best and deepest and free from stagnant moisture, and our healthiest and tallest Ash grows beside the Oak.

Spanish Chestnut.—Although this tree only flowers and fruits under favourable conditions of climate, still it is one of our hardiest trees, being almost as good as the Sycamore in that respect, which seems to prefer a cool climate. Hereabouts the Spanish Chestnut makes one of the loftiest as well as most spreading trees on hills from 800 feet to 1000 feet above the sea, and we have it thriving equal to the best in plantations about twenty years of age, situated about 1200 feet above the sea, and that, too, on very thin soils. One of the largest trees in Yorkshire here grows literally on the rock, there being scarcely soil on the surface to support a good herbage, and below nothing but rag for many feet down. How rapidly the tree grows in good soil, those who grow Hop poles in the south know, and if only the wood was more useful in a correspondingly young state, it would be one of our best timber trees. Old Spanish Chestnut timber is as hard and enduring as Oak, but old trees are not always found in such a sound state as old Oaks. The tree likes a dry site, and if it has that it will grow fast and live long on very cold situations, where it never by any chance produces any fruit, although it flowers in summer and produces empty husks.

Sycamore.—This is the tree to rear its top on exposed situations. A few Sycamores of great age and size are often found sheltering a farm steading on a hill top when no other tree is near. A grand tree to grow is the Sycamore, and it seems to defy the sea breeze at its worst, as, for example, on the east coast. I was greatly struck lately by the difference in the texture of the leaf on Sycamores near the sea. The leaves are much stouter and so much more leathery and strong in texture, as to almost look like the leaves of some other tree. Near Filey I saw a group of young trees with leaves of remarkable substance and colour compared to those produced inland. I suppose the Sycamore makes one of the finest trees in the north of Scotland, and in that country Sycamore timber fetches a rather tempting price when it has become old and is sound. It is not particular as to soil, and in this part of Yorkshire it is propagating itself naturally at an extraordinary rate, and threatens to out-grow all other timber trees when left to itself. Talk about thick planting! I was in a plantation the other day, near Wakefield, where the progeny of one Sycamore formed an impenetrable jungle for a hundred yards round, the trees being from 6 feet to 10 feet high, not much more than a foot asunder, and as straight as ramrods.

The Spruces.—With this note I must close these remarks. So far as I have seen, the proclivities of the Spruce are different from the Firs of the Austrian and Corsican type, and even from the Larch, so far as choice of soil and climate are concerned. The last tree prefers a dry climate and a dry soil, and the Spruces enjoy conditions just the opposite. Nowhere do you find the Spruce doing better, if as well, than on the west coast of Scotland, where the rainfall is heaviest, the climate damp, and the soil the same. In such places the common Spruces make specimen trees of gigantic size and grow at a rapid rate; hence they have been planted for covert there more than any other tree. The best deer woods of the south of Scotland and best game coverts generally are there composed of Spruce principally. The wild pigeon and the pheasant are alike partial to such woods, and the pheasant is more thoroughly naturalised there than anywhere else, perhaps, in the United Kingdom. YORKSHIREMAN.

The Larch disease.—I notice "J. F." does not attempt to reconcile the fact that the older plantations of Larch raised from foreign seed are admittedly better than younger plantations presumably from home-raised seed, with the general assertion or belief that the Larch failure is in some parts due to propagation from foreign seeds. The fact of the matter is this, Larch disease, which foresters are so glib in talking about, has no distinct existence. The Larch suffers from several complaints, and unhealthy plantations are to be found, both young and old, that can be attributed to local causes, no two cases resembling each other, while at the same time plenty of healthy plantations are found also. Neither do I believe quite in "J. F.'s" scare about bad seeds, although he declares it is carried away in burdens from his own locality, thus furnishing about the worst argument against the use of home-raised seed he could find, for if it be admitted that bad Larch seed is produced in such abundance in those districts where the home seed usually comes from, as to be far more readily procurable than any other, as "J. F.'s" "burdens" would indicate, what can be said in favour of such naturalisation? Still, the seed sown in our nurseries is not so poor as we are told to believe, otherwise the Larch quarters in nurseries would not be such a beautiful sight, the plants usually being both thick in the rows and as healthy as can be, and it is well known poor seed never produces good or strong seedlings. The physiology of "J. F." and others who teach that diseased seed produces fine young plants that only show the disease later in life after being transplanted—perhaps to an unsuitable soil or situation—will not do. Larch seed like "J. F.'s," that did not contain "above one per

cent. of vital seed," ought to tell a tale in a very short time after sowing.—Yorkshireman.

HEDGES—TRIMMED AND UNTRIMMED.

There is a medium between closely-trimmed hedges and allowing them to grow at will. There are two hedges here which will serve as examples, and I adopt both plans under different conditions. One of these hedges is composed of Hawthorn only, and is of ten or twelve years' growth. The other is much older, and is formed of bushes of Hawthorn, Hazel, Maple, &c. Both are by the roadside in a nearly straight line, and one is a continuation of the other. The young Hawthorn hedge fences in the shrubbery and the lawn. The older hedge is one boundary to the kitchen garden. The Hawthorn hedge is on the summit of a considerable grassy bank. This I like to keep frequently cut and level and uniform in appearance. In some cases I like to see hedges gradually tapering to the top, but in this case I prefer to trim it perpendicularly. To break any monotony I allow a large plant of Traveller's Joy, which grows in the shrubbery just within the hedge, to droop over it. This makes a break in the even line, and when in blossom and in fruit forms a most effective mass. Each autumn I cut it back, for if left to grow on year after year it would soon ruin the hedge it is intended to enliven. There is a young Spruce some 8 feet or 10 feet high which has been gradually dying away at a short distance from the Clematis plant, and this season I have allowed the growth to cover it. This raises a portion of the mass a few feet above the hedge, and is a decided improvement. The old hedge I treat differently in respect of cutting. The inside it is necessary to keep trimmed, or it would encroach upon the kitchen garden and injure the crops. The top and the outside I have only cut once in a couple of seasons, and then only enough to keep it within reasonable bounds. In this way I get a pleasing diversity. The old hedge on the outer side is naturally very varied and uneven. This serves to contrast with the trimmed part, and makes it look neater. The trimmed hedge in its turn serves to show up the inequalities of the old bushes. I thus get a double effect. The drawback with old hedges composed of a number of different kinds of bushes is, that they often get thin at the bottom and gaps gradually open up. The trimming on the inside, however, considerably lessens this. Beyond the contrast which has been spoken of, by treating the old hedge in this way it is of itself a great part of the year really ornamental, and in some seasons produces edible fruit. In the way of ornament this season I have had Dog Roses and Bramble blossoms. Now there are Hazel Nuts, and plenty of Blackberries are growing. There are also some bushes of the Wayfaring Tree, and the berries of these are very pretty. These, of course, are only two simple instances of different treatment, but they will suffice to show that even in the matter of trimming hedges it is not well to be too dogmatic, or to adhere too closely to one particular line of practice. Rustic.

TREES OF MONMOUTHSHIRE.

Although the timber of the Horse Chestnut is not sought after for any particular purpose in this county, I believe it is very suitable for carving. Looking at this tree from an ornamental point of view, there is no other more beautiful, especially when in flower. In this county we can boast of some very handsome specimens of Horse Chestnut. Some of the finest trees are in Tredegar Park, and these have an imposing effect in the distance. There is also a very fine row of Horse Chestnuts planted alongside the road leading from Caerleon to a residence called Belmont, and growing among other deciduous trees.

The Poplars flourish admirably in this county, with the exception of the very hilly districts. The Black Poplar (Populus nigra) grows well on our moors, in the hedges, and alongside the brooks and dikes. It grows so fast, that in the course of thirty to forty years it becomes a very large tree. I know of trees now that have not been planted fifty years with 100 feet to 200 cubic feet in them, many of them with a height of 100 feet. The soil in which they grow is a dark, loamy clay, close to the edge of a brook. I measured trees last spring which were felled with a length of 60 feet, and a circumference of 8 feet 5 feet from the ground. The soil they grew in was a rich, loamy clay on sandstone near the margin of a brook. There are, also, many fine specimens of Populus alba and P. tremula in this county. The wood of the Poplar is used here for brake blocks for railway wagons, and also for cart and barrow boards. The Black Poplar is a very profitable tree, and may well be recommended before the other species for profitable planting. Young Forester.

THICK PLANTING OUTSIDE TREES.

"In crowded plantations there is a marked difference between the trees on the outside and those in the centre; the former, having their branches and leaves fully exposed on one side, grow with comparative vigour, and form excellent timber on that side of the stem where light and air are admitted; while the latter, hemmed in on all sides, are drawn up like bare poles, and produce a small amount of ill-conditioned wood." I cull the above from a recent issue of The Garden; it is an excellent example of misapprehension of a plain lesson. It is true than the trees on the margin of a plantation always grow comparatively more vigorous on the exposed side than the trees inside the wood do, but they are seldom or never better timber trees in consequence, but worse: hence for that reason, and because they form a good wind guard to the plantation, they are not often felled or set out in a fall. Trees so situated send out far-spreading boughs as soon as they rear their head above the fence, make more branchy tops, and contain perhaps more timber in the aggregate than the single-trunked trees in the centre, but which are practically useless as timber. Whenever you find a tree producing a broad spreading top, either on one side or both sides, it is always at the expense of the trunk, which is shorter and less bulky in consequence. In fact, marginal trees are but little better in shape than hedgerow trees, which are unprofitable anyway. A better argument for thick planting "Scot" could not have cited, for the outside trees are the worst shaped in the wood, and buyers will not look at them if they can help it. I object, of course, to growing trees of different sorts together so thick as to smother each other, but it has yet to be proved that what scientific foresters call rank growth in a plantation is not much better than the severe thinning usually resorted to. Until an explanation is furnished why foreign trees and poles, imported in the rough, are so much taller, straighter, freer from knots, and generally more useful throughout than our home-grown timber, notwithstanding that the foreign trees "grow as thickly as seedlings in a hotbed" and are never thinned, I shall condemn our system of thinning in this country, and which the Scotch foresters are more responsible for than any other practitioners. There are neglected, and what would be called ill-managed, woods in England that would better bear to be measured by a debtor's and creditor's account than some of the much-talked-of Scotch examples of culture. The fault of the Scotch foresters is that they do not crop their ground sufficiently, and some of them have made the still worse error of planting the wrong kind of crop. I doubt if there be any forests in Scotland to be proud of from a professional point of view, unless it be the natural forests of Scotch Fir. The French professor, M. Boppe, in his report before alluded to in these pages, speaks of the pride with which the "father of Scotch forestry" showed him a 400-acre plantation of Oak, sixty years of age, in which the trees stood from 24 feet to 30 feet asunder, the necessarily much-too-spreading tops forming "a canopy overhead." This cannot be called forestry in the sense of timber production, and the Frenchmen did not need to tell us to go further than their own forest of Fontainebleau to see proof of this. In some vast tracts of that forest the first crop of Oak has long since been removed, and the second crop, at the rate of two, three, and four fine tall poles or trees from each stool, now covers the ground as rank as possible, the result being that the trunks are all drawn up straight and clean and remarkably uniform in size.—Yorkshireman.

—— What the writer of the note (p. 258) says about the development of branches and leaves where the trees have more room and access to light and air is true enough; but to deduce from this circumstance the conclusion that the best timber is grown on the margins of woods, or that it is better in any position where the trees have full opportunity to develop branches, is erroneous. I speak, of course, practically, as from our side of the forestry question theories are out of the reckoning. Except in very special cases, the freer trees are from these branches of which your correspondent speaks, the better we like them for timber purposes. In the Fir tribe this straightness and freedom from branches is everything, and, so far as my observation goes, this growth is only obtained by moderately thick planting. The same thing holds true about the Oak, but with the Elm it is rather different. For some purposes long and straight trees are wanted in this latter wood; but, generally, shorter lengths will answer. On soil which naturally produces good Elm, the best timber is very often found in trees which grow isolated in fields, but then the prime part is really only the butt of the tree, *i e*, the part from the ground to the first large limb or branch. Beyond this the wood is only fit for second class uses. Speaking as one who has had a good deal to do with home-grown timber purely from the market point of view, I think, on the whole, that "Scot's" advice on this point is bad. As I have said, there is the case of the Elm where really marketable timber is produced by isolated growing, but in this respect it stands almost by itself. With the Ash, we almost always pay a higher price for plantation-grown wood where it is grown thick, and therefore cannot produce branches and consequently knots. The Oak is regarded in the same light, except where very large dimensions are wanted, and then a large field butt sometimes comes in. In this case there is almost always half of the tree which is only fit for secondary uses. The sentence about producing ill-conditioned wood by being drawn up like bare poles is very unfortunate, as in almost all kinds of timber this is just what we seek for.

The Beech is typical of this. Grown, say, in open avenues, it has a grand effect and grows to a large size; but it is, nevertheless, generally unprofitable to the merchant to handle these trees, as there is such a large proportion of waste. On the other hand, Beech grown so closely that there is no room for branches, if in other respects good, always fetches the highest price. There are some Beech woods, I know, from which cuttings are made most seasons, and the trees are so thick, that they grow to a height of 40 feet to 50 feet without a branch. There is always a keener competition over this wood and a better price realised than for any other I know. I could easily quote many instances of this, but it is perhaps unnecessary. My object in writing is to let your readers know that, from a trade point, the ideas expressed in the paragraph under notice are about as backward as can be, except in here and there an instance. In short, buyers do not mind trees being grown like bare poles, but fight shyly over timber too highly developed in the shape of branches, which means a lot of wood of relatively little value. That trees growing thickly naturally produce ill-conditioned wood is certainly opposed to my experience.—A Timber Merchant.

Ornamental Conifers.—My favourites amongst Coniferæ for planting as single specimens where space can be afforded for them to develop themselves are Picea nobilis, P. Nordmanniana, and P. cephalonica, all truly noble objects; the latter, however, is somewhat tender, and should only be planted in positions where the sun does not shine on it in the morning so as to excite early growth or cause a too rapid thaw after severe frost, as that is how the soft, prominent buds generally get injured. P. nobilis and P. Nordmanniana will endure almost any amount of frost, as will also P. grandis, which is another very fine Conifer that should have a place even in the choicest selection.—D. S.

"This is an Art
Which does mend Natnre: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

FORMING NEW ORCHARDS.

PREPARATION.—Where the planting of young trees is contemplated now is the time, or as soon as existing crops are off to commence preparing the ground. The way in which this must be set about depends entirely upon the nature and quality of the land, and the system of management which will best dovetail in with other arrangements and requirements. When Grass orchards are to be planted with standards the only practical method is taking out large circular or square holes, but unless the land is thoroughly drained or light and porons when its suitability is doubtful, these pits only become so many reservoirs for the gathering of water in which the roots of the hardiest trees cannot live. Better take a smaller area in hand, and either cultivate, dig, or trench, and after taking a crop of Potatoes plant early in the following autumn. The cost at the outset would he more, but the result in the long run would pay, as the roots and branches would keep pace with each other, and fruit of the finest quality might reasonably be expected. In private places where small plantations only are needed and a very choice selection of sorts is about to be made, I would certainly drain well and trench 2 feet deep if the nature of the subsoil would permit, and plant with pyramids and bushes on the Paradise stock. By far the finest fruit is now gathered from this class of trees; a great number of varieties can be grown on a small piece of ground, the crop is sheltered from wind and storms, and the trees are easily manipulated and kept in order. October is the best time to plant, and the ground is now in good order for trenching, as it can be worked without becoming adhesive. If stiff and inclining to clay or marl, the system known as bastard trenching should be adopted, *i. e.*, the bottom spit should be broken up, but not brought to the surface—at least, until properly ameliorated by the addition of burnt earth, charred refuse, road-scrapings, or the like. This, by degrees, under the process of root-lifting, would become incorporated with the better soil, and the masses of fibres which these stocks produce would be ever finding suitable food, but there would be little danger of their descending to the detriment of the trees or fruit.

MANURES.—Next to a sharp pruning-knife the amateur thinks there is nothing like manure and plenty of it, but, necessary as this commodity is in nearly all gardening operations, there is a time to feed and a time to withhold, and it is questionable if the knife and the manure heap have not brought more trees to an untimely end than all other modes of treatment combined. If the land is light, hungry, and thin, a fair dressing of manure may be of use, but when thoroughly broken up to the depth of 2 feet, it must be very poor indeed if the correctives which I have named are not found quite sufficiently stimulating until the trees get well into bearing. As a rule, however, animal manures are not needed, and when the land really does require enriching, a crop of vegetables should precede the trees for the twofold purpose of taking crude or rank substances out and giving time to get the soil and manure thoroughly incorporated. As a mulch for the protection of the roots in winter and food in summer, good manure of some kind is indispensable and must be forthcoming when it is wanted. Light warm soils cannot easily be over-mulched; not so cold heavy loams, as a thick layer of rich non-conducting material not unfrequently keeps out summer warmth, forces a coarse crude growth, and induces a disposition to canker.

PLANTING.—Hardy fruit trees are now planted from October up to the end of April, but the best time to remove them from the home nursery to their permanent quarters is the month preceding the fall of the leaf. Why this is the best time may be explained in a few words. Vital force in the trees, perhaps never at rest, is still active, and the ground retains a portion of its summer warmth. Moreover, it is moderately dry and in good condition for working without becoming adhesive, and solar influence favours the formation of new roots before the winter sets in. The mode of planting depends upon the nature of the surface and subsoil, the lie of the ground, its elevation or the reverse, and its tendency to become wet in winter or too dry in summer. All these points have to be taken into consideration, and when the best mode has been decided upon, dispatch, combined with good workmanship, must be brought to bear upon the operation. On light, deep soils not subject to cold stagnant water, planting below the surface level will be found to answer best, and the compost should be made very firm, not by treading with the unmerciful heel, but by flooding home with water, the best of all solidifiers, and firming with a broad-faced rammer when the last of the soil has been placed over the roots. On cold, thin soils, or in low situations, the roots of the trees may be placed on the level and mounded up with fresh compost or the best of the surface spit where the general staple is considered good enough. In all cases, be the trees standards or free stocks, pyramids or bushes on the Crab or the Paradise, a dull day should be chosen for planting them, and having leaves upon them, water should be applied immediately. When trees are bought in from a distant nursery one cannot always insure suitable planting weather immediately on their arrival, and temporary laying in becomes the only way out of the difficulty, as permanent planting when the soil is wet or frozen cannot be too strongly deprecated. If received early in the autumn the roots should be lightly covered and the trees supported, as they soon commence making a fresh start, and great care should be observed in their removal, otherwise many of the tender rootlets will be destroyed. Trees, on the other hand, which have been grown for a year or more in the home nursery can be removed when the stations are ready and the state of the weather is favourable. Newly planted trees, it is hardly necessary to say, should be well secured to stakes to prevent wind-waving, and half rotted manure or long litter should be placed over the mounds to exclude frost and drought as well as to keep in warmth.

DISTANCE APART.—Standard trees should be planted from 30 feet to 40 feet apart in large orchards, but just now I have my eye upon the garden plantation of pyramids, bushes, and cordons, and as these are sometimes worked upon the Crab, but most frequently upon dwarfing stocks, the distance must be regulated by the stock and the mode of future training. The majority of planters, either for pleasure or profit, aim at variety and early fertility, and, notwithstanding the fact that root-lifting is intended to form a portion of their programme, they not unfrequently plant too thickly and find themselves in difficulties. Trees on the French stock are often planted from 3 feet to 4 feet apart and 6 feet from row to row, but these distances compel annual, or at most biennial, root-pruning and constant pinching; and although I have trees thus planted and bearing crops of fine fruit, I question if a little more space will not be an advantage in the long run. This difficulty I intend to get over by transplanting every alternate tree when more space is needed. Pyramids or bushes on the English Paradise stock require more room, 8 feet between the rows and 4 feet to 6 feet from tree to tree being near the mark. Some years ago—more than twenty—I planted long single rows of trees on this stock in rather rich garden soil, allowing 12 feet for each tree. These were trained into half globular bushes and now nearly touch each other. They are 5 feet in height, and some of them have borne as many bushels of fruit this season. Vertical and oblique cordons against east walls and trellises I plant 18 inches to 2 feet apart, and find the latter distance quite sufficient for ordinary varieties. Strong growers should have more room and be kept to two shoots each. When quarters containing larger trees are bordered with horizontal cordons, either double or single, 3 feet to 4 feet are generally allowed to each shoot, and where this mode of culture is made a hobby, the trees can be kept in condition for a great number of years; but quantity and quality of fruit being the object, 6 feet will be found the best distance apart to plant on well-prepared garden soils.

Eastnor Castle, Ledbury. W. COLEMAN.

ROSE GARDEN.

STAYING PROPERTIES OF ROSES.

IT is incredible that any practical exhibitor will endorse "D. T. F.'s" surprising suggestion that Roses fade when cut in proportion to the liberality of their culture! This is certainly contrary to the experience of most growers, and presumably it is not intended to record the actual experience of "D. T. F.," as he prefaces all his remarks with "possibly," "it seems," "are likely," and similar expressions involving no definite statement; nevertheless, it is none the less misleading coming from so high an authority, and might easily tend to raise the already too high rate of mortality among Roses through starvation. In practice it is found that the blooms that stand best are those that are grown on the richest and best soil, with plenty of manure and copious supplies of weak liquid manure when the buds are swelling, and it is only when exhibitors have learnt to produce by these means the strong growth that alone can carry first-rate flowers, that they can ensure their blooms withstanding successfully the ordeal of long journeys to and from shows. No doubt watering with liquid manure may be overdone if used too strong, and soapsuds and house-slops are perhaps the worst form for an inexperienced grower, since they always make the surface of the soil foul and sour, unless the hoe can be kept constantly going. But apart from such misuse, that copious supplies of liquid manure destroy the colour, and that the substance of Rose blooms is reduced to a gossamer by the richness of the soil, will be news to the majority of growers. It is rather difficult to get at the meaning of the remark that "blooms suddenly cut off from a full larder are the likeliest to fade or lose colour, unless their wants can be supplied afterwards," as a cut Rose's only want is fresh water, with which, if the bloom is cut for exhibition or vase decoration, it is, of course, always supplied at once. Again, there is not the slightest analogy between a Rose tree and an athlete, beyond the fact that it is an object of interest to both to be at their best at a given time. An athlete's one object in training is to attain to a perfect state of health, and while, if he were a bit off colour any morning, his trainer might prescribe him a glass of port or some other tonic, he finds his end is best attained by the avoidance of everything of a luxurious and enervating nature in favour of a strength-producing diet. Now there is nothing

in a plant growing out of doors to correspond with the human capability of indulging in or avoiding luxuries. Moreover, in the case of the athlete, whatever special development is aimed at, outward appearance, at any rate, never receives the slightest consideration; whereas, in the case of flowers, external beauty is the sole object in view. In fact, the preparation of a fat beast for a Christmas show would have been a more appropriate simile than "D. T. F.'s" athletic training. Our good Rose soil being of limited area, it has been necessary to plant a good many trees on beds of the natural sandy soil, made up as well as could be managed; but flowers from the latter are never used for exhibition when enough can be obtained from the richest soil beds, since, as a matter of practice, it is found that the flowers from the poorer soil, however beautiful they may be at the time of cutting, do not under trying circumstances stand as the "fat" flowers may be relied on to do.

La France is not by any means one of the easiest Roses to carry in perfection to a show in very hot weather, as it expands with astonishing rapidity after being cut. Frequently when staging a box of twelve blooms of this variety, if there are hardly enough of the richly-fed flowers, a few from plants on the light soil are taken as spares and as often as not, if the morning be a hot one, they arrive at their destination as yellow-eyed as Daisies.

In addition to Merveille de Lyon, the following varieties may be noted, which, though generally thin or not of first-rate quality, have occasionally produced a bloom which has been the cynosure of all eyes at some particular show: Bernard Verlot, Duchess of Edinburgh (T.), General Jacqueminot, Mabel Morrison, Madame Berard (T.), Madame Chedane Guinoisseau (T.), Madame Sophie Fropot, Princess Louise Victoria, Safrano (T.), and Ville de Lyon. Mr. Haywood's marvellous bloom of the last named, which gained the Royal Horticultural Society's medal as the best H. P. at the Reigate Show this year, will not readily be forgotten by those who saw it.

T. W. G.

SOUVENIR DE LA MALMAISON.

This exquisitely beautiful, delicate, flesh-coloured Rose has been so often recommended, that it may seem like a mere work of superarrogation to commend it yet again. But beautiful and useful as this Rose is, it is by no means so generally grown nor so extensively cultivated as it deserves to be. Some of us can look back to the time when hardly any garden belonging to cottage or palace was thought to be furnished without one or more pink or crimson monthly Roses. Never until Souvenir de la Malmaison is equally or more popular will it be time to leave off sounding its merits and advocating its universal cultivation. No wonder that "W. I. M." winds up his list of desirable September-blooming Teas with a eulogy on the merits and usefulness of this Bourbon (p. 283). Notwithstanding the beauty and usefulness of most of these, there is not one among them all—barring, perhaps, the Gloire de Dijon—that in all points of beauty, usefulness, and continuity of blossoming can compare with Souvenir de la Malmaison. To prevent disappointment, however, it must be repeated what has been so often stated in The Garden, that this Rose is emphatically an autumnal one, not merely in a general, but a special sense, the latter being so emphatic, that it may almost be said of it, with absolute truth, that it is good for little or nothing at any other season. This fact cannot have too wide prominence, for virtually it may be said there are two Souvenir de la Malmaisons—a worthless one in the early summer, and the best of all our delicate pink or flesh-coloured Roses throughout all the autumnal months till the frost cuts them off. It is the more needful to emphasise this difference, as a writer of "W. I. M.'s" experience claims for this Rose as one of its merits that it flowers before any of the hybrids. Yes; but, as a rule, most of these early flowerers are mere useless abortions. So generally is this the case, that this Rose on its own roots is not infrequently treated as double-bearing Raspberries are. It is well known that the latter will fruit in the summer like ordinary Raspberries if a crop of canes is left over for this purpose. But as the first crop on such canes never equals that on canes of the ordinary varieties, most good cultivators remove them and concentrate the entire vital and fruiting force of the double or autumnal bearing Raspberries into the current year's shoots, that start into growth early in the spring and ripen their fruit in the autumn. So, by cutting back dwarf beds or bushes of Souvenir de la Malmaison Roses on their own roots in February or March, strong shoots will spring forth from the stools that will yield a rich harvest of perfect flowers from July to December in mild winters, and in most ordinary seasons up till the middle or end of October. These strong shoots are not seldom crowned with huge masses of from five to fifteen blooms that open for a month or six weeks in succession. These shoots supply the richest furnishing for vases, cut in great branches, and will bloom for several weeks in succession after cutting, especially in the late autumntide. But for general purposes the buds should be gathered singly off the trusses in a half-opened state, and in this condition they are most useful for bouquets or other decorative purposes. If the entire plants are left to bloom in the ordinary manner from the first and the early shoots are cut to the ground as soon as they have finished flowering, the base buds will immediately break afresh and push forth other shoots in time for late autumnal blooming. Another most successful way of treating this Rose in beds is to peg down the strongest shoots almost level with the ground. The strain upon the neck of those near to the collars of the plants forces them to break. These breaks are allowed to grow upright and bloom, if so disposed, late in the season.

At the end of the growing and flowering season all the pegged-down shoots are cut close back, the beds top-dressed and pointed over, the vertical shoots pegged down, and in cold localities a few Fern fronds or boughs worked in as protection against severe frosts. By this simple mode of culture the Souvenir de la Malmaison really renews its growth annually, and the same beds continue to grow and bloom on the same spot for years. In warmer localities the overhead protection may be dispensed with. It must, however, be borne in mind that this fine Bourbon Rose is equally or more tender than most of the family to which it belongs, and is rendered yet more so by the cultural expedients here advised to accentuate its autumnal blooming proclivities. The Souvenir de la Malmaison is also a good wall Rose, either out of doors or in a cool house. By planting one or more plants on every aspect from south to due north, the cultivator will mostly be able to cut buds from the open for eight or even nine months out of the twelve. Unlike every other Rose, this fine Bourbon is improved considerably by cultivation under glass. The malformation of petal and horrid distortion of the eye so common to early blooms in the open are rare or wholly unknown under glass. Either in pots or planted out nearly all blooms under glass are equal to the best autumnal ones in the open air. Finally, to enjoy this Rose to the full cut it early, and discard the blooms so soon or even before they are fully expanded, for, however delicate in colour or exquisite in form in the bud, they are little or nought to be admired when fully expanded. As to fragrance, perhaps the less said the better, for I have met with rosarians loud in their praises of its odours subtle and rich, and others who compared its scent to stale dish-washings. That both were mistaken those who know this most useful autumnal Rose best will admit. It may also be admitted that the odour is unique and peculiar, but its chief merits are its soft colour, good form in the bud state, and its profuse blooming in the late autumntide and early winter.

D. T. F.

Rose Cramoisie Superieure.—I was much pleased to see "W. G.'s" note on this in the open air in the Handsworth Nurseries. It used to be a favourite Rose in pots or against warm walls, but I do not remember to have seen it bedded out in considerable masses; hence a few more particulars o the age of the plants described, and the mode of protecting them in winter, &c., would prove of interest to me, and probably be useful to many readers. This was always considered to be one of the brightest and most brilliant of the older China Roses.—D. T. F.

NOTES OF THE WEEK.

Richmond Hill.—The Local Government Board have sanctioned the application of the Richmond Vestry for power to borrow £15,000, to enable them to purchase the Buccleuch Estate on Richmond Hill, so as to convert it into public pleasure grounds, and preserve the view from the Hill.

Tuberous Begonias.—These, in Mr. Laing's nursery at Forest Hill, are now in greater beauty than they have ever been before this season. Both foliage and flowers seem refreshed by the recent rains and cool weather, thus superseding the Pelargoniums, which are now on the wane.

Diplopappus chrysophyllus.—This is a neat-growing and beautiful shrub. Its rich yellow stems and undersides of the leaves contrast strikingly with its heads of white bloom. It is a fine plant for isolating upon lawns or for shrubberies. We recently saw it in good conditiou in the Berkhampstead Nursery.

Nerine filifolia.—This, the thread-leaved Nerine, is distinct from others of the genus on account of its grassy foliage. The flowers are, moreover, different, inasmuch as they have narrow sepals with wavy margins, and are of a bright rose-pink colour. Mr. Ware sends us a few flowers of it from Tottenham.

Cox's Emperor Plum.—The crops borne by this thoroughly good all-round Plum, sometimes called Denbigh, are very heavy this season in the Berkhampstead Nursery. There we saw many trees of it, and also of that best of all Damsons, the Crittenden, with their branches bent down to the ground under their load of fruits, and in some instances large limbs were actually splintered off by their weight.

Sweet-scented Clematises.—Mr. Lynch tells us that the odour of the old bluish Clematis Davidiana is like that of Stephanotis, and that he finds the leaves fragrant when dry. He also sends from Cambridge the prettiest specimens of this somewhat neglected species we have seen.

Watsonia rosea.—This is one of the handsomest Cape bulbous plants now in bloom. It has tall and slender branching spikes beset with large and showy flowers of a deep rose colour flushed with a purplish hue. It is one of those half-hardy bulbs that repay any little extra attention bestowed upon them as regards protecting them by a handlight or a frame during winter and spring while they are developing their tender growth.

Narcissus serotinus.—This is perhaps the smallest of all Daffodils and the latest to flower. It is so unlike any other Narcissus, that it may readily be mistaken for a plant belonging to another genus. The flowers are only about an inch across, pure white, and have such narrow petals that they look like the blossoms of a Jasmine. There is the characteristic cup, but so small as to be scarcely seen. Each flower is borne on a slender stalk about 6 inches high. Mr. Ware, of Tottenham, sends us some flowers of it, presumably from plants grown in a frame, as we doubt if it is quite hardy.

Apple Prince Albert.—This is a handsome Apple, and one of the very best for culinary purposes, keeping in good condition till March. Intending planters cannot be too often reminded that it is only fruits of good quality that find a ready sale at remunerative prices, inferior produce being quite a drug in the market. The Prince Albert Apple, which we recently saw bearing heavy crops in Mr. Lane's nursery at Berkhampstead, is a variety that seldom or never fails to yield a good supply, even in seasons when most kinds fail to produce a crop.

Ixoras.—These brilliant-flowered stove shrubs are among the most useful of autumn-flowering plants; indeed, we might call several of them perpetual-flowering, for they are seldom without some of their clusters of brightly coloured blossoms. In the Victoria house at Kew there is a collection of Ixoras, most of which are now in flower, and these for purposes of selection might be turned to account by those who want to know which kinds of Ixora are likely to be most serviceable. Here is a list of what we saw in flower a few days ago: I. Pilgrimi, a very free-flowering kind with handsome bright green foliage, a shrubby habit, and large trusses of bright orange-red flowers, which are yellow when they first open. I. Prince of Orange, also a free-blooming sort with medium-sized trusses, flowers similar in colour to those of the preceding. I. javanica has dark green leaves

and large trusses of scarlet flowers. I. Fraseri is distinguished by its large flowers, enormous trusses, and compact habit, the colour of the flowers being first yellow and afterwards almost crimson. I. spectabilis, similar to I. Pilgrimi, but has smaller trusses. I. Bandhucca has a stiff habit, rather rigid foliage, and twelve-flowered trusses, the individual flowers measuring quite 1 inch across. I. parviflora has small white flowers; as has also I. laxiflora. Other species which may be seen at Kew are I. macrothyrsa (I. Duffi), the grandest of all Ixoras, but a strong woody grower; I. hydrangæfolia, characterised by leaves 1 foot long and 4 inches wide, very leathery in texture and recurved, whilst the stem is erect and unbranched; I. Ragoosola, I. brachiata, I. Griffithi, I. Findlaysoniana, I. ferrea, and I. Williamsi. Some of these are of botanical interest only, their flowers being very poor when compared with the garden kinds.

A finely-grown Eucharis.—A photograph of a finely-flowered Eucharis has been sent to us by Mr. Jupp, gardener at Torfield, Eastbourne. The plant is represented as bearing thirty-five flower-spikes, each showing from six to eight blooms. "The plant," says Mr. Jupp, "is growing in a 20 inch pot; only five years ago it was in a 10-inch pot. We have never been troubled with the Eucharis mite, and we are seldom without flowers of this plant. The plant photographed I hope to have in bloom again at Christmas."

September Pansies.—Mr. Rawson sends us from his garden, at Windermere, a gathering of Pansies, which for the season are most admirable. The flowers represent a different race from that of the ordinary border Pansies. Every flower has its petals adorned with a golden or silvery margin, while the ground colours are intensely deep and rich. No doubt Mr. Rawson's climate is favourable for the production of these fine September Pansies, but if he has any secret to divulge respecting the treatment which he gives them, we should like to know it.

Aristolochia elegans.—This plant, of which we gave a coloured illustration in The Garden in June last, is now flowering profusely in 3-inch pots, and the fact that such miniature plants do so should enhance the value of this beautiful species. Another new Birthwort to be found in Mr. Bull's establishment is A. ridicula, which makes a fit companion for elegans. It is equally free flowering, and though not so beautiful as elegans, singular enough to be attractive. The shell-like flowers of elegans when cut keep well in water.

Lasiandra macrantha.—This fine Melastomad is deserving of more extended recognition than it has hitherto received, its rich blue flowers, which are produced at this season, being specially attractive. Of this plant there are two distinct forms—so distinct, indeed, as to almost lead one to suppose that the distinction is more than varietal. The normal form is very free, producing large blossoms in abundance; while that called floribunda is even more floriferous. It is, moreover, dwarf in habit; its leaves are more rugose than those of the type, and the flowers are nearly double the size of those of macrantha. We recently saw both kinds in great beauty in Messrs. Veitch's establishment at Chelsea.

Hibiscus coccineus is a plant we have often read about, but never saw in flower in England till the other day, when we were shown a flowering specimen of it in the temperate house at Kew. In the United States it is looked upon as the most gorgeous of the indigenous plants, and is cultivated with the same fondness as H. syriacus or H. rosa-sinensis is in this country. It is just a little awkward with us, as it cannot be treated as a hardy plant because it flowers very late in the year, and it is not happy in winter, and it loses its foliage rather badly if treated as a greenhouse plant. It would, however, be a useful plant for late autumn flowering if it were planted out in a sunny border during summer, and taken up and planted in pots about the beginning of September. Meehan, in his "Native Flowers and Ferns of the United States," calls this plant the American Scarlet Rose Mallow, to distinguish it from the Chinese scarlet-flowered species (H. rosa-sinensis). It is not a new plant in English horticulture, Curtis having figured and described it in an early number of the *Botanical Magazine* and Collinson in a letter to Bartram, dated February, 1768, said of it: "The crimson Hibiscus is a charming flower. I could have no perfect idea of it, but from thy elegant painting. Pray desire thy father to spare no pains to get us seeds from Charleston, where I daresay it will ripen seeds." In the cooler parts of the Northern States it grows and flowers freely, and it is equally happy in the deep coast marshes of Florida and Georgia. In habit it grows to a height of from 4 feet to 6 feet, has smooth green branches, leaves as in Manihot, or the Hemp-plant, and axillary flowers, composed of a large green calyx and five spreading deep crimson petals, each nearly 3 inches long by 1 inch across. The name H. speciosus is sometimes given to this plant. It is probable that if we could induce some of our skilled hybridists to interest themselves in this fine Hibiscus, a race of gorgeously coloured hardy flowering shrubs might be obtained by crossing it with H. syriacus.

Nymphæa Sturtevanti is now in vigorous flowering condition in the Water Lily house at Kew, where it flowered in England for the first time last year, having been obtained from the nurseryman, Mr. Sturtevant, of New Jersey, after whom this grand hybrid is named, and who pays a good deal of attention to Nymphæas and aquatic plants generally. The extraordinary beauty of this new Lily is marred by its habit of closing its large, deep, rose-coloured flowers early in the day, the blooms on the plant at Kew closing at about 9 a.m.—very early closing hours, even for Water Lilies. All the species belonging to the N. Lotus set close their flowers before noon, and do not open them again till night, so that visitors to Kew do not have an opportunity of witnessing the display that is made in the morning by the flowers of these plants. To atone for this, however, we have, in the stellata group, the habit of expanding flowers about mid-day, and they remain open all the afternoon. To the latter belongs N. zanzibarensis, the giant purple-flowered Water Lily, and this has been flowering at Kew for the past three months; N. Daubenyana and N. stellata itself also open in the afternoon; so, too, does the tiny species N. pygmæa.

Coral tree (Erythrina Crista-galli).—This magnificent autumn-flowering plant is not always treated properly by those who use it for out-of-door effect, wrong treatment revealing itself either in the shoots being flowerless, or in the flowers not appearing before it is too late in the season for them to develop outside. Here is the kind of treatment this plant should have if wanted to flower in the open-air: The stools should be wintered in a shed or cold frame and kept just moist; in February they must be looked over and trimmed preparatory to placing them in a slightly protected frame to start into growth. The stools should be planted in this frame in a light, leaf-mouldy soil, so that when shifting time comes they will lift with good balls. By the middle of May the shoots should be from 6 inches to a foot long and sturdy, and there is no difficulty in getting them into this condition if the lights are removed from the frame on mild days, and the sunlight allowed to get to the plants. The bed or border in which the stools are to be planted for the summer should then be prepared; a strong, rich loam is most suitable for this Erythrina, and it likes plenty of water. Treated thus the shoots make their growth, set, and develop their showy flowers by the beginning of September.

Lonchocarpus Barteri.—This is a gigantic climber from West Tropical Africa, and is now flowering in the Palm house at Kew. In habit it is quite as vigorous and quick growing as Wistaria sinensis, so that except in very large houses it would not be at all happy. The Kew plant is, however, quite at home, stretching its long rope-like branches from the floor up the pillars, round a portion of the gallery, and on over a gigantic Date Palm till it reaches the top of the house, its whole length being at least 80 feet. But, notwithstanding this growth, it is only this year that the plant has borne flowers, and it is supposed that too heavy cutting back was the cause of its failure to do so in previous years. Some valuable lessons in pruning may be learnt from observations of this kind; it is not every plant that will submit to the annual shearing sometimes practised. The Lonchocarpus has pinnate leaves 9 inches long, and bears large panicles of flowers, some of the panicles being 2 feet long with six or eight branches each about 9 inches long, the whole being covered with fascicles of flowers and buds. The flowers are Pea-shaped, half an inch across, and coloured bright rose. The genus is important economically, owing to one of its species, also West African, being the source of the Yomba indigo, a valuable dye obtained from the flowers.

Orchids.

Cattleya gigas regalis (*G. Lawr.-Schofield*).—A magnificent flower—larger and richer in colour than usual. It is interesting to know that the flower is from the plant that first bloomed in this country.

Aerides Lawrenciæ.—This valuable Aerides is now flowering freely in Messrs. Veitch's nursery at Chelsea, thus showing it to be a good autumn bloomer. In general appearance it resembles a lax-growing A. quinquevulnerum. The raceme, which is very long, bears large, inflated, pure white waxy flowers, the sepals and petals and frilled front of the lip of which are tipped with rich magenta-rose.

Renanthera matutina.—This rare and beautiful Orchid has been flowering for a long time in Mr. Bull's nursery at Chelsea. Its flowers are not so large, nor so richly coloured as those of R. coccinea, which they otherwise much resemble, but they are produced more freely and on younger plants. It will, therefore, let us hope, escape the charge of being a shy bloomer, which coccinea is. In foliage matutina is quite distinct from coccinea.

Odontoglossum grande.—Though an old member of this genus, this is still one of the finest plants we have for enlivening either stove or Orchid houses during autumn. Its large, rich, yellow flowers, barred with tiger-like bands of chestnut-brown, are most attractive. It is a bold, free-growing species, and one which gives the least trouble as regards cultivation; all it wants is to be kept cool and moist. We recently saw this species beautifully in bloom in Mr. Bull's nursery in Chelsea.

Sale of Orchids.—The fine collection of Orchids formed by Dr. Paterson, at Fernfield, Bridge of Allan, was sold the other day at Messrs. Protheroe & Morris's rooms, Cheapside. Some of the highest prices realised were the following: Cattleya Trianæ, 45 guineas; Lælia elegans Turneri, 35 guineas; Vanda suavis (Paterson's variety), £32; Odontoglossum Alexandræ (extra fine variety), £33; Lælia Perrini alba, 20 guineas; Cattleya labiata (autumn-flowering variety), 18 guineas; Cypripedium Veitchianum, 15 guineas; Vanda Cathcarti, 15 guineas; Cœlogyne Gardneriana, 15½ guineas; Cymbidium giganteum, 12 guineas; C. Lowianum, 13 guineas; Vanda tricolor Patersoni, 16 guineas; Dendrobium Ainsworthi, 13 guineas; Vanda suavis, 14 guineas; Lælia superbiens, 9 guineas; Cœlogyne cristata (Chatsworth variety), 8 guineas; Odontoglossum Klabochorum, 10 guineas; and Lælia anceps Dawsoni, 9 guineas.

Is wire hurtful to Orchids?—I have seen so many leaves of Orchids, and particularly of such soft genera as Phalænopsis, Aerides and Cypripedium injured by being in contact with the wire suspenders used for hanging baskets, that I am persuaded that there is something in the wire, possibly of an electrical nature, which is a source of danger to the health of many Orchids for which it is used. Galvanised wire is seldom used for Orchid baskets, but we do meet with it now and then. We know that in mixing some plant washes galvanised iron pails have to be avoided, or the wash will be turned into a poison by the effect of the pail on the mixture. Here is a subject of enquiry and experiment for chemical horticulturists. It may be that whilst wire does little or no harm in one place it has the opposite effect in another, the difference being possibly due to the atmosphere, or the water or the soil being different. This, however, the experimentalist could decide; but that the matter deserves attention very few observant plantsmen will deny.—W.

Orchids at Chelsea.—The beautiful Lady's Slipper (Cypripedium Spicerianum) is now opening its flowers in Messrs. Veitch's nursery. As an autumn-flowering Orchid it is simply invaluable; and the same may be said of Cattleya Sanderiana, of which many fine forms are now in full beauty. Odontoglossum Roezli album is also now very fine. The beauty of this plant appears to us to have been much undervalued; for than this Odontoglossum few finer

autumn-blooming plants are to be had. Vanda-Sanderiana and the beautiful Aerides Lawrenciæ may also be looked upon as autumn bloomers. Both are now opening their flowers in this establishment. Among other Orchids of note now in bloom may be noted Coelogyne Massangeana, Dendrobium bigibbum, Odontoglossum Alexandræ in great variety, O. Pescatorei, and that striking novelty amongst Odontoglossums, O. Harryanum; and the beautiful old favourite, O. grande.

NOTES FROM THE CONTINENT.

Hailstorm at Paris.—The following, from the *Moniteur d'Horticulture*, shows how disastrous to horticulturists was the hailstorm which occurred at Paris in the last week of August: "On the 23rd of August an avalanche of hail fell upon Issy, Malakoff, Vannes, Bagnolet, Saint Mandé, &c., but more particularly on Montreuil aux Pêches, and has left irreparable traces of its course. We had the opportunity of seeing the damage caused by this scourge, and we may safely say that a description thereof is impossible. It is heartrending to see the naked gardens and to witness the complete destruction of all market-garden produce. The Peaches having such a wide reputation, and which are the support of the locality, are hacked to pieces; the trees cut about by the hailstones are condemned to certain death; all the espaliers have suffered terribly; there is not a whole frame of glass or a cloche left entire; they were crushed by the falling masses of ice. In brief, it is complete devastation—a ruin which is the precursor of frightful misery for a great number of cultivators, especially those newly established. To give an idea of the disaster, it is sufficient to say that the commission of examination has fixed the damage at more than £1200." This appears to refer to the glass erections, as the writer states that the total loss is estimated at £40,000, of which Montreuil is credited with at least £10,000. In commenting on the above the editor of the *Moniteur* bitterly laments the apathy of the French National Horticultural Society, which, he observes, has now a rare opportunity of making itself worthy of its name. Up to the present it seems to have done but little. Committees of inquiry have, it is true, been formed, but these have not been governed by any central authority, so that up to the present nothing substantial has resulted from their labours. It will, indeed, be sad if a number of worthy hard-working men should be ruined by a visitation which no foresight could guard against, and it is to be hoped that the influential members of the National Society will bestir themselves in the endeavour to lighten the distress which must result from this most fearful of scourges to which gardeners are liable. Glasshouses smashed in, the crops of the year annihilated, and the noble, beautifully-trained trees, the pride of French gardeners, mortally wounded, their death being but a question of time, and this extending over an area of many square miles, form one of the most desolating pictures imaginable.

Preserving fruit.—The *Illustrirte Garten Zeitung* states that the best way to keep fruits, such as Apples and Pears, is to place them between two layers of wadding in a tin box, soldering on the lid so as to hermetically close the box. This is put in a cool place, where no abrupt changes of temperature can occur. Even quite ripe fruit, it is asserted, can be kept thus in excellent condition for several weeks. Grapes may be preserved in the same way. In the case of choice Pears, the natural season of which does not last so long as is desirable, this plan of extending it might sometimes be found valuable.

Cantaloup Melons.—These are scarcely known in this country, and it is doubtful if they will ever find much favour with English growers. The Cantaloups mostly grow big, and some of the plants, even under the most favourable conditions of soil and climate, cannot be relied on to ripen off more than one or two fruits. In this country such large Melons could scarcely be utilised, but where the fruits are so universally consumed they are valuable. With fruiterers in France the Cantaloup holds the place of honour. During the summer season there is always a large one in cut which the thirsty workmen buy at a halfpenny a slice. Although we may scarcely hope to grow Cantaloup Melons profitably in this country, I see no reason why we should not eat them. We import largely the fruits we can produce ourselves, but we know next to nothing of one that we could obtain at a cheap rate, and which would doubtless become popular when well known. There is, of course, a difficulty in inducing people to eat what they know nothing about; but when one thinks of the way in which the Tomato has leaped into popularity, one may be allowed to speculate on the probability of any known fruit becoming a staple market commodity. The only Cantaloup Melon that would be likely to find favour with our growers is that called the Early-frame Prescott (Prescott petit hâtif à chassis). It is a small-fruited kind, but has scarcely enough flavour to satisfy the somewhat hypercritical taste of the regular Melon-eater, familiar with the delicate aroma of our best kinds. Its strong points as compared with these latter are robustness and hardiness, which naturally give facility of culture. There is, however, another variety in high repute with French growers called Noir des Carmes. It is larger than the preceding and of much better flavour. If any readers of The Garden have a sunny house empty in summer, they might use it worse than in giving these Cantaloups a trial. I have often wondered what sort of a race of Melons we should get by the intercrossing of these two with such kinds as Golden Perfection and Victory of Bath. Possibly a new departure of considerable commercial value. The two kinds above mentioned are those most favoured for culture under glass, especially for forcing, but the bulk of the Cantaloups is furnished by the Prescott de Paris and the Prescott argenté (silvery Prescott), which run up to a weight of eight pounds, the latter being rather the larger. Only one fruit is left on a plant. The Paris market growers cultivate these on a large scale, the markets of that town being supplied with them up to November. Melon culture is certainly a great industry in France; even more than that of the Grape. I look on the Melon as the national fruit there. Grapes are not grown everywhere, but Melons are. Through the length and breadth of France the Melon is the recipient of loving care; it is scarcely regarded as a fruit pure and simple; it is an article of food, and in a sunburnt region gives refreshment, health, and strength to millions of thirsty toilers. Two things strike an Englishman with surprise in France—the enormous amount of Melons consumed in towns and the way in which they are eaten. It certainly jars with our preconceived notions of the proper way of eating this sweet, juicy, aromatic fruit to see a Frenchman scatter salt and pepper on it with an unsparing hand, and yet seventy per cent. of the working men eat it thus. Perhaps it is necessary to use these condiments where the Melon comes into the daily dietary A friend once told me that I should never know the true flavour of the Melon unless I ate it in that way; it is "so much more wholesome," he said, "than eating it alone."

Hardy Apricots.—It is stated in the *Obstgarten* that M. Scharren, director of the Tiflis Botanic Gardens, has an Apricot of exceptional vigour and hardiness. It is considered as certain that this Apricot will live in the far north where Apricot life is now impossible. The ripening of the fruit is guaranteed, it is said, by the precocious nature of the tree. It is to be hoped that the Flor Ziran, as it has been named, will respond to the bright anticipations formed concerning it. We sadly need a climate-proof Apricot in this country, and if Flor Ziran is clothed in such armour, the sooner it finds its way here the better. The Apricot is the neglected fruit of English gardens. The hybridiser takes no heed of it, and, judging from what one sees, the small amateur has almost forgotten its existence. Truth compels the admission that the Apricot is a sad deceiver. It grows for a time with quite an astonishing vigour, and has such a happy look about it, that the heart of the possessor throbs with joy at the prospective sight of bountiful crops of luscious fruits. Then, without warning, comes the collapse; the fairest portions of the tree die away, leaving a mutilated wreck, which can be nothing but an eyesore and a reminder of misspent time. If we could but get a variety in which this element of uncertainty does not exist, the regeneration of our Apricot plantations would be certain. Every kind having a reputation for hardiness should be tried; and I therefore advise those engaged in the raising and cultivation of this fruit to endeavour to procure the Flor Ziran for trial. It might supply a long-felt want.

J. Cornhill.

CLEMATIS MONTANA.

As a wreathing or garlanding climber for early summer bloom nothing can approach this lovely Clematis. Its beauty is best seen when trained loosely and freely; nailed tightly and flat against a wall, the many graceful forms it is willing to fall into are lost. In the case of the annexed engraving it was guided first round the taller window; a long trailing shoot falling to the left, and partly caught by a Sweet Brier, gave the idea of training it across the lower window, which is now, and will be for many years to come, adorned with its wreath of living beauty in May and early June.

Lathyrus Drummondi.—"J. C. B." (p. 274), who complains of the difficulty of raising this plant from seed, will doubtless be interested in learning that, if not absolutely identical with L. rotundifolius, it is scarcely distinguishable from it. He will find this quoted in every seedman's catalogue, and will experience no more difficulty in raising it than with the common Everlastiog Pea, though it takes a somewhat longer time to obtain a good flowering plant than with that species. If there are any real points of difference between the plants bearing these names, I shall be glad to know what they are.—East Anglian.

Thunbergia laurifolia.—We learn that this plant has become naturalised in many parts of Tropical India, and that in many old gardens about Calcutta, Ceylon, &c., it may be seen festooning the largest trees, and in some cases completely smothering them with its long twine-like shoots and large clusters of blue flowers. In the Ceylon Botanic Garden it is used for tree-clothing in the same way as we employ Ivy and Clematis. It is obvious from this that to attain its full glory this Thunbergia must be allowed plenty of space. The illustration in The Garden last week of a small pot specimen of this plant was taken from a newly-rooted portion of a branch which had been cut from a large specimen. It is possible to obtain small well-flowered specimens of many large growing plants in the same way, but the pieces must be struck annually.—W.

Tropæolum speciosum.—I saw this the other day flowering in profusion at Reading. It was planted at the foot of a north wall, and evidently delights in a shady, but yet light, position. When growth commences, the young shoots are easily damaged by strong winds, being at that stage very slender; therefore, to obviate this, some slates about 6 inches high or more should be placed on edge, so as to shield them from harm. The roots require copious supplies of water, and free syringing should be given overhead to keep down red spider, to which this plant is liable.—E. Molyneux.

QUESTIONS.

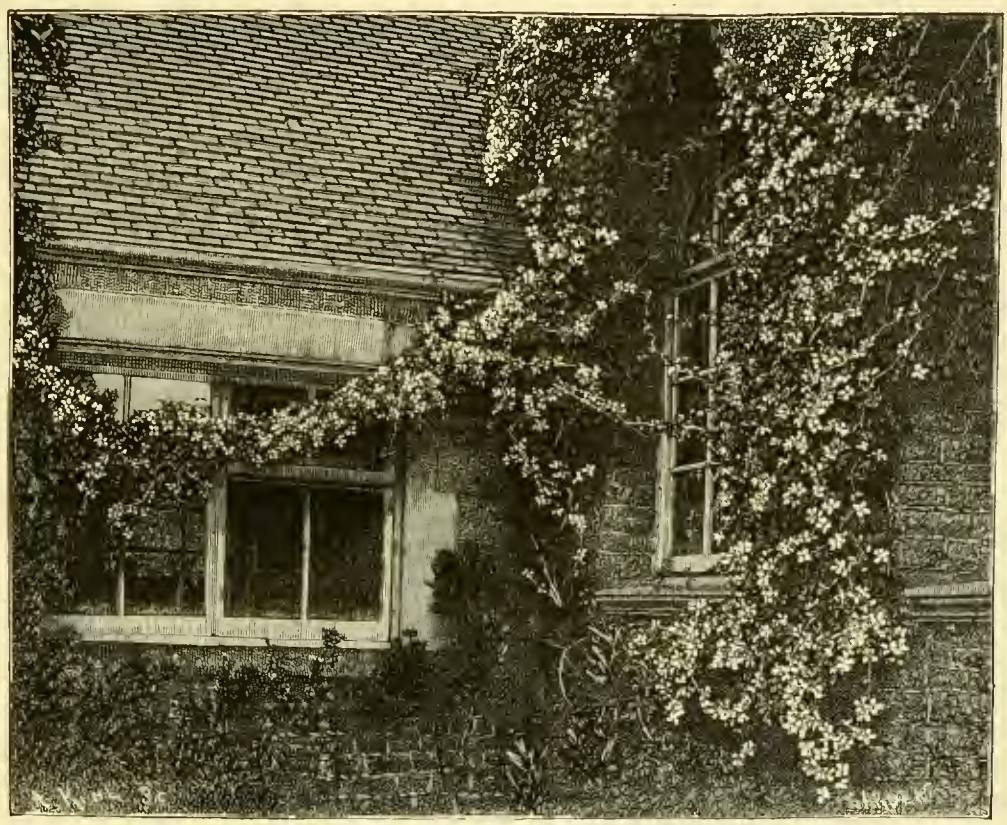
5519.—**Victoria Nectarine.**—Have any of the readers of The Garden been successful in ripening this Nectarine out of doors? I have a fine, healthy young tree of it on a south wall which has borne fruit for the last three years, but it has failed to ripen any properly. It has done well with me in a late house.—E. B. L.

5520.—**Ceylon creeper.**—A friend of mine describes a very beautiful creeper that grows in Ceylon on the hills, in the same temperature as that in which the Passion Flower grows. The native name is Tangapoo. It is said to be a very free-blooming climber, producing clusters of deep yellow, almost orange-coloured, bells. Can any of your readers tell me the name of it and if I can get it in this country?—E. R.

Indoor Garden.

WINTER FLOWERING PLANTS.

Calanthes.—These are simply invaluable for winter decoration, and ought to be grown in quantity in gardens where there is a great demand for flowers. In nearly every plant stove there are one or more shelves not far from the glass, and these, if shade is afforded during the hottest part of the day, exactly meet the requirements of Calanthes. Many recommend that loam be added to the compost in which they are grown; but if this is of a heavy character, it is altogether unsuitable for them, and as a rule they will thrive better in a mixture of turfy peat, horse-droppings, chopped Sphagnum, broken crocks and charcoal. Into this the roots ramble freely, and then, with the assistance of plenty of water and occasional supplies of weak liquid manure, strong bulbs will be matured, those of the Veitchi type being capable of producing fine spikes of bloom 3 feet or 4 feet in length. The bulk of our C. Veitchi bulbs are now between 6 inches and 12 inches long, and those of the C. vestita type are proportionally strong. I mention these facts in order that those who may have failed with Calanthes may form some idea as to why that happened and be enabled to obviate such a mishap next season. I have known instances in which the plants have received the best treatment imaginable during the growing period, and yet have failed to bloom satisfactorily owing to the cultivators of them being under the impression that some sort of rest is needed prior to flowering time. Directly the flower-spikes appear, *i.e.*, sometime in September, the whole of the plants are transferred to a cool house and kept dry for about six weeks, this being just long enough to completely cripple them. At no time should they be placed in a cool house, not even after flowering, for the purpose of resting them. Our plants are kept on the shelves in mixed plant stoves till the spikes are partially developed and the first blooms commence to expand, and receive water whenever they are at all dry. The atmosphere of these houses being, however, rather close and moist, causing the blooms to become spotted, the whole of our Calanthes are transferred to a larger span-roofed structure, where there is a better circulation of air, and this just suits them. This house is principally devoted to Ferns (Maidenhairs chiefly), among which they are mixed, and the temperature is maintained at from about 55° to 60° at night, and 10° higher in the daytime. After the foliage is cleared from the bulbs much less water is given to the roots, but it is not altogether withheld till the flowering is nearly over, unless it happens that some of the plants are required for house or cool conservatory decoration for a time when no water is given. Some admirers of Calanthes regret that they lose their foliage before the flower-spikes are fully developed, but I am disposed to think this a point in their favour, as the foliage is very stiff, and if it remained green, the plants could not be so effectively grouped as they now can be among Ferns or other decorative plants, as it does not matter where the pots are so long as the arching spikes of bloom are displayed to the best advantage. Calanthes, as has just been pointed out, are not suitable for greenhouse or cool conservatory decoration, except for a short time; a long stay in such places injures the bulbs, and, besides, the bloom does not last so long as it does in a warmer house. For ball-rooms and large front halls they are unrivalled, and with us they are available in quantity from November till the end of February, this long succession being maintained by means of two batches each, consisting of rather more than a hundred strong bulbs, one being nearly a month in advance of the other. We have when required formed four groups of Ferns and Calanthes in an entrance-hall, the outer fringe to C. vestita being of Maiden-hairs facing outwards, so as to hide the pots, while Davallia Mooreana and Adiantum tenerum, with spikes of C. Veitchi thickly studded through them, made a singularly attractive arrangement. Our bulbs are, for the most part, in 6-inch pots, but we have some in 4½-inch pots, and these, producing as they do much shorter spikes, are the best for mixing with Maiden-hair Ferns and Lycopods on mantel-pieces, in fireplaces, and small stands. Single flowers mounted are of service for bouquets and button-holes, and compact spikes with fronds of Maiden-hair Fern are frequently worn by ladies.



The Mountain Clematis (C. montana) in Surrey. Engraved from a photograph for The Garden.

Arum Lilies.—The demand for these appears to be increasing. Where cultivated in good earnest they are usually planted out soon after they have ceased to produce flowers, sometimes in well prepared trenches where they can be given abundance of water in hot weather, and often on ordinarily dry, well-manured land. On our heavy ground the latter method is adopted, and they invariably grow strongly without any aid from the watering-pot. Although we frequently hear cases of Arums surviving the winter in the open air, they are by no means hardy; indeed, an early autumn frost will seriously cripple the foliage, and when this happens little or no bloom will be available at Christmas. The whole of ours were potted up early in September, and after a week's time under canvas shading they were transferred to the central staging of a large span-roofed greenhouse, where they do not appear any the worse for the rough treatment to which they have been subjected. Unless they receive plenty of room and light, Arums soon become drawn and weakly, as well as badly infested with green fly. We always endeavour to keep them well together, even when in full bloom, in the conservatory, as when crowded with other plants they soon get spoiled. Moreover, they are more effective for house decoration in groups than in the shape of single plants. Arum Lilies will bear a moderate amount of forcing, but forced plants are not continuous flowerers; they are much more profitable in a warm greenhouse where they receive air whenever the weather outside is favourable. They require abundance of water and liquid manure very frequently, treatment which maintains them in a healthy flowering state from Christmas until Whitsuntide. They are very liable to attacks from green fly, and gentle fumigations with tobacco paper are the best remedy for this. Arum Lilies are very much used for church decoration, the bulk of the flowers sold being for that purpose, but the smaller blooms are very effective in crosses and even in wreaths, and very durable they prove to be when used in that way.

Bouvardias.—Under good culture these flower continuously for several months at a time, and that during the worst part of the year. Some fail with them because they imagine that they require greenhouse treatment; others err in believing them to be stove plants; whereas they are neither one nor the other, but really require an intermediate temperature. In a greenhouse they may flower very well for a time, but not long, simply because the heat is not strong enough for them; while, if treated similarly to the majority of stove plants, the blooms will be found to be flimsy and poor in colour, and the subsequent growth either too soft or too weakly to be floriferous. Supposing the plants to have been planted out during the summer in cold pits and recently potted up, after being shaded for a few days till recovered somewhat from the check sustained by that operation, they ought to be placed on stages, beds, or shelves not far from the glass, and receive plenty of air whenever it can be given without lowering the temperature below 55°, closing early and maintaining the night temperature not below 50° nor much above 55°. This genial, yet not at all forcing, heat serves to develop the blooms strongly

and of good colour, and the old wood, being well matured, continues to push out young flowering shoots, which, if not so fine and plentiful as at first are nevertheless very serviceable. Bouvardias require to be carefully watered, and liquid manure may be occasionally given, but only to such as are thoroughly well rooted. Plants kept constantly in pots are rarely so strong as those that have been planted out for a time, and they require more assistance in the shape of liquid manure. Those bought in from nurseries usually occupy comparatively small pots, and consequently often need a shift. If the loam used for this purpose is light and fibrous, it may be employed at the rate of two parts to one of leaf soil and a little well-prepared rotten manure, plenty of silver sand being added. Where the loam available is of a clayey nature it is advisable to use less of it and to substitute one part of good fibrous peat. Our largest supply of cut blooms will this season be obtained from strong plants growing in a light, well heated pit. They are planted out in good light soil, and with very little attention bloom strongly and continuously. The principal enemies to Bouvardias are mealy bug and red spider. The former if at all plentiful is not easily got rid of. Two ounces or a wine-glassful of paraffin to a gallon of soft water at a temperature of 110° or even hotter, and kept well stirred, will, if syringed forcibly on to the infested parts, prove fatal to the bugs, and subsequently the few that survive should be searched for and destroyed. When the leaves curl badly, red spiders will be found to be at work. These little pests are very minute, requiring a lens to detect them, and this accounts for the mysterious disease that many find to so completely disfigure and check the growth of their Bouvardias. Once established on a plant, no amount of syringing appears to affect them, but a sprinkling of flowers of sulphur soon destroys them. We have several plants on which the lower leaves of the shoots are curled and sickly-looking, while those formed since the sulphur was applied are broad, clean, and healthy. A handful of the sulphur is worked through a muslin bag into a gallon can of water, with which it mixes sufficiently well to admit of being distributed with a syringe. The sulphur which is not syringed off again on sunny days smells strongly, thus further discommoding the spider. We find Vreelandi, single white, the most useful sort, and Alfred Neuner is a good double companion to it. Dazzler is the brightest single scarlet variety, and with us will gradually replace Hogarth, though the latter is also good in colour and free. Maiden's Blush, blush-rose, is very free and good, and is worthy of culture where variety is liked, though, as far as we are concerned, red and white are the only colours cared for, and this is the reason why we grow but few of President Garfield, double pink. Humboldti corymbiflora and jasminiflora are both very beautiful white varieties, but with us they are scarcely so continuous flowerers as those just named.

Double Chinese Primulas. — These are of great value to all who have to maintain a regular, and perhaps heavy, supply of white cut flowers. According to my experience, the old Double White is still the most useful. Others there are which produce large blooms, but not in such profusion, nor are they so easily increased. Many err in treating double varieties similarly to single-flowered sorts. The semi-doubles from seed thrive well in cold frames during summer, and flower strongly on greenhouse shelves; but this seldom suits plants raised from cuttings or divisions of the old Double White, and unless a little heat is given the latter, they are liable to damp off badly. They will also fail if potted high so as to expose the bare stems; whereas if sunk into the soil up to the lowest healthy leaves, the stems emit roots, and thereby become a source of strength instead of danger. They are best kept on shelves in a gentle heat, where, if carefully watered, the more the blooms are cut the more the plants spread and bloom. Mixing them with other plants on stages and beds in stoves or even in an intermediate house is only to court failure; they must have light and air. If they must be kept in a greenhouse, a little fire-heat should still be given, if possible, and this, if the house is properly ventilated, will prove beneficial to all the other occupants of the house. Plants of white Primulas, strongly rooted, will be greatly assisted by occasional or bi-weekly supplies of liquid manure. Coloured semi-double varieties succeed best in a well-ventilated and heated greenhouse, as, when grown in a rather warm house, the flowers are of a sickly hue. Old plants of semi-double whites bloom very abundantly and continuously in heat, and are very serviceable. The pyramidal or "run-out" trusses of double white Primulas are particularly effective in vases. We have frequently used nothing but these, white Begonias, white Bouvardias, and Maiden-hair Fern fronds in silver stands on dinner tables, an arrangement that invariably gives satisfaction, especially when contrasted with other stands or miniature banks, as the case may be, of semi-double red Primulas, red Begonias, Bouvardias, and Ferns. Indiscriminate mixtures are much too common both in the case of plants and cut flowers. W. I. M.

Vallota purpurea eximia and V. p. magnifica.—Allow me to take exception to your assertion in The Garden (p. 260) that the above named forms of the so-called Scarborough Lily are identical, as they are quite distinct the one from the other. That sent you by Mr. Hartland under the first cited name is a much lighter shade of red than the variety known as magnifica, and has also a clear white throat, which the other has not. I have bloomed both of them well this summer, and consider the one you figured to be merely a fine form of the type, V. purpurea, with rounder and less pointed petals and larger and more cupped flowers, but inferior in beauty to V. eximia. —W. E. Gumbleton.

Tree Carnations in winter.—In the course of last winter a statement was made by a writer in one of your contemporaries to the effect that Tree or Perpetual Carnations do not bloom so well under glass in winter as is generally supposed. Yet it is a fact that plants of Tree Carnations in a greenhouse, with the assistance of just enough fire-heat to keep out frost, will bloom all the winter, even through the dullest portion of the year. But supposing there might be room for the objection as applied to propagated plants, it cannot possibly apply to seedlings. When at Slough, a few days ago, I saw three truly marvellous beds of seedling Tree Carnations, each bed containing about 700 plants. These plants had been raised from seeds, sown in January in a warm greenhouse, and they were planted out in the open ground in March. A good many of them are already in flower, and nearly every plant had produced buds. It is Mr. Turner's intention to take advantage of two or three fine days to pot up these plants in pots just large enough to hold the balls of earth lifted from the open ground, filling up with a suitable soil and potting firmly. Then they will go into a cold house, where a little fire-heat can be applied to keep out frost, and, if necessary, to ward off damp. Doubtless the bulk of these plants thus treated will flower freely during the autumn and winter, and their value for cutting purposes will be great. Near these was another bed of seedlings raised from seeds sown in March; they were getting well forward, but not so forward as those sown earlier, but they also will be potted up, and there is reason to believe they will flower in spring. If anyone, therefore, wishes to possess a batch of winter-flowering Carnations, let him obtain some good seed; sow in January in heat and plant out in good soil in March, lifting the plants in September to bloom in October and throughout the autumn and winter. To do them justice they should have a house to themselves and be treated as above described. But a little heat is indispensable in order to have blooms throughout the dullest weather of the season.—R. D.

Begonias from seed. — Begonias are well grown at Beddington House, Croydon, where many of the flowers measure 5 inches in diameter; their petals are round and fleshy in texture. They attain their largest size the second year, but after that time they become smaller; therefore, if very large flowers are desired, the plants should be raised from seeds.—W. H. G.

Winter-flowering Pelargoniums. — These highly useful plants ought now to be in their winter quarters. Those who have a light span-roofed house that is kept at from 50° to 55° in winter may have plenty of bright trusses of bloom during the dark days, when they are far more appreciated than in summer. Many, however, have to make shift with a few shelves in any warm structure, as houses cannot always be devoted to one variety of plant; and if the Pelargoniums have been carefully treated, they will flower very freely for a long time, provided the requisite temperature is maintained. They must not, however, be hurried too much at first, as the temperature of any glass house is high enough for some time yet. Ventilate freely on all favourable occasions; keep a dry, sweet atmosphere, and do not overwater, and such kinds as Vesuvius, Henri Jacoby, and Wonderful will form a mass of beautiful trusses of bloom quite equal to those of midsummer, and they will last in perfection much longer than at that season. Husband the strength of plants intended for mid-winter display by picking the blooms off until wanted. Summer-flowering kinds are now on the wane; but autumnal flowers may be obtained from open-air gardens, in which they are still abundant.—J. Groom.

NOTES.

White Chrysanthemums.—Herodotus tells us that now and then pure white oxen were born among the ancient herds of Egypt, and that these were held sacred for sacrifice. To this end it was essential that not a coloured hair could be found on their hides! This seems an impossibility, and yet as a fact he assures us that such perfect examples now and then appeared. It is so with Chrysanthemums. Look at all the white varieties ever obtained before Mr. Dowuton was so fortunate as to rear the snow-white Elaine! Many were considered white and beautiful before its birth, but of all the varieties of Chrysanthemums known to-day—and there are many—Elaine is, so far, the best and most useful of all the Japanese kinds. So, also, when we come to the now popular early or summer-blooming race we have nothing equal to Madame Desgrange, which has indeed very many of the good qualities which distinguish its fairer and taller sister Elaine. These two varieties are irreproachable in their way, nor would we willingly cease to remember Fair Maid of Guernsey, Mons. Astorg, Lady Selborne, and a score of other good late white-blossomed kinds, and yet there is still room for good seedling white Chrysanthemums of all sorts, shapes, and sizes. I believe Mr. John Thorp and Dr. Walcot, of New York, have some wonderful single or Daisy-flowered white kinds in store for us; but it will be a most exquisite blossom, and a fine-habited plant to boot, that will surpass either Elaine or Madame Desgrange. It might be worth while to offer a special prize for the best new white Chrysanthemum of 1886-7, and I hope it may be done.

Verdure only.—Of two remarkable women, both born gardeners, as their printed works abundantly testify, one scarcely knows which to most admire, whether Georges Sand or our own George Eliot. Ivan Tourguenieff has just published a letter he received from a French lady who was an intimate friend of Georges Sand and who was with her when she died. Her last words were, "Laissez verdure," that is, "place no stones over me, but let grass and flowers alone grow there." It would not be easy to find a more telling protest against the modern practice of making our cemeteries unbeautiful, and winged words like these can never die; on the contrary, they, like good seed, will bud, and leaf, and blossom again and again in the hearts of all who

love Nature, and whose sympathies are awake to the beautiful things ever with us. Do you know Alphonse Karr's story of the "Two Carpets," in his delightful "Tour Round my Garden?" If not, read it at once (chapter iii., p. 11). Speaking of his lawn, he says, "Now here is a carpet that I like, always fresh, always handsome, always rich. It cost me sixty pounds of grass seeds at twopence-halfpenny the pound—that is to say, twelve shillings, and it is about the same age as that carpet in my studio which cost me twelve pounds ten shillings. This last is becoming poorer and more faded every day, threadbare, disgraceful, and patched, while the one in the garden is every year more green and thick-tufted, every season more beautiful." What testimony is here for Grass or verdure only! "Ah!" said a rich Australian to me the other day as we stood on an English lawn, "if I paved my ground with sovereigns on edge I could not get Grass like this to grow in my garden." The fact is one must go to the south of Europe, or to the Tropics, to find out how rich, and green, and satisfying in its beauty is a well kept English lawn.

Androsace lanuginosa.—Tufts of silvery leaves, seemingly strung on pink thread, hang gracefully over the rockery boulders, each tuft bearing one or more cluster of delicate Primula-like flowers. Even if it never flowered, we could ill spare its little cascade-like masses of burnished leafage. One can well imagine the delight of old Dr. Mackay when he first saw seedlings of this plant blooming in the College Gardens at Dublin in 1844. Seeds had been sent to him from India, and he was the first to see flowering plants of it in Europe. An original portrait of Mackay hangs before me as I write, showing a fine, strong, thoughful face above the high-necked coat collar of half a century or more ago. He was a genial, kindly, studious man, author of "Flora Hibernica," and his name will live long in connection with Mackaya bella of Wm. Harvey, and Zygopetalum Mackayi of the late Sir W. J. Hooker, even if there was any doubt of his being ever forgotten as the man who formed the College Garden, Dublin, now nigh on a century ago, and lived long as its first curator. But the Androsace which he had the honour of being the first to flower still lives on, luxuriant in its original European home, and recalls many pleasant memories of a kind and gifted man. The plant is quite easily increased from slips, inserted now in sand under a cap or bell-glass, and such slips, planted out in May next, will go on blooming all the summer and autumn. It has quite recently (p. 100) been figured in The Garden, but although the plate shows a profusion of leaves and blossoms, the elegant habit of the plant has for once evaded the pencil of the artist.

Outdoor Grape Vines.—The immortal Mr. Samuel Pepys writing in his diary under date July 22, 1661, says: "I came to Hatfield before 12 o'clock and walked all alone to the vineyard, which is now a very beautiful place again, and coming back I met with Mr. Looker, my lord's gardener (a friend of Mr. Eglin's), who showed me the house, the chapel with brave pictures, and above all the gardens, such as I never saw in all my life, nor so good flowers, nor so great Gooseberries, as big as nutmegs. To horse again, and with much ado got to London." Not a word of Grapes, but July would, of course, be too early for them, and the "great Gooseberries" had to do duty for them, as it appears. The above extract, however, reminds me that I have repeatedly seen good crops of outdoor Grapes in the south and midlands of England, and even allowing that the wine formerly made from the produce of English grown Grapes was poor and thin, yet it had the advantage of being pure and undefiled. There is now an alcohol industry developing in Jamaica, the product of sweet Potatoes; this, we are told, is shipped to Spain for the avowed purpose of fortifying the poorer Spanish wines! Even if Vine culture out of doors fails us we can at least grow the "great Gooseberries," and make excellent and wholesome wine of them. Why is the Grape supposed to be the only wine-yielding fruit? Apples, Pears, but more especially the Plums, now going to waste in Kent, and the Gooseberries and Currants, which seldom fail us of a crop, would make better wines than the bulk of that imported from the Continent year after year. But it is, perhaps, too much to expect us to grow wine-yielding fruits, seeing that our fruit crops are often wasted for want of fruit-preserving or marmalade-making industries on the spot, *i.e.*, wherever large quantities of fruit are annually grown.

Change of place.—Someone has said that "a change of seed means a change of soil," and the veriest beginner in gardening soon discovers that many, even if not most, cultivated plants are benefited by a change of locality. Of course, the reverse of this is sometimes true, but this fact need not prevent us from giving plants which do not succeed with us a fresh position, and, as far as is possible, a change of soil now and then. Many greenhouse plants grow far stronger and better out of doors during summer than they will do under a glass roof. So, also, we often find hothouse plants improved by a change of quarters, which in reality also means a change of temperature and of light, unless the aspect of both houses is precisely the same. Of course, very often a change from one hothouse to another is accompanied by an entire change of cultural treatment, but even if the treatment be precisely the same in both cases, the results gained in the one house will be different from that obtained in the other, and especially is this so if the angle of the roof happens to be different. I know of a case in which Eucharises grown luxuriantly in a damp, half-shady corner of a plant stove, absolutely refuse to flower there; but if these plants are transferred to a light, sunny house for a few weeks, heat and moisture remaining the same, they soon throw up flower-spikes when returned to their old shady quarters, and the same is true of many other things.

Lilium auratum.—The Gold Star, or Gold-rayed Lily of Japan, is really a noble flower, a sort of professional beauty, one may say amongst garden blossoms, and as capricious and hard to please as a *prima donna* of the highest type. I read in the papers the other day of a specimen of this Lily bearing over three hundred flowers, the plant being the produce of a single bulb planted nineteen years ago. I did not think it was so long ago since Mr. John Gould Veitch introduced the plant, but time flies on silver wings, and never so quickly as in a garden. I can remember gazing with wonderment long before I saw the flower itself on an original drawing of this fine Lily by the late Mr. Andrews, who thirty years ago was the great portrait painter—the Sir Joshua Reynolds, let us say—of florists' flowers. Who can tell us how to grow Lilium auratum? No garden flower is quite safe and perfectly at ease in our gardens unless we can rear it from home-saved seeds, and this is especially true of this noble Lily. Of course, if we could make sure of getting up a stock of home-grown bulbs from the old bulb scales, the results might be better than now. As it is, in nine gardens out of ten Lilium auratum culture resolves itself into planting imported bulbs every season or so to replace those which die away after the second or third year. I wish those who can get up a healthy stock of home-grown bulbs from seeds or bulb scales would tell us of their soil and climate, in a word, how it is done. I hear the Bagshot sandy peat and cow manure suit it, also of its doing well at Ormskirk, but more information is needed in order to ensure its permanent beauty in our gardens generally.

Dendrobium formosum.—Colonel Benson, who introduced so many fine Orchids from India, told us long ago of the Lily-like beauty of this plant as seen at home in Moulmein. The collection of its ivory-white sprays is quite an industry during its natural-blooming season, when the flowers are gathered by the natives of the villages and brought by them into the towns by the basketful for sale. It is the old, old story, for the Eastern beauty, with an olive skin, must have these fragrant blossoms for her blue-black tresses just as must her fairer sister of the west. Well grown, it is certainly one of the finest of all known Orchids, and I remember an engraving of a specimen plant which was exhibited at one of the London flower shows in 1851 (*vide* Gard. Mag. of Botany, vol. iii., p. 239) which bore over one hundred of its great white blossoms. It was in a comparatively small wooden basket, and came from Mr. S. Rucker's collection. My own experience is, that this species and all its variations grow best on a bare block of wood or cork, hung up near the glass in the full sunshine, and when growing freely their roots should get water from a syringe three or four times a day. Thus treated, they grow and bloom freely year after year. Fine strong imported pieces of this plant are now readily procurable at a cheap rate, and I strongly advise any who have failed to grow this plant under basket or pot culture to try it once more on a bare bit of wood or cork bark in full sunshine. For cut flowers its single blooms or clusters of two to five are well-nigh perfect, remaining fresh and fair in water for many days.

The Japan Bramble.—In a sheltered sunny corner we planted out a small specimen of Rubus phœnicolasius a couple of years ago. It is now 6 feet high or more, and has fruited very freely, the flavour being something between that of a Blackberry and a Raspberry. It is of most value however, as an ornamental shrub in a sheltered corner, where its bright green leaves can show their silvery lining as blown by the autumnal breeze. One of the finest specimens of this Rubus I ever saw is that in the great temperate greenhouse at Kew, and in all cold, wet localities the plant should be planted out in a cool conservatory and allowed to grow up one of the pillars, so as to show off its fruits and silvery-backed foliage to advantage. Another good plant for a similar position would be the singular and nearly leafless R. australis, which, when planted out in a cool conservatory and allowed to grow up in its own free and prettily entangled way, becomes one of the most distinct of all ornamental greenhouse plants. A specimen of this last-named in a large pot had attained a height of 6 feet, as exhibited last autumn at the Antwerp Floral Exhibition, and it was very much admired. As so grown it reminded one of a well-grown plant of Asparagus plumosus as seen at a little distance, so light and feathery did it appear.

Rosa rugosa.—In the "Rosarum Monographia; or Botanical History of Roses," by the late Prof. Lindley, published half a century ago (1820), at p. 5 there is an etching of this plant by Lindley's own hand. The drawing was made from a Japanese figure, and it is quite evident that Lindley had never seen the plant, since his sketch reminds one of the celebrated statue of Artemus Ward, the peculiar advantage of which was its resembling no one in particular, so that it could be made to stand for nearly

every celebrity in its turn. And yet, Rosa rugosa is now in every garden, with its great rose-purple, crimson-rose, or snow-white blossoms, attar scented, and followed by great orange-red or lacquer coloured fruits, beloved here, I am sorry to say, by the birds; hence their beauty is but short-lived. My opinion is that Rosa rugosa was really in cultivation in Ireland fifty years ago. At any rate, when its re-introduction took place a few years back, it was sent to Ireland as a new thing, and more than one amateur was a little startled to find it a Rose which had grown in his garden since he was a child. Who can tell us the history of this species? The great Apple Rose—Rosa pomifera major of Parkinson, 1629—is another case in point, lost sight of for centuries, and then it turns up by no means unplentiful in the isle of saints! A friend of mine who has had many pleasant rambles in search of old Roses suggests that a good coloured plate of Rose fruits would be effective, and that it might call attention to a peculiar phase of their beauty. Rose fruits are of nearly all sizes, shapes, textures, and colours, so that I hope his suggestion may bear fruit. VERONICA.

Cyperus Papyrus.—Permit me to correct an error in "Veronica's" statement (p. 269) that this plant "exists yet near Syracuse in a wild or naturalised state." The plant which is found growing in considerable abundance in the river Anapus, near Syracuse, is the Papyrus syriacus, a different species. The Cyperus Papyrus, or Papyrus antiquorum, "once so important in the world of letters," and known as the "Paper-reed of the Ancients" and "Paper-reed of the Nile," although formerly extensively cultivated in Egypt, has long been extinct in that country, in remarkable and exact fulfilment of the prophecy in Isaiah (chap. xix., 7), and is now, I believe, confined to the remote upper waters of the Nile. These two plants are well described and illustrated in the fifth volume of THE GARDEN (p. 504).—NARCISSA.

Bees and rosy Sedums.—In "Veronica's" interesting note on the Magnolia grandiflora the following sentence occurs: "Again it is fruity autumn-time, and the bees and the butterflies are happy honey-hunting on the rosy heads of the Sedum." If happy at all, their happiness seems about as short-lived as that of moths, which, fascinated by the glare of lamp or candle, singe their wings. The majority of the bees that go honey-hunting to the rosy Sedum flowers return no more thence. Whether they feed too freely at first or the flowers poison the honey is uncertain. What is known is, that bees and butterflies speedily become rivetted to the flowers, merely expanding a wing or lifting a foot when disturbed, but totally deprived of will or power to leave the rosy heads of the Sedum. At the present moment we have a row of the latter in full beauty, pincushioned over mostly with humble-bees and a few butterflies. These remain night and day on their rosy bed, gradually becoming helpless, until they finally fall off and die, the ground being now strewn with their dead bodies. The wasps and honey-bees, and even white butterflies, seem to have sufficient sense to avoid this rosy field of sweetness and of death. The chief victims are butterflies of the peacock type and medium-sized humble-bees, mostly of one species. Perhaps "Veronica" will be able to say why the honey-hunting that begins so happily on the rosy Sedum heads should produce stupefaction and end in death.—D. T. F.

Anagallis cærulea.—Mr. Peter Inchbald (p. 284) expresses surprise at meeting with A. cærulea and A. arvensis in the same field, but, both being British, their occurrence together is not at all uncommon. In the north of London, between Hornsey and St. Albans, I have frequently met with both in friendly contiguity. I am of opinion that the species just named are distinct, but have been hybridised. The varieties from the shores of the Mediterranean, viz., A. Monelli, Phillipsi, &c., are delicate and will not stand our winters without protection. All the tender sorts now in commerce are varieties from the last mentioned species, with one exception, viz., A. fruticosa, from Morocco, a yellow variety which has somehow or other become orange-red, owing, I presume, to hybridisation while under cultivation by the seed growers in the south of France and Italy.—S. A.

ANCIENT EGYPTIAN PLANTS.

SOME two or three years since I called attention in THE GARDEN to the curious discovery in Egypt of flowers which still retained their shape and colour, though they had been buried with the mummies with which they were found for some 3000 years. Further discoveries have recently been made of flowers, fruits, and seeds in the old Egyptian tombs, which were alluded to by Mr. Carruthers in his opening address to the biological section at the recent meeting of the British Association, when he mentioned some very interesting particulars regarding these ancient flowers. He said, to quote the report given in *Nature*, "The recent exploration of unopened tombs belonging to an early period in the history of the Egyptian people has permitted the examination of the plants in a condition which could not have been anticipated, and happily the examination of these materials has been made by a botanist who is thoroughly acquainted with the existing flora of Egypt, for Dr. Schweinfurth has for a quarter of a century been exploring the plants of the Nile valley. The plant remains were included within the mummy wrappings, and, being thus hermetically sealed, have been preserved with scarcely any change. By placing the plants in warm water, Dr. Schweinfurth has succeeded in preparing a series of specimens gathered 4000 years ago which are as satisfactory for the purposes of science as any collected at the present day. These specimens consequently supply means for the closest examination and comparison with their living representatives. The colours of the flowers are still present, even the most evanescent, such as the violet of the Larkspur and Knapweed and the scarlet of the Poppy; the chlorophyll remains in the leaves and the sugar in the pulp of the raisins. Dr. Schweinfurth has determined no less than fifty-nine specimens, some of which are represented by the fruits employed as offerings to the dead; others by the flowers and leaves made into garlands; and the remainder by branches on which the body was placed, and which were enclosed within the wrappings."

Then follows a list of the fifty-nine plants determined by Dr. Schweinfurth; several different kinds of fruits were found, three of different Palms, varieties of Dates, and two kinds of Figs, all exactly resembling the fruits grown at present in Egypt. The Figs still show the incisions made in them to destroy certain insects which feed on them, just as is done at the present day. Branches of the Sycamore, one of the sacred trees of Egypt, which were used in the bier of a mummy nearly 3000 years old, were moistened and laid out by Dr. Schweinfurth, who said they equalled "the best specimens of this plant in our herbaria," and that they differed in no respect from living Sycamores. Grapes were common, and besides familiar kinds there were others which are now unknown. The leaves exactly agree in form with those in cultivation at the present day, but the under surface is covered with white hairs, which have not been observed on any modern Egyptian Vines. Wheat and barley were frequently found; some of the latter was in a tomb 5400 years old. It is curious that the seeds of various weeds, which at this day are a source of trouble to the Egyptian agriculturists, should be found among the seeds of cultivated plants in the tombs, showing that the fields in the time of Pharaoh were infested with just the same weeds as they are at present.

It is strange, indeed, how these flowers have been preserved for such an immense period of time, even though kept from the air, when one remembers that a flower is typical of what is frail and ephemeral, and that, with all our care, there are not many flowers which we can keep in our rooms for more than a few days after they are gathered; and it is remarkable that they should be exactly the same as those grown at the present time. The explanation of this, I presume, is that the circumstances of growth (climate and soil) have not changed; that the Egyptian is not a commercial nation nor one given to change in any way, so that new plants or methods of cultivation have not been introduced.

Mr. Carruthers further points out that "the cereals are good specimens of those still cultivated. This observation is true also of the cultivated grains which I have examined belonging to pre-historic times. The Wheat found in the purely British portion of the ancient village explored by Gen. Pitt Rivers, is equal to the average of Wheat grown at the present day. It is remarkable that in our own country, with all the appliances of scientific cultivation and intelligent farming, we have not been able to appreciably surpass the grains which were harvested by our rude ancestors of 2000 years ago. G. S. S.

FLOWER GARDEN.

ANEMONE JAPONICA IN MASSES.

THERE is nothing finer at this time of year than large plantations of the white and coloured Japan Anemones. When many hundreds of blooms of these look us in the face on a bright October day they seem to enhance our estimate of floral life. The flowering power of the Japan Anemone dies hard; the frosts and heavy rains of chill October only impair it; it needs murky November to kill it. Even through this month, when not too unkind and precociously wintry, the red and white stars still appear, and, in company with the brilliant Cardinal Lobelia and the common Marigold, they enjoy the faint gleams of the autumn sun. It is when frost has played havoc with the flower garden that the worth of the Japan Anemones is seen. To those who want many flowers for cutting, a large bed of them is a harbour of refuge when the beauty of the September flowers has been suddenly blighted. Cut and come again; the more flowers you cut away the more quickly do the buds swell up to expansion size; the supply is inexhaustible. Thousands of flowers can be cut from a few square rods of ground. Moreover, the flowers are perfection for cutting, although here the question of culture comes in, for if you grow them meagrely you will get small flowers, and, what is worse, they will not come well away from the axil, so that when you cut them you will, in taking off a piece of stem with a mass of embryo buds, destroy the source of plenty. Plants well established, good food, and to spare, with deep culture in light soils, and you will never have occasion to regret the pains bestowed, and will never have to go far for cut blooms at this time of year. I do not know why the red form is so little grown, probably because the presumably superior merits of the white have overclouded it. In their case comparisons are invidious. What one lacks in form is made up in colour. In the coloured forms the pink variety sometimes takes the place of the red. I think it washy and lacking in effectiveness as compared with the latter. The red kind wants good culture even more than the white; in poor arid soil it is a miserable stunted little object with the colour starved out of the flowers. It is food and moisture that give colour. With plenty of both this is a gloriously bright, joyous-looking autumn flower. BYFLEET.

Crocus speciosus.—I am afraid that the bunches of blossom of this beautiful species which Mr. George Paul exhibited at the last meeting of the Royal Horticultural Society scarcely got the attention which they deserved, and yet what, among autumn-flowering plants, can be more charming than this lovely Crocus? I have some bulbs of it round a circular bed in my forecourt garden, and they are now sending up flowers of very large size and beautifully coloured. It is on a north aspect, and rather shady and moist, but the bulbs appear to do well. It is also growing on the verge of another border in a spot fully exposed to the sun and flowering equally well. I therefore conclude that it is an accommodating

subject, and will do well in any spot, provided it has a proper depth of suitable soil. Passers-by wonder what the pretty blue flower is which seems to be so fresh and bright; and well enough they may, for it is rarely to be seen. It follows the Colchicums, which rank amongst the pleasantest of autumn flowers.—R. D.

PLATYSTEMON CALIFORNICUS.

In making selections of annuals some of the very best are often overlooked. The beautiful little Californian Poppywort shown in the engraving, though of high garden value, is very seldom seen, and by no means deserves such neglect. In light, warm soils it is quite hardy, and when autumn sown each plant will cover a space of 2 feet in diameter. The stalks and foliage are of a pleasant glaucous colour, and the flowers a rich cream colour with a large spot of full yellow at the base of each petal. It is not only good out of doors, but of value for cutting, the flowers lasting well in water.

Tree roots in flower borders.—If "H. R. C." carries out his intention of planting a row of Yews at the back of a border only 8 feet wide, he must be resigned to a comparative want of vigour in the greater portion of the occupants thereof. In dry seasons, unless there is an absolute command of water, the growth of hardy flowers is sure to be disappointing if their larder is invaded by the robber roots of gross-feeding trees. Only just lately I was noting, as instructive in this matter, the different appearance of two lots of red and white Japan Anemones, one of which is within the reach of the roots of a large Wellingtonia, the other just out of it. In the one instance, the dry summer notwithstanding, growth is strong and flower production continuous; in the other the plants are making a sorry show, and will soon be out of bloom. Wherever hardy flowers are grown in the vicinity of trees, the roots of the latter ought to be cut every three years. The better you make the border the more will the trees appreciate it, and with the instinct which roots seem to possess they will come straight into it from a considerable distance. I have often remarked that the roots of trees and shrubs fill a piece of ground that has been well stirred and manured much more quickly than when such ground is left in its original state.—J. C. B.

Platystemon californicus; flowers creamy white. Engraved for The Garden from a photograph.

Artichokes as decorative plants.—"Veronica's" note on the value of common Asparagus for ornamental purposes (p. 291) reminds me of the usefulness of the Globe Artichoke and garden Cardoon for mixing with herbaceous plants, or grouping with or contiguous to shrubs. These form a sort of connecting link between Yuccas and Thistles, and are almost a match in ornamental value to the general run of either, or both. The first is hardy in warm situations, and only requires a handful of Fern fronds or other litter in those that are colder. Cardoons are more tender, and are better raised from seeds and planted out annually towards the end of May. Artichokes rapidly form good stools, and grow and bloom with great vigour and profusion. The silvery leaves are among the most beautiful of all foliage plants, and the rich purple flowers are also strikingly beautiful in all stages from budhood to full expansion in rich looking thistledown. The effect against almost any sort of plants is rich, but particularly so contiguous to yellow Dahlias, blue Delphiniums, or Larkspurs, or purple Stocks. Sprays of the Clematis Jackmanni, either behind or before Globe Artichokes, also heighten their own beauty as well as enhance that of the Artichokes. The plants look best with the flower-heads uncut for use when grown in single specimens among other plants in beds or borders. But where masses are growing among or contiguous to shrubs, a supply of heads for culinary consumption may be cut in season without greatly lessening the general effect. Hence, those fond of Globe Artichokes and who have small kitchen gardens may grow their entire stock of these in the herbaceous borders or shrubberies. Without saying that these common plants are of equal merit with Asparagus for ornamental purposes, I commend them to "Veronica" and other readers, though it may be doubtful if even "Veronica" will be able to evolve such a rich combination as he does on p. 291 from Torch Lilies, Asparagus, Windflowers, and Violets.—D. T. F.

TRANSPLANTING CHRISTMAS ROSES.

There are two periods of the year when these may safely be transplanted, viz., spring and early autumn. The best time I consider is from the middle of March till the end of April, but the first week in that month is the time I would preferably choose. Just then growth recommences, the buds are beginning to break away into leaves, and young roots will soon issue from the collar. If care is taken not to allow any of the old roots to become dry, no check is experienced, but the plants break away into new growth quite freely. If in autumn moving is deferred until the heat of the soil has been lowered by late autumn rains the chances are that many of the roots which are by nature fleshy will rot. I know by experience how dangerous it is to transplant Christmas Roses during the late autumn and winter months, and it is probably because they suffer so much at that time that they are commonly reputed to be difficult subjects to remove. Few things recover so tardily from a severe check, and when the planting has been badly done, a year or two will elapse before the plants recover their pristine floriferousness. It is quite as possible to err in commencing the work at too early a date as in delaying overmuch. The soil does not get sufficiently warmed to induce root action before the sun has attained considerable power, and plants removed before March is well advanced are apt to stubbornly resist the coaxing influences of genial spring later on. They will often remain in a semi-inert condition all through the growing time. An instance of this occurred to me this year. I procured a number of young plants in February and was much pleased with their appearance. They had several crowns, and were furnished abundantly with good roots. They were laid in in a warm position in light soil for a month, and were then carefully planted and well cared for later on. Notwithstanding this, they seemed unable to make headway, and some grew less. On examination I found that some had rotted completely away, and not one of them has made really good growth. From our failures we learn much, and this has been emphatically impressed upon me, that we court one by transplanting Christmas Roses before the circulation is active. Never again will I move Christmas Roses whilst winter still leaves its traces with us. Recent examination, however, shows that the germ of future good growth is there. Numbers of little buds are formed on the crowns of the old roots whilst their future activity is assured by young white fibres 1 inch or so long immediately beneath them. Thus I lose through over-haste one season's growth, but I gain experience which I think proper to lay before your readers. With respect to old plants, I believe that no greater mistake can be made than in moving them bodily. The more they are divided the better the chances of success. By splitting them up a greater amount of root surface is presented to the soil, and young fibres issue where inactivity would reign. There are, doubtless, soils in which Christmas Roses will retain their usual vigour for years; but in the generality they seem to need the stimulus which replanting and dividing give. We know that with many herbaceous plants, such as Phloxes, age after a certain time brings with it comparative sterility, and it is so with Christmas Roses; they often come to a standstill. If old stools are cut into pieces, leaving but one crown to them, they will almost equal seedlings in growth. If large clumps are desired, plant a number of crowns together, and a large specimen will at once be formed. Christmas Roses like a little protection from cold winds, those from the east and north ruining the foliage and much retarding the expansion of the blooms. The foliage is, apart from the blooms, ornamental and worth conserving, for it gives variety of form to the garden in winter. Good food in plenty and moisture in abundance when growing, however, give beauty in winter, because they are the agents which build up robustness of tissue. Ill-nourished plants have flimsy leaves, which soon feel those adverse climatic conditions which assail them when at rest. Well-nourished plants remain in undimmed beauty through times of trial which are ruinous to those not so well favoured.

If autumn is selected for moving them, it is hardly safe to be later than the end of September, especially if the crowns are to be divided. There is still at that time a sufficiently quick circulation of sap and warmth enough in the soil to heal wounds and allow the roots to get hold of the soil before winter. In light soils planting can, of course, be done at an earlier date in spring or later in autumn than in those of a cold nature. If the plants are too much cut up, I would certainly prefer spring, as frost and worms are apt to loosen the root-hold of small non-established plants.

J. C. B.

Salvia patens.—We are apt to overlook good old plants whilst eagerly searching for novelties, and it is just possible that dozens, aye hundreds, of new Salvias are getting in front of and hiding the good, useful sorts which have proved themselves to be first-rate garden plants. S. patens is one of these. It has the best of all habits for a bedding plant, viz., a perennial tuberous root-stock, which may be kept under a greenhouse stage all winter as easily as one keeps Dahlias, and is a quick grower; its stems attain a length of 2 feet or 3 feet, and bear large, downy, soft green foliage and long erect spikes of flowers, which open perpetually nearly all summer, are large and attractive in form, and coloured the most lovely blue, almost as deep as that of Violets. Whether planted in beds, in ribbons, or in groups

among border plants, this Salvia never fails to look beautiful, and, so far as our experience goes, it grows freely in almost any garden soil. It has been a bedding plant for fifty years, but so also have been the Verbenas and other once popular, but now more or less neglected, plants. Wherever there is a bit of garden this Salvia should have a place, and it is one of the very best of all blue-flowered plants for use in the largest efforts at ornamental gardening.—B.

SELECT CARNATIONS AND PICOTEES.

No doubt some Carnation growers may like to know the names of the best sorts shown at the various shows this season at South Kensington, Manchester, and Oxford. I, therefore, give a list of the finest I have noted in the stands. *Scarlet bizarres:* Admiral Curzon (Easom), Arthur Medhurst (Dodwell), Edward Adams (Dodwell), Fred (Dodwell), George (Dodwell), Master Stanley (Dodwell), Robert Lord (Dodwell), and Tom Power (Dodwell). *Crimson bizarres:* E. S. Dodwell (Hewitt), Harrison Weir (Dodwell), H. K. Mayor (Dodwell), John Harland (Adams), J. D. Hextall (Simonite), Master Fred (Hewitt), Mrs. Gorton (Dodwell), Rifleman (Wood), and Samuel Barlow (Dodwell). *Pink and purple bizarres:* James Taylor (Gibbons), Mrs. Barlow (Dodwell), Sarah Payne (Ward), Sir Garnet Wolseley (Hewitt), Squire Llewellyn (Dodwell), Thomas Anstiss (Dodwell), Unexpected (Turner), and William Skirving (Gorton). *Purple flakes:* Dr. Foster (Foster), Florence Nightingale (Sealey), George Melville (Dodwell), James Douglas (Simonite), the best of its class; Mayor of Nottingham (Taylor), Sarah Payne (Ward), a sport from the bizarre bearing this name; Sporting Lass (Flowdy), Squire Meynell (Brabbin), and Squire Whitbourn (Dodwell). *Scarlet flakes:* Clipper (Fletcher), Dan Godfrey (Holmes), Figaro (Abercrombie), Henry Cannell (Dodwell), John Ball (Dodwell), Matador (Abercrombie), Robert Morris (Dodwell), Scarlet Keet (Dodwell), and Sportsman (Hedderly). I have not included Annihilator (Jackson), because it is difficult to propagate and sportive in character. *Rose flakes:* James Merryweather (Wood), John Keet (Whitehead), Miss Erskine Wemyss (Dodwell), Mrs. Bridgewater (Bridgewater), Mrs. Tomes (Dodwell), Rob Roy (Gorton), Sybil (Holmes), one of the best, and Tim Bobbin (Gorton).

A selection of Picotees will be as follows—*Red-edged, heavy:* Brunette (Kirtland), Dr. Epps (Smith), Henry (Matthews), J. B. Bryant (Ingram), John Smith (Bower), Mrs. Dodwell (Turner), and Princess of Wales (Fellowes). *Light:* Clara (Bower), Mrs. Gorton (Simonite), Thomas William (Flowdy), and Violet Douglas (Simonite). *Purple-edged, heavy:* Mrs. A. Chancellor (Turner), Muriel (Hewitt), and Zerlina (Lord). *Light:* Alice (Lord), Clara Penson (Willmer), Her Majesty (Addis), Jessie (Turner), and Nymph (Lord). *Rose or scarlet-edged, heavy:* Constance Heron (Fellowes), Edith Dombrain (Turner), Louisa (Addis), Miss Horner (Lord), Mrs. Payne (Fellowes), and Royal Visit (Abercrombie). *Light:* Daisy (Dodwell), Evelyn (Fellowes), Favourite (Liddington), a real beauty, and so reliable; Nellie (Rudd), another lovely flower, dividing with Favourite the honour of being at the head of its class; and Miss Gorton (Dodwell). R. D.

Tritoma Rooperi.—In my note on the Torch Lilies (Tritomas), p. 261, T. Rooperi is by an error described as being T. Hooperi. T. Rooperi is a handsome plant, which with me produces spikes rather more than 6 feet high, terminating with heads of bloom 18 inches long. Although this variety is described in many catalogues as only growing 2½ feet high, I find it to be a strong, robust-growing kind and very distinct. I may mention, perhaps, that T. Burchelli is sometimes sent out under the name of T. Rooperi, although the two are quite distinct, the latter being the earliest to bloom.—W. J. G.

Harpalium rigidum —This fine hardy perennial has been most striking in our herbaceous border for some weeks past, and it will continue in good condition for some time to come. It should be grown by all who cultivate hardy plants. It grows freely and looks best in large clumps. The flowers, which are very useful in a cut state, last a considerable time in water.—E. B. L.

THE GENUS TRITOMA.

One of your correspondents has expressed his desire to see the genus Tritoma revised. I should myself gladly welcome a treatise on this rather obscure subject, and, as a means of obtaining the information necessary for such a revision, I would suggest the following plan: That all who grow Tritomas should send specimens of their plants to the botanist who may be entrusted with the study of the genus; that they shall also subscribe a sufficient sum to defray the expense of printing the work, of which one-half of the copies shall be the honorarium of the botanist, and the other half sold for the benefit of any horticultural work that may be decided upon. Towards this monograph of the genus Tritoma I will subscribe 100 francs (£4), and I will also, of course, contribute specimens of all the species of these plants in my possession. Should the sum of the subscriptions be of any considerable amount, it would be easy to have the work illustrated with coloured plates. In a matter of horticultural interest like this it is of especial importance that no time should be lost. I may here remark that the genus Tritoma has already given birth to a certain number of hybrids, and in a few years it will be very difficult for anyone who may then endeavour to reduce them to order to steer clear of confusion. I have some plants of Tritoma Leichtlini which exhibit very distinct characteristics, the spikes of some specimens commencing to flower at the base, and those of others at the top, while Professor Duchartre has also shown me some spikes which commenced to flower in the middle. The other species here mentioned come into flower in the following order: In May, Tritoma præcox; June, T. Macowani; July, T. Saundersi, T. nobilis; August, T. corallina, T. media; September, T. Uvaria, T. Burchelli, T. Leichtlini, T. carnosa; October, T. formosa; November and December, T. Quartiniana; January and February, T. caulescens, and any other species now in cultivation. I am quite convinced that the elucidation of this genus is not so beset with difficulties that it would not be possible to bring out a work of present utility, and I hope that you will allow this appeal to go forth, through The Garden, to all who would be inclined to favour the project. Incidentally, I wish to mention another genus which is very popular just now—the genus Primula—and I would invite you to direct attention to the "Yunnam" species, amongst which there are some wonderful things, of which I have some dried specimens.—V. F. Lebeuf, *Argenteuil.*

—— I have read "W. J. G.'s" remarks (p. 261) about his apparently very rich collection of Torch Lilies, very handsome plants, of which I am a great admirer, with much interest, but think, from what he says as to the relative height of T. Macowani and T. corallina, that he can hardly have got the latter of these varieties true to name, as I had my plant thereof direct from its raiser, Mons. J. B. A. Deleuil, of Marseilles, as soon as it was sent out, and have always found it to be a much taller, stouter, and more vigorous grower than the slender, pretty, and comparatively dwarf-growing T. Macowani, which is one of its parents. I may add that both these varieties are growing under precisely similar conditions side by side in small beds, cut out of the Grass in front of my house, and facing the south-east. Of the variety T. Rooperi, mentioned by your correspondent, I have never before heard, but should not be surprised if it turned out to be a synonym for some variety that I know under some other name. As to the variety so pompously named T. Uvaria maxima globosa, I think it must be the same plant as I grow under the name of grandis, which is much shorter and, I venture to think, quite as expressive of the characteristics of the variety as the longer name. I should be glad to exchange spikes with your correspondent, and so set this doubt at rest.—W. E. Gumbleton, *Belgrove, Queenstown, Ireland.*

—— Two correspondents, I think, have referred to the want of a monograph of the genus Tritoma; allow me, therefore, to tell them that there is a good monograph of the genus by Mr. Baker in the *Journal of Botany* for September, 1885.—R. J. L.

KITCHEN GARDEN.

SOWING V. REAPING.

I am, not, as a rule, a stickler for dates in the matter of getting in crops, but, nevertheless, I am willing to admit that old gardeners of a past generation had some tangible grounds for their superstition or belief in such matters, and we know that they had red-letter days in their cropping calendar, which if not observed they believed would result in misfortune in some shape or other. This subject has interested me much this season in reference to a crop of Wheat that I have taken notice of from the day it was sown till the day it was reaped. Old-fashioned farmers hereabout say that the nearer to the 11th of October the winter Wheat is got into the ground the better and earlier will be the crop. The 11th of October last year was a good dry day, and on a journey I often go I noticed a farmer sowing a field on that day—the very first sown in the district that I know of. I have passed the field about every month in the year since and I noticed that this crop was the first up, the strongest in the neighbourhood, and that during the whole of last severe winter it looked better than any other crop near on the same kind of land; and finally, that it ripened first, and was reaped and carried first by a week or more, being also a good crop. A field sown considerably later, and only separated by the roadway from the other, was partially green when the earlier sown crop was cut. I attributed the better and evener condition of the crop in winter and spring to the deeper hold the roots had got of the soil, and its earliness to the earlier sowing. This is not, of course, a gardening example, but it is instructive. There are important crops in the garden that require considerable labour to get in, and which it is important to get in in good condition, and there is a shorter limit to the period in which sowing must be begun and finished than some appear to imagine. Much, of course, depends on climate and locality, and everyone must make allowance accordingly; but, after all, the time is not long in which to get in some main crops to do well. It is an advantage for hardy seeds to be in the ground if they do not vegetate, because they are ready to start as soon as favourable weather arrives. Thus, Onions in the north and midlands always do best if got in between the middle of February and middle of March. I have seen fair crops raised from sowings about the 1st of April, but except in favourable seasons that is too late to sow. Onions sown late seldom get large or ripe. In speaking of "hardy" seeds, however, I do not allude to all kinds of vegetable crops, because some seeds are much hardier than others. The hardiest seeds are those of Onions, Leeks, Turnips, Beans, early Peas, all the Kale and Cabbage tribe, Spinach, Parsnips, Celery, Lettuce, Parsley, Cress, and the like. These seeds are all safe enough under a covering of earth so long as they do not germinate, no matter how severe the weather may be; but such subjects as late Peas of the Marrow sort, Carrots, Scarlet Runners, French Beans, Marrows, &c., are not and will rot, nor are the seeds of any half-tender vegetable safe in the soil till the latter is nearly warm enough to promote vegetation soon after sowing.

In the case of early Peas, crops sown in the back end of the year—say in November—are usually in a week before the same sort sown in February at least; but in some seasons there is not much difference between them, and the spring-

sown crop is, as a rule, the most prolific, producing the most straw. Still, the fact that the autumn-sown crop is generally ready first, although there may be little between the spring and autumn crops in appearance in April, shows that, as in the case of the Wheat before mentioned, the autumn-sown crop has the advantage. The Turnip crop is a peculiarly erratic one, and much depends on the date of sowing of main crops. Early crops are very apt to "bolt" right off without bulbing, and the earlier the crop is sown the greater the liability to bolt. Sow the Early White Dutch Turnip every month from January till the end of July, and the tendency to run to seed grows less and less until it disappears altogether; hence, farmers relying upon a knowledge of this fact do not sow till May and June, and sometimes not till July. Why the Turnip is so disposed to seed right away almost from the first rough leaf without bulbing, or almost as soon as small bulbs are formed, and to bulb only later on in the season, is a matter as yet unexplained. Other tuberous-rooted subjects have the same habit, as, for example, Beet, Carrots, and other Crucifers.

The latest, tallest, and best cropping Peas of the wrinkled Marrow section take from sixteen to twenty weeks to produce gatherings in the northern parts of England and Scotland in ordinary seasons; hence the advantage of sowing two main crops sometimes, in April and May, according to the locality. If the season be good, the first crop will be early, and the second sowing will afford gatherings till the frosts set in. Good late Peas are almost always tall in the straw, and, notwithstanding what is said about dwarf sorts, tall Peas, or Peas with plenty of straw, are, as a rule, the most prolific and the longest bearers. If it was not for their earliness, early Peas would not be worth growing. They are scant croppers, small in pod and Pea, and deficient in flavour. Both quality and crop improve as the season advances, and the varieties become more robust.

Celery is a crop which may be lost or won very much according to the time of sowing. I doubt if those who aim at having large heads—prize heads—make the best of it. Large heads can only come from early sown and planted crops, and how many of the heads in a row become useless from bolting, those who grow early or large Celery know. We have seen the apparently fine heads at autumn shows rejected one after the other in judging when laid open by the knife, every head having "run." There is not much good, therefore, in producing very early Celery. It is never so tender as later crops, is really not so much needed, and, besides, by timely and judicious earthing up small heads of later crops can be had in September. Large Celery is no better to eat than small, and in the pantry the large stalks are split into fragments of suitable size for salad. Small Celery, sown late enough to avoid risk and loss from bolting, can be grown proportionately thicker in the trenches and is the best paying crop. Market gardeners in the provinces endeavour to hit the right mean, and seldom have whole ridges of Celery run to seed and waste before a stick can be used—as may often be seen in private gardens. Celery is an expensive crop to grow, and bolted crops repaesent a serious money loss, not to speak of the disappointment.

Spinach is a crop which no gardener dare well be without every day in the year, and it sometimes requires nice calculation to have a succession of crops. Both the common kinds—prickly and smooth-seeders—produce abundantly in spring and autumn, but under the best culture run to seed as soon as up during the summer unless the weather be cool and moist and the soil rich; hence the value of the New Zealand Spinach, not nearly so much grown as it should be, as it never fails to produce abundance of leaves when the common kind fails—that is, from July till frost cuts it off. The common prickly Spinach yields the best crops in winter and spring, but seldom affords abundant gatherings in the north unless sown about the middle of August or a little later. Sown sooner than that, it runs to seed and is useless; sown later, it never gets forward enough in the foliage to afford good pickings during the winter, and never gets into plentiful leaf till late in spring. This is, however, a good and most useful vegetable from September till May, and even June, in late districts, provided a sufficient breadth is sown.

As to the predominating crop of the kitchen garden—the Brassica tribe—their maturity is subject to great fluctuations. Some gardeners say that by sowing at different intervals in spring Broccoli can be had in succession during winter and spring following, but I never found it so. The coming in of the crop depends on the weather between November and May. No matter how early the crop is sown or planted, it will not come on unless the winter be mild. Late and early varieties stand still in cold winters, and, as a rule, only begin to heart freely from February to April. Then the different sorts do come in in succession according to their character; but in fine springs all come on too fast, what should have been the supply during the winter coming in when the very latest are supposed to be in season. It is a good plan to sow Broccoli early in spring, and to plant early, too. There is no fear of the plants heading before winter under any circumstances, and the longer the season of growth the larger and finer the heads. The summer Cauliflower will button prematurely if checked in any way, but hardly any amount of rough usage will cause Broccoli to do so.

S. W.

MUSHROOMS IN SHEDS.

When some notes of mine on this subject were published in The Garden last winter I received several letters which proved that Mushroom-growing in sheds was to many a subject of considerable interest, and as the time has again arrived when beds, to produce a crop during December and January, should be made up, I will, with your permission, offer a few more remarks in reference to this mode of Mushroom-growing. Our Mushroom house has not been used for four or five years; consequently, we save the expense of fuel and of working it, for shed-culture costs us but a mere trifle compared with house cultivation. I have nothing to say against open-air culture in winter, but must own that I have never managed to make it quite a success, owing to the beds suffering so much from damp and from checks to growth sustained through opening the coverings in unfavourable weather. I, therefore, now adhere wholly to shed culture. We have made some dozens of beds up in all sorts of sheds during the last half-dozen winters, and every one of them proved to be a success, the Mushrooms produced by them both in quantity and quality being quite astonishing. The temperature of an ordinary shed suits them better than great heat or a damp atmosphere, such as is generally kept up in a Mushroom house, and the substantial manner in which they develop, and the extraordinarily long time during which they continue to be produced from the same bed, are most gratifying to the cultivator. When we began to desert our Mushroom house—properly so-called—we made up a bed or two under a stage in a slightly heated pit, in order to try what could be done there: but a bed made up in the potting shed at the same time proved so satisfactory, that we carried the practice into other sheds, and found all to do so well, that sheds are now the only places in which we grow Mushrooms. In the potting shed we put as many beds as it will accommodate, and we have had equally productive beds in the tool shed, the wheelbarrow shed, and in the orangery, which is a large, unheated structure. Others in this district, who have seen how well Mushrooms have succeeded in such places, made up beds in empty stalls in cowsheds and stables, and although some of them knew little or nothing about Mushroom-growing, the crops which they obtained astonished them and proved highly remunerative. Such growers as those to whom I am now referring—farmers and others—would never be at the trouble of growing Mushrooms by means of fire-heat, but when they can make up a bed in any odd corner of a shed to-day and find on going to it in four or five weeks' time that it is bearing, and promising to bear, Mushrooms abundantly, no further inducement is needed to make Mushroom-growing in their case both a pleasant and profitable occupation. I cannot say so much for outdoor culture, for if anyone unacquainted with Mushroom culture makes up a bed now and expects to gather its produce in five or six weeks hence, he will most likely be disappointed, and on this account no further attempt will be made to grow Mushrooms.

The present is a most excellent time to begin the shed mode of growing Mushrooms, and I hope that everyone who can obtain a cartload or two of horse droppings and can have access to any odd corner in a stable, cowhouse, or shed of any kind will try their hand at their culture. Gardeners, too, who have still faith in the old hothouse style of growing them might give this plan a trial. Many fine Mushrooms have been produced from cowshed manure, as well as from material in which there were but few horse droppings. The latter are, however, undoubtedly best, and should, if possible, always form the main body of all beds, especially those belonging to beginners. Horse droppings alone do not, however, make a good bed; we prefer the manure which we use for such a purpose to consist of about half short straw from the stable. It must never be used when wet and sticky, but if turned over every day for a week or so in any open shed it will soon become dry enough to enable it to be made up. It is best when just sufficiently moist to ferment slightly in a day or two after being made up. Rough pieces of loam are very serviceable for mixing with the manure, as these, if dry, absorb superfluous moisture, and they also help to keep down any intense heat which may be inclined to arise in the bed. It need not be thought that, because the manure only consists of one cart-load or so, it is not worth putting into a bed, as we have made up many with no more, and we have gathered dish after dish of Mushrooms from a bed not more than 4 feet square. The beds should always be from 1 foot to 15 inches in depth, but the width and length are unimportant. We are, however, greatly in favour of beds about 3 feet in width, as they can be easily covered up, and it is a simple matter reaching over them to gather the Mushrooms. As soon as the manure is sufficiently dry for making up it should be put together. It loses its virtue when allowed to lie and dry day after day after it is ready for being made up, and I am sure there is as much danger of failure through the manure being too dry as when it is too wet. It is almost impossible to make the bed too firm, and in a day or two after it is made up it should be spawned. We invariably make up our bed one day and spawn it the next, and here I come to the most important point of all, which is this, let the spawn, above all things, be good. To begin with spawn of a doubtful character is useless, and the only way of insuring its being good is to get it from a respectable dealer. In my own case I am now using spawn from two firms, and I am absolutely certain that it is good, as the parties from whom I bought it know what good spawn is, and they also possess a reputation which they take good care to maintain. I cannot give a

better guarantee of the spawn being genuine than this, as the cleverest expert would often fail to tell whether it was sound or not simply by looking at it.

In breaking up the bricks for insertion in the beds a hammer may have to be used, in order to get them into bits about the size of a pigeon's egg. These should be dibbled into the surface about 8 inches apart and 3 inches deep, and the small material that falls away in breaking the bricks should be thrown on the surface. The holes should be covered over and the surface trodden down as firmly as it is possible to make it; then a quantity of gritty soil should be put over the surface to the depth of 2 inches. Ordinary garden soil of a light character is very suitable for this purpose, and it should be beaten down firmly with the back of a spade. This completes the making of the bed, and we finish off all our beds by spreading a thin coating of hay over them. This wards off cold winds which may happen to blow through the shed, and if the hay becomes too wet it is taken off and replaced by dry material. In very cold weather this covering is increased sometimes to 1 foot in depth if the frost is severe; Mushrooms will spring up under it as fresh and freely as anyone could possibly desire. J. Muir.

Margam.

MARKET ASPARAGUS IN AMERICA.

The first thing to be done by one who wishes to grow Asparagus for market is to see if he has any soil that is suitable. It should be a light loam and as deep as it is possible to obtain. Asparagus will grow on almost any soil, but I do not think that its cultivation will prove profitable on a heavy clay soil, nor where a stiff clay subsoil comes up within a few inches of the surface. It can be made profitable on very light sand by the use of plenty of manure.

The next thing is to arrange for a supply of plants. These can either be purchased or can be grown from seed. Dry Asparagus seed when sown in the open ground is slow to germinate, and it is difficult to prevent weeds from taking possession of the ground before the Asparagus plants appear. My own plan has been to soak the seed in hot water until swollen and softened before sowing. It should be sown in long rows a foot or more apart, so as to be tended with a hand or horse cultivator. If a few Radish or Cabbage seeds are sown with the Asparagus they will come up at once and show where the rows are, so that the ground can be cultivated before the Asparagus appears. Some growers, after soaking the seed, put it into a coarse bag and bury it deep in the ground until it begins to sprout, and then when sown it comes up immediately.

During the season, while the plants are growing, you should prepare the permanent bed. It is not necessary, as was formerly supposed, to dig out all the earth to the depth of 2 feet or 3 feet, and then fill in the bottom with all manner of trash and fertilising material. The land must be deeply ploughed and thoroughly pulverised. It cannot be made too rich. A successful market gardener in Illinois, writing some years ago upon the raising of Asparagus for market, used the following language: "The profits are just in proportion to the amount of manure used, which should be more than most people think enough." This is strictly true. The kind of manure and its mechanical condition when applied to an old bed are not material. Fresh stable manure may be used, no matter how coarse so long as it can be ploughed under. But in preparing the ground for a new bed well-rotted manure is to be preferred. Asparagus always starts into growth early in the season, and the bed should be ploughed late in autumn, that it may dry and be ready to work as early as possible next spring.

The proper distance between the rows and between the plants in the rows is a matter of dispute. Years ago the rule was 3 feet between the rows, and from 12 inches to 18 inches between the plants. This is universally conceded now to be too close; 2 feet by 3 feet or 4 feet, usually the last, is the closest planting allowed. Many set their plants 4 feet apart each way and cultivate the bed both ways. The growers of the celebrated Oyster Bay Asparagus make their rows 5 feet or 6 feet apart, and set the plants 2 or more feet apart in the rows. In planting, the crowns should be set at least 3 inches under the ground, and in many places 4 inches or 5 inches would be better.

The first season all that is necessary is to keep the bed clear of weeds and the surface mellow. In most parts of the north winter protection is a great benefit. If there is no danger of injury to the plants from severe cold, still a heavy mulch, put on before the ground freezes, will keep all, or nearly all, the frost out of the soil, so that the plants will start much earlier in spring. A thick coating of fresh stable manure is the best possible mulch, and that is also an excellent way to apply manure. The coarsest of the litter should be raked off in spring and the balance ploughed under. This may be supplemented by the application of a few hundred pounds per acre of some good commercial fertiliser, ground bones being one of the best. The question whether salt is needed on an Asparagus bed is by no means settled. While some claim that it is necessary and should be applied every year, others say that Asparagus does not need salt any more than any other vegetable. Without undertaking to decide the question, it is certain that Asparagus is not injured by the application of sufficient salt to destroy almost all other vegetation near it. If not specially useful as a fertiliser, the free use of salt on an Asparagus bed is an advantage; it has a tendency to prevent the growth of weeds, and by attracting moisture from the atmosphere helps to carry the bed safely through a drought. Coarse or refuse salt may be applied every spring, and enough may be used to make the surface of the soil look quite white.

In spring, run a cultivator along the top of each row two or three times, and then harrow in order that the soil over the plants may be loose. Between the rows stir the soil often enough to keep it mellow and clear of weeds until the tops shade the ground. The second year a few heads may be cut, but be very careful not to continue the cutting too long. The third year a few more may be used, but a full crop cannot be expected until the fourth year. It is a good plan each year, when you stop cutting, to apply at that time a liberal dressing of stable manure and fork it in; the object of this is to insure a strong growth of tops and roots during the summer and autumn. In autumn, just before the seeds are ripe enough to drop off easily, mow off the tops and burn them; otherwise the ripe seed falling upon the bed will grow there, and young Asparagus plants are undesirable weeds anywhere, and especially so in an Asparagus bed.

Oyster Bay Asparagus is very popular; it is all white, being cut 8 inches or 10 inches under ground as soon as the top shows itself above the surface. The rows are 5 feet or 6 feet apart, and the crowns are set very deep under ground. Every spring the earth between the rows is ploughed until it is very mellow, and then with ploughs and other tools specially contrived for the purpose they ridge up the earth over the rows until the bed looks very much as if it were intended for planting Sweet Potatoes, except that the ridges are broader and are not sharp, but rounded off rather flat. Though this blanched Asparagus sells for a higher price than green, yet as it costs much more in time and labour to grow and gather it, I doubt if it would generally prove any more profitable than that grown in the ordinary way. Asparagus should always be cut a little below the surface of the ground, if for no other reason than that the sharp stubs left may be out of the way.

The stalks must always be cut before the heads show any signs of breaking; the lengths should range from 6 inches to 10 inches. The size of the bunches must depend upon the market in which it is to be sold; for New York they should be 4 inches or 5 inches in diameter, about 7 inches or 8 inches in length, and should weigh from 3 lbs. to 3½ lbs. To put up such large bunches in good shape requires the use of a regular bunching machine, which costs from 12s. to 16s. In western markets the size varies according to the taste of the growers. For Chicago market a good saleable size is about 3 inches in diameter and from 6 inches to 9 inches in length. Great pains should be taken to have the tops exactly even, and after the bunch is tied up the bottom should be cut off square, so that all the stalks will be of exactly the same length. The bunches should be tied in two places, near the top and near the bottom. The tying material must be broad and soft; common twine will not do, as it cuts into the stalks too much. I have seen it tied with strips of white cotton cloth, having the name of the grower printed upon them, so that every bunch sold advertised his business. Bast is one of the best tying materials, and is probably most commonly used.

If the crop is to be shipped to a distant market it is packed in crates with tight bottoms, but with slat sides and tops. The crate should be large enough to hold three or four dozen bunches, and just deep enough for one layer of bunches when standing upright. The Asparagus should be perfectly dry when put into the crate; this is indispensable, otherwise it will surely heat and spoil, and it should be packed so snugly as to prevent any shaking about in the crate, which would perhaps cause the tender tops to be broken off, thus rendering the Asparagus unsaleable. Shippers often put a layer of dry Moss over the bunches to protect the tops. When shipped a long distance, a layer of wet sand or Moss in the bottom of the crate, on which to set the bunches, will help to keep them from wilting.

The profits of growing Asparagus depend so much on soil, manure, cultivation, and market, that it is difficult to fix on any reasonable average. The range is from £20 to £200 per acre; the average is probably much nearer the first figure than the last. Usually, however, that is the fault of the grower. If he restricts the amount of manure and cultivation, he illustrates the old adage, "He saves at the spigot and wastes at the bung-hole."—W. C. Steele, in *Vick's Magazine.*

Garden Flora.

PLATE 564.

CHRYSANTHEMUM-FLOWERED ANEMONES.*

For some three centuries Crown Anemones have been cultivated in our gardens, and in March and April few plants are more attractive. Beautiful as they are, however, they are inferior to the Chrysanthemum-flowered race, which constitutes an entirely new section, the flowers of which are differently formed and much more double than those of the ordinary Crown Anemone, resembling in this respect a perfect German Aster or a fine Chrysanthemum flower. This the sorts figured in the annexed coloured plate fully confirm. Their flowers, which are large and brilliant, are in the spring garden what German Asters are in that of autumn. The first variety belonging to this class was raised accidentally in 1848 amongst seedlings of A. coronaria, but it was not distributed till 1870. Since that time this class of Anemones has been greatly improved—so much so indeed, that at present varieties representing nearly all colours may be had, and if planted in good soil and situations, few other plants can compete with them in spring as regards display. Cut flowers of them will last a week if kept in water, and they are now largely used by florists instead of Roses. The following varieties are the best at present in cultivation, viz.: Gloire de Nantes, the flowers of which are very large, double, and blue-violet in colour, as shown in the annexed plate; this, being the first variety obtained, is the parent of all the others. Lilas, another variety and one of the oldest, has very large and very double flowers of a fine lilac colour. Etoile de Bretagne, which is robust and good in habit, has large and very double flowers of a fine peach or apple-blossom colour—one of the oldest and also one of the best of the class to which it belongs. La Brillante.—A fine bright red flower and

* Drawn from flowers sent by M. D. Guiheneuf, Nantes.

CHRYSANTHEMUM-FLOWERED ANEMONES.
1. GLOIRE DE NANTES, 2. PONCEAU, 3. MAUVE CLAIR.

very double, producing, amongst other varieties, a striking and grand effect. Mauve Clair.—Very large and double, and, as will be seen by the plate, delicate mauve in colour. It is a strong grower, and blooms very profusely. Ponceau.—This, as will be seen by the annexed illustration, is a charming variety and unusually double, the petals being regularly imbricated and more brilliant in colour than those of even Anemone fulgens. It is a free bloomer, and probably the strongest grower in the class to which it belongs. Rosine has very large double flowers of a fine rose colour and green in the centre. This, amongst other sorts, produces a striking effect. Belle Bretonne has also large and very double flowers of a delicate red colour, and the plant is dwarfer in growth than other varieties. Rouge pourpré has small flowers of a dark purplish red colour, but they seldom fully expand. Meteor has large double or semi-double flowers, each petal of which is red, bordered at the end with white. Armoricaine.—The flowers of this are very large and double, and the petals, which are well imbricated, are of a dark blue colour; it is probably the strongest grower of all the varieties in this class. La France has very large double flowers, the petals of which are well imbricated and of a fine violet colour, which contrasts

Tuft of Chrysanthemum flowered Anemone.

strikingly with that of other varieties. Yvonne.—This is not yet in commerce. Its flowers are very large and double and pure white; therefore a welcome addition to this class of Anemones.

These Anemones, which are dense and compact in habit, grow from 1 foot to 2 feet high; good sized roots will each produce successively from fifteen to thirty blooms every week from February until May; they are invaluable for either beds or borders, and also for pot culture indoors.

Cultivation.—Anemones belonging to this section should be planted, like other kinds, in September about 10 inches apart and an inch deep; they soon make their appearance above ground, and bloom, according to the character of the season, from February to May. If to bloom in June they should be planted in February and March. If need be they may be planted in October after the summer bedding plants are removed, and the roots will be ready to be lifted at the end of May. Being quite hardy no frosts hurt them. A light, rich, deep, well-manured soil suits them best; in heavy, damp ground the roots are apt to rot. They do admirably on a south border in front of a wall, which protects the flowers against cutting north winds in early spring.

These Anemones may be lifted as soon as the leaves and stems have become yellow. They may be propagated by dividing the roots, but that is not advisable, as the largest roots produce the finest plants. Roots of this class of Anemone are still scarce, and therefore others are sometimes substituted for them. M. Guihéneuf, to whom we are indebted for the beautiful flowers from which our plate was prepared, grows them well at Nantes, where both soil and climate seem to be most favourable for Anemone growing; indeed, we doubt if in any other place they could be cultivated and propagated with such success.

WORK DONE IN WEEK ENDING SEPT. 28.

September 22 and 23.

Though much colder, the weather continues fine and bright, but rain is sadly needed for outdoor crops of every description, as it also is before we can plant out Cabbages, Endive, and Lettuce with any degree of confidence that they will start into kindly growth if planted under such adverse conditions; therefore, our present resolve is that we will wait for rain. Hoeing all and sundry in the kitchen garden department; weeds do not pay, and, after such a dry season, we shall have no legitimate excuse for any crop being weedy. Cleared from Brussels Sprouts the decayed leaves, as well as a portion of the largest good leaves, to let in light and air to the sprouts. The old Cabbage plot we served the same, and in a piece of Autumn Giant Cauliflower that had grown so abnormally large, all the yellow bottom foliage has been pulled off. Housed Onions; having plenty of space in a cool, airy shed, they are laid in a single layer only on the shelves. Harvested all herbs that are likely to be required in a dry state. We tie them in small bunches and hang them in an open, airy shed, and there they remain till needed for use. Notwithstanding the drought, Peas are still abundant; No Plus Ultra, Latest of All, and British Queen are our best late kinds. Deep trenching and mulching defy drought, as is shown not only by our present good supplies of Peas, but also of French Beans, Cauliflowers, and Turnips, &c. Gathering Apples and Pears. Except the very latest kinds, Peaches are over, and the trees are being gone over to pinch back the few side lateral growths that have formed on the main shoots, our one aim now being to keep the shoots thin that sun and air may have that hardening effect on the wood, without which there could not be a satisfactory crop of fruit next year. The same remarks apply to Apricots, the new growths of which we persistently pinch back. Two or three of the trees have grown far too strong, and root curtailment is in prospect for these as soon as the soil is sufficiently moist to admit of its being done with the least amount of injury to the surface roots that are nearest the point where the roots are to be severed. Got in a few Chrysanthemums—the latest kinds; the bulk of the plants we shall leave outside till there are signs of really cold weather. Meantime, we are bottling all the Grapes our room will hold to make room in the vineries for the plants. Black Hamburghs, Gros Maroc, Madresfield Court, and Mrs. Pearson are the varieties that we are now placing in bottles. Having had no previous experience as to the keeping properties of Madresfield Court Grape when thus housed, I am rather fearful of the result, and it will, therefore, be the first to be used. The susceptibleness of this Grape to cracking is a terrible drawback to its extended cultivation. This season it has done better than usual with us; indeed, at one time we thought we should escape it; but no, it began, after several "knowing ones" predicted we were safe. No pains were spared; every conceivable plan and method were adopted to steer clear of the evil, but without effect; and now, though inclined to give it up as hopeless, we mean to give it one more trial, but faith as to succeeding is of the weakest description. Pinched out small side crowns and cut runners off Strawberry plants in pots, and to prevent rooting into the ash beds on which they stand, each pot is lifted, and the roots rubbed off as frequently as the plants are gone over for removal of runners. Prepared frames for cuttings of Calceolarias and Violas. Top-dressed Cucumbers and thinned out growths. Potted up Capsicums, Bouvardias, and Callas from the open borders. They will be kept rather close in a warm moist pit, and well syringed early in the afternoon till well established in the pots, after which air will be freely applied.

September 24 and 25.

Still far too fine, because so dry. Where watering can be done, it is just right for flowers. Our flower-beds having had good supplies, there has not been a greater profusion of flowers all the season than now. Single Dahlias are grand; seed-pods are not tolerated; hence their free and continuous flowering. Picked over all flower-beds, and made all the surroundings as neat as the use of scythe, edging-shears, and garden-roller could make them. Note has been taken of mistakes in colouring, and arrangement for rectification another season, and one or two extra favourite bits have been noted for repetition. In regard to herbaceous flowering plants, no arrangement of them that I have ever seen, or that I have attempted to make myself, seems to have been the best of which such plants are capable. Grouping the plants according to genera or species which some have attempted is simply execrable—I mean as to general effect—because of the unevenness of height and varying habit of growth. The straight-line way of planting, with all tall kinds at rear of borders, is very little better, because so formal. Neither of these plans have we attempted; but our present mode is not better, and must be altered. The plants are mainly in groups of three or five, but some stand alone, and though not dispersed over the border in regular heights, some care was taken to have the bulk of tall kinds at the back of the borders. All have to be lifted this winter, and we have been taking note of varieties that look best both in flower and foliage, of these that flower for the longest period, of those that look best as single specimens, and what number of plants will look best for size of groups, for those that are most effective when planted in this manner. Of necessity the tallest must mainly be in the rear part of borders, and these, I think, should be planted in single file, with the moderate-sized growers grouped between them. The same will hold good with respect to the front portion of borders, the plants being graduated as to height from rear to front. I think, by some such arrangement as this, we may get uniformity without undue formality. These borders are getting still more gay with Michaelmas Daisies and the varied section of herbaceous Sunflowers, and the only attention they need is safe tying up against injury from wind-storms which are now due. Gathered more Apples and Pears. The latter have matured very rapidly, I suspect, because of the dryness of the soil, as most kinds are undersized, but this does not appear to affect the quality, as these that have already ripened have been unusually good. The fruit-room ventilators we leave open night and day till the fruit has got inured to the temperature of the room, for then sweating ceases, and the chances of decay are less. Re arranged Pines in the fruiting pit, and filled up from first fruiting succession pit the vacancies made by cutting ripe fruit. Watered all Pines; fruiters have clear manure water on every occasion that water is needed, and syringing of walls and floors for atmospheric moisture is done twice daily. Looked over all Grapes to cut out decaying berries; cut back laterals on late Vines to let all the air and sun possible reach the fruit and wood. Inside border of Lady Downes Vines has been given another drenching, and at once was covered with clean dry straw as a mulching, which adds neatness, and will probably prevent its being necessary to water the border any more this year. Put Pelargoniums in Strawberry house for winter flowering, and put a few Poinsettias in strong heat, but the bulk of the plants will still be kept in an intermediate house to bring them on successionally. Cleaned out and re-arranged plant houses, and tuberous Begonias that had

done flowering were taken out and given space in a pit to gradually dry them off for the winter.

September 27 and 28.

At last we have been favoured with rain, and planting out of Cabbage, Lettuce, and Endive is finished for this year. Pricked out Cauliflower plants at the foot of a south wall to stand the winter. Earthed up late planted Kales and Broccoli. Thinned out winter Spinach; the plants are 1 foot apart and the rows 2 feet. Ground is now being freed of old Pea haulm in readiness for wheeling on the ground manure that is to be trenched into the soil on the first convenient opportunity. Pinching back the lateral growths on wall trees, and began root-pruning Apricots. Partially root-pruned Peaches and Nectarines in second house; this house is somewhat shaded by other houses, so that the wood does not put on that nut-brown colour that one likes to see in well-matured wood, and this severing of part of the roots will check the flow of sap and help the ripening. Potting Hyacinths, Tulips, and Crocuses. Trained Euphorbia jacquiniæflora to Melon trellis in one of the warmest divisions of Melon house, in which form it does best for use as cut flowers, and blooms freely from November to March. Pricked out on a south border a quantity of seedling Wallflowers, Brompton Stocks, Canterbury Bells, and Sweet Williams that will become useful in spring for filling up blanks that may be made by a severe winter in flower beds generally.

Hants.

FRUITS UNDER GLASS.

Cucumbers.

The weather so far has been all that could be desired for frame Cucumbers, which at this season generally keep up the supply, but long cold nights will soon be too strong for fermenting material unaided by fire-heat, and we must once more look to our houses. Winter fruiters, in the proper acceptation of the term, are now only growing, but the bright, sunny weather is favouring them, and under fair treatment they will make short-jointed Vines capable of responding when called upon about Christmas. A sound, sturdy constitution being so important, a genial heat, principally from fermenting material, should be kept up for the benefit of the foliage and roots, as it admits of a free circulation of moist air almost independently of the hot-water apparatus. Hot water, it is hardly necessary to say, cannot be dispensed with; it must always be in readiness for turning on at the shortest notice; but, provided the proper degrees of heat can be maintained through the autumn, the milder it is applied the better. In many old country places, where manure from a well-appointed hunting stable formed a very important item amongst heat-producing materials, linings broad and deep and covered with close-fitting shutters ran parallel with the fronts of Pine and Cucumber ranges. Into these once a week a given quantity of fermenting manure was introduced, and, provided rank steam did not bring the steed to a sudden stand, fire-heat was only a supplementary agent in ordinary weather. But the plants liked it, for they grew dark and dense, and seemed ready for a summer's bearing after working all the winter. Mildew was not more troublesome than it is now, and spider—now the curse of our winter system—was unknown under good culture in an atmosphere well charged with ammonia. Where these old linings still exist, I would link the old with the modern by filling them, not with rank manure, but with mild, well-worked fermenting leaves, to which some horse manure might be added, and pot culture being in the ascendant, the same might do good service in the plunging bed. In deep pits where the bottom-heat pipes are absent, or as good as absent by being placed too far away from their work, the pot system is the best, as dry, brick pedestals, built hollow immediately over them, form channels for the ascent of fire-heat and the descent of diluted liquid followed by the roots which have escaped from the drainage. The pots placed on the tops of these pedestals stand firm and altogether independent of anything so unstable as fermenting leaves, while the latter can be renovated, turned over, or turned out at pleasure without disturbing the pots or interfering with the roots clustering about the interior of the pedestals. Where plants have been kept waiting for the removal of Melons and the pits are abundantly supplied with top and bottom heat, many people prefer planting out, as they seem to make up for lost time by supporting a few fruits at a very early stage. But for growing Cucumbers from Christmas onwards through March, they should be divested of every fruit and flower until they have filled the trellis, and a firm, steady growth, neither gross nor puny, should be encouraged. To develop this, the pit must, of course, be kept close and moist for a few days, when more air and all the light attainable must be given. Direct syringing will be slackened, but a moist, growing atmosphere, so essential to health, and freedom from insects must be maintained by damping the beds and walls, and that important aid, cleanliness, must not be overlooked. Pure soft water and soap are quite as valuable in the forcing as in the dwelling-house, and quicklime applied to the walls prevents offensive matter from accumulating in the wrong place. Fresh maiden loam, burnt earth, dry peat, or charcoal dust, little and often, thrown over the surface of the bed in winter are excellent deodorisers and absorbents of impurities.

Melons.

Having an abundant supply of October Peaches, Pears, and Golden Drops, if we can induce the latter to become golden, many consumers will not care for November Melons, but will be willing to leave off with the flavour of a good green flesh on the palate. Others who insist on having them as late as possible, after providing a house specially for their culture, should make every allowance for collapse and failure. This season so far has been very favourable and fruit is swelling fast, but the next break in the weather may put an end to our summer, and more care, even to maintain that which we have gained, will be needed. Bottom heat being right, the next important point is full control over and the judicious use of water. Aquatics when in full growth in summer, Melons require very great care when cooped up in semi-light houses in late autumn; hence the importance of growing late crops in pots which can be moistened or dried at pleasure. Where plants are carrying crops of fully developed fruit they must not have more than will prevent the foliage from flagging, as an excess may cause many of the best to crack, neither must they be kept too dry, otherwise the foliage will ripen before the fruit, when the latter will be worthless. Water in moderation, then, being absolutely necessary, early bright morning is the best time to give it without wetting the stems or foliage, and, prevention being better than the necessity for frequent repetition, some good dry mulching cast over the tops of the pots will tell favourably in two ways. The foliage of late Melons should be kept thin, not by mutilation, but by the removal of every particle of lateral growth, and free from insects by a bi-weekly blast of smoke from the Eureka Fumigator. I have given up set forays or field days, but smoke lightly every week, and the plants never touched by fly require very little direct syringing, no small matter in late culture. Next to freedom from insects, cleanliness in the care and keeping of the house is a great factor. Filth, Lichen, decaying leaves and stems tell quite as unfavourably on Melons as they do on Cucumbers, and for this reason should never be allowed to accumulate.

Plants in manure pits and frames, now finishing off fruit, should be kept as dry and warm as possible by the frequent addition of fresh fermenting manure to the linings and good dry covering every night. If laterals persist in growing, they must be closely pinched to let sun and air into the bed, and in order to obtain the best attainable flavour, the fruit may be elevated until it nearly touches the glass, which, by the way, must be kept perfectly clean.

Figs.

Where trees in early houses were root-pruned early in September, they will now be bare of leaves, and none the worse for three weeks' or a month's exposure to the elements. The roof-lights being portable, they may be taken in and painted, and, provided the branches are untied and slung, the trellis and rafters may have a coat also. Figs are almost invariably infested with insects of some kind, and no matter how well they are cleansed, the work is only half done where the woodwork and walls are neglected. The best wash for the walls is quicklime and sulphur, applied hot, and turpentine, a pint to a gallon of oil, should be used when mixing the paint. If nothing worse than spider and scale have attacked the trees, washing with soap and hot water will remove them, and the trees need not be painted; but bug will require a little more attention. Washing, of course, comes first, and the tar mixture, half a pint of tar to a gallon of dry sifted loam, must follow. Tar paint should always be applied when the trees are quite at rest, otherwise I should not like to be held answerable for its action. Once upon a time, I was induced by a man of great experience to paint some trees with castor-oil; but the oil, or the operator, took the wrong turn, and the first crop of Figs came to nothing. Friends to whom this suffocating varnish is recommended will please to take warning. If late Figs are in demand, houses in which the tail end of the crop is likely to ripen must have constant fire-heat to keep them swelling and prevent damping. Brown Turkey often gives nice dishes up to November, but unless they are really needed, the trees will pay best for being divested of their fruit and rested.

Pot Vines.

Where the earliest Grapes are obtained from Vines in pots, the time is now at hand for getting them into position. Some growers, through force of circumstances, others from choice, place their Vines out of doors after they are ripe to lose their leaves and have a short season of complete rest; but, space being plentiful, this end is best attained by keeping them in the dry, airy house in which they have been grown until the leaves part freely from the canes. Assuming that they are still in the open air, or perhaps in the nursery, steps should be taken for putting the fruiting house into thorough working order, first, by cleansing and painting, and secondly, by forming pedestals or solid stations for the pots to stand upon, as there must be no sinking or strangling after forcing is commenced. The Vines, previously divested of all laterals to plump up the buds, will require careful washing with soap and warm water; the pots also must be washed and the apertures examined to insure the free passage of water, for, much as they enjoy good living, they soon resent a clogged condition of the roots. These matters satisfactorily arranged, place a good sod of turf, grass side downwards, on each pedestal and arrange the Vines according to their strength, shorten the rods more or less to suit their position, dress the points with styptic, and sling them in preference to tying up to the wires, to insure an even break. Having removed all inert soil, top-dress with good loam to which bone dust and rotten manure have some time previously been added, and keep the house open until the time arrives for starting. If they can be started with a gentle bottom heat from fermenting Oak leaves and a little short stable manure placed about the pedestals and the lower parts of the pots, much time will be saved at the outset. Moreover, the constant use of the syringe at a critical period of the year can be dispensed with, as the warm vapour from the bed will feed and swell the buds, when saturation of the soil from constant syringing might prove injurious. Where good leaves, the best of all bottom-heat-producing materials, cannot be obtained, well worked tan may be used, but leaves are milder in their action and feed the roots and foliage throughout the season. Vines intended for cutting back

or planting out in the spring should now be ripe enough for removal from the pit in which they have been grown. Nurserymen who produce them by the thousand are obliged to turn them out of doors, but the private gardener, who grows a few for his own use can generally find room for them along the back walls of Peach houses or cool vineries, where moderately watered and the rims of the pots covered over with old tan or leaves, they will sink gradually to rest and be fit for cutting back in December. Gardeners who have to buy in for early spring planting should lose no time in making their selection, not only of varieties, but of canes. The best and in every way most satisfactory course is to pay a personal visit to the nursery while they are yet in full leaf, as everyone is anxious to have the first pick of the stock. Unless thoroughly ripened under glass, the strongest Vines in large pots are not always the best. For my own use I should give preference to stout, short-jointed canes, well clothed with healthy foliage, turning off to a bright nankeen colour in 8-inch to 9-inch pots nicely filled with roots. If in a light, airy house they might remain until the leaves fall; otherwise, I should have them home and under my own care without further delay. W. Coleman.

Fruit Garden.

NOTES ON DWARF APPLE TREES.

The culture of Apple trees on stocks calculated to restrict their growth is a much more fascinating pursuit than that of standard trees. I have found that dwarf trees frequently escape frost-winds when tall trees are greatly injured thereby. Of this the present season affords ample proof. In our own garden, which is surrounded by a wall, very few of the dwarf trees failed to bear good crops, while those on tall trees are comparatively a failure. Some four or five years ago the same thing occurred in the gardens of the Royal Horticultural Society at Chiswick. The dwarf trees in a large quarter were bearing a full crop, while large trees were very scantily furnished. Apple trees are more certain to bear a crop of fruit than Pear or Plum trees, not because the blossoms stand frosts better, but because they are produced later. No kind of fruit tree is better adapted for small gardens than the Apple, and its produce is always appreciated both by rich and poor. Now, therefore, being the right time to obtain the trees, and also to prepare ground for them, perhaps a few notes in reference thereto may be serviceable. Few gardens contain soil exactly suitable for Apple trees, but it can be made so in most of them by suitable preparation. It is only in gardens where the subsoil is good clayey loam, and not liable to become too dry in such seasons as the past, that good Apples can be grown without trouble, and even under such favourable conditions careful preparation of the soil is needful, if not absolutely necessary. The worst of all garden ground for fruit trees is light sandy loam overlying a dry gravelly subsoil. That, at least, is my experience. The trees in such a soil are liable to canker, and to be attacked by insect pests. In order to obtain anything like permanent success, the depth of loam over the gravel ought to be at least 18 inches. It is all very well to say "choose a suitable position for the garden, and one where the soil is good." Ninety-nine out of every hundred have no choice in the matter, and those who purchase ground for building purposes generally look out for a gravelly subsoil. They care nothing about the value of the ground for fruit trees or other cultural purposes. I have before now got as much gravel out of the soil during the process of trenching as made up the whole of the garden paths with good material. That nearest the top is always inferior and must be used for the bottoms of the paths; all the best should be laid aside and used afterwards on the top of the walks. The soil taken out of the paths will replace the gravel that has been removed, and if nothing better can be obtained, turf cut from the sides of roads may be buried in the bottom of the trenches. Even if full of Couch Grass, none of it will come to the surface when buried 18 inches deep. In the neighbourhood of large towns good turf and loam can readily be obtained where new ground is being broken up for building purposes. "Will such work pay?" may be asked by some, and I may reply, perhaps not directly, but the difference between a well cultivated and a badly managed garden is so great, that it is always worth while to set matters right at first, *i.e.*, make a good beginning. Some prefer bush trees, others those of a pyramidal form. I prefer the latter. Two, three, or four-year-old trees ought to be selected in some nursery now, and be sent home when ready. In the meantime the ground ought to be trenched when the weather is favourable, and if rich no manure will be needed. It is easy to stimulate too much; therefore it is better to work in some short manure, or apply it as a mulching to be dug in afterwards, than to put in too much, which will cause the trees to make gross growths, and to form few flower buds.

In some parts of the neighbourhood of London the long back gardens attached to villa residences might be made to contain many varieties of fruit trees. They are generally narrow; therefore the best arrangement would be a 4 feet or 5 feet wide pathway down the centre, and a border 6 feet wide, or so, on each side of it. In the centre of a border of this size might be planted a row of fruit trees 6 feet or 8 feet apart; they might be planted 4 feet apart at first, and each alternate tree might be removed when the branches encroach on each other. The superfluous trees might be planted in another place, or might be sold; or, as a last resource, given away to some neighbour who neglects his garden, but who might be constrained to pay attention to it if he could have his trees for nothing. In planting dig out a pit wide enough to take hold of the outstretched roots, and if half a barrowload of maiden loam can be placed round them it will encourage the formation of fibres. Trees for small gardens should be worked on stocks that restrict growth, and the union between stock and scion should be close to the ground, so that it may just be underground. The soil ought to be well worked in amongst the roots, if necessary with the fingers, and be pressed moderately firm. The first year the trees will not require very much attention. They will form plenty of roots, and also blossom buds, but probably not much young wood; any shoots that straggle out too much should be pinched back, when they will make three shoots instead of one, which will ripen by the end of the season. Long shoots not pinched back early, but cut back at the end of the season, will make their growths the next year, and in that way a season is lost. By judicious summer pinching fruit trees may be increased in size in double quick time. Insect pests must be carefully watched during the growing period. Few collections of Apple trees are quite free from that troublesome pest, the American blight (Aphis lanigera). Its first appearance is that of a white downy substance to be found in the crevices of the bark. When that is observed take a fine hair-brush; dip it in paraffin, and with it thoroughly wet the retreats in which the insects have established themselves. In hot seasons red spider also attacks the leaves, and if not destroyed causes them to drop off prematurely. It may be destroyed by syringing the trees daily with clear water, or more speedily by means of a solution of Tobacco; but daily syringing with clear water is highly beneficial during hot, dry weather. It keeps the trees in health, and unless that is so and the foliage good, well developed fruit cannot be expected. Mildew often appears in dry seasons, but the treatment recommended for red spider will keep that fungus in subjection. If badly attacked, dust with sulphur. The caterpillar of the goat moth (Cossus ligniperda) attacked some young trees in a small villa garden near here. The mouths of their tunnels were near the ground, where a swelling existed at the union between graft and stock. I destroyed them by thrusting a flexible wire into the holes. A very tiresome pest is the codlin moth (Carpocapsa pomonana). In dry autumns like the present it has things pretty much its own way. Many of our young trees were loaded with fruit, and the grub of this moth has destroyed quite a third of them. One tree of Lord Burghley had every Apple injured by it. The only cure is to destroy the Apples containing the grubs.

Canker I believe to be caused by the roots getting down into an unkindly subsoil, and, as pretty conclusive evidence of this, I have lifted the roots of cankered trees nearer the surface, placed a barrow-load or two of good loam for them to work into; the cankered portions were at the same time removed, and under this treatment the trees grew away again with renewed vigour. The late Mr. Thompson, of Chiswick, believed that severe and untimely pruning induced canker. He says, in "The Gardener's Assistant" (p. 381): "If a large limb is cut off late in spring when the buds are just breaking, the sap must either overflow by the wounded surface and cause weakness, or it must stagnate, and when it does so, being partly in contact with the air it very soon becomes vitiated and the bark cankers."

The following are a few of the best Apples, both for dessert and kitchen, viz.: Dessert—Irish Peach, Kerry Pippin, Adams' Pearmain, Cox's Orange Pippin, Court of Wick, Golden Reinette, Pitmaston Golden Pippin, Ribston, Hubbard's Pearmain, King of the Pippins, Mannington's Pearmain, and Sturmer Pippin; kitchen—Lord Suffield, Cellini, Cox's Pomona, Hawthornden, Loddington, Lord Derby, Alfriston, Dumelow's Seedling, Lane's Prince Albert, Brownlee's Russet, Blenheim Pippin, and Yorkshire Greening. James Douglas.

The best Currants.—After trying nearly all the kinds of Currants grown, I have come to the conclusion that the following are amongst the best, viz., Black Naples and Baldwin, both extremely fine Black Currants, having berries more like Cherries in size than ordinary Currants. Of Red Currants, Raby Castle is probably the finest in cultivation, and of a good dark colour. Amongst White Currants, which are not so much grown as they ought to be, the Dutch variety and the Transparent are good trustworthy sorts. If people grubbed up their old worthless kinds, and substituted young healthy plants of the above, they would soon find the produce of their Currant trees augmented. There is, moreover, no need to wait long for fruit, as the finest crop I had last year was obtained from young bushes, three years old, from cuttings that had been left in nursery rows; the berries were of great size, and the bunches long and full. In the old kinds of Black Currants the fault is that there is one or two large berries at the base, and the rest are small, and, if not picked directly they are ripe, the largest drop off, leaving the small ones, that do not pay for the picking. Let anyone interested in Currant culture try a few bushes of the above, and if they do not find them superior to the older sorts, their experience will be different from mine.—J. Groom.

Autumn Apples.—There is no better class of Apples in our gardens than those which produce fruit for use during the autumn months—say, from the middle of September until the new year. Amongst leading kinds for this purpose must be included Lord Suffield, Keswick Codlin, Hawthornden, Cellini, Worcester Pearmain, and Kerry Pippin. Those who have these varieties in their gardens need never be without Apples in autumn. They are heavy and sure fruiters, and it is very rare indeed that they miss a crop. Anyone who plants a dozen Apple trees, including two of each of the kinds named, might rely on always having a crop, let the Apple season generally be what it might, as when there are any Apples at all these are always among the first and best; and I do not remember a year when we were without quantities of fruit of them. Many plant a great variety of trees to fruit in succession from July to May, but amongst these many are indifferent bearers; in fact, in many districts they do not bear a crop once in three or four years. Therefore, growers generally would find it more profitable to

plant sure-fruiting sorts than a succession of uncertain bearing kinds. The varieties which I have named are notable for excellent quality as well as for constant bearing, and when their fruit is properly stored it is astonishing how long it may be kept in good condition. The Keswick Codlin is in prime condition now, and it will be so for the next two months; while Hawthornden and Worcester Pearmain will both remain good until the end of January or beginning of February. This being the case, doubtful fruiting sorts to come in during November, December, and January should be planted sparingly, but it is almost impossible to plant sure fruiters too numerously. I do not know of any midseason or late Apple which fruits so surely and freely as the old Keswick Codlin, and the others named are in no way behind it. They will succeed north or south in garden or orchard.—Cambrian.

NOTES ON PEACHES.

In my paper on Peaches a week back I emitted, not altogether unintentionally, as I had limited myself to numbers, four excellent varieties which I have grown and can strongly recommend. Unfortunately, they are pale sorts, and some, I know, object to the Noblesse family on account of their want of colour. "Hortus," on the other hand, evidently convinces himself, if he does not convince others, that colour in Grapes is a defect, and, assuming that he looks upon Peaches with the same eyes, I feel sure he for one will endorse the few words I have to say in favour of my old friends. The first is

Malta, a variety to which belong three or four French synonyms. It is now rarely met with, and I never saw it on the exhibition table, but it is one of the most luscious Peaches I ever tasted. The fruit is large, flattened on the top, with a broad shallow suture. Skin greenish yellow in the shade, like the old Noblesse, blotched with purple next the sun, and beautifully suffused with pink when grown under glass. Flesh greenish white, red next the stone, tender, juicy, and very rich. Flowers large, leaves without glands, bears carriage well. This and Dymond were strongly recommended to me by the late Mr. J. Veitch, no mean authority on fruits.

Sulhamstead.—This is a very hardy form of Noblesse, ripening about the end of August on open walls, and with me for many years carrying heavy crops of handsome fruit. Like Malta, the fruit is depressed, giving it a large appearance in proportion to its weight. Skin pale yellow in the shade, but highly coloured, for this family, next the sun. Flesh fine, rich, and excellent. Flowers abundantly produced and very large; leaves without glands.

Montagne or Montauban, sometimes called Double Montagne.—This is a very large Peach when grown under glass and forces well. Fruit roundish, running to a nipple at the apex. Skin pale yellow all over in the shade, but beautifully marbled with red next the sun. Suture very distinct. Flesh white to the stone, rich, and juicy. Flowers large, often semi-double; hence its name. Leaves without glands. The tree bears well, and years ago was a great favourite in the neighbourhood of Dublin.

Raymackers.—Since my paper was published, Mr. Bennett, the gardener at Rangemore, Burton-on-Trent, has sent me a most beautiful fruit of this excellent variety. In his letter he says he looks upon it as one of their best late sorts, and, judging from the size, shape, and high colour of the example now before me, I should say there is no other member of the family so well adapted to late house culture. The tree is hardy, a good bearer on the open wall, and leads well up to Walburton Late Admirable; flowers large, leaves without glands. I have seen very fine fruit from the Oolite formation, shown by Mr. Birch, gardener to Sir T. Bazley, rather deficient in colour, but complete bags of luscious pulp.

Late Peaches.—Mr. Gilbert, at p. 287, says he succeeds with Princess of Wales and Late Admirable, but fails with Walburton. The fruit on the latter swells to the size of marbles, then falls, and he attributes his loss to imperfect fertilisation. Mr. Muir, same page, succeeding article, says, "once formed, the fruit is sure to swell and prove satisfactory." Where this is not the case, "failure may be put down to want of protection when the trees are in flower." Possibly both of these cultivators may be right, but I am inclined to think they are wrong, as I have yet to learn that Walburton is more tender than Late Admirable or the Princess, which gives good crops under identical treatment. When Peaches set and make a stand at the stage named by Mr. Gilbert it is evident that something is wanting, and that something, in my opinion, is water, for I have proved to my own satisfaction that a dry stratum of compost near the drainage will produce this result, not only on walls, but also in glasshouses. If I might venture a suggestion to an old hand, I should say, lift all your Walburtons now and replant in fresh, certainly in properly-moistened, loam—not too rich; for the variety a strong late-grower takes a little coaxing to get the wood and blossoms properly ripened. Having replanted and mulched with stable litter for the winter, he may protect with fishing-nets, as Mr. Muir suggests, and fertilise with foreign pollen in the spring. I have a large tree on the open wall which never fails. It is now loaded with fine fruit, but I never fertilise the flowers, and the spring covering of netting is very scant indeed. I root-prune every year, and deluge the roots with water. Our garden lies low, between two cold-condensing limestone hills, which render our climate if anything inferior to that of Burghley.

Eastnor Castle, Ledbury. W. Coleman.

WATERING LATE-FRUITING VINES.

In my opinion late Grapes, as a rule, are not sufficiently watered at the root during the autumn and early winter months. When they are green and growing they are watered pretty freely, but when once they begin to ripen, and especially when three parts ripe, as many of them are now, water is almost withheld from them, and by the time they are ripe or nearly so the roots are so dry, that the fruit soon begins to shrivel and loses its crispness and freshness. When this happens the wood must suffer too, and many of the young rootlets must also shrivel up and become useless. Therefore, both fruit and Vines would be better were more water applied to the roots in winter; many keep their borders dust-dry during the short days to prevent the fruit from damping, but observation leads me to remark that Grapes keep better when the roots of the Vines are in a moderately wet soil than in a dust-dry one, and the fruit is not half so much inclined to decay when the border is damp as when the atmosphere is in that condition, arising from spilling water about the floor and pathways. Indeed, I think dry roots and a damp atmosphere are fertile sources of decay in Grapes and should be avoided; some who are afraid of watering freely give them a little drop on the surface of the border, but this is not good practice at the present time, or, indeed, at any time, as the subsoil is sure to become very dry, and Grapes never keep better than when the border is in a uniform condition throughout as regards moisture. All surface dribblings are deceptive, and do more harm than good. A thoroughly good watering is more beneficial than anything else; the border, indeed, should be kept constantly saturated so long as the foliage remains on the Vines. It will have often been observed that late Vines with their roots wholly outside and with no protection have perfected as good a crop as any can do with their roots inside. In fact, those with their roots in the outside border often do much better than others inside. The fruit is always more plump, juicy, and crisp, a circumstance wholly owing to the roots being supplied with sufficient moisture to prevent any shrivelling in the fruit, root, wood, or foliage taking place. The best practice is, as I have said, to keep the border quite moist so long as the foliage keeps green, and it will be a great advantage to the Vines if the border is not allowed to become too dry afterwards, as a dust-dry border is injurious to the present and future well-being of the Vines. Cambrian.

THE SEASON FOR AND PLANTING FRUIT TREES.

I have been into several fruit-tree nurseries of late, and I scarcely ever before remember to have seen the trees in such excellent condition as they are this year—so vigorous, with such a strong clean summer growth, and with the wood hardening off and ripening in the most satisfactory manner under the influence of the dry weather of September. So far, then, all is favourable. What planters and nurserymen alike want just now is a good ground rain, a warm soft fall, for in many places the earth is very dry, and it will be unwise to attempt to plant until the soil has been saturated by rain. But there are indications that this fall of rain is near at hand. As to the time for planting, fruit trees may be planted from the fall of the leaf until the rising of the sap in spring, but an autumn planting is preferable to any other when the soil is suitable. Nevertheless, it is often advisable to plant at different times according to the nature of the soil. If the borders have been formed such a length of time as to be fit to plant in at the latter end of October or beginning of November, this is unquestionably the best season for the performance of the work; for if the trees be then planted, they will in many cases have pushed forth some new roots before the commencement of severe weather, which is generally looked for at the end of December and in January and February, and will have materially established themselves before the moving of the sap in the spring following, which greatly assists them in making new wood the following summer, and this will, naturally enough, be more vigorous and matured than in the case of trees the planting of which had been deferred until the spring. This is one advantage attending planting in autumn; therefore the planting of fruit trees should be performed at this season of the year whenever it can be done.

Sometimes it is not convenient to plant until winter has set in, or necessity may demand its postponement until then, but it should be done when the weather is mild, as a frosty air and soil soon damage the tender fibres of the roots. But in all cases where the borders are formed of a moist, heavy soil, the planting had much better be deferred until spring, and the reason for this recommendation is, that the roots will not strike so soon into such a soil as into one lighter and more porous. Therefore, it is better in such a case to plant either in early autumn or in early spring. In a cold, wet soil roots are slow in putting forth fibres; it rarely happens that they will strike root until the spring has well advanced; therefore, plant in September, or not till March or early in April, for removal gives a check, and by reason of the soil being cold, stiff, and moist, the fine roots are frequently injured; indeed, we have known the tender fibres to rot away. And so in the spring, when their assistance is wanted to aid in the speedy establishment of the tree, the rot thus caused acts as a kind of paralysis, and the welfare of the tree is retarded rather than promoted.

But whatever may be the time of year chosen for planting, it should not be done in wet weather, for, in order to assist the roots to strike into the soil as soon as possible, it is requisite to press it firmly about them, so that it closes upon them. If this be done when the soil is wet, it becomes lumpy, and when it dries, bakes hard together, and in that state is unsuitable for young trees. It is also apt to crack in hot, dry weather, and then it is decidedly unsuitable for the trees.

If by some means the planting had to be deferred until spring, and it is high time the tree should be planted, though the weather may be continually wet for some days, then some drier soil should be provided to place about the roots at

the time. But the soil so introduced should be of a similar quality to that forming the border, and it is not difficult to provide this. If it is not handy, then let some of the soil forming the border be dried preparatory to planting the trees. When a plantation of fruit trees has to be made, the ground should be previously prepared by draining (if necessary), trenching and manuring; time should be allowed for it to settle, then the proper position for each tree should be marked out; and some planters hold the reasonable opinion that the longer time the holes are made before the planting is done, the better for the soil, as it is improved by being exposed to the action of the atmosphere.

The size of the hole dug for the roots of the tree must be regulated to a great extent by their dimensions. It is too often the practice (especially in the planting of suburban villa residences not yet occupied) to make small holes, and when the roots are placed in them they cannot be properly extended; indeed, they are frequently obliged to be unnaturally twisted and cramped in order to get them into the restricted space. The roots of trees are naturally inclined to proceed in a straight direction outwards; therefore it is always proper to allow them to be placed as much as possible in such a position. The roots of trees that have been grown in pots require special attention in this respect, and it is a practice with experienced planters not only to make the holes intended for such plants large enough to admit of the roots being fully extended, but 12 inches or 18 inches wider all round. And the reason for the practice is that when a hole is made only just large enough to take the roots, they, on pushing, strike immediately into the soil that has not been recently disturbed or that in which the tree is planted; the latter consequently settles more than the other; and when the roots begin to establish themselves in the other part of the border, the ends of them are often forced upwards and out of their proper lateral direction; this is more particularly the case with trees that are planted late in the winter or in the spring. But if the trees are planted in November or December they will not be thus liable to injury, because the roots will not begin to spread until the soil in which the tree is planted will generally have settled equal to the other part of the border.

Great care is necessary that the trees be not planted too deep in the soil, as it is always injurious to them. In the case of fruit trees planted against a wall, 6 inches will be found deep enough in such a soil as that in which they would be placed. But it should be observed that in the case of wet, heavy soils the roots should be placed nearer the surface, and a little deeper in those that are of a lighter character. When trees are thus planted, the roots will always find their way down into the border or along the upper part of it in search of necessary food; when, on the contrary, if planted too deep, they do not nearly so readily find their way to the surface, unless in a border that slopes away from the wall a good deal, a form that should be avoided if possible. But although the roots of those trees that are planted too deep may after some length of time find their way to the surface of the border, yet they will be a long time without having enjoyed the benefits of sun, air, rain, &c., which they would have done had they been nearer the surface. Neither will the trees have made so much progress, nor have proved so fruitful, nor the fruit be of so good a flavour; but by being planted at the depth directed, the trees will derive every advantage from the influence of sun-heat, and mulching placed on the border.

Great care should be exercised in digging fruit-tree borders for the cultivation of any vegetable that the roots be not damaged, for where they are, considerable injury is often done to the tree, which will frequently show itself afterwards in the shape of canker, &c, also in the production of suckers from the roots, which generally are caused by the spade in digging the borders, for the sap frequently makes a callosity at the wound, and the production of suckers is a consequence. Only surface-rooting subjects should be permitted to grow on fruit-tree borders, or, at any rate, near where the roots of the trees are likely to be found. R. D.

SPOTTED GRAPES.

Would you kindly tell me the cause of the spot on the Grapes sent? Both black and white are alike spotted. Our vineries are 30 feet long, 15 feet broad, and the borders, which are 3 feet deep, rest on a putty clay, with no drainage between them and the clay except the ordinary drains 9 feet apart. I watered my borders this season, as recommended in The Garden, with diluted liquid manure of the strength of one of liquid to four of water, giving them about 250 gallons each time, *i.e.*, the inside borders. The outside ones I renewed some years ago; the Vines are sixteen years old. The Muscats are always full of stoneless berries, which spoil their appearance. I syringe them when in flower, but all to no purpose.—M.

EDWARD BECK.

*** The Grapes sent to me in dry Sphagnum dust did not arrive in good condition for examination, but they conveyed unmistakable signs of a bad case of spotting. The above communication, however, more than the berries leaves but little doubt that the borders, "3 feet deep and resting on putty clay, with no drainage between them and the clay," are the cause of the mischief. The borders, it is said, were renewed some years ago; but it is not stated whether concrete was introduced; drainage, beyond ordinary drains 9 feet apart, is, it is asserted, absent. It is, therefore, not to be wondered at that the Grapes set badly, became spotted and putrid in autumn. Ordinary liquid manure, one to four of water, would not injure healthy Vines, but in the case in question it most likely would do harm, as the roots, already gorged with crude matter from a cold subsoil clay, could not assimilate it. The remedy lies in lifting, concreting, draining, and relaying the roots in warmer and shallower borders; but before commencing refer to copies of The Garden, in which you will find full instructions for lifting and renovating repeated over and over again. Lose not a day in setting about these matters; obtain suitable materials for the purpose—turf from an old pasture, old lime rubble, burnt clay, and crushed bones. Also get an abundance of clean broken brick or sandstone for drainage and a supply of mortar for concrete. Renovate the borders at twice taking the internal or the external border—whichever may be worst this autumn—this month, if possible, and the other twelve months later. Excavate carefully, saving every root, down to the clay; give a good slope outwards to the front or longitudinal drain; then concrete the surface of the clay, also the bottom and sides of the drain. Allow a few hours for the mortar to get stiff; then on the top of the concrete lay transverse drains of 4-inch pipes 4 feet apart, and cover evenly with a foot of drainage. Lay on the turf Grass side downwards, using the same for the front or retaining wall, and wheel in the compost. Trim and relay the roots as near the surface as may be practicable, and when all is finished the result will be a warm border from 2 feet to 2½ feet deep, completely cut off from the clay, well ventilated, and capable of taking any quantity of water.

Look well to the ventilators, as imperfect ventilation or sudden rushes of cold air when the atmosphere is charged with moisture not untrequently aggravate this disorder.—W. Coleman, *Eastnor Castle, Ledbury.*

THE LATE MR. EDWARD BECK.

By way of perpetuating the memory of one who in his lifetime did good work in relation to floriculture, we present our readers with a portrait of the late Mr. Edward Beck, of Worton Cottage, Isleworth. Few men did more in their time than he did to improve the show Pelargonium, and bring about that development which has been going on during the last twenty years. It was he who practically showed us the points of excellence which the Pelargonium should possess as a florist's flower; in all he did he aimed at securing breadth of petal, and consequently roundness and fulness of flower—stoutness instead of flimsiness, smoothness instead of coarseness, and refinement and harmony as regards colours; these he secured in a large degree by crossing, judiciously, different varieties. Half a century has elapsed since he commenced work of this kind. I can just remember some of his flowers which stood high in public estimation forty years ago. Amongst them were Rosamond, Aurora, Arabella, Bacchus, Cassandra, Desdemona, Gulielma, Centurion, Competitor, Blanche, Refulgent, Princess, and Star. Of the last two, excellent coloured illustrations were given in *The Florist* for 1848, a work started by Mr. Beck, and for some time carried on by him. At the time of his death, in January, 1861, he, in conjunction with his contemporaries, the late Mr. Edmund Foster, of Clewer, and the late Mr. G. W. Hoyle, of Reading, had brought the show Pelargonium to a high stage of excellence; at that time his leading flowers were Apollo, Bridesmaid, Emperor, Fairest of the Fair, Mars, Sappho, Sunset, The Bride, and Vestal. After his death, the raising of seedling Pelargoniums was continued by his son, Mr. Walter Beck, at Worton Cottage, until within the last few years. Mr. Edward Beck was an enthusiastic gardener, ever ready to put into practice anything which seemed to be an improvement on former methods of procedure. When heating by hot water in tanks first made its appearance he at once adopted that system, substituting slate for wood in the construction of the tanks. He was the first to show that plants could be grown in non-porous pots, *i.e.*, in little square slate boxes, and the Roses which he grew

and showed in such receptacles will be still fresh in the memory of many. Being a sailor in early life, he had something useful to say on emigration, and wrote a series of papers on that subject for the benefit of young gardeners about to emigrate. He also wrote a little book called "A Packet of Seeds Saved by an Old Gardener," the object of which was to elevate the condition of gardeners generally, but especially to induce employers to give them better "bothy" accommodation than they had hitherto been having. This at the time it was published was read with interest. R. D.

Trees and Shrubs.

THE HATCHET-LEAVED THUJOPSIS.

(T. DOLABRATA.)

I was forcibly reminded of the extreme beauty of this a few days ago when looking over the fine collection of trees in the grounds at Baronhill, the residence of Sir Richard Bulkeley. Here several of the specimens have attained to heights of fully 16 feet, with well and regularly branched stems and an abundance of bright, healthy foliage, due in a great measure, no doubt, to the sheltered site and sea breezes to which they are subjected. This is usually termed a slow-growing Conifer, and rightly too, for neither as regards its yearly increase nor ultimate height attained has it much to boast of. As an ornamental tree, however, it ranks high, and deservedly so, for perhaps in no other Conifer is the tinted green of the upper and silvery hue of the undersides of the leaves more prominently seen. Planted in a rather moist, cool loam and a semi-shady position, this tree seems to thrive best; and though the upward rate of growth is slow for the first dozen years, yet when fairly established, a change for the better usually takes place, and occasionally an average yearly increase of half a foot is attained, but this is rarely maintained, here at least, for many years in succession, although our favourable situation and mild genial clime is enjoyed by most Japanese Conifers. For lawn purposes, and especially where space is limited, I know of nothing among Conifers to equal this ornamental tree, and being of the easiest culture and perfectly hardy is therefore well suited for almost any part of the United Kingdom. I fancy, however, in judging from specimens growing in the grounds at Penrhyn, that a shady position is best suited for this tree, as those planted where exposed to direct sunshine have not the glossy appearance that is characteristic of others growing in partially shaded positions, or even where never a ray of direct sunshine strikes upon the foliage.

In well-grown specimens of this Thujopsis, the whole contour is usually strictly pyramidal, with branches that are somewhat vertical and drooping towards the points. The leaves are hatchet shaped (hence the name dolabrata), loosely imbricated, and of a beautiful shining green above and silvery beneath. Usually the main branches are few, but the branchlets are numerous and compressed, and certainly constitute the most striking feature of the tree. Cones have been produced in some abundance on two of the trees here, but they are rather inconspicuous, being small and globular in shape and usually with five-winged seeds at the base of each scale.

The propagation of this tree is simple, indeed, for whether an attempt be made with seeds, from cuttings or by grafting, a fair amount of success is usually the result. Cuttings, however, form the best trees, perhaps not better than those raised from seeds, but the operation is quicker, grafts being particularly liable to be broken over either by wind-pressure or other accident. August and September we find the best months to insert cuttings of this Thujopsis, which should be placed rather thickly in boxes or pots of free, sandy soil, and these stood in a cold frame until rootlets are formed. When grafting is the mode of increase, it should be borne in mind that the nearer to the ground level the scion is inserted the better, as by this means roots may be made to emit from the latter, thus, to a great extent, minimising the danger of loss through the scion becoming detached from the stock through accident.

There are two varieties of the above—variegata, with irregularly variegated leaves of an indistinct yellow; and nana, in which the original is by some means dwarfed into a neat, erect, dense bush of 4 feet or 5 feet in height. If Mr. Coleman will tell where the hedges of Thujopsis dolabrata, to which he recently referred, are growing, he will answer a query that has been asked by more than one correspondent. A. D. Webster.

Cotoneaster frigida.—Among trees and shrubs remarkable for their bright fruits in autumn this is one of the finest. It is of robust growth, not particular as to soil, and produces freely large bunches of bright red fruits. These, too, seem less liable to be attacked by birds than those of many other trees and shrubs, and, therefore, remain in perfection for a long time. Their depth of colour seems to vary a good deal in different individuals, no doubt owing to the plants being raised from seed. Comparatively common though it be, it is certainly better worth the attention of planters than many oftener employed by them.—A.

The golden Weigela (W. Looymansi aurea).—This beautiful shrub is seen at its best during the height of the summer's sun; indeed, last season some plants of it employed to hide an unsightly fence to which they were secured formed one of the brightest pieces of leafage that I ever noticed, the colour being greatly heightened by the roasting to which they were subjected. This Weigela may be struck from cuttings put in during autumn or winter when in a deciduous state, but I have been most successful with young shoots made into cuttings in summer. These latter must be kept close and shaded till rooted, which will not be long. Care must be taken to stop damp or decay should any signs of either be seen.—H. P.

Fine-foliaged Vines.—The varieties of Vines that are usually grown for their fruit in this country all possess very ornamental foliage, but in this respect they are surpassed by the North American species, some of which are among the finest of hardy climbers—that is, where bold, strong-growing kinds are desired. They make very rapid growth, and, if unchecked, quickly festoon neighbouring trees and shrubs with their long rope-like shoots and huge leaves. The North American kinds bear a good deal of resemblance to each other, and of these the Fox Grape (Vitis Labrusca) may be taken as a type of the whole. It is very vigorous in growth, with heart-shaped leaves, sometimes more or less three-lobed, and of a stout leathery texture. In autumn the decaying foliage sometimes changes to a bright crimson hue. Vitis amurensis is another in the same way, whose huge leaves are conspicuously veined on the under surface. Like the last, its autumnal tints are sometimes very bright. Among the varieties of the common Grape Vine may be mentioned the cut-leaved apiifolia, the foliage of which is much laciniated, thus imparting to it a distinct and singular appearance. Another noteworthy variety is purpurea, the foliage of which during the first half of the season is but slightly reddish, but the colour is much intensified by the summer's sun, and before the fall of the leaf it is very pronounced. The little variegated form of V. heterophylla is too tender to hold its own as a hardy climber, and too delicate to compete with the giants of the genus. While on the subject of Vines I may mention that my plants of humulifolia, that bears pretty little blue berries, are this season very sparingly furnished with fruits—less, indeed, than has been the case for some years.—T.

Golden Ribes alpinum.—This little shrub forms a dwarf-spreading bush a foot or so in height, very suitable for exposed parts of rockwork and similar places, where, during spring and early summer, it is very conspicuous, but as the season advances it becomes much greener. Where the shoots come in contact with the earth they often root, so that it can be increased in this way, especially if artificially layered. Cuttings of it by no means strike root readily unless the stock plant is taken into a little heat a short time beforehand, in order to draw the young shoots out, as is done in the case of Fuchsias and similar subjects. When putting in the cuttings it should be borne in mind that, though hardy, as they were grown in a little heat, the same should be maintained till they are rooted, for if put in a lower temperature than that in which they have been grown, many will probably be lost.—A.

THE PLANTING SEASON.

As the tree planting season has again come round, a few notes relative thereto may be useful. Planting may be done from October till March, but I would prefer the first or the last of the months named, as the weather is generally changeable and trying during the shortest days; I know, too, from experience, that planting between intervals of frost is often injurious to the plants. In dealing with a quantity of trees, I planted part of them in favourable weather in October with the best results; others, again, were put in in January, and much loss occurred; while with the remainder, planted in March, I had greater success. Much, however, depends on the subjects operated on and their condition. Small plants of the hardiest kinds are not so easily killed at any time; but large tender ones have to be dealt with most carefully. In established places there is often a good deal of transplanting and thinning out to do at various times in a number of years, and by doing this at the proper season very large plants may, as a rule, be shifted without injury; but it is a mistake to buy very large plants at a distant nursery in the hope of securing immediate effects with success. I am referring now to such plants as large Hollies, Evergreen Oaks, and Evergreens generally. Large deciduous trees can, as a rule, be more successfully transplanted than Evergreens.

In lifting any kind of tree, especially when the leaves are on it, the roots should never be divested of soil; on the contrary, as good a ball as possible should be retained. Where trees are treated as in properly conducted nurseries, the roots can always be had in a compact ball; being often lifted and transplanted when young, the roots become matted in a very confined space, and plants of this kind may always be moved with safety. Crowding them into a small hole is a mistake. This may not kill the plants outright, but it will check it for years to come. When lifted, the roots should never be long exposed to the influence of sun or wind. This is one of the very worst things that can happen to them, and should be strictly avoided. When plants are brought in from a nursery, it is, of course, impossible to plant them all at once; but the first attention they require is to cover up the roots with damp Moss, straw, or soil.

As to pruning and cutting generally, the period named in which planting may be done also answers for these operations. We begin cutting our bushes in October, and go on from time to time as the weather and other work will allow until March. That this time is right we have annually ample proof in the luxuriant manner in which the trees grow afterwards. It is, however, only hedges, Laurel banks, and upright-growing bushes near the edges of walks on which we use the shears, the knife, or bill-hook. J. M.

Golden-leaved Ptelea.—This (P. trifoliata variegata) is one of the handsomest of golden variegated trees, and its variegation is much more enduring than that of the golden Oak, which speedily burns in the sun. It is also much brighter than the golden Elder; in fact, in the distance it appears to be covered with rich golden flowers. Nevertheless, it is a tree which is seldom seen. Why is this, for it is not new?—T. S.

The Pyramidal Birch.—Allow me to draw the attention of ornamental planters and nurserymen to the Upright Birch (Betula fastigiata); it deserves to be better known than it now is, for I think it is destined to become a most effective and useful tree, especially adapted for town and suburban parks and

gardens, as well as for general landscape planting. It is not so stiff in outline as the Lombardy Poplar, being more light and airy in habit, with a strictly fastigiate growth. I believe it is of continental origin, and, as yet, only sparsely distributed in this country. The specimens I have of it were imported from France some few years back; they are now about 12 feet high, and I must say that I am much impressed with their distinct and characteristic appearance.—B. G.

DWARF TREES IN JAPAN.

By examining closely the specimens in Japanese gardens one may see traces of the dwarfing process. The leading shoots have been clipped or bent downward; the lateral branches turned in and tied back; lusty limbs twisted and wrenched into quaint postures; marks of the torturing pins, and bands, and cuts are still observable; it is a crippled dwarf of a tree made quaint and picturesque by years of struggle. Among Conifers may be noted young plants of that Japanese species seen under the wings of Japanese buildings—quaint pigmies not 3 feet high, yet over seventy years old. They are gnarled and twisted as if they had fought the winds and caught their picturesqueness of form—as old Oaks catch theirs—by battling with tempests and wintry storms upon the hills. And yet is there a compensating beauty in them? Not surely as we reckon the beauty of plant growth. But consider that the Japanese, in their horticultural system, have offices for such dwarf trees. With them no homestead is complete without its garden; a few square rods may be all at command, but this area must have its garden treatment, and the gardens are modelled after Nature. "San-sui" (mountain and water) is the term which in the Japanese describes the cultivator's work. The aim is—within, however, a limited area—to present a complete landscape, with rock, valley, plain, water, and mountain. Under such miniature presentment, trees and plants must be dwarfed to bear proper relations to the dwarfed valleys and rocks. To such an extent is this copying of Nature in miniature carried, that a rocky landscape, with its heights and level spaces and trees, is wrought out, with close attention to proportions, within the limits of a great bronze basin. We doubt if cultivators of the West will emulate them in their mimicry of Nature; but they may well emulate the painstaking skill which makes such small successes possible, and the assiduous care and the close study of plant life which are enforced by such arts.

W.

The Douglas Fir.—For growing for ornament as well as profit no Fir surpasses Abies Douglasi, the growth of which in free, loose soils is as rapid as that of the Larch, and the tree, containing as it does so much resinous matter, would, no doubt, form sleepers for railways and telegraph posts quite as, or even more, durable than those obtained from the latter. The wood of the Douglas Fir when cut down is remarkably heavy, and were it only better known and more plentiful, it would not be long before planters would turn their attention to it and grow it extensively.—D.

Skimmia japonica.—This is the best known and most commonly cultivated of the Skimmias. It may now be seen quite laden with bright red berries, while other kinds are fruiting but sparsely. Its foliage is not, however, always in as good a condition as might be desired, for, though naturally deep green, it often assumes a yellowish tinge, and the whole plant bears an unhappy appearance. This I am convinced is owing to the plants disliking exposure to full sunshine—an opinion confirmed by specimens with which I met the other day; all of them were heavily laden with fruit, but while the plants that were in full sunshine had a yellowish tinge, others, so situated that they were completely shaded without being overhung by trees or choked up in any way, were in robust health. The Skimmia, too, delights in a soil that does not, even during summer, become too dry. S. japonica transplants readily—indeed, it may be lifted when full of berries; and if this operation be carefully performed, and the plants potted at once, they will sustain no check, and retain their berries as well as if left undisturbed. Thus Skimmias may often be utilised for decorative purposes indoors during winter, as, being hardy, the plants may be used in cold, draughty places where more tender subjects would be injured. Skimmia seeds germinate readily, and in this manner large quantities of plants can be raised without difficulty. S. oblata is altogether a more vigorous shrub than S. japonica. It forms a neat, sturdy evergreen bush, very densely furnished with dark green leaves. Its flowers are pretty, but it fruits sparingly. Its berries are, however, brighter than those of S. japonica.—H. P.

Books.

IRISH DAFFODILS.

"Whatever may be introduced, especially in the way of novelty, is and ought to be subjected to the closest, keenest, and most unflinching examination; then, after passing the trying ordeal, we may expect it to be good because of the removal of everything pertaining to it of a doubtful nature." We recommend these words to the attention of advertisers of new plants, and especially new varieties of Narcissus. They may be found in an essay on "opposition" at the end of Mr. Hartland's "Little Booke of Daffodils" for this season, a work which discourses not only of Daffodils in particular, but of most things in general. Mr. Hartland will, therefore, undoubtedly be pleased if we take his own maxim as a kind of text for a short commentary on his "Little Booke," even though little of it should survive after the "removal of everything pertaining to it of a doubtful nature." We should not thus examine an ordinary trade catalogue, but this pretends to be a scientific treatise, and is a good example of the kind of crude production which hinders the work of the Narcissus committee and other really careful workers at this extraordinarily interesting family of plants. We are sorry to criticise Mr. Hartland unfavourably, for he is an enthusiast about Daffodils, and so far we have much sympathy with him; nevertheless, we wish he would content himself with a simple catalogue until he has digested his knowledge more completely. His "Little Booke," like the memorable plum-pudding and other things, has two sides—an outside and an inside. As to the former, we cannot imagine what we have done to Mr. Hartland that he should punish us with such an atrocity as the illustrated cover of his book. In one of the upper corners, a damsel, entangled in a growth of impossible Daffodils, is apparently defending herself with the poker against the attacks of a flight of noxious insects; while on the opposite side a gouty caterpillar—or is it meant for a cornucopia?—is pouring a shower of objects like jointed dolls and Cabbages down upon ancient John Parkinson and a short-sighted gentleman, whose botanical studies are much impeded by a swarm of bees hovering round his bald head. Turning to the inside, we are pleased with the toned paper and excellent type; but is not the fashion of old English, long s's, "bookes," and "Daffodyls" becoming a little sickly to the taste?

The wildest remarks about the botany of Daffodils begin in earnest with the first pages. The native Lent Lily, we are informed, is "not much found in Ireland. If found—strange! it would be in pure yellow." Is Mr. Hartland sure it would not be in pure blue? As a matter of fact, it is found in Ireland and is not pure yellow. We do not object to the canine Latin of "Bulbocodium citrinus grandiflorus"—it is good enough for a catalogue—but we do to the addition of grandiflorus. Is Mr. Hartland's variety larger than that already in commerce? And why is the long-known white Hoop-petticoat described as a beautiful new white form? How can Mr. Hartland know that his seed of princeps is "naturally hybridised" (p. 3) until he has actually raised hybrids from it? The double form of obvallaris, he says, is not worth growing (p. 3). As this has never yet been identified and probably does not exist, everyone is entitled to his own opinion about its value. Of Ard-Righ, the yellow, or Irish King (p. 6), he observes that he sent it out last year as Golden Dragon. He might also have added that he sent out Golden Dragon as spurius coronatus. This was our personal experience of his Irish Kings last year; it is a pity they have so many aliases. We will not presume to follow Mr. Hartland into the largish subject of the arrival of Ard-Righ with the advent of Christianity from the East, lest we should be landed at Jacob's stone and among the lost Ten Tribes, but will proceed to point out that the five varieties of dwarf Ajax of last year's "Little Booke" have reduced themselves this season to three. We invested our hard-earned savings in all five last year, and had the gratification of seeing at least three of them changed into one and the same plant by the unfortunate peculiarity of our soil. We fear lest the same thing should happen with some of Mr. Hartland's new white varieties now offered; he will increase his reputation, we think, by keeping and watching his plants rather longer before distributing them. Why should Horsfieldi (p. 9) be called so loudly the King of Daffodils? It is a noble flower, but Empress is undoubtedly finer in all points; let him who doubts this go to Whitton next April and see Empress grown as Mr. Walker grows it. Mr. Hartland is "certain" (p. 12) that princeps is a cross between a yellow pseudo-Narcissus and a white or moschatus variety. We are equally certain that it is not, for the home of princeps is in N. Italy, where the wild moschatus has not been found, and at elevations where it probably could not be found.

Our chief quarrel with Mr. Hartland is that he is doing his best, like some others, to make the lamentable confusion of Narcissus nomenclature worse confounded. Thus, he first fits the new and unauthorised name of tortuosus tenuifolius to the plant hitherto known and long sold by Mr. Barr as tortuosus, and then assumes it to be identical with that named Leda by the Narcissus committee. In this he is quite mistaken, for Leda is the same as his Bishop Mann, and distinct from typical tortuosus. We notice that Mr. Barr, too, makes the same mistake; both he and Mr. Hartland have been misled by the similarity to tortuosus of the cut flowers of Leda which were brought to Kensington. They are unacquainted with the entire plant of Leda, which is early, tall, and large-bulbed. We have grown it in our garden side by side with tortuosus. We see that the little white Minnie Warren has changed its scent this season from that of Violets to that of Cowslips. In our garden it smells very little of either. On p. 15 we are again reminded of the wonderful and protean properties of Ard-Righ, for Sir Watkin, we are told, "probably" reminds one in outline of Ard-Righ! Talking of outlines, will Mr. Hartland tell us what qualities constitute a "remarkably æsthetic outline"? (p. 14). We have made ourselves tolerably sure, in a negative way, as to what outlines are not æsthetic by studying the cover of the "Little Booke," but we have not yet attained to any positive knowledge about such mysteries. On p. 25, Mr. Hartland gets into a terrible muddle about the great "doubling" (not Dublin) controversy. He devotes a laborious paragraph to refuting the theory that "the true English pseudo in its double form becomes (in cultivation) what we call Telamonius plenus." No one has ever said it does, and he entirely misses the point of the discussion. It is a pity, too, that he should struggle to assign each double Ajax to its own single form (pp. 25—28). This attempt has long ago been demonstrated to be hopeless and useless. Of double forms in particular we will instance Rip Van Winkle, despite the praise of Mr. Hartland and his friends, as a Daffodil which should be promptly discarded as an ugly and unworthy little monster—a veritable Daniel Quilp among Daffodils. There are good Daffodils enough in cultivation to enable us to dispense with such abortions; we hope Mr. Hartland will go on collecting the beautiful sorts, and especially the lovely white varieties in which Ireland is so rich. But we hope, also, that before

publishing another "Little Booke" he will get it revised by competent authorities upon such matters as languages, living and dead, æsthetics, and Daffodils. G. H. E.

FERNS.

HARDY FOREIGN FERNS.

Those about to plant a new fernery in the open air, or those who are desirous of producing greater diversity of form in one already established, will find that an admixture of some of the most distinct of hardy Ferns from foreign countries with our native species and varieties will produce both a striking and pleasing effect. The majority of Ferns from North America are quite hardy in this country; so, also, are many of those introduced from China, Japan, Chili, and some of the kinds from New Zealand and Australia; therefore, ample material exists with which to add to the charms of outdoor ferneries. It often occurs in the arrangement of a new garden that everything in the way of accommodation for plants under glass, and also out of doors, is settled before a fernery is even thought of, and, therefore, it is often relegated to any unoccupied corner that can be found for it without the slightest consideration as to its adaptability for plant growth. It must be recognised as a fact in the formation of a fernery that Ferns are lovers of both shade and moisture, but they must be free from drip from overhanging trees. The majority of North American hardy Ferns are fond of moisture; therefore, in planting, this should be, if possible, secured. In all other respects the species and varieties hereafter quoted will be found to readily conform to the ordinary treatment usually given to the more common native kinds.

Cystopteris.—This is a genus of small-growing, deciduous, and elegant Ferns, amongst which our indigenous kinds are amongst the most interesting. It comprises, however, some bold-growing foreign forms, which are perfectly hardy in our climate. Being deciduous, they should be planted in positions in which no water rests about their crowns in winter. They thrive best in stiff, well-drained soil, and enjoy an abundant supply of moisture.

C. bulbifera.—The fronds of this species are slightly arched, and are, when well developed, about 18 inches long; they are divided into numerous finely cut segments of a pleasing shade of pale green. This species bears numerous small bulbils on the under side of the rachis, which germinate freely and soon form a considerable sized mass. It comes from North America.

C. tenuis.—This is another North American plant, known also by the name of C. atomaria. It forms dense tufts and produces erect, finely divided fronds upwards of a foot high, lanceolate in outline and deep green in colour, but it does not produce bulbils on the undersides of the fronds. Other handsome, but somewhat rare, kinds are C. Douglasi, C. fumarioides, and C. tasmanica.

Ceterach aureum.—This resembles our native plant, but is larger; those who have seen our native scaly Ceterach covering stone walls, as it does in many parts of Ireland, may imagine what the appearance of this gigantic form would be under similar circumstances. The fronds are a foot or more long, deeply sinuate, with broad, obtuse lobes. The upper side being deep heavy green, but below, densely clothed with large, brown chaffy scales. It is a limestone-loving plant, and should occupy a sheltered, but not too shady a nook. It comes from the high mountain of Teneriffe.

Antigramma rhizophylla, popularly known as the Walking Leaf Fern, is a small-growing, decumbent plant, with simple dark green fronds from 6 inches to 9 inches long, and lobed at the base; the points are much attenuated, and bear young plants at the apex; these take root and speedily form young fronds, which again extend some 6 inches or 9 inches; hence its vernacular name. It delights in shade and moisture, and thrives best when planted in good leaf mould. It comes from North America.

Botrychium.—This is a widely distributed genus belonging to the section known as flowering Ferns. Its species should be planted in well-drained sandy loam, and the situation should be such as to afford them plenty of moisture after the fronds have fallen in autumn, and they should not be subjected to frequent removal, as this is inimical to their well being.

B. virginicum.—This is the Rattlesnake Fern of the Canadians. It produces large decompound infertile fronds of a deep green colour. The fertile or flowering frond, as it is commonly called, attains a height of from 9 inches to 12 inches, and springs from the base of the barren segments. This is wholly contracted, somewhat paniculate, and bears reddish brown sori. It is widely distributed in North America and elsewhere.

B. lunarioides is somewhat similar in general outline to the species just named, yet it is abundantly distinct. Its sterile fronds are much broader and of a deeper green than those of virginicum.

Lygodium palmatum.—This species is an outlying member of a family widely distributed throughout the Tropics. It has the twofold advantage of being the most distinct of the genus (although not the handsomest) and in being hardy. It is, nevertheless, an interesting and elegant Fern, which bears slender climbing fronds from 1 foot to 2 feet long. The infertile pinnæ are palmately lobed and bright green; the upper portion of the frond is similar in shape, but the segments are much contracted and wholly sporangiferous. This plant should be placed in a well-drained secluded position. Like the last-named species, it comes from North America.

Onychium japonicum.—This is a robust growing plant, which produces from a creeping stem fronds from 12 inches to 18 inches in height, divided into numberless finely cut segments. The latter are bright, shining, green in colour, a circumstance which has led to its sometimes being called O. lucidum. When fertile, the sori form a continuous line near the margin of the pinnæ. It is a distinct and handsome plant in an open-air fernery. It comes from Japan.

The North American Climbing Fern (Lygodium palmatum).

Anchistea virginica.—An erect, bold-growing deciduous species, producing from underground stems large fronds, which are twice divided, the pinnæ being deeply sinuate. They are from 18 inches to 30 inches high, 12 inches wide, and bright green, the under sides being ornamented with dense lines of sori,

arranged on each side of the midrib. It comes from North America.

Onoclea sensibilis.—In this we have one of the most distinct of hardy Ferns. It is sometimes placed in the genus Struthiopteris, but it is so thoroughly distinct, especially in a garden point of view, that we prefer the name here quoted. It produces fronds of two kinds, which are totally unlike each other. The barren fronds are erect, some 2 feet or 3 feet high, deeply pinnatifid, the lobes being broad and obtuse and bright green. The fertile fronds are erect, bearing sori in bacciform segments, totally different from any other known Fern. These are only produced upon well-established plants, and are persistent during winter. It comes from North America.

Osmunda.—The general appearance of this family of what are called flowering Ferns, is well represented by our native species, O. regalis, popularly known as the Royal Fern, the most majestic in the genus. Osmundas are thorough bog plants, and in order to have them in vigorous health in the fernery, they must be so treated.

O. Claytoniana.—This very handsome Fern attains a height of from 2 feet to 3 feet. The fronds, which are erect, are twice-divided, segments obtuse and rich deep green. When fertile, some three or four pairs of the pinnæ, in the centre of the fronds, are shortened, contracted, and wholly sporangiferous, a circumstance which has led to its being called O. interrupta, a name under which it is sometimes cultivated. It is, without doubt, one of the very finest of decorative Ferns. It comes from North America.

O. cinnamomea.—A plant of noble port, its style of beauty being quite different from that of O. Claytoniana, inasmuch as it produces two entirely distinct forms of fronds. The infertile fronds rise to a height of from 2 feet to 3 feet or more, and are some 9 inches broad. They are erect and spread outwards in a vase-like manner. The segments are obtuse and deep green. The fertile fronds, which are numerous, are contracted, and profusely laden with sori, which are cinnamon-brown. These fronds rise up like plumes in the centre of the others, giving the plant a very attractive appearance. It is widely distributed throughout North America, the West Indies, China, and Japan.

Struthiopteris (the Ostrich-feather Fern).—A genus of highly decorative deciduous plants, which, from their habit of producing underground stolons, soon form fine clumps. The fronds are of two kinds, the fertile ones always being surrounded by others which are barren.

S. germanica.—This is a European species, which grows to a foot or more in height, the infertile fronds arching and of a soft light green colour. The fertile fronds, which are about the same height as the barren ones, have all their segments contracted. It comes from the south of Europe.

S. pennsylvanica.—This is considered to be only a variety or form of the European plant; nevertheless, under cultivation it is abundantly distinct. The fronds attain a height of from 18 inches to 2 feet, and are about 6 inches in breadth. They are more erect than those of the previously described plant, and of a pleasing shade of green. It comes from North America.

S. orientalis.—This very distinct plant has large, broad, somewhat ovate fronds, the segments of which are deeply divided and dark green. The fertile fronds when mature are deep chestnut coloured. It comes from Northern India and elsewhere.

Lomaria striata.—A fine, bold, erect plant, and one which produces fronds of two kinds. The infertile ones, which are arched, measure when vigorous from 3 feet to 6 feet in length and nearly a foot in breadth. The pinnæ are thick and leathery in texture and deep, heavy green. The fertile fronds are similar, but much contracted and deep chestnut-brown when mature. The stems and crown of the plant are densely clothed with large ferruginous chaffy scales. This is one of the most distinct and striking of hardy Ferns yet introduced. It comes from Chili.

Adiantum pedatum.—The stems of this beautiful species are black, smooth, and polished, the rhizome creeping, and the fronds deciduous. The latter attain a height of from 1 foot to 2 feet. They are broad and spreading and pedately divided, the pinnules or segments being of a pleasing shade of light green. It comes from North America and Japan.

Lorinseria areolata.—This fine plant is often named Woodwardia, but its contracted, fertile fronds and habit of growth sufficiently separate it from that genus. The barren fronds, which are erect, are deeply sinuose or sub-pinnate, some 12 in. to 18 in. high and 6 inches broad, and pale green in colour. The fertile fronds are very much contracted. It is a conspicuous and handsome North American plant.

Pellæa atropurpurea.—This is not a bold or conspicuous plant, but very distinct and effective when planted in a crevice of rockwork, about on a level with the line of vision. The fronds, which are evergreen, vary from 6 inches to 12 inches in length; they are simply pinnate, the segments somewhat oblong in outline, leathery in texture, deep heavy green on the upper side, but paler below. They are borne on deep purplish stems. It comes from North America.

P. gracilis.—An elegant evergreen plant, delighting in limestone. Its fronds, which usually attain a length of 9 inches, are pendulous, the segments being twice divided and deep green in colour. It is a native of North America.

Lastrea Sieboldi.—This is a plant of robust habit and distinct appearance. The crown and base of the fronds are furnished with large brown chaffy scales. The fronds are somewhat drooping and pinnate, the terminal pinnæ being about the same size and shape as the lateral ones. The fronds, which bear about four pairs of thick leathery pinnæ, are from 6 inches to 12 inches long, nearly 2 inches broad, and pale green in colour. The sori, which are on the undersides of the fronds, are large and conspicuous. It comes from Japan. Other species of Lastrea, too handsome to be overlooked, are L. Goldiana, marginata, sparsa, atrata, erythrosora, and varia.

Polystichum acrostichoides.—An erect-growing plant with pinnate fronds, the upper portion of which is, when fertile, somewhat contracted. The pinnæ are auricled and deep green. It may be considered as a somewhat gigantic Holly Fern. It comes from North America.

Cyrtomium.—This is a small genus consisting of distinct species, which are very effective when contrasted with kinds having finely divided fronds. It contains two species admirably adapted for the purpose which we have in view. One, C. caryotidium, produces arching fronds a foot or more long, the segments of which are large, auriculate, and light green; the crown of the plant and base of the fronds are furnished with brown chaffy scales. It comes from Northern India. C. falcatum, the other species, is similar in general appearance to the preceding, but more erect in habit; the pinnæ are thick and leathery, and deep shining green in colour. The crown of the plant and base of the frond are densely clothed with large ferruginous chaffy scales. It comes from Japan. W. H. G.

NEW AND RARE FERNS.

Gymnogramma Muelleri.—This plant is widely distinct from the common type of Gymnogrammas, popularly known in gardens as Gold and Silver Ferns, but the genus is very variable, and G. Muelleri is one of its most remarkable kinds. It forms a tuft of erect fronds 1 foot long, with the stalks covered with brown scales, and the upper part bearing two rows of roundish pinnæ, 1 inch long, arranged alternately, their texture thick, almost leathery, the underside thickly covered with silvery scales, and the upper surface, which is bright green, having a few of these silvery scales scattered over it. As a stove Fern this species should find favour because of its distinct and pretty foliage. It is a native of Australia, and seems to prefer a moist stove. There are several handsome examples of it in the Kew collection. G. vestita, a closely allied species with larger fronds, but requiring cool-house treatment, being a native of the highest elevations of the Himalaya; and G. rufa, a pretty kind from the West Indies, are also in cultivation at Kew. A collection of Gymnogrammas would be a very interesting and highly ornamental group of Ferns, which any amateur Fern-grower would find worth his attention.

Davallia fumarioides.—There are several species of Davallia with fronds 3 feet and 4 feet in length, or even more, and a climbing habit, the fronds growing up trees or over shrubs by means of the sharp prickly spines which clothe their stalks and stems. D. aculeata, which is common in the West Indies, where its fronds reach a length of 6 feet, has been in cultivation in England several years, but it does not attain with us the dimensions of specimens in a wild state. Lately plants of D. fumarioides have been introduced into Kew from Jamaica, and they are so exceedingly pretty, even in a small state, that we wonder the species has not long since become popular with Fern growers. It has a creeping rhizome, fronds as long as in D. aculeata, tripinnatifid, the lower divisions 12 inches to 18 inches long; whilst the pinnules are divided up into small segments, as in the foliage of the common Fumitory—hence the specific name. For baskets this Fern seems fitted to become of great value as an ornamental plant. It is also very interesting on account of its climbing habit and the spiny character of its fronds, the latter being a rare character among Ferns.

Cheilanthes radiata belongs to the group Adiantopsis, and is remarkably like Adiantum pedatum, except that it is smaller. It is a stoutish kind with erect fronds, the stalks of which are black-brown, polished, and a foot long, whilst the blade is formed of from six to nine radiating divisions, each 8 inches to a foot long and bearing two flat rows of small three-sided bright green pinnules. It is a native of Tropical America and the West Indies, and prefers a stove temperature. C. pedata, a Jamaica species, is very similar to the above, and both are pretty stove Ferns, deserving a place in all Fern collections. They are of no value for cutting purposes, fading very soon even when placed in water; but as pot plants they have a pretty effect. We saw it at Kew a few days ago.

BEWARE OF WEEDS.

"One year's seeding makes seven years' weeding." Seventy might almost be substituted for seven without much exaggeration. And yet, with what a light heart various cultivators of field and garden go to work seeding the land with weeds. The first practical results of agricultural depression on field and garden have been the sowing of more weeds. Money is scarce; knock off a weeder; draw labourers by twos, threes, half dozens from the garden for the harvest, and let the weeds run riot and to seed in all directions. It is only for a few weeks—a month, five weeks at the longest—and then we shall make raids upon the weeds and out with them. No, no; this is simply impossible; a crop of weeds is by far the most impoverishing and embarrassing legacy of these bad times. It is also the most expensive luxury that can be indulged in; too expensive, in fact, for any but the most wealthy to experiment with. Hence a crop of weeds must needs hasten the ruin and intensify the distress of all cultivators struggling with the difficulties of hard times and low prices. Weeds lower prices still further by lessening produce, not only for the current year, but many, one might almost add with but little exaggeration, all future years. And then, weeds add to the cost of production, the second great outlay of cultivators. If one year's seeding means seven years' weeding, who will tot up the money-cost involved in getting rid of the weeds? The more we hoe up or pull out, the more and the faster they grow, until every clod has its weekly colony of weeds; and they must be destroyed before any produce of value can be realised. Left to themselves, the weeds would simply possess the earth, the survival of the fittest meaning in this connection the strongest and most worthless. And yet with all this as obvious as that twice two are four to practical cultivators, rank weeds and Thistledown are possessing the land and smothering the plants and flowers out of not a few gardens this harvest-tide. Weeds, weeds, more weeds! are the practical response not a few cultivators are

making to threatening distress and impending ruin. In a drive of 20 miles I have lately seen more Nettle-seed and Thistle-down than would suffice to stock the whole of East Anglia for seven or seventy years. The impoverishment of the soil is another evil rapidly accomplished by weeds. All of us have heard of a man so keen at a bargain that, failing any other customer, he used to deal with himself, and impoverish one pocket to enrich another. But the weed grower does his best to empty all his pockets at once. There is his best bank, the earth carefully filled by Nature and art with productive force in the form of plant food. He lets the hungry weeds empty that rich safe while he rubs his hands in glee that he has saved a few farthings in the wage of the weeders that would have kept them out. The cultivator has another bank to guard in the earth below and the air above; the roots need room, the stems, leaves, and flowers light and air to do their work of growth and to finish their produce. The weeds cramp the roots into weakness, and crowd out light and air from the tops to the reduction of the yield, or the impoverishment of the sample below marketable value. Never will agricultural or general prosperity be restored by such suicidal tactics. If farms or gardens are too large for the capital or labour available for them, let them be reduced in area. For if cleanliness will not pay, foulness cannot, and those who have least to spend are the very last to be able to afford to grow weeds either in field or garden, to say nothing of the luxury now, alas! by no means uncommon, of growing weeds *ad libitum* in both. D. T. F.

Garden Destroyers.

MILDEW ON ROSES.

This has assuredly reached its zenith this season. It began early and continued late; in fact, still—September 28—abounds. It has refused to be sulphured or showered off, and hence it is still plentiful with us. Begotten of red rust, which has also been most virulent, or running abreast of it, the mildew has in many cases stripped the Roses bare of leaves and arrested the development or lowered the quality of their blooms. The fact that it has not yet been showered off or yielded to the solvent or cleansing powers of the rains is strong proof alike of its persistency and potency. For, as a rule, mildews that abound on Roses in the early summer dissolve or disappear at the touch of autumnal rains. They are either washed off or grown out of the Roses, as the longer, cooler nights of autumn cool the feverish heat of Rose growth and moderate the express speed with which that ill-matched pair, hurry and weakness, endeavour to develop flowers. But this season it seems as if mildew were to abide with us to the very end of the growing season. Assuredly at this late period were it now to leave our Roses there is no time left for them to recoup themselves. Leafless, and not a few of them shootless, one trembles to think of their speedily encountering the winter, all unprepared for battling successfully against its sudden changes and probably severe cold. Sulphur in all its forms has proved powerless to arrest, kill, or brush off the mildew this season. The most telling check to the ravages of the mildew consisted of quicklime applied in heavy doses when the leaves were wet with rain, dew, or overhead syringing; and in these cases the check seemed to arise from the quantity applied rather than from the chemical or other effects of the lime. The Roses looked like dusty millers after their lime dressings, the mildew being overborne, and perhaps mechanically subdued, by the sheer mass of the heavy lime dressing. The mildew plague of this season has been no respecter of persons—that is, classes of Roses. As a rule, it is so to a very large extent. The more rough and hirsute the leaves and stems, the more do Roses suffer from mildew. But this season the smooth Teas, and even such robust and anti-mildew Roses as Gloire de Dijon, have been as white with mildew as the most miffy Perpetuals. Still, amid the impartial and almost universal reign of mildew over the Rose, one variety has stood forth as almost wholly proof against it. That variety is the smooth-leaved, robust-growing, profuse-blooming Homère. Next to this variety, the one that has suffered least from mildew is the fine old Bourbon Souvenir de la Malmaison, also a very robust growing smooth-leaved Rose. But this, the Gloire de Dijon and its near allies, are almost as smooth-leaved as either of these, though not quite so shiny. Further, the Glory types mostly escape, and this year it is coated over thickly with mildew alike on warm walls and in beds and borders. All forms and ages of the Glory seem also to have suffered with almost equal severity. As to remedies, can the fungologists instruct or guide us to these? Can the germs of mildew survive the winter on bark or bough, or in or on the earth? The reply to this question may lead to various means of warring against mildew in the dead season, such as early pruning, the speedy and severe reduction of the tops of Roses by the reduction of all weakly and worthless shoots, the baring of the collar of the plants down to the roots, and the smearing of every portion of the Rose left with a mixture of half and half of quicklime and sulphur. This might destroy the germs of mildew and red rust, as well as assuredly cleanse the Roses of Moss, Lichen, maggots, aphides, or other vegetable parasites or insect pests. Then, lest mildew germs should survive in the soil, the surface of this should be removed bodily clear away from the Roses, and the latter top-dressed with maiden loam or good manures. Should this not be practicable, the old soil could be burned and returned to the Roses, as, so far as is known, fire destroys the germs of all fungoid pests, and burnt earth is found to be one of the very best dressings for Roses. Further, as the mildew has rendered Rose plants abnormally tender as well as weak, it will be wise to protect them more heavily as well as earlier than usual. Teas and Noisettes denuded of their foliage and deprived of the stamina incident to healthy growth will need skilful and liberal top protection, as well as stem and branch clearing and root culture and feeding, to bring them up to their normal vigour in floriferousness next season. D. T. F.

Wasps.—"D. T. F." would make his communication about wasps more interesting by stating the locality from which he writes. Here we have no wasps. In spring and early summer queens abounded. It was a common occurrence to catch twenty or thirty a day; now not a wasp is to be seen, nor has a single nest been found. It is curious, however, that, though unlike "D. T. F." we have no wasps, we have any amount of blue-bottle flies, and the same, I hear, is the case in Devonshire. House flies are not at all plentiful. A hard dry winter is most favourable for the queen wasps. If warm weather comes in March and wakens them up, they come out before there is any proper food for them, and they are starved. This is my impression, and the late Mr. Darwin agreed with me. This year the long and severe winter kept them in winter quarters till late, and so they abounded; but a very cold and wet May followed and they perished by starvation.—A. R., *Windermere.*

—— Here in the spring we killed over 100 queens. I never remember seeing so many, and when moving some heaps of rubbish in the latter part of June we found a nest just forming containing about twenty cells and some of the larvæ just forming, while some were only just visible, but since that time I do not remember having seen one solitary wasp. Last year we had them in thousands; I destroyed six nests within a radius of 100 yards of our vineries. Blue-bottles have been very troublesome, but the east winds of the last few days seem to have driven them away. —Alfred Gardner, *Broadwater Hall, Worthing.*

Tar paint.—I would strongly advise "M." to use the black varnish advertised in the gardening papers, and thereby avoid the trouble of making up any mixture of tar and paraffin. Common tar is, I find, going out of fashion, as the black varnish is quite as durable and can be used exactly in the same way as paint. It does not require boiling, but is laid on as taken from the cask. In cold weather it may be necessary to warm it a little to make it work more freely, though even this precaution is not, I am told, indispensable. For the future I shall use no more tar.—J. C. B.

Schubertia grandiflora.—This is a beautiful white-flowered stove climber, which appears to have been introduced about forty years ago, figured in the magazines, and a good deal written about at the time, and then allowed to drop out of cultivation; at all events, we never saw or heard of living plants of it till a correspondent sent us, a few days ago, a flower and leaf of "a climber which had grown 20 feet or more in length, and had on the last 10 feet clusters of white flowers, about six in a cluster, looking before opening like a bunch of Filberts." This plant proves to be the Schubertia above referred to, but whilst apparently the same species as that introduced in 1811, the flower sent to us for identification is at least twice as large as any in the figures of the earlier plant. One of these figures will be found in the *Botanical Magazine*, t. 3891, under the name of Physianthus auricomus (golden-haired), and another in the *Botanical Register*, xxxii., t. 21, where it is called S. graveolens. For garden purposes our correspondent's plant might well be kept out of the company of the form figured in these two works, which is vastly inferior to the flower before us now. And yet it is stated of this smaller variety that "it was not inferior to Stephanotis as a flowering plant, whilst the flowers are larger and at least as fragrant." The Royal Horticultural Society awarded this smaller-flowered form a Banksian medal in 1845. We do not think the Schubertia is quite equal to Stephanotis in respect to fragrance or purity of whiteness, but it is nevertheless a beautiful plant, and apparently easily grown and flowered. Here is a short description of S. grandiflora: Stem woody, twining, covered with yellow hairs; leaves obovate, pointed, undulate, 5 inches long, 2½ inches broad, light green, softly pubescent; flowers on axillary peduncles, about six in a cluster on each peduncle; calyx of five brownish green sepals three-quarters of an inch long; corolla 2 inches long, 2½ inches across, and in shape and substance like that of Stephanotis; in colour it is a soft creamy white, becoming primrose-yellow with age; fragrance very powerful and heavy, not unlike the scent of Gardenia flowers. We learn that the blooms of the Schubertia last a long time in perfection. The genus belongs to the Asclepiad Order, and is sister to Physianthus. Our correspondent obtained his plant from seeds imported from the Argentine Republic.—W.

Names of plants.—*J. T.*—Adiantum Capillus-veneris, apparently the Algerian form.——*J. Morgan.*—1, Rondeletia speciosa ignea; 2, Posoqueria longiflora; 3, Asclepias curassavica; 4, Diplacus glutinosus; 5, Lælia Dayana; 6, Pleione lagenaria.——*E. H. K.*—Alstrœmeria aurantiaca var.——*A. C. Bartholomew.*—Schubertia grandiflora.——*R.*—Sedum purpurascens.——*J. G. Cattley.*—Next week.——*H. Archer-Hind.*—Aster (Biotia) corymbosus, Ait. (=Aster cordifolius, Michx.), but not the plant recognised by Asa Gray as A. cordifolius; an old Linnean name; a plant nearly allied to Shorti, Drummondi, and sagittifolius.——*W. E.*—Aster dumosus.——*B. B.*—Cephalanthera rubra.——*Tahiti.*—Crocus tessellatus; Pear is Williams' Bon Chrétien.——*Miss C. Mangles.*—Zephyranthes candida.——*Tenby.*—1, Solanum sp.; send better specimen, with information as to the country whence it was obtained; 2, Rudbeckia amplexicaulis.——*Jessamine.*—Narthecium ossifragum (Bog Asphodel).——*X. Y. Z.*—1, Aster Novæ-angliæ roseus; 2, A. longifolius formosus; 3, Galatella dracunculoides; 4, A. horizontalis; 5, Polygonum Brunonis.——*D. D.*—Yellow flower, Deudrobium chrysanthum, Sarcanthus sp.; name next week.——*R. W.*—Angræcum pellucidum.

Names of fruits.—*S. K. T.*—Plum, Peach; Apple, Downton; Pear—1, Green Achan; 2, not known.——*Anon.*—4, Williams' Bon Chrétien; other not known.——*G. Smith.*—1, Emperor Alexander; 2, not recognised; 3, Manks Codlin.——*J. Fotheringham.*—*a*, Winter Strawberry; *b*, Tower of Glamis; *c*, Hawthornden.——*Two Apples, without any letter, numbered 6 and 7.*—6, Brabant Bellefleur; 7, Beauty of Kent.

WOODS & FORESTS.

FORESTRY NOTES.

Future management of our woods.—If the nation will not appoint a school for the education of our woodmen, landlords and owners of woods can still help themselves and improve matters. They can, if they choose, place the care of their woods in better hands. Gardening never was more depressed than at present. Reduction is the order of the day in many establishments, and nowhere more so than in the garden, throwing many good men out of places altogether or reducing their salaries. Why not, therefore, employ such men as foresters? or, what would be better for both parties, as foresters and gardeners combined? Unless in the drudgery of woodcraft and perhaps a trifling inexperience in valuing and disposing of timber—things that can be learned in a very short while—a gardener's education fits him for the duties of woodman as well as gardener. The culture of trees is as much in his way as the culture of fruits, vegetables, or flowers. In fact, he has practically in times past performed some of the most important duties of the forester, for in almost all establishments it is he who propagates and nurses all new subjects intended for the woods, and in many other ways assists by his advice and work in planting and management. There are good foresters, of course, who have been bred to the business and who are a credit to it, but they are the exception, for the general run of woodmen—masters, foremen, and men—are far behind the gardener in practical and theoretical knowledge. The best proof of this exists in the fact that forestry as a craft is practically destitute of a periodical literature of its own, and has few books comparatively, while gardening is abundantly supplied with both. Woodmen do not read, have no records, and I believe I am within the mark in stating that it has been found all but impossible to sustain a paper devoted to forestry alone, so little encouragement has any venture of the kind received either in England or Scotland. But let the two be combined, or place our woods under the care of trained horticulturists, and you at once lift forestry into a higher level, and give it a chance it never has had before. The burden of the evidence given before Sir John Lubbock's committee all went to prove that our British woods were mismanaged, and that the cause was the ignorance of agents and their subordinates employed to look after them. Here, then, is a class of men (gardeners) qualified for the task; why not employ them? It is not a new idea. There are not a few gardeners employed as woodmen, and, so far as I am aware, the plan has been always found perfectly successful.

Norway poles, how grown.—I examined and measured some of a pile of these the other day. They were about 30 feet long, and in that length the quarter girth top and bottom varied from about 1¼ inches and 2 inches, that is to say, the poles did not taper more than that from end to end. The cause of this, it was plain to see, had been the crowded condition of the forests in which the poles grew, thereby preventing the trees from carrying more than just a top of branches—perhaps extending to a quarter of the tree's length. They could not be produced any other way. Where Spruce trees are thin on the ground they carry all their branches down to the ground, and are consequently much more tapering and crowded with knots that are deep seated, rendering the timber partly useless for many purposes. In the Norway poles the lower branches had long ago disappeared. The fault of mostly all the Firs in English and Scotch woods is that they are too thin on the ground. On one extensive estate I am acquainted with in Scotland, where the woods were at one time proverbial for their "good management," the Spruce trees were so severely thinned out, that they, in almost every case, carried their branches to the bottom, and so regularly that I have seen the wood-boys amuse themselves by climbing to the tops of the highest trees and sliding down over the branches to the ground. We shall never produce good Larch, Spruce, or any kind of Fir poles in this way. We have excellent examples of the effects of the two modes of culture here. In one plantation on an exposed hillside, where the Larches grow thinly among rather stunted Oaks of the same age, they carry most of their branches, and are consequently thick at the base of their trunks, which, however, taper like a carrot to the top and are full of knots. This Larch the collieries will not use, because it is too thick at one end and too small at the other. Elsewhere Larch of the same age drawn up in consequence of having been crowded and never having more than just a top of branches is exactly of the shape of the Norway poles, not being very thick at the base nor very small at the top, but carrying their girth evenly throughout a length of from 40 feet to 70 feet. Another instructive example of their culture grows at the margin of the park in the shape of a Larch some eighty years of age still carrying its bottom branches 20 feet long or more—very thick limbs indeed. The tree is a very rough specimen and big, but as it is a good plank could not be sawn out of it, because of the numerous deep-rooted knots caused by the branches. Like the others mentioned, it tapers greatly also. A contrast to this tree are the other members of the same group growing inside the wood and which have never carried anything but top branches. Some of these are bare now up to nearly a height of 40 feet, and are clean, straight, of uniform girth, with no sign of knots, the lower branches having long ago fallen off and their places grown over.

Comparative bulk of trees.—Of some examples of standing timber reckoned the other day, I find the Spanish Chestnut tops the list, one here, about eighty or ninety years of age, having about 170 feet of timber in its three limbs and larger branches. Beech of the same age or perhaps a little older contains about the same, the branches having plenty of room, the measure being in the trunk chiefly. Larch eighty or ninety years of age have 60 feet or 70 feet in them. Scotch Fir and Spruce have both less than the Larch considerably, though of the same age; and the Oak has the least measure of the deciduous examples mentioned. The Beech is a much faster grower than is generally supposed, and with the increasing market for timber in this country it is one of the trees to plant where it will grow. Good trees fetch a little less price than Oak at present, but much depends upon bulk and quality of the timber. It must not be forgotten, however, that the Beech is much the fastest grower of the two.

Good examples of Corsican Fir.—These, I am told, are to be found at Alnwick Castle, Northumberland, where trees with 60 feet of timber in them have been felled and the quality proved. I wonder if the authorities there could furnish you with any information on the subject. Y.

My Scotch Firs, of from 60 to 100 years old, and generally in a healthy state, are dying from the attacks of an insect. I send you herewith a twig and piece of the bark to show how it works, and would be glad to know if any steps can be taken to stop such serious ravages.—W. H. M., *Dalbeattie*.

*** Your Firs are attacked by the Pine beetle (Hylurgus piniperda), which is, unfortunately, a very common pest. When trees are of the size that yours are it is almost, if not quite, impossible to do anything to kill the insects, but much good may be done by removing all stumps, felled timber, broken branches, &c., in which the females might lay their eggs, and by at once cutting down any trees which are showing signs of want of vigour or which have been partially uprooted by storms. I believe it is seldom, if ever, the case that thoroughly healthy trees are attacked.—G. S. S.

OAK PLANTATIONS.

The difference between Oak plantations and those of Larch or other Firs is, that the Firs are swept away at a single cutting, while the Oak is gradually exploited. The nature and rate of growth of the two classes of wood will at once suggest the reason why this should be. This gradual system of cutting Oak makes the management of the woods or plantations a more intricate business than the mere dealing with a given acreage of Larch or other similar wood, and the greater variation in size and form of the Oak adds to the difficulty. In most Oak woods and plantations, too, there is generally more or less underwood, which is very seldom to be met with in the other class of plantation. There are many ways, however, in which the periodical cuttings may be disposed of, and the particular method chosen which best adapts itself to the surrounding circumstances.

Selling trees and underwood together in the winter is a plan which takes all expense and further trouble off the vendor at once, but it must be for each to judge for himself as to its merits when the whole bearings of the system have been looked at. Whether the sale is effected by auction or private treaty does not greatly alter the preliminary work to be done or the information which is necessary to gain as to the value of the produce. Before, however, the sale of the underwood and trees in a single lot is attempted, it will be well to be satisfied that there are buyers who deal with both branches, as the timber and underwood trades are essentially distinct, although the two are sometimes combined in the person of one individual. In setting out an area for selling in this way as the wood stands, it will obviously be necessary, first of all, to be satisfied as to the acreage, in order to fix the worth of the underwood, and then to select and value the proportion of timber which has to be cut. In practice with standing wood this is in nine cases out of ten an unpleasant and difficult task, and is therefore, as a rule, performed in a perfunctory manner, and generally leads to the buyer getting the best of the bargain, as the dimensions of the trees are not readily seen, and their relative positions with respect to each other is to a great extent guesswork. To obviate this, even if it is deemed best to sell both the underwood and trees standing, the transaction may be divided into two, the underwood being dealt with first and the thinning and sale of the trees as soon as this is cut down. In this way the size, character, and position of each tree may be at once seen, and a difficult operation reduced to one of ease and comparative certainty. In going over trees in this way the matter of marking must lie to a great extent with the operator, but I prefer, if possible, to have the marks upon the trees which have to be felled, and not upon those which are to be left. When the proportion intended to remain is very small in relation to the number to be thrown, it may be a small saving of labour to mark the least in bulk, but as the operator should visit each tree to ascertain its contents and value, the labour cannot amount to much.

The cutting of the underwood by the vendor and arranging it in drifts of uniform width and ascertained lengths, and selling the trees which it is necessary to fell as they stand, is another plan which is sometimes adopted. This is chiefly the case where there are woodmen on the place for whom work must be found in winter. At first sight it may be thought that if the men are employed to cut the underwood, that there can be no advantage in allowing the buyer to take the trees as they grow. On large estates, where sales of wood are not confined to a fixed time annually, this is true; but in places where the sale of the underwood takes place during the winter or early in the spring, and there is little or nothing but the thinnings from the area from which it has been cut to come into market during the ensuing season, it is often a matter of policy to close the whole business at once, by selling the Oaks as they stand, and allowing the merchant to fell and remove them at barking time. But, as it has been said, where the

amount of timber is enough for a subsequent sale and the woodmen have to be found employment, it may be better to do the work of felling and barking and dispose of the trees at per cubic foot. At any rate, from these general rules there should not be much difficulty in working out a plan to answer to individual circumstances and requirements. One thing about it is perfectly clear, and that is, when there is underwood, this must, either by the underwood merchant or the owner, be cut and laid before anything can be done in the matter of tree-felling; and, further, that to do the work carefully and well, even the operation of selecting and marking the trees should be deferred until the underwood is felled, to allow free movement amongst the trees and a clear view of the character and positions of the trees with respect to each other. On the whole, as the businesses are quite distinct, even if both transactions are concluded with the same person, I look upon it as more satisfactory to make the sale of underwood and of timber trees separate and independent bargains.

D. J. Yeo.

EXTINCTION OF ASH TREES.

There is one good point about our American friends in forestry matters, and that is, they never seem loth to cry out about the entire destruction of certain of their species of trees within a given time, although the event seems to recede as we approach it. It may be pardonable, therefore, although I possess a good deal of optimism in relation to forestry matters in general, to again point out that the Ash and the Sycamore as timber trees will soon be things of the past. I know there is nothing at all new in this assertion, and the Sycamore, useful and ornamental though it be, could probably be better spared of the two. I am quite familiar with the reasons given why the Ash is not more planted, and why, where it exists, it is so assiduously felled, but in the face of it all it is a matter of regret that such an indispensable tree should be allowed to become practically extinct. The remedy I take to be that of raising in plantations either by itself or with Oak. If this is done, the objection of the roots impoverishing the soil when grown round fields, and the objection some have to the appearance of the tree, would be quite overcome. Ash plantations and Ash alone are not often met with, but if the tree is to be preserved from practical extinction some such plan of growing must be tried. For aught I know, there is no reason why Sycamore should not be grown in the same way. So much having been said with apparently so little practical result makes the iteration of such views a little discouraging, but the facts speak for themselves, however ignored. Sentimentally, one would deplore the loss of these trees, but, practically, the extinction of the Ash means a greater inconvenience than can be seen on the moment. It is true that a proportion of Ash is brought into this country from abroad, but this is not a sufficient reply to the question, and we have no guarantee, even if the quality of the wood were equally good, that the supply is inexhaustible. The use of the Ash dates, I suppose, from almost pre-historic times, but never probably was the rate of consumption equal to that of the present moment. Little or no planting and rapid consumption when taken together cannot go on for ever. At the lowest calculation half a century must elapse before trees planted now can reach a size large enough for many uses for which they are required, and as events are marching it seems a puzzle how the existing supplies can be made to last so long. The fashion of planting Larch—a very useful wood in its way—suddenly attained a great height, presumably on account of its novelty, and one would like to see something in a smaller way occur with the Ash and Sycamore—the latter, perhaps, to a fourth the extent of the Ash. In matters agricultural the Ash is the chief wood. Mowers, reapers, ploughs, harrows, wagons, and, in fact, almost every implement of the farm contain more or less of English Ash, and it is only when the supply is gone that its real utility will be seen. J.

CIRCULAR AND BAND SAWS.

The circular saw and its appendages above all others is the most essential machine used in connection with British wood. The saw, worked by mere manual force, has done much in the past and is doing good work now, but it can hardly be classed under the head of a machine. To the circular saw, then, must be accorded the premier place, and this no doubt on account of its comparative strength and simplicity. There are other saws, however, which are well suited for cutting up own home-grown woods, and one occupying an honourable place in the list is the band saw. On the other side of the Atlantic this style of saw has been developed in a way which is hardly dreamt of here, and is capable of cutting up very large logs. In a few cases in this country some large machines of the band saw type have been laid down, but it is the smaller forms with which we have more to do. These are now made extremely portable, and require a very small power to drive them. The saw or web, running on two or three wheels according to the construction of the machine, is necessarily very thin and flexible, and not capable of standing the rough usage to which a circular saw is sometimes subjected; but with care and judgment it is a tool which will perform a surprising amount of work thoroughly well and with a very small amount of wear and tear; indeed, we know machines which are used for cutting up home-grown hardwoods to a thickness of 5 inches or 6 inches merely actuated by manual power in the manner of a chaff machine, a handle being fixed to the periphery of one of the wheels or pulleys upon which the saw runs. This is the most rudimentary form in which the power can be applied, and is not to be recommended beyond trifling uses, as it is laborious and not economical. The quality of the work, however, is quite as good as if the machine was driven in any other way. A better plan, and one which may often be available, is to supply the motive power by means of the horse gearing, which is generally attached to a place of any size for chaff cutting and other work of the same class. This power is, of course, equally capable of being applied to the circular saw, but the thinness of the blade of the band saw makes the cutting a much more easy task. A step beyond this is, of course, when steam is to be had, but with this comes the point where the utility of the band and the circular saws approximate, as with a sufficient power the ease and rapidity of using the latter is at its maximum. It is to the smaller resources that the band saw so well adapts itself, and with material of not too large dimensions there is scarcely any limit to what it will do. Even the somewhat rough work of sawing off fire logs is a thing which a horse-power driven band saw would be able to do, providing the wood was not of such a nature as to subject it to sudden jerks and strains. Small Oak logs, if not too dry and knotty, Elm logs, Ash or Beech, could easily enough be reduced to any desired lengths. It may be mentioned, however, that for cutting such pieces longitudinally the power of the band saw is not suitable, or rather its construction, as from the way the table is usually made it would be inconvenient to support very long lengths. For the type of saw to which we are referring, logs of some 6 inches in diameter would be large enough to cut transversely. One great use of the band saw is that of sawing in curved lines, as the narrowness of its blade makes it easy to direct the wood in any required direction, providing, of course, it is not too sudden and acute. With the ordinary narrow frame saw, worked by manual power, the saw is made to follow upon the wood the direction marked out upon it. With the band saw the operation is just the reverse, as the wood, though marked in the same manner, is brought to the saw, *i.e.*, the saw itself is always running in the same position, and the wood is advanced upon it. The same, of course, is true of the circular saw, but with this the wood must be advanced in a direct line, whilst with the band saw the direction may be varied to right or left at pleasure.

Boring for fence posts and similar purposes is work which consumes a lot of time when done by hand, and when a large quantity is required some appliance to expedite the work is almost a necessity. This may be supplied by means of an auger attached to the shaft or spindle of the machine. This perhaps is more frequently done with circular than with band-saw machines, on account of speed, but there is no reason why it should not be applied to the latter for such work as is contemplated in this paper. D. J. Y.

Quality of Scotch Fir timber.—That there are two descriptions of timber in this country is undoubted. One is red in the grain and resinous; the other white, woolly, and not so resinous, with annual rings larger, indicating a quicker growth; the produce of P. montana and sylvestris respectively There is no doubt but that certain soils will alter and modify the character of the timber, but the two varieties grown on the same soil will exhibit these characteristics. But the quality of Scotch Fir timber is not of so much importance, except for home estate use, at the present day, as so much is used for temporary purposes, in which the quality of the timber is of little consequence.—J. S. R.

Gathering Fir cones for stock.—It is now a well-established fact that stunted and decrepit specimens are prone to produce cones more abundantly than vigorous healthy trees. I am not in a position to say whether the nurserymen in Scotland, who raise such enormous numbers of seedling Pines, gather their seeds from such trees or not; but should this be really the case, it would be well for planters and for those nurserymen who purchase quantities of one-year-old seedlings from northern growers to enquire into the matter. That stunted Pine trees bear cones freely cannot be questioned; but that they are more prolific than fine old full-grown trees, no one really acquainted with the Pine would maintain. This is an important question for landed proprietors and those interested in the commercial value of timber trees.—Old Forester.

The Black Birch (Betula nigra).—This is a close-grained, handsome wood, and can be easily stained to resemble Walnut exactly. It is just as easy to work, and is suitable for nearly, if not all, the purposes to which Walnut is at present applied. Birch is much the same colour as Cherry, but the latter wood is now scarce, and consequently dear. When properly stained it is almost impossible to distinguish the difference between it and Walnut, as it is susceptible of a beautiful polish, equal to any wood now used in the manufacture of furniture. In the forests throughout Ontario Birch grows in abundance, especially if the land be not boggy. There is a great difference in the wood of different sections. Where the land is high and dry the wood is firm and clear, but if the land is low and wet the wood has a tendency to be soft and of a bluish colour. In all the northern regions it can be found in great abundance, and as the tree grows to such a size, but little trouble is found in procuring a large quantity. The forests of the Manitoulin Islands abound with it, as well as those of the Peterborough and Haliburton districts. The Muskoka district also contains a plentiful supply.

No. 777. SATURDAY, Oct. 9, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

ROSE GARDEN.

NAMING AND CLASSIFYING ROSES.

So beset with difficulties is this matter, that even the above title hardly expresses my meaning; the naming of Roses is simple enough. The difficulty is arranging them into classes, each distinguished by some prominent and constant characteristic, and to find names fairly descriptive of the classes so formed. Our present arrangements may be fairly described as not only confusing, but uncertain and incomprehensible. The net results of not a few of our current high-sounding phrases are little more or better than a series of sounds signifying little or nothing. For example, who shall say what the term Hybrid Perpetual means? Assuredly it will not bear its natural interpretation, that of Roses that grow or bloom in perpetuity, for the majority of them bloom but once a year, and mayhap yield a stray bloom occasionally in addition. Could perversion of words or misrepresentation of facts go further? Hardly, unless by some freak of fancy or of fortune someone were to dub the old Damask Roses Perpetuals in virtue of their being among the longest lived Roses we possess. Such a name for this hardy old class would have a more substantial basis of fact to rest upon than our Hybrid Perpetuals, not a few of which in many situations are approximating to the character of annuals, biennials, or triennials. Length of life is a more substantial basis of classification than an assumed character for growing and flowering, which has little or no existence in fact. But it is much easier to condemn existing names and classifications than to devise better ones. Still, the first step towards improved arrangements must be the abolition of those that are wholly misleading and radically faulty, such as the calling of Roses, which in the mass make but one growth and yield but one harvest of bloom a year, Perpetuals or Hybrid Perpetuals. Nor must the system of classifying Roses by the countries from whence they come be adhered to. Chinese, Indian, Persian, for instance, may mean much, little or nothing, according to time, modes of culture, purity to original types, &c. For instance, China Rose had a definite meaning once, but who shall define its meaning now so as to be understood by the public at large? And as to botanical species, they are a deep well of varying mysteries, that, by much mixing and many uncertainties, have grown into a veritable bottomless slough of despond to common capacities. It seems physically impossible to make botanical species of Roses the basis of any practically useful nomenclature or classification that shall be understood by rosarians. For, as Lindley wrote nearly seventy years ago, "There are no limits to the species; it is impossible to give them rigorous definitions." The same distinguished botanist says with truth, the genus Rosa is easy to define, and a tyro finds no difficulty in recognising it. The case is quite otherwise with the species; precision now gives place to vagueness, and the alleged points of distinction break down almost at the first trial. This exactly agrees with the testimony of Mr. Wm. Hewett in THE GARDEN (p. 267), "that although the botanical classification and history of the Rose are very interesting, they fail to throw much light on the question of their classification or nomenclature." Hence, I also agree with this writer that a mere practical garden classification is about as much as we shall be able to obtain. Mr. Hewett also seems to have seized upon the two most vital points—if, indeed, there be two—as the bases of his classification and naming of classes for practical purposes, viz., the character of the plant and the number of times it blooms in an ordinary season in the open air—that is, without the shelter of glass or the stimulus of artificial heat.

As to the two characters of shrubs and climbers, probably bushes would be a better title than shrubs, as it conveys a more distinct meaning, though not a few Roses become either one or the other according to circumstances of culture or training; such, for example, as Gloire de Dijon and Homère, which may be grown into nice spreading bushes or run up walls or trees to heights of from 5 feet to 15 feet, at the option of the cultivator. Again, Coupe d'Hébé and Charles Lawson form fine bushes and equally magnificent climbers if only aided by a rich border and a high wall, though neither would be termed climbers in the sense in which the Banksian or Dundee Rambler merit that character.

Still, on the whole, climbing and non-climbing are words that would fairly describe large classes of Roses. How far such subdivisions of subordinate value as prickly and prickless, hairy and smooth-leaved, those bearing their flowers singly or in trusses—might be used to determine or distinguish classes, it is not possible to determine. For example, the prickles of Roses, while differing widely in structure and character from proper spines, differ almost to infinity from each other; while we have one or two species of Rose that are without thorns—viz., the Banksians. To those conversant with this branch of our subject it might seem possible to base a tolerably sound system of classification on the varying lengths, forms, characters, and even colours of Rose prickles. During the dormant season, these and the size, character, and colour of the shoots are almost our only possible means of identification.

But doubtless the number of times a Rose may be reasonably expected to bloom in the open air during one season forms the most valuable basis for a mere garden, as distinguished from a botanical or historical, classification. And probably we can hardly make a better start in the direction of such than by adopting Mr. Hewett's threefold division of Roses into annual, periodical, and ever-blooming Roses. Of course by carrying this threefold division through the two classes of climbing and bush Roses, we will have six classes in all. But as very few climbing Roses properly so called are more than annual bloomers, perhaps these could be included among the annual, and thus all Roses could be included in the three classes of annual, twice-blooming, and ever-blooming Roses. It may be suggested that twice-blooming would be at once more definite and more correct than periodic blooming. All Roses that in a normal state in the open air bloomed more than once could be classed among the twice, while those that bloomed oftener than twice a year would be called ever-blooming. However scientifically faulty and flimsy such a classification would be, it would really prove of high practical and commercial value, and would deliver us from those gross impostures of so-called Hybrid Perpetual Roses, the great majority of which are but annual bloomers, and hardly any of which, unless it be the two that have but a slender claim to be considered Hybrid Perpetuals, viz., La France and Boule de Neige, would rank in our new class of perpetual bloomers.

Mr. Hewett is entitled to our warmest thanks for grappling with this difficult subject, which is one eminently worthy the attention not only of the horticultural societies of America, but of our own National Rose Society, which might take the useful initiative of remodelling their list of best exhibition and garden Roses on the new basis of once, twice, thrice-blooming varieties, those that bloom thrice or oftener receiving the honoured title of ever-blooming. HORTUS.

STAYING PROPERTIES OF ROSES.

THIS subject is of so much practical importance, and the principles that govern it are so little understood, that at the risk of being again criticised somewhat severely by "T. W. G." and others I venture to return to it. In the present state of our knowledge, however, as to the effect of feeding on staying power, it will ill become any writer whose sole object is the elucidation of truth to go beyond the problematic mode of statement so severely handled by "T. W. G." True, he has totally abandoned the language of doubt and advanced into the regions of absolute certainty in such sentences as the following: "In practice it is found that the blooms that stand best are those that are grown on the richest and best soil, with plenty of manure and copious supplies of weak liquid manure when the buds are swelling, and it is only when exhibitors have learnt to produce by these means the strong growth that can carry first-rate flowers, that they can ensure their blooms withstanding successfully the ordeal of long journeys to and from shows." It is seldom one reads so many positives in a single sentence as in this. As a rule, it will be found safe to thread one's way cautiously through such a difficult subject as the staying properties of Roses, and how far this may be effected by dietary and culture than to ride rough-shod through the whole matter on the high level of strong assertion. A brief analysis of the foregoing sentence, however, proves that, however positive it may seem, it is, after all, fully as vague and uncertain under critical examination as the "possibly," "it seems," &c., so severely condemned by its writer. For example, what constitutes "the richest and best soils" for Roses? How much is "plenty of manure?" What is "weak liquid manure water?" How much in gallons is a "copious supply?" and at what stage of the "bud swelling" process should the copious supply be given to change the swelling buds into model blooms that will go anywhere and last long enough without flagging or flushing to sweep off any number of first prizes?

Positively, "T. W. G." and other writers of the same school may be rather surprised to learn that some of those most conversant with the latest knowledge of root formation and function, and the true system as regards the manufacture and conveyance of food, are disposed to doubt whether much or any of the manures offered to swelling buds is in time to greatly influence the size or quality of bloom developed from them. Again, is it so unusually true as to have grown up into the region of absolute truth that strong growths alone can carry first-rate flowers? My experience is that, barring accidents, they may be always made to reproduce their like—that is, shoots of equal or greater strength. But there are so many objections to the rule, that strong growth alone can carry first-rate flowers as to totally upset the rule as reliable.

Other assertions abound throughout this article; as, for example, that "the already too high rate of mortality among Roses might be raised through starvation." The last word is "T. W. G.'s" strong definition of my advocacy of a moderate regimen for Roses. But, to let that pass, we have not an atom of proof, direct or indirect, of any Roses having been starved to death; whereas there are

comparatively few gardens in which visible signs may not be seen of their having been less over-fed into conditions of growth and tenderness as to result in disease and death. Besides, the growing mortality among Roses began with, and has run abreast of, over-feeding. More than that, it may almost be affirmed that the richer the soil and the more manure added the higher the rate of mortality. I still prefer my comparison of a healthy Rose tree and its products to an athlete, to "T. W. G.'s," of a fat beast for a Christmas show. No animal suffers so soon or so much from change and deprivation as these pampered, petted monsters of obesity. And so with Rose blooms, I still contend that blooms suddenly cut off from a full—over-full—larder are the likeliest to fade or lose colour, unless their wants can be supplied afterwards. This after-supply may be within reach of the grower and exhibitor of the future, when strengthening mixtures may become as common for keeping up the staying properties of cut blooms as they are for maintaining the stamina of fat beasts at shows.

We have further illustrations of the indefiniteness of "T. W. G.'s" positivism in the closing sentence of his first paragraph, in which he writes of the limited area of his good Rose soil from the richest soil beds only producing fat flowers that may be relied on, while the sandy soils, made up as well as could be managed, produced flowers that, however beautiful at the time of cutting, do not under trying circumstances stand.

Taking the statement as it stands, it affords strong confirmation of my views against over-feeding. For from anything that appears to the contrary, no manure was added to the good Rose soil from the richest soil beds, or whatever that may mean, on which the best staying Roses were grown. Nor is it by any means clear that the Rose had more or richer food from this orthodox Rose soil from the richest soil beds than from that of a more sandy character "made up as well as could be managed." Most practical rosarians would interpret the latter phrase thus: "A very heavy dressing of rich strong manure," and thus accepting the natural interpretation of the phrase, "the making up of sandy soil for Roses as well as could be managed," it follows almost as a matter of certainty that the Roses grown on the sandy soil were more abundantly fed than those grown on the good Rose soil from the richest soil beds. My remnant of doubt or uncertainty on the matter vanishes as we take into consideration the following among other facts. Sandy soils decompose manures and convert their constituents into plant food more rapidly than most others. The mechanical texture of a compound of sandy soils and manures is most favourable to the rapid multiplication of feeding roots. Given a superabundance of suitable and palatable food in closest proximity to abnormal numbers of hungry open mouths, and all the conditions of a large consumption are fulfilled, and this, as I have shown, is exactly what happens to Roses on sandy soils largely made up of, and liberally enriched with, manure. Hence I contend the Roses grown on sandy soils are overfed, not starved out of their staying properties, and, further, that "T. W. G.'s" case in point and matter of practice so confidently advanced to prove the contrary, but clenches my argument and renders its logic of facts the more clear and irresistible; that argument may be succinctly stated thus, that over-feeding, whether of man or Roses, results in a loss of physical stamina, and it is a mere truism to add that such a loss lessens the force and duration of the staying properties of either. This is a very different thing from advocating what I am already virtually accused of doing, anything that could be correctly described "as raising the already too high rate of mortality among Roses through starvation." There is many a means of good culture and grand results to be found between gross feeding and penurious starving, and my contention is that the likeliest methods of lengthening the lives of our Rose bushes, and adding to the force and durability of the staying properties of their blossom, will be found in the adoption of, and rigid adhesion to, one of those means. D. T. F.

ROSES IN POTS.

Some useful hints on the culture of Roses may be found in an article published in the "Rosarian's Year-Book" for 1880 by Dr. Bennet, entitled "Winter Roses on the Genoese Riviera." During his residence in the south of France Dr. Bennet has evidently studied carefully the peculiarities of the Rose, especially during the autumn and winter months. Most cultivators are aware that Roses in pots, or other deciduous plants, may be rested by keeping the soil dry during summer, and that they may be pruned, started again, and induced to flower in the late autumn and winter months. From the middle of October to the middle of January is a period during which well-formed and handsome Roses and Rose-buds are scarce. After stating in the article just alluded to that the Rose "flourishes in all regions and climates from St. Petersburg to Calcutta," Dr. Bennet has the following pertinent remarks regarding resting: "In cold climates the Rose gets the rest that most plants require. Through cold and frost it loses its leaves, and the branches hang as if life had departed from them, to revive, however, under the first warm breath of spring, bursting into buds, leaves, and branches with energy renewed by the winter's rest. In warm, dry, arid, rocky regions, most plants get their rest in a different way. The absence of rain for months together, combined with a burning sun, dry up the ground so that it can afford no moisture to the plants which it bears; active vegetation ceases, and in this way a rest is obtained, often extending over many months, although the heat is very great. Such is the case with most of the plants that grow on the north shores of the Mediterranean. They get their rest from heat and drought, while those of most northern regions get theirs from cold and frost. Generally speaking, northern plants that rest from cold die if long exposed to heat and drought. The Rose, however, is an exception. It rests in the north of Europe through cold and frost; it rests in the Genoese Riviera through heat and drought, and in either case with equal facility, without its health or vigour being in any way impaired." These last sentences deserve attention from those who wish to successfully cultivate Roses in pots, *i.e.*, obtain the largest quantity of good blooms from their plants. A Rose show in November would be something new, but it is not more difficult to get good Roses in that month than it is to exhibit such beautiful zonal Pelargoniums as we are accustomed to see at Chrysanthemum exhibitions in London and elsewhere. The right thing is to give the plants a season of rest; in fact, to imitate the conditions so well described by Dr. Bennet, who states that "after nearly three months' rest pruning is begun in the first fortnight in September."

The hybrids are the first pruned, as they are the most difficult to flower. The young wood is cut back to three or four buds in the case of Tea Roses, but not so far back in that of the hybrids; the flowering commences after the first rains, and goes on throughout the winter, more or less freely, until the middle of January. The winter temperature of the Genoese Riviera, as registered by Dr. Bennet, is as follows, viz.: November, min. 49·2°, max. 60·1°; December, min. 44·2°, max. 55·1°; January, min. 42·8°, max. 53°; and February, min. 43·5°, max. 55·7°. These temperatures can easily be maintained in light, well-ventilated houses in this country, and for the rest all that is required is good cultivation. If there is any difficulty to face, it is want of sunshine, and that is one over which the cultivator can have no control. In many cases failure to grow Roses well in pots results from want of attention to their cultural requirements. Tea Roses are by far the best for pot culture. I like plants on their own roots better than budded or grafted ones. The seedling Brier is perhaps the best stock for Tea Roses. It might be best to work weakly varieties on it, and keep the more vigorous ones on their own roots. The best Rose growers keep their Tea Roses under glass all the year round, and this affords an excellent opportunity to rest them after they have made their season of growth and have flowered well. The Riviera Roses, which produce flowers so freely in autumn, flower also abundantly in May. By the middle of June all is over, and the period of rest has arrived.

Careful potting forms an essential part of successful culture, both in the case of large specimens and small yearling plants. The staple material in potting should be good yellow loam, say four parts, and to this add one of peat, one of leaf-mould, and one of decayed manure; if necessary, some sand. Crushed bones are excellent mixed with the potting soil, also some pounded charcoal. Have the pots well washed, and use good clean drainage, consisting of broken pots; we prevent the potting soil from mixing with the drainage by placing over it some tough fibre, from which most of the clayey particles have been shaken. One serious error in culture is the not uncommon one of placing the plants in pots that are too large for them; better by far err in an opposite direction. A well-flowered Rose bush can be cultivated in a 7-inch pot, and in that size the plants will remain in good growing and flowering condition for twelve months, but at the end of that time they will require repotting; before doing so the roots should be disentangled a little, the drainage worked out from the bottom with a pointed stick, and also some of the old soil. A pot 9 inches in diameter would be the best in which to re-pot—rather smaller than larger. The compost should be pressed in rather firmly, and if the operation is carefully performed, the plants will sustain no check whatever. Roses may be repotted when in full leaf, and it is better to repot them after they have been pruned and started into growth than when they are at rest. I am alluding now to plants that are resting in summer; by being kept dry in winter they may be potted at any time while at rest. Repotting during their summer rest would excite them into growth before their time. Success can only be attained by maintaining free and continuous growth; any check from want of water at the roots, from too much of it, or from a sudden change of temperature, would inflict one or more of the ills to which Rose-life is heir, especially when under pot culture. Very seldom, indeed, can they be successfully carried through the various stages of growth up to the flowering period without one or more attacks from green fly. For this I can only recommend the old specific, viz., tobacco smoke, two or three fumigations with which will clear the plants from this pest. Flowers of sulphur, dusted on the leaves in a dry state, is the best remedy for mildew. Sulphur dissolved in water and painted on heated pipes will also destroy it. If the plants flag when in full growth from want of water, and this happens more than once, the check will tell upon them. On the other hand, if the roots are gorged with too much water, the points of the thicker young roots will get killed, the leaves will become sickly-looking, and many of them will drop off; the happy medium experience will indicate. When at rest very little water is needed—just enough, indeed, to keep the soil from becoming dust-dry. J. Douglas.

Three good autumn plants.—It would be difficult to match the following trio when seen at their best, viz., Belladonna Lily (Amaryllis Belladonna), Tritonia or Crocosma aurea, and Schizostylis coccinea. That these are most beautiful everybody knows, or should know, and we fear a good many also know that in some gardens and localities they are very disappointing. Give the Amaryllis a place in a border against a south wall, the wall to be that of a stove or some heated structure, and it is perfectly happy, sending up in September its tall scapes with clusters of large, beautiful, trumpet-shaped rose and white flowers. Treated thus, the Belladonna is every gardener's plant, but, so far as we have seen, it is useless trying to grow it in England unless a wall such as is here described is available. The Tritonia requires only a warm sunny border, where the soil is light, but not dry. Here it will grow like a weed, spreading very rapidly, and in autumn throwing up flower-scapes in abundance. The bright orange of the flowers has a particularly telling effect among autumn-tinted plants. Schizostylis is happiest in a strong loamy soil, but it must be kept watered in dry weather, and in

midsummer the assistance of manure of some kind is a great assistance to the growth. All three plants have been, and still are, in fine display at Kew. The Schizostylis flowers latest of the three, its bright crimson flowers continuing in beauty even in frosty weather.

NOTES OF THE WEEK.

Hedychium Gardnerianum.—This plant is admirably adapted for open borders. In the summer-time, especially in somewhat sheltered positions, not only is its foliage very ornamental, but its bright yellow flowers are deliciously fragrant. We recently saw it blooming freely in the gardens of Mr. Holland, The Brooklands, Tooting Common.

Nicotiana affinis.—This deservedly popular plant is just now in great beauty in Mr. Holland's garden at Tooting. It is planted where shrubs keep the sun off it until after mid-day, and in that position its large pure white fragrant flowers remain open during the greater portion of the day; whilst in more open situations the flowers close early, and do not open again till after sunset.

Marie Louise Violets.—I send you a bunch of Marie Louise Violets. Our plants are very good this season, and are now yielding quantities of flowers in the open border. I am looking forward to many rich gatherings from them after they are placed in their winter quarters, which will be in the course of a week or ten days.—J. Crawford, *Coddington Hall, Newark-on-Trent.*

*** Excellent flowers of this fine Violet.—Ed.

Solanum jasminoides.—I was pleased to see in The Garden (p. 274) a note in praise of this useful old climbing plant. With me it thrives better in the open air than it does under glass. We have one planted against a south wall covering a space of 10 feet by 8 feet; it is now bearing a profusion of bloom, and will continue to do so until frost sets in. The plant in question was planted out seven years ago, and the only protection we give it is to place a little dry Bracken among the branches in winter.—T. B. Field, *Stanley Hall, Bridgnorth.*

Boltonia asteroides.—In his new "American Flora" Dr. Asa Gray has dropped the name glastifolia, so well known in connection with this plant in gardens, and substituted that of B. asteroides. Another plant also well known, Boltonia decurrens, has been made a variety of the above. Bæria coronaria has been substituted for Hymenoxys californica and Shortia californica, an annual of rare merit. Aster æstivus has been placed under longifolius, A. fragilis under vimineus, Harpæcarpus madarioides under Madia filipes, and Brachyactis ciliata under Aster angustus.—D.

Autumn Crocuses.—These look well flowering on turf. C. nudiflorus is a species well adapted for this purpose, as its unusually long tube bears the flowers well up above the Grass. It has already been successfully naturalised in many localities in the midland counties, and, indeed, should be planted far and wide wherever space on an undisturbed field or lawn can be had. It begins to flower in September when the Meadow Saffrons (Colchicums) are at their best, and, in mild seasons, continues on until the middle or even the end of October. The flowers, which are rich, unstriped, bluish-purple, contrast strikingly with the pretty orange stigmas. C. speciosus, which has a wide geographical distribution, is also a free-flowering species, and one well adapted for the purpose just indicated. It increases with great rapidity by means of numerous small bulbils which form at the base of the corms, and which are not long in arriving at a flowering stage. Mixed with nudiflorus, it is very effective, the colour being distinct and the feathering fantastic. The flowers, which are large, are bright lilac, and have three distinct purple veins proceeding from the base to the summit of the segments. From these also proceed a network of other veins covering the entire outer surface of the flowers. C. pulchellus, a species nearly allied to the above, though equally handsome in its way, seems rather miffy, and not at all adapted for this purpose; indeed, it seems hard to keep unless specially cared for. C. medius comes next. It is a little in the way of C. nudiflorus, inasmuch as it has self-coloured flowers; it, however, belongs to the reticulate section, having a strong reticulated fibre over the corm. The segments of the flower are bright purple, marked on the inside with six or seven purple lines a short distance from the throat; the stigmas, which are much and finely divided, are bright scarlet. The flowers are shorter than those of nudiflorus, and are produced a little later in the season. Others, a few of which might be utilised in the same way were they plentiful, are C. iridiflorus, a most peculiar and interesting species; Parkinson's byzantinus; C. Boryi, white; C. hadriaticus, white; cancellatus and its varieties; and the many forms of sativus, longiflorus, Clusii, and ochroleucus.

Scirpus Holoschœnus var. Linnæi.—This very distinct variety—for so at least it must be considered in gardens—is decidedly ornamental. In the Cambridge Botanic Garden it forms a graceful and even elegant specimen about 5 feet in height. The stems are curved, polished, and of a deep green colour. The flowers, which are produced in dense globular spikelets, add to the ornamental character of the plant. It grows in a dry bed, and does not appear to suffer in the least from drought.

Hieracium villosum.—So ornamental a plant as this is could hardly have been expected among Hawkweeds. It is of good habit, neither weedy nor coarse, and is certainly worth growing. It is very different in appearance from other cultivated species. The leaves are tufted, about 7 inches long, obovate, and covered with long hairs which form a thin pile a quarter of an inch deep. The stems reach a height of about 18 inches, and bear pale golden flower-heads about 2 inches across. It is flowering in the Cambridge collection.

Nemesia versicolor var. compacta.—This is decidedly one of the neatest and prettiest of all annuals. A quantity of it in the herbaceous ground at Cambridge is exceedingly attractive just now on account of the multitudes of white and bluish flowers which it is bearing, and which slightly resemble those of a Linaria. The habit of this variety is erect, and it grows about a foot high; the stems are square, the leaves opposite, lanceolate and toothed, and the flowers are in terminal racemes. It is a native of the Cape, but may be sown out of doors in spring.

Highgate Woods.—A movement is on foot with the view to secure the woodland known as Churchyard Bottom Wood, Highgate, for the use and recreation of the public. This wood is fifty-two acres in extent, and is represented as one of the finest pieces of woodland in England; it is separated only from the wood lately given to the Corporation by a public road, and the price asked for it by the Ecclesiastical Commissioners is £25,000. The acquisition of this wood as an open space would be a fitting complement to the one already made public; the two would form a noble and unique recreation ground for the whole of the northern portion of the metropolis.

Sternbergia angustifolia.—I send you herewith flowers of Parkinson's Winter Daffodil, the narrow-leaved form, viz., S. angustifolia, a very free-blooming plant. I have a large bed, consisting of 1500 bulbs, against a south wall, planted two years since, and at noon it is a sight to see just now. Every bulb carries three blooms, and more are coming forward. "Cut in the bud," as "Veronica" would say, and put in water, the bloom holds good in a cool room for four or five weeks.—W. B. Hartland.

*** The flowers of this narrow-leaved species are, we think, brighter in colour and larger in size than those of the ordinary S. lutea.—Ed.

Mistletoe is well grown at Streatham Lodge, in Surrey, one pyramid Apple tree, in particular, some 7 feet high and about 6 feet through, being a dense mass of it from top to bottom and laden with berries. The Apple tree thus smothered by the parasite does not bear any fruit, but this loss is compensated for by the ornamental character of the Mistletoe. Those who wish to introduce Mistletoe into their gardens should devote an Apple tree specially to it. The berries from which it is to be grown should be gathered in March or April—not earlier, or success may be doubtful; earlier in the season the berries are not ripe. The branches on which they are to be placed should be from three to four years old. Selecting a clear bit of bark on the upper side of the branch, rub the berries on it, and they will be found to adhere to it. Blackbirds and thrushes are very partial to them; therefore trees thus operated on should be netted. After a lapse of some three months the seeds will be seen to have thrown out sucker-like claws, when all danger from birds will be at an end, and the young plants will after that rapidly increase in size. Young Apple trees with Mistletoe established on them may also be bought in some nurseries.

Physostegia virginiana and imbricata, so called, are two plants, about the names of which there is considerable confusion. For the first of the two, P. virginiana is the proper name, but both are frequently met with under those of Dracocephalum speciosum, virginianum, lancifolium, variegatum, and Physostegia purpurea and coccinea, and possibly others. Its height in the larger forms is from 3 feet to 4 feet; in the smaller, 1 foot or 2 feet, usually terminating with a simple unbranched spike, sometimes, however, with several panicled spikes. P. virginiana var. speciosa includes imbricata, a figure of which appeared in the *Botanical Magazine*, tab. 3386, also Dracocephalum speciosum (Sweet, &c.). This is distinguished from the above by its tall, robust habit from 6 feet to 8 feet high. Its leaves are lanceolate, very acutely serrated, and the spikes dense and panicled; both are purple or rose-coloured.

Kniphofia (Tritoma) corallina.—This comparatively new hybrid or seedling is a very fine addition to the genus on account of its neat habit, brilliant colour, and long period during which it flowers. In the Cambridge Botanic Garden it was about the first to bloom this year, and it is likely also to be the latest. It far surpasses K. Macowani, from which it was raised, and is easily distinguished from it by having no clear yellow colour on the lower side of the flowers. It is much deeper in colour altogether than Macowani; the bells or tubes are longer and more slender, and the limb of the perianth appears to be more spreading. The buds are red or reddish instead of being greenish, as in the parent. In habit this plant is an improvement upon K. Macowani, as the leaves, instead of growing almost rigidly erect, are spreading and make a better specimen. Its height is about 5 feet, and it produces a large number of scapes.

Aster Bigelowi.—I send you flowers of this Aster, which appears to me to be amongst the best of the perennial kinds. The flowers are from seed sown in slight heat in the spring and planted in the open ground in May. Some of the plants bear flowers of a lighter tint than that of the blooms sent, but the majority are of a good violet colour. The plant is vigorous, but I am not able to say whether or not it will withstand a severe winter, although it is described as hardy. Its height is 3 feet.—Thos. Laxton, *Girtford, Beds.*

*** Aster Bigelowi, also known as A. Townshendi, is one of the very finest of its race. It has pale green leaves, stem clasping, and coarsely toothed. The flowers, which are borne in large corymbose heads, are uncommonly handsome. The ray florets are violet purple, and the disc orange-yellow. A really grand Aster, and one which should displace many of less worth now grown in gardens.—Ed.

Gloriosa superba.—This fine old climber is now in great beauty at Park Hill, Streatham. It has tuberous roots, and when vigorous attains a height of from 6 feet to 12 feet, producing numerous branches and tendrils, by means of which the plant in its wild state is enabled to climb, and support itself. The flowers, which are produced freely, are large and showy; the petals are long and reflexed in such a way that all the points meet. The lower portion of the flowers is bright orange, the upper part brilliant red. Gloriosas should be grown in a mixture of loam, leaf-mould, peat, good decomposed manure, and sharp sand in about equal parts. The tubers should be started into growth in spring in small pots, and placed in a warm, moist atmosphere. When they need a shift, place them at once in their flowering pots, and when the roots begin to work

freely into the new soil, the temperature of an intermediate house will suit them admirably. As the growth decays in autumn gradually withhold water, and after the stems and leaves are dead the tubers should be taken up, stored in dry sand, and kept in a cool place until the following spring.

Nerines.—I herewith send you blooms of ten varieties of Nerine, all distinct with the exception of N. atro-sanguinea. These, with the spike of Fothergilli major sent three weeks ago, make eleven varieties which have bloomed here this season.—E. Peters, *Somerset Terrace, Guernsey.*

*** The blooms received from Mr. Peters consisted of the following, viz.: N. excellens—Flowers large, petals long and narrow, crisp at the edges, colour soft carmine, with a central line of a deeper colour in each segment. N. atro-sanguinea—Flowers short, very open; petals recurved, not undulating, deep blood-red. N. pulchella—Flowers large, open, petals recurved, crisp on the edges, rosy pink with a bright carmine line on each petal. N. pudica—Pure white, petals not reflexed nor undulated, each petal streaked in the centre with flesh. N. Fothergilli—Flowers bright scarlet, open, petals reflexed to the ovary and narrow, stamens scarlet and very long. N. Planti—Flowers open, reflexed, much resembling those of Fothergilli except in colour, which is intense crimson; stamens very long, crimson. N. elegans cærulea—Flowers large, petals recurving at the tips, centre carmine broadly bordered with violet. N. carminata—Flowers recurved, but not so much as in those of Fothergilli. N. Fairy—Flowers cup-shaped, slightly recurved at the tips, pure rosy pink. N. rosea crispa—Flowers small and open, petals undulated and in colour soft rose.—Ed.

A TRIO OF GUNNERAS.

In the tastefully planted grounds at Bowden Hall, the seat of Mr. T. D. Burchell, four miles from Gloucester, two unusually fine plants of Gunnera manicata and one of G. scabra are now growing most luxuriantly. The sites for these handsome specimens, which are not too close to each other, are well chosen on the margin of a closely-mown lawn, dipping away from the terrace garden to a small lake. Although within a few yards of the water, the roots are several feet above it, and the charmingly broken ground which skirts the Cotswold Hills being decidedly oolitic, one would hardly expect these marsh or bog plants to attain such large dimensions. Mr. Burchell, who is a great lover of fine-foliaged plants, has, however, made satisfactory provision for the roots, and, judging from the strength of the foliage, there exists but little doubt that they have gone down to the water line, as very little, if any, is given to them from above. A fine clump of G. scabra stands in the centre, and measures some 14 feet in diameter, the tallest leaves, on 4-foot stems, being fully 4 feet across. Some 20 yards away, on either side, this grand mass is flanked by enormous plants of a variety which Mr. Burchell calls G. manicata. All the stems start from a common centre, like Rhubarb, but none are quite upright; consequently, these 7-foot petioles, carrying perfect rugose leaves 4 feet or 5 feet across, form graceful masses nearly 6 feet in height and 18 feet through. In the centre of the plant which I measured I observed starting apparently from the crown, and at an angle of about 45°, drawing towards the sun, a very remarkable hirsute stem, whose office, I suppose, is the production of flowers and seeds; but, judging from the lateness of the season, I am doubtful if any of them would open. It is said in "Sub-tropical Gardening," "The inflorescence is more remarkable than the leaves. The little flowers and seeds are seated densely on conical, fleshy masses a few inches long, and these in their turn being seated as densely as they can be packed on a thick stem, the whole has the appearance of a compound cone 2 feet high, very heavy, and perhaps the oddest looking thing ever seen in the way of fructification." It is also said, "It is not difficult to obtain, and may be raised from seed, although this is a slow way. It should be planted in some isolated spot, and not, as a rule, in the 'flower garden proper,' as it must not be disturbed after being planted, and would associate badly with the ordinary occupants of the parterre. The plant cannot have too much sun or warmth, but makes little progress if its huge leaves are torn by storms." Whether or not Mr. Burchell has studied this useful book I did not ascertain, but certain it is that he has hit off the management of Gunneras to a nicety, for every leaf on both varieties was perfect.

Speaking of the plants at Kew, Mr. B. says they met its wants very cleverly by building a little bank of turf around it, so as to admit of its absorbing a thorough dose of water now and then, while in winter it was protected with dry leaves and a piece of tarpaulin. His own plants in a wet peat bog received less care, for one was grown in deep rich soil, with the crown raised well above the level, and the whole protected under a couple of barrowloads of leaf-mould; the other was left exposed and not allowed any particularly good soil. Both plants survived the severest winters, but the protected and well-fed one grew much the larger. The Bowden plants have a quantity of dry tree leaves packed about the crowns sometimes during the autumn, but I did not gather that they were treated to the luxury of sheets of tarpaulin; neither have they the benefit of a warm soil or climate. With these facts for our guide, surely there are few gardens of any extent in which lovers of noble foliage plants may not find a suitable spot for the Gunneras. W. Coleman.

Eastnor Castle, Ledbury.

WHITE FLOWERS FOR AUTUMN.

The constant demand for white flowers at all times of the year, but especially in autumn, renders it of the highest importance that cultivators should have a constant succession of them. None of those mentioned below require much artificial heat, and precedence is given to such as are quite hardy. Some of the old-fashioned border plants come out in quite an improved form when accorded liberal culture. A real gem in this way at present finely in flower is the white Japan Anemone, which has stems from 5 feet to 6 feet high, crowned with innumerable clear white flowers. It does best when well established, and should be top-dressed with manure in winter. Dahlia Constance, belonging to the white Cactus class, is a grand autumnal flower; blooms of it have lately been invaluable for harvest festivals. There is also a small clear white fancy or Pompon kind called Guiding Star which is useful for similar purposes. Asters of the Victoria kind sown late are invaluable in a cut state; when planted near a wall they are easily protected from storms of wind and rain that damage autumn flowers more than frost. Chrysanthemums, such as Madame Desgrange, are capable of yielding a long succession of clear white flowers; cuttings taken off now will flower in July next, while those taken off in spring will keep up a supply until early show kinds are ready to take their place. Pyrethrum uliginosum ought to be in every garden. It is of strong growth, and well repays liberal culture; where this is accorded the blooms grow large in size, and are produced by hundreds on stems from 6 feet to 7 feet high. We lift its roots and divide them every alternate year, giving it at the same time fresh soil. Eupatorium odoratum produces feathery white flowers in great abundance; old plants of it cut down close in spring like Pelargoniums, and grown out of doors until the blossoms are ready to expand and then put into a greenhouse, are very ornamental. Begonia miniata is also a useful plant for furnishing cut flowers now. It is easily increased from seed or from cuttings struck in gentle heat in spring, and if grown on in cold frames during summer it will now be in full bloom, and if in a little heat it will keep flowering for a long time. Abutilon Boule de Neige is such a capital all-the-year-round bloomer that it must not be omitted from any list of autumn flowers. We generally set our old plants of it out of doors in summer after their long spell of winter and spring blooming, and take them under glass in September, when they are literally covered with bloom. Pelargoniums, especially double whites, are most useful autumnal flowers, *i.e.*, if rested in summer, the blooms pinched off, and the soil moderately dry. Thus treated and placed under glass they will flower freely in autumn, and their blooms will be much more pure in colour than those from outdoor plants. J. G.

Hants.

MOTHS CAUGHT IN FLOWERS.

I promised to reply again to Mr. R. H. Wade in reference to this subject. It appears that it is by no means uncommon for moths to be caught in the flowers of Physianthus; indeed, I imagine it must constantly be the case wherever the plant flowers in such a position that large moths can gain access to it. One observer, writing on this subject in the *Entomologist's Monthly Magazine* in 1878, says: "This plant is one of the most deadly moth-traps I know. Every day I find from two to eight humming-bird moths caught by the proboscis; they appear to die in about ten minutes. I often find other insects dead in the flowers." It does not seem by any means the rule that the insects caught in the blossoms die so quickly; for another person, in a note on this insect, says: "As a rule the moths were alive the morning after their capture. I have released as many as eighteen Plusia gammas from one plant in a morning." By many persons this habit of capturing insects is supposed to facilitate the fertilisation of the flowers in some way, but how this is I do not understand. Surrounding the style and ovaries are five plates; the edges of these plates where they meet one another are produced outwards into a kind of flange. The only way in which a moth can obtain the nectar of the flowers is by inserting its proboscis between the flanges of two adjoining plates, as the entrance to the nectaries is just beneath them. If the moths were able (as perhaps in many cases they are) to withdraw their probosces, they would most likely dislodge the pollen masses, which are placed one behind the edges of each plate, and are connected together in pairs by a filament and a gland, which is just above the crack between the flanges of the plates. But if the moth be unable to withdraw its proboscis from between the flanges, I do not see how the pollen masses would be removed, or what benefit the plant derives from the moth being caught. The flowers of the Evening Primrose (Œnothera) are said to catch moths at times. G. S. S.

SHORT NOTES.—VARIOUS.

Early Peaches.—Very early Peaches are seldom of good quality. Hale's Early is by far the best of them. Early Beatrice and Early Louise are bad, very bad. Early Albert is the best of that class, but quite a fortnight later than either Beatrice or Louise.—W.

Schuberti a grandiflora.—Might I add to last week's note on this plant (p. 326) that the seed was raised and the plant grown in an ordinary greenhouse? The plant has now about twenty blooms open or on the point of opening. It is growing in a pot.—B.

Lonchocarpus Barteri.—Allow me to make a slight correction in the latter part of the paragraph relating to this plant in The Garden (p. 307), where it is stated that an allied or African species yields Yomba indigo from its flowers. This should have been Yoruba indigo, which is obtained from the leaves like ordinary indigo, and not from the flowers. It is not clearly known what species yields this indigo, but it is supposed to be Lonchocarpus cyanescens.—John R. Jackson, *Curator, Museums, Royal Gardens, Kew.*

RECLAMATION OF SAND-WASTES.

At the late Sanitary Congress at York, Dr. Poore read a paper on this subject, from which the following are extracts. They relate to what was effected by Bremontier in fixing blowing sands on the Landes or Moorlands that skirt the Bay of Biscay between the mouths of the Adour and Gironde. Bremontier recognised the fact that the best protection for a bank against the fury of the elements is to plant it. A loose heap of earth is liable (no matter how huge it may be) to be washed or blown away. If, however, the bank be planted, the roots of the trees and plants hold the soil together, and the spreading branches and leaves form at the same time a protection from the fury of wind and water. It is true that even planted hills and banks may suffer severely in times of exceptional storm, but the storm once past, the silent forces of Nature commence at once the work of reconstruction. This spring I was astonished at finding, close to Biarritz and within a few yards of the sea, a very flourishing crop of Peas which had been sown in the sand without, apparently, the admixture of any manurial matter. They were protected from sea-winds by hurdling made of Gorse, and enjoyed an ample exposure to the sun, and thus bid fair to yield a good return in due time. The Pea is a plant that roots very deeply, and the roots doubtless found moisture and nourishment at a great depth below the surface. For fixing blowing sands, however, something more permanent than Peas is necessary, and Bremontier resolved to try Pinus maritima, a Pine known to flourish in sandy soils near the coast. It is nearly related to the Pinaster, and in habit and size resembles the Scotch Fir. Bremontier made his first sowings of the seeds of P. maritima in the year 1789. I wonder what the dull-minded peasant thought of this enthusiast who went forth to do battle with the mighty ocean and still mightier wind, armed only with a few handfuls of Pine seeds. These were sown mixed with seeds of common Broom, and the sowings were made in a direction at right angles to the prevailing wind. A screen of hurdles made of Gorse or of planks deeply driven into the sand was placed on the windward side of the seed-ground, and the seed-ground itself was thatched with Pine branches and other suitable material. At the end of the first year the Broom would be 9 inches or 10 inches high and the Pine saplings only 2 inches or 3 inches, and thus the tender little saplings were nursed and protected by the plants of Broom. In half-a-dozen years or so the Brooms had reached their full growth, but the Pines continued to grow, and, in course of time, overtopping the Brooms smothered their nurses, and being themselves judiciously thinned and pruned, grew into fine trees able to resist the fury of the elements, sending their long tap-roots and laterals in all directions through the sand dunes, and causing them to become year by year a stronger and stronger protection to the inland wastes instead of a dangerous menace. The Pinus maritima has proved to be a very profitable tree for this purpose, and within twenty or twenty-five years of sowing it began to yield a return. The timber is of very moderate quality, but is largely used for packing cases, railway sleepers, and for fire-wood. In some places clearings have been made in the forest and vineyards planted, and I need scarcely state that the most valuable vineyards in the world are on the southern bank of the Gironde on the very fringe of the Pine woods which I have been describing. There has been a good deal of talk of late about the reclamation of waste lands in this country, and the opinion of some seems to be that worthless soil presents a glorious opportunity of wasting money. These are questions concerning which I cannot speak, but it seems certain that the problem of reclamation must differ with the circumstances of soil and situation, and that it is far more easy to do the wrong thing than the right. The first thing necessary is to find a Bremontier to show the way. We shall want a Bremontier to show us the way out of the pestilential quagmire which we Londoners are making by dint of large expenditure in the estuary of the Thames. We want a genius and enthusiast who will do for the bogs of Ireland what this great Frenchman did for the Landes of Gascony.

Leucanthemum atratum. From a photograph taken in Mr. Loder's garden, Floore, Weedon, in August. Engraved for The Garden.

Tree roots in flower borders.—"D. T. F.'s" advice to plant Sweet Peas, Clematises, and even trellised Roses at the back of a border of flowers instead of Yew or Holly would not answer where the object is to shelter flowers from north-east and east gales. In such a case hardy shrubs or trees not less than 5 feet in height are wanted. What shrubs or trees would best suit such a situation? A 3 feet high hedge would be of no use. I want a good, strong belt or thin hedge of hardy Evergreens, moderate in price and of rapid growth. Can 4-feet or 5-feet Hollies be planted in October or November with hopes of success? The flower borders face due south and south-east, but are exposed to north-east gales from a mountain range at the back, so that some shade and shelter are needful, especially as the soil is dry and limestony.—Querist.

Flower Garden.

LEUCANTHEMUM ATRATUM.

Leucanthemums, Pyrethrums, and Chrysanthemums have, by the latest authorities, been merged into one genus, viz., Chrysanthemum. On the Continent, however, the three genera are still maintained, and it may be well for English readers who are in correspondence with foreign growers to still bear in mind the old names. Foreign botanists seem to consider that there is ample material for three distinct genera, and the section to which the annexed illustration belongs is still kept up as Leucanthemum atratum, the name Chrysanthemum being confined to annual species, and that of Pyrethrum to P. Parthenium, corymbosum, &c. In whatever light their amalgamation may be taken, there can at least be no two opinions regarding their usefulness as garden plants, whether for beds, borders, or rock-work. They should, however, be grown in masses, a solitary plant in a border of any of these Daisies giving but an imperfect idea of their real worth. The different kinds seem to vary very much, even in a wild state, and more so when cultivated. Indeed, it is often puzzling to know where to refer the extreme forms with which one meets in old gardens; especially is this the case with L. latifolium and L. maximum, in which there is a good deal of Aster Novi-Belgii character. Both are indispensable autumn-flowering plants, coming in, as they do, after the annual Chrysanthemums are past their best, and nothing but P. uliginosum could give us anything approaching the distinct character which we find in the Ox-eye Daisies.

L. arcticum.—This is a useful plant for the rockery, where, if allowed plenty of room, it yields a large amount of charming flowers early in the season. These, if permitted to remain on the plant, change from white to a pinkish colour, and often, especially in wet weather, to a dirty grey colour. It never grows more than a foot high or so, and may be readily increased by means of underground stems. The leaves, which are deeply pinnatifid, are Fern-like and pretty even without the flowers. It is a useful plant for covering dry banks, &c., making a fine groundwork for the stronger kinds of bulbs that thrive in dry positions.

L. atratum, of which the annexed is a representation, is said to have been introduced about 1775, and yet it is by no means common in gardens. It grows from 1 foot to 2 feet high, and makes a

charming plant for the rock garden. It produces large flowers of a much purer white than that of any of the others, and the rays generally overlap one another. It is a plant which looks well in masses, and is well worth attention. It comes from Styria, Tyrol, and elsewhere, and flowers well on into the autumn.

L. latifolium.—Extreme forms of this have much broader leaves than those of L. maximum; the serratures, too, are much sharper, and latifolium comes into flower a fortnight or so later than maximum. The leaves are often 2 inches across and blunt at the point; those on the stem are shorter than the others, but not much narrower. It is said to grow from 8 feet to 10 feet high in its wild habitat, but in gardens the largest we have seen measured between 6 feet and 7 feet in height. It makes a handsome border plant, and its flowers, which last until frost comes, are useful in a cut state. It is a native of Portugal.

L. maximum.—This is a handsome species, and useful alike for the rockery and border. When well treated it produces white flowers, which often measure 4 inches or 5 inches in diameter. It forms, being spreading in habit, a large tuft, and seems to do best when annually pulled to pieces late in autumn. The leaves are smaller than those of latifolium, and the plant is usually much dwarfer. It is a native of the Pyrenees.

Others, such as sibiricum, vulgare, pallens, montanum, &c., if generally cultivated, would add much to the beauty of our gardens in autumn.

K.

CLIMBERS FOR WALLS.

I saw the other day the front of a house completely covered with Veitch's Virginian Creeper. A faint bronzy tint was just making its appearance round the edges of the leaves, as an indication of the glorious metallic lustre which the plant assumes later in the season. Near it another house was covered with the common Virginian Creeper, which looked also exceedingly pretty. In real grandeur, however, no plant used for this purpose can rival the Exmouth Magnolia. In sheltered situations, south or west of London, it always does well. Roses and Clematises are beautiful on walls, as everybody knows, and Glycine or Wistaria sinensis in spring has but few equals where a considerable space has to be covered; but it is bare and gaunt in winter. For winter effects, the Pyracantha and Cotoneaster Simonsi and microphylla are bright and cheerful. They are slow growers at first; but, when well established, they cover a house front rapidly. Near where I am writing are several houses whose fronts are covered with the Pyracantha, and in winter, when the plants are laden with brightly coloured berries, the effect is snug and cheerful. Two evergreen plants, well adapted for covering a considerable space, will be found in Escallonia macrantha and Garrya elliptica, both strikingly effective, especially in autumn and winter. The Escallonia has very handsome foliage of a deep glossy green, and its flowers, which are freely produced on the ends of the young shoots in autumn, are of a bright rose colour. The flowers, when cut, are useful for bouquet making. The Garrya is covered in autumn and winter with long drooping catkins, which give the plant a singular and interesting appearance, and a whole house front covered with either of these plants is sure to attract attention. Then, for special situations, the white Jessamine, Stauntonia latifolia, and blue Passion-flower are worthy of being brought into prominence. The Honeysuckles, too, are a numerous family, all sweet and pretty, either on wall or bower. Ceanothus azureus, in a warm, southern aspect, sometimes does so well as to induce one to wish there were more of it and its relatives to be met with; but, rightly or wrongly, there is a feeling among planters that the family is a delicate one. A house covered with Ivy always has a cosy appearance suggestive of warmth. Among green Ivies, Emerald Gem is the brightest. Its small neat foliage is placed compactly on the stems, and its name is suggestive and appropriate. It is less rampant than the common Irish Ivy, but superior to it as a wall or border plant. Several of the variegated Ivies are very effective; but in planting climbers, if we wish them to do their work quickly and well, the borders should have some preparation. The soil should be deepened and manured, in order to give the plants a start, and they should have the walls to themselves from the beginning if they are to make rapid progress. E. Hobday.

NEW FRENCH HARDY HYBRID GLADIOLI.

Having again grown for comparison with older varieties during the summer now drawing to a close the set of fifteen new varieties of the above named beautiful and most easily managed hybrids raised and sent out by M. Lemoine, of Nancy, I am in hopes that the notes taken as to the respective merits and beauties of each variety as it opened may be of some interest to those of your readers who admire these flowers, and may also serve as a guide to them as to what varieties to add to their collections when the season of replanting comes round, as it will do now in from a month to six weeks' time. I may premise that one variety, named Lamartine, which will be fully described in its order of opening, stands forth pre-eminent above all the others for the size and beauty of its handsome flowers, taking place in the front rank with Victor Hugo and W. E. Gumbleton as quite the three finest varieties of the whole set.

Etoile opened its first flower on July 24, and is a fine tall grower with large cream-coloured flowers, faintly flushed with red on the outside, and most distinctly and beautifully blotched on the lower petals with quite a novel shade of orange-carmine. This is quite a lovely variety.

Atlas opened its first flower on July 26. This is a variety with flowers of a dingy and somewhat washy shade of colour, and though figured on the raiser's coloured plate, is certainly not worth growing.

Charles Henry opened its first bloom on July 26. This is a tall and slender growing variety of much distinctness of colour and great beauty, with medium sized flowers of a clear light shade of scarlet, the lower petals being of a deeper shade, each of them distinctly streaked with gold.

Lamartine opened its first flower on July 30. This is a fine robust grower, with a tall and branching flower-stem, bearing large and fully-sized flowers of a pleasing shade of light salmon-rose colour, heavily marked with rosy carmine on a yellow ground in the lower petals. One of the finest of all.

L'Orient opened its first bloom on July 30. This is a rather dwarf-growing variety, with fair-sized tubular flowers of a somewhat dull shade of pale yellow faintly washed with rose colour, and with a deep purple blotch on the lower petals.

Le Sphinx opened its first bloom on August 1. This is a medium-sized variety, with light vermilion flowers heavily blotched with deep purple on the lower petals, and with a golden spot in the centre of each blotch.

Sceptre d'Or opened its first bloom on August 2. This is a variety of medium height, with rather small flowers of a pretty clear shade of sulphur-yellow, with a well-defined maroon blotch on each of the two lower petals.

La Tour d'Auvergne opened its first flower on August 3. This is a variety with medium-sized flowers of a dull shade of purplish red, and is of but little beauty or merit.

President Grevy opened its first bloom on August 5. This is a charming variety, of medium height and with freely-branching flower-spikes and medium-sized, well-opened flowers of a most pleasing shade of deep, clear rose colour, prettily and distinctly washed with creamy yellow on the lower petals.

Turenne opened its first bloom on August 10, and is a variety of medium height of growth and medium-sized flowers of a light shade of purplish red; the two lower petals are velvety maroon on their inner half, the remainder being clear canary-yellow edged with light red.

Voltaire opened its first bloom on August 12, and is a medium-sized flower of a pleasing shade of light rose colour, clearly and distinctly blotched with creamy yellow on the lower petals, each blotch having a maroon eye in its centre. This is a very pretty variety.

Etendard opened its first flower on August 22, and is a medium-sized, well-opened flower of a pleasing shade of light orange-red; the three lower petals are clear canary yellow, distinctly edged with light red, and with a carmine blotch on each of them. This is an exceedingly pretty variety.

Milne Edwards opened its first bloom on August 14, and is a comparatively worthless variety with flowers of a dull shade of red, and carmine blotches on the lower petals.

General Chanzy opened its first bloom on August 24, and is a vigorous growing variety with good sized, well-opened flowers of a pleasing shade of light red, blotched with carmine on the lower petals.

Ceres opened its first bloom on September 4, and is a medium sized flower of a rather dull shade of light red; the three lower petals are clear canary yellow edged with light red, and distinctly blotched with carmine. W. E. Gumbleton.

Belgrove, Queenstown, Ireland.

SINGLE DAHLIAS.

In "T. W. G.'s" exhaustive article on single Dahlias (pp. 297, 298) one of their chief weaknesses for decorative purposes is concealed, viz., the fragility of the individual flowers, while double or semi-double Dahlias, or such flowers as the true Cactus, will last a week, a fortnight, or even more. Hardly are vases or baskets filled with single Dahlias than the falling petals begin to litter the tables or rooms. This may be partially avoided by cutting the blooms before they are fully expanded. But at best and longest, single Dahlia blooms are short-lived and evanescent compared with double or composite ones, and this fleeting character tells heavily against single Dahlias for decorative purposes indoors. In the garden the numbers and constant succession of blooms compensate for their evanescence, provided always the faded flowers are not allowed to ripen seed. When and where this is the case, and especially when seed ripening and a dry hot season run abreast of each other, the brilliancy of beds and borders of single Dahlias is apt to be eclipsed in a full crop of very prosy and uninteresting seed-pods. With the latter picked off, however, few ornamental plants run through the later half of the season with more credit decoratively than single Dahlias. "T. W. G." is also deserving of the best thanks of all their admirers (and who is not?) for his praiseworthy efforts to raise the character of the plants and improve the quality of their blooms. Mere stature, coarseness of habit, size of leaf or bloom are points to be discouraged, not fostered, in single Dahlias. Weakly stems that allow the blooms to droop, instead of striking the observer's eye, are, I may say, comparatively worthless for decorative purposes, either in the garden or the house. The due proportion of ray-floret to disc is also a matter of very considerable importance, and will turn the attention of hybridisers in a direction likely to lead to most successful results in the raising of new and improved varieties. Already it is generally found that the smaller the blooms in reason, the more useful and the more lasting. As to the form of single Dahlias, probably the less formal the better for merely decorative purposes. We have long had an excess of circles and semispheres among Dahlias and other composite flowers; hence, however useful for mere exhibition perfectly circular single Dahlias formed of broad petals with rounded edges, lying flat and overlapping each other, may be, yet for effect in beds and borders ragged-looking, star-shaped quilled flowers are far more striking.

In a word, the Cactus Dahlia, rather than Paragon, is, for mere decoration, a better model of form and a higher standard of excellence; and the next great step in Dahlias for the embellishment of gardens and dwelling-houses is the production of the true Cactus form in fact as well as in name in all the colours found among Dahlias. At present, notwithstanding names, we can hardly be said to possess more than one Dahlia of this superbly useful class for decorative purposes.

The Cactus Dahlia can hardly be said to have more than one fault, and that would be accounted a merit in most others. It is so set upon keeping up a constant succession of bloom, that long before one set of flowers is fully expanded they are partially hidden by the leaves, shootlets, and buds of their successors, which rise several inches above them, and so on and on in succession throughout the growing season. The striking flowers are thus partially at times almost wholly concealed before they are fully developed. This tendency in no way detracts from the value of the blooms for cutting, though it seriously detracts from the decorative value of the Cactus Dahlia in beds or borders. It would, therefore, be an improvement if this upward successional growth could be checked or modified by hybridisation or cross-breeding. Meanwhile, something can be done in both directions by culture. For example, it is found that old tubers do not conceal the blooms so much as spring-rooted cuttings. Neither is the reason of the difference far to seek, as the former bloom more freely and grow less vigourously than the latter, and hence the difference in decorative value between old and young Cactus Dahlias in beds or borders. Poor soil is also preferable to rich for this Dahlia, and for exactly the same reason, as it checks luxuriance and fosters floriferousness. As to other points regarding the raising of seedlings, selection and separation of different strains, &c., "T. W. G.'s" remarks are so reliable and exhaustive, as to leave little or nothing to be added thereto. HORTUS.

Anemones.—The exceedingly short period of time which Anemone roots left in the ground all the summer need for rest is well evidenced in the fact that mine were without foliage only six weeks, and that some were carrying flowers as early as the middle of September. Generally the plants have made strong foliage and growth, and promise to bloom freely for some time whilst the weather is open. Thus, we get from them quite ten months of foliage and certainly eight months duration of flower production. As some who have light soils complain that they cannot induce Anemones to thrive well, perhaps they would find that leaving the tubers in the soil all the year through would conduce to floriferousness, and if a dressing of well-rotted manure was added in the summer there can be little doubt that the result would be satisfactory.—A. D.

Tritoma Rooperi.—Mr. Gumbleton appears, from his remarks (p. 314), to be unacquainted with the origin of this fine and very distinct species. If he will turn to the only volume of *Garden Companion* (p. 113), published by Orr & Co. in 1852, he will find the original figure of it from the imported plant flowered in the winter season by the Rev. T. Rooper, of Brighton, the plant having been sent from Kaffraria by his son, Captain E. Rooper. Mr. Rooper stated that it had subsequently bloomed in the open garden, and was in that case of a much higher colour than the specimen sent to me for illustration. We have the plant growing here as originally given to me by Mr. Rooper, and find it hardy with a slight protection of fibre or ashes, blooming in the early summer months. "W. J. G.'s" description of his plants as being 6 feet high does not at all correspond with the stature of ours, which are remarkably dense and stocky as to the recurved foliage, with the flower-stems 2 feet to 3 feet high, never exceeding the latter height.—T. MOORE, *Chelsea*.

Sunflowers.—I have read with much interest Mr. Cornhill's remarks (p. 299) on Sunflowers, but I trust you will allow me to uphold my favourite, the Miniature. I procured seed of it last summer, but the plants raised from it were very poor, and it was with difficulty I saved a few seeds. This year I have been well repaid, for we have over forty plants, none of which exceed 4 feet in height. They are very bushy, and literally covered with flowers 3¼ inches in diameter, and quite round. There is only one plant which has the florets a little curled or ragged, so they are perfection for cutting, and last well in water. The foliage of mine is very pretty, bright, not woolly; the leaves are small, scarcely exceeding 2 inches in length. As regards tardiness of flowering, ours have been in bloom since the beginning of July, and show no signs of ceasing. They were sown in March in a cool frame, and then planted in not over-rich soil. I am saving plenty of seeds of it this year. We have some plants which my gardener thinks must be a cross between the Miniature and the ordinary Sunflower. They have grown some 6 feet high, and have lovely blooms with dark centres about 6 inches across. They, too, are early and continuous bloomers, and are a great acquisition. They are very shy as regards seeding.—ANNETTE S. WAKEFIELD, *Uxbridge*.

NOTES ON HARDY PLANTS.

Helianthus orgyalis.—Among the hundreds of herbaceous plants which we possess this perennial Sunflower stands out in bold relief, being both tall and graceful. If it were associated with fine-foliaged plants, and in good positions, many of us would see this plant in a new light. With me it accidentally happens to be growing behind a small clump of Aster acris now in flower, and the Aster, not being more than 2½ feet high, effectually puts out of sight the naked parts of the Sunflower stems. By noting such chance arrangements of plants one is often able to plant more effectively than they otherwise could do. What could be better than a line or central specimen of this Helianthus, fronted or run round with one or two rows of the brightest and dwarfest of the Michaelmas Daisies?

Festuca punctoria.—Somehow this short, sharp-pointed Grass had a good name given it, and quickly got into numerous trade lists, but a more rubbishy plant was never taken within a garden gate: it is quite destitute of beauty, and that is not all, for if planted as an edging to narrow walks, its sharp points are most annoying. This Grass belongs to a class of plants which do harm to the cause of hardy flower culture; one disappointment is longer remembered than ten successes.

Azalea (Loiseleuria) procumbens.—This is now past its flowering period, but the young growth at this season, so ruddy, is nearly as effective as its minute and spare flowers. It is a most desirable dwarf shrub for rockwork. It rarely grows more than 2 inches high, but is dense and spreading in habit. Though a British species, few alpines, perhaps, suffer so much as this under cultivation. I find it to be safest to handle when the roots are quite active, and successfully cultivated specimens, which have not stood without being lifted for say three or four years, may be divided nearly any time like a tuft of Milkwort. Such stock is invariably well furnished with silky fibre well up to the leafy parts; this is not the case with scraggy wild specimens, which have often bare and very hard wood between the top and ground surface. Such material I have dealt with during the period of growth, and have succeeded better with it than when at rest. The scraggy wood should be put well down into narrow, but deep pots, only leaving the green tips exposed. Ram hard with peat and sand to the pot side, half plunge in moist sand, and scatter lawn croppings over the plants to protect the young shoots. When well established let them be fully exposed to sunshine; the more the better. Under this treatment I have rarely lost a division, and good wood is formed during the same summer. When once such pieces get into good root action the plants grow very fast, and, as already stated, further propagation is easily effected at almost any time. A peaty soil made heavy and solid with clean sand and firm planting are essential, as also are plenty of sunshine and a fair amount of moisture. The latter is partly secured by the nature of the compost, and even more surely if the roots are set close to big sandstones.

Œnothera lobata.—Though there are two important distinctions between this and taraxacifolia, both plants are often mistaken one for the other; besides having a less deeply cut leaf, this kind has yellow flowers, and is only of annual duration. Taraxacifolia has much larger white flowers, and though but an indifferent perennial, it proves to be one under favourable conditions as to soil. Notwithstanding the superiority of taraxacifolia, this pretty kind, with its dwarf and compact habit, should not be neglected. Its flowers are very numerous, commencing when the plants are but six or eight weeks old and continuing in succession till severe frosts set in. It is one of those annuals which should have a place in every garden, so verdant and gay does it remain to the last.

Linaria Cymbalaria maxima.—A friend kindly sent me a glowing description of this, and as it was further described as a giant Ivy-leaved Snapdragon in a trade list, I ventured to get a plant of it, and I was in no way surprised to find that this nomenclature had been applied to no new thing. What actually came was Linaria pallida. It may not be much amiss to have a Toad-flax called a Snapdragon, but it is amusing, if not misleading, to hear a Toad-flax of from 3 inches to 6 inches in stature and producing flowers half-an-inch in diameter—the longest measurement—being described as a giant Ivy-leaved Snapdragon. Linaria pallida is very different from the smooth-leaved creeping Cymbalaria. In every part except the flower it is a much smaller plant, and its roots run terribly about and soon become objectionable among plants of its own stature.

Cortusa pubens.—Not only is this small species a fast grower, but if, after the first flowers have faded, the plants are shaken out and placed in fresh rich soil, even when severely divided they will bloom quite freely again in September. Plants consisting of a few crowns are now beautifully in flower, and, sweetly pretty as they looked in the spring-time, they are even more welcome in autumn. It is astonishing, too, with what vigour they grow after being placed during the warm season in fresh soil.

Gentiana Pneumonanthe.—This pretty native Gentian never fails to flower under treatment implying anything but much care. In fact, with the exception of a little special sort of peat being given it, it may be said to do well both in pots and in the open border with most ordinary attention. Given a little sticky peat which can hardly ever become dry, and a flat position, which further secures the needful moisture, and you have done all that is necessary. The neat habit of the plant, and the large, high-coloured, long-tubed flowers are such as ought to secure for this Gentian a place in even the choicest collections.

Senecio argenteus grown in poor soil is not more than 6 inches or 8 inches high. For so dwarf a plant the leaves are somewhat large; they are deeply cut and variously contorted, so as to render a good-sized plant of it a pretty object, especially on rockwork and among dark stones. Thus situated, its silvery or white foliage stands out in pleasing relief, and the plant has the further merit of not showing dirt-splashes. The way to keep it, not only in good shape, but both vigorous and well clad with foliage down to the surface of the soil, is to raise cuttings during summer, winter them in a cold frame, and plant them out in spring, or, if well rooted as early as September, it will be as well to set them in their permanent quarters. Such young plants are quite safe, while old ones are apt to die off.

Crocus Fleisheri.—Again this lovely early autumn Crocus is in flower, and although I have but one small potful of it in a sheltered corner, it attracts one by its perfume, which is like that of Violets. When well expanded the flowers measure from 3 inches to 4 inches across. The outer divisions of the perianth are of good substance, somewhat acute, and boat-shaped, and, like the inner ones, mauve-purple slightly feathered with darker lines. The stigma has three deep divisions, and each division is further subdivided at least thrice. The filaments largely overlap the three inner perianth divisions, which for several days remain closed in the form of a tube—the prettiest stage in the development of the flower. The three long

anthers are orange-yellow, but not much seen, owing to the closeness of the inner portion of the flower. In order, if possible, to lengthen the period of bloom of this pretty Crocus, I take the pot into the shade during powerful sunshine, and shortly after it has been moved it is interesting to watch the flowers close, which they do by a twist-like action. The closed flowers are very large and inflated, and hardly less beautiful than when open, being of the same colour outside and inside.

Polygonum vaccinifolium.—This is certainly one of the most useful of rock plants. Though it has a fast-spreading habit, it may at least for a season be allowed to run freely amongst other choice things. For that short period it would hardly do them any harm, and its pretty little rosy spikes, rising above the slender prostrate stems, and little Box-like leaves would be sure to be appreciated. The flowers are numerously produced, too, even by young plants, and it is astonishing what an amount of cut bloom may be obtained from one or two roots. Its hardiness is beyond question, and it will grow pretty nearly anywhere or in any kind of soil.

P. cuspidatum.—This is an annoying plant in borders on account of its sending up suckers where they are not wanted, and spreading abroad its strangling roots to the detriment of their neighbours. All this is, however, compensated by the appearance of specimens of it at the present time. Ours are from 8 feet to 10 feet high, and have grand laterals arching in all directions and furnished with big, deep green, heart-shaped leaves arranged in most symmetrical order; issuing, too, from the axil of each leaf are pretty little clusters of creamy white flowers, scented like Elder flowers. Seen in this form, one forgets past troubles which the plant may have given. I saw the other day a bouquet of Roses dressed with the creamy white spikes of this giant Knotweed, and the effect was very beautiful. The flowers do not last long, but they keep good for a day or two, and I know nothing else that can take their place, especially in autumn.

Chelones.—These, in Yorkshire, are now at their best, and their rigid, bush-like habit shows off the terminal clusters of flowers to advantage. Lyoni is not only a very hardy kind, but one of the most showy, and obliqua and its white variety are also well adapted for border decoration. They come into blossom when flowers are getting scarce, and the foliage in no small measure helps to set off the flowers to good advantage. These, like Phloxes, are all the better for being divided occasionally, though Lyoni, which, with me, has been left undisturbed for at least six years, is not only in perfect health, but one of the handsomest of hardy plants in flower at the present time.

Aster acris.—This is one of the earliest to flower amongst the Michaelmas Daisies. Individually the blossoms are not good, either as regards colour or form, but they are produced in sufficient numbers to be effective; though not more than 1½ inches across, and the ray florets both narrow and straggling, they are arranged in huge clusters, each measuring some 18 inches in diameter. The ray flowerets are bright lavender and the disc greenish yellow. The plant itself seldom grows more than 3 feet in height.

Aster ptarmicoides.—This comparatively new comer must, one would think, take rank amongst our Michaelmas Daisies as a distinct white variety. Plants of it well grown and of good size are most effective, and nowhere more so than when in close quarters with plants of its own family. The white may not be very pure, but it is the whitest Aster with which I am acquainted, and fortunately the stature of the plant admits of its being placed in a front row where the somewhat small flowers can be seen to advantage. The flowers, too, are more durable than those of some kinds, and although I mentioned just now that acris was the earliest, it is certainly not earlier than this white sort. It improves if divided and given fresh soil every year. But as the flowers look best on large plants, a compromise may be effected by setting the divisions in bold groups of not less than half-a-dozen and as many inches asunder.

Centaurea alpina.—This is a late blooming plant, and its flowers are unusual in colour, *i.e.*, for the genus, being lemon-yellow. They measure about 2 inches across, and seem to be well adapted for personal adornment and for bouquets consisting of the choicest flowers. They are arranged in heads borne singly on slender stems 2 feet high, and the plant is very spare in the way of foliage, which, generally speaking, resembles that of an Ash, and it is slightly spinous. This Centaurea has proved to be hardy, and will doubtless become one of the finest of autumn flowers. So far as I see, it likes a dry situation, plants of it in dry soil having thriven best with me. J. W.

BEDDING AND BOUQUET DAHLIAS.

The question as to the duration of Dahlia blooms was replied to the other day by the statement that all depended upon the season, but that fine show flowers may often be found as late as the middle of October. It may be that in consequence of the greater rainfall and cooler temperature of Michaelmas-time, show Dahlia blooms come a trifle coarse, but even that may to some extent be due to lack of attention after the show season is over. As to the duration of bloom and general character of the flowers of the bedding and bouquet kinds, there can be little doubt that both improve as the autumn deepens, as is evidenced at the Slough Nursery, where the show of flowers of these sections of the Dahlia was, even directly after a heavy thunderstorm but a few days since, almost marvellous, presenting a sight which even the finest stands of bunches of blooms at any show fail to convey. The big plants standing in long rows perfectly even in height, according to sort, and literally covered with flowers, give far better notions of their fitness for bedding or for the production of flowers for cutting purposes than can any formal exhibition of blooms. Bedding Dahlias of the present day do not materially differ from bouquet Dahlias in habit or character of flower. As a rule, the flowers are rather larger, but hardly less perfect in form; indeed, it would be difficult to find in any section a more perfect or beautiful flower than is the soft primrose Flora Macdonald, which reaches a height of 3 feet. It is really a lovely kind, but its blooms are about one-third larger than are those of a good bouquet Dahlia. A fine companion kind for height is Carl Mendel, bright rich crimson and having a capital habit; and a very pleasing foil to both is found in Lucinda, peach shaded with rose, a charming kind. The best yellow is Cloth of Gold, pure bright yellow, and medium height. Mont Blanc is the best white, very free and effective; and the best scarlet is Rising Sun, also of moderate height. The three first named kinds planted in the centre of a big bed, with the other three alternated round them, would make indeed an effective mass of bloom. But whilst the bedders are so good, they are a much more restricted class than are the bouquet forms, of which there are many, and others still come in yearly. Though the blooms of these are smaller, they are wonderfully perfect in form, and whether of self-colour or tipped or mottled, are very beautiful, and so enduring as to prove most valuable to all charged with decorative work. The following selection of these made from the plants as seen in bloom may be relied upon as the best, viz., Professor Bergeat, rosy crimson; Little Duchess, white, with crimson edges; Countess von Sternberg, yellow, white tipped, exceedingly pretty; Hedwig Polwig, orange-scarlet, white tipped; Nemesis, dark maroon, sometimes white tipped; Cupid, white suffused with rose; Butterfly, orange, heavily tipped with claret, a charming flower; Brilliant, Gem, and Isabel, all diverse shaded scarlet selfs; White Aster and Lady Blanche, distinct pure whites; Hilda, primrose, rosy lilac tip; Prince of Liliputians, rich deep maroon; and E. F. Jungker, amber-tinted, very free. This is a selection of fifteen kinds, from which, if well grown, it will always be possible to select a dozen bunches of diversely coloured blooms which cannot be excelled. A. D.

GLADIOLUS CULTURE AT CAMBRIDGE.

There seems to be somewhat of a revival in the cultivation of this beautiful autumn flower, and it is the hope of increasing the interest in it that I would like now, as the season is at hand for purchasing bulbs, to draw attention to it; the symptoms of this revival that have especially struck me were the increased number of exhibitors at the Crystal Palace Show in September. This increased number of exhibitors was not due to any excessive share of the prize list allotted to them; there were only two classes, one for nurserymen—although called open, it was one in which an amateur could not very well compete, and one of small amount for amateurs. In the former there were four competitors, all new to the Palace, and two of them made large and excellent exhibits—Messrs. Burrell, of Howe House Nurseries, Cambridge, and Messrs. Harkness, of Bedale, in Yorkshire. It will thus be seen that the two exhibitors who have in previous years so largely contributed to the exhibition with their magnificent stands were absent—Messrs. Kelway, of Langport, Somerset, and Messrs. Campbell, of Gourock, N.B.; had they been present, it would have been the finest exhibition of Gladioli ever held; as it was, the two exhibits which gained the first and second prizes (Mr. Burrell's and Mr. Harkness's) were remarkable for their excellence, as the first exhibits these growers had ever put up in the metropolis. I am desirous of drawing attention to the former, as I believe it indicates quite a fresh departure in Gladioli-growing and raising in this country. Mr. Burrell lives at Cambridge, a locality, I imagine, peculiarly adapted for the cultivation of this flower. I have often thought that the neighbourhood of Spalding, where many bulbs are cultivated, especially Snowdrops, would be a very suitable locality, and one friend there who grew them was loud in his praises of the manner in which they succeeded. Cambridge seems even better adapted; the rainfall is about the lowest in England, the autumns are especially dry, and there is good loamy soil; these are three conditions in which it assimilates a good deal to Fontainebleau, and make it better even than Somersetshire with its mild and soft climate, where the rainfall is 10 inches higher and the autumns are wet. Mr. Burrell has started with these advantages, and he is not, like some who have opportunities and do not know how to make use of them, content with cultivating the named varieties; he has gone in for raising seedlings and has been most careful in hybridising, selecting such flowers as he believed would be most suitable for obtaining fine flowers and gaining a good deal of experience as he has proceeded with his work. He has found that some kinds would never do as seed-bearing plants, as they never, whether naturally or artificially hybridised, produce seed; but as some of them, such as Baroness Burdett Coutts and Mabel, are good flowers, their pollen is used for other sorts; the result has been the obtaining of a very fine strain of flowers which, from what I have already seen of them, are likely quite to equal the French flowers; indeed, comparing some of his with the French novelties of last season, I must give the preference to the English flowers.

I have had the opportunity of seeing some of his spikes, and have now before me half-a-dozen. Of course, it is hardly to be expected that at this season the flowers should be as good as those cut earlier in the season, but these have the characteristics which mark all the flowers that I have seen of his raising; the flowers are all so closely placed together as to make the spike very dense. I have no doubt that this is in some measure due to the character of the soil. I gather this from my own experience. The same varieties planted in the lighter soil in my garden do not come with nearly so dense a spike as those planted in the

heavier soil. It seems to me that the footstalk of each flower not being so strong, instead of slanting upright, is apt to hang about, and this makes the spike loose. Of course, one naturally defective in this respect will not much improve under any treatment, but I do not think a flower ought to be discarded if only it has been grown on light soil.

Of the half-dozen spikes which are now before me, No. 1 is of a very peculiar shade of apricot, deeper in tone than Abricoté, creamy white in the centre. No. 2 is a remarkably striking flower, a very bright pink with broad white lines in the centre of the petals, and a very dense creamy white spot in the lower petal, edged with pink; it is in character like Caméleon, only of a different colour: the spike is perfect, the flowers lying as close to one another as possible, and ten flowers being open at one time. No. 3 is a flower very similar in character, a somewhat lighter shade of pink, and with a crimson feathering in the centre of the white bloteh; it is equally dense in the spike. No. 4 is a delicate lilac-white, with very little marking of any kind. No. 5 a good white. No. 6 is another pink-coloured flower, somewhat in the style of No. 3. These have been gathered from small bulbs, and probably will be larger another year.

There is certainly something very peculiar about the Gladiolus. I have just taken up a corm of a French variety called Pasquin. It gave a good spike, but soon afterwards showed symptoms of decay; it was now quite gone, and on taking it up I found that the flowering corm which had been formed on the top of that which had been planted was small, and with a good many specks upon it, denoting disease. The old corm had not rotted, and from it was shooting out what appears to be a strong healthy shoot, while another is starting from the new corm. There were no fleshy roots, but only hard, wiry ones. I have now potted it, and am anxious to see what will be the result. I am sure the more one studies any class of flowers, be it Roses, Auriculas, Tulips, or Gladioli, the more will idiosyncrasies be discovered, and the more varied will be the treatment to which they are subjected, and the more likely is success to be obtained.

DELTA.

Clematis graveolens.—Some time ago Colonel Stuart-Wortley described the flowering of this Clematis in America, and kindly offered some seed which he had gathered to anyone who would apply. I received a few from him which readily germinated in a pot, and for two years I kept a plant of it during winter in my window, as I had no other glass protection. Last year, however, it was planted out-of-doors against my bay window and remained there all the winter. In spring it grew away vigorously, competing with a dark purple Jackmanni. This outstripped it at first, and covered the mullions of the window with its purple blooms. Graveolens steadily followed, creeping up between the stems, and before the last flower died away it saw the first one of graveolens looking into its face, as much as to say, "I have caught you at last." Since then it has been master of the situation and blooming freely. Its flowers are not very showy, being of a dull yellow on solitary stems. But after they drop the bearded styles of the fruit lengthen out and form a silvery tuft which is quite as effective as the flowers. With this I enclose a few specimens of the flowers and fruit just gathered above my window, in order to show that the offers of spare seed occasionally made in THE GARDEN are not unappreciated. I need hardly add that if these seeds ripen, I shall be happy to return the compliment to anyone who will apply.—R. JNO. G. READ, 10, *Marlborough Road, Bedford Park, W.*

Anagallis cærulea.—I have frequently found the blue Pimpernel during the past summer in this district, and always in company with A. arvensis. The plants noticed by Mr. Inchbald (p. 284) were smaller than the scarlet Pimpernel. With the exception of colour I have been unable to detect any difference between the two plants, viz., cærulea and arvensis, growing in this neighbourhood. For what reason it has received specific rank one cannot understand. Hooker, in "Student's Flora," records it as a variety of A. arvensis, although I noticed at Kew lately that it was labelled as Anagallis cærulea without any reference to the type, A. arvensis. This summer some seed of Anagallis indica, received from a well-known seedsman, turned out to be A. cærulea, and after a careful examination no difference could be detected between our native cærulea and the so called A. indica. A. arvensis is said to have a very wide distribution, extending to the Himalayas. Is it possible that seeds could have been collected there of the blue variety? The only record of A. indica I can find is in Johnson's "Gardener's Dictionary," where it is stated to be a native of Nepaul and introduced in 1824.—JOHN W. ODELL, *Barrow Point, Pinner.*

The One-blade (Smilacina bifolia) on rock wall at Munstead. Engraved from a photograph for THE GARDEN.

THE ONE-BLADE.

(SMILACINA BIFOLIA.)

A VALUABLE and beautiful little plant when rightly placed; not often seen in gardens, and though its beauty is of the modest kind, it never fails to attract attention in the blooming season. Its right use is as a carpeting plant in shady places, but care must be taken that it does not over-run choice plants, for it increases quickly, and the roots form dense matted masses that easily choke other plants. It is also charming in chinks of rockwork, as shown in the engraving, and is a suitable companion to groups of Ferns.

HARDY FLOWERS FOR MASSING.

SIX YEARS ago we planted a circular bed, 25 feet in diameter, with the white Japanese Anemone. The soil had been deeply trenched and manured before planting, and it has had a heavy top-dressing of rich manure every season since. The growth of both foliage and flowers has, therefore, been very strong. Late though the season was this year, the first flowers opened about the end of July, and a succession will be kept up till November unless autumn frosts should be very severe. The flowers do not last long in a cut state, but there are always so many of them, we can "cut and come again," as the saying is. The white and red varieties do not appear to thrive well together in the same bed, and if in direct contact in a border one or the other seems to disappear—usually the red. In contrast with the white Anemone, Tritoma Uvaria, or Torch Lily, has a striking effect. This also requires liberal treatment when growing and in a dense mass. It should have a liberal supply of water in dry weather during the growing season and liquid manure is also beneficial. Grandis and flavescens are good Torch Lilies. Hardy Fuchsias in a sheltered part of the lawn can hardly be equalled as regards grace and beauty. Corallina makes a very effective bed. Riceartoni and an old kind named gracilis are also very ornamental. For making a striking group in a sheltered place springing out of the Grass few things are superior to Polygonum cuspidatum. Plants of this sort take some time to get established, and some patience is needed if one has to rely upon young specimens; but once get a single plant well established in the right situation, and every year it will improve. We have a larger kind named P. sachalinense, but though of larger growth (the shoots are over 10 feet high) it is not so effective as cuspidatum. The family of Knotweeds for the most part has underground stems, and therefore if encouraged soon covers a large space. The Pampas Grass, either in groups or as a single specimen, is one of the most effective of autumn-flowering plants, and this season it is in fine condition, though I think I have seen finer spikes. A dressing of manure is a great help to this Grass, and the spring when the annual trimming takes place is a good time to apply it. That is also the best season in which to propagate it, and which should be by division. This plant always associates well with water, but it is apt to suffer from cold if planted in too damp a situation. Hollyhocks are certainly not surpassed by any other plant for making a good bold mass. I do not say that they should be placed just beneath the windows, but they should stand within view in some distant part of the grounds, against a background of shrubs. They have gone back a little in public favour of late years because it was thought they could not be grown in consequence of some mysterious disease which attacked and destroyed the leaves. But good cultivation will, I apprehend, banish this fungus or, rather, keep it at bay. All large-leaved plants bearing long heavy spikes of flowers need a good deal of support. Give good food and the water required, and the fungus will not do much harm. One of the most useful plants we have in blossom now is Pyrethrum uliginosum; in appearance it is like a very large form of the common Ox-eye Daisy, and a good mass of it makes a good display, even better than that made by the white Anemone against a background of Evergreens. This also requires time to become really effective. I purchased a little plant of it in a small pot six years ago, and every year since it gets better, extending itself by means of underground stems. Among plants of dwarfer growth there are the Star-worts or Asters, Lobelia syphilitica and fulgens. The last named is not quite hardy, but it makes a most effective autumn bed, and the larger it is the better. Syphilitica is a useful old plant, not very showy, but refined looking. I remember

beds of it in the old time as far as my memory extends. Lythrum roseum superbum has a graceful habit and is distinct in colour. It has done well planted thinly over a bed of Golden Tom Thumb Tropæolum, which has been selected for several years from cuttings, and which so treated makes a very effective bed, very useful where Calceolarias are untrustworthy. The Lythrum requires a rich, moist soil.

Among autumn-flowering bulbs, Colchicums will shortly be very effective. The slender dark green leaves of the Sternbergia lutea, too, are covering the ground on a south border, and will by-and-by be succeeded by golden flowers, and the larger the masses of them the more effective they are. E. H.

FRUIT GARDEN.

APPEARANCE *v.* QUALITY IN FRUIT.

A good deal has recently appeared in The Garden about Strawberries, good and indifferent, and it will, I think, be admitted that the subject is one deserving discussion, not only as regards Strawberries, but equally so with respect to other fruits, as at present there is evidently an inclination on the part of those who buy the fruit which they use, and also on that of many who grow their own fruit, to be led more by appearance than by quality. No one is likely to urge that appearance should go for nothing, but to allow that which is pleasing to the eye to take precedence of that which is gratifying to the palate is a mistake. To state the matter fairly, it may be said that the properties essential to fruit consist in its being good in quality and fair to the eye, the former being of more importance than the latter. Nevertheless, as has just been said, the latter now carries more weight than it deserves. In proof of this, it is only necessary to point to the big-berried, fine-looking Grape Gros Colmar, which, despite the way in which it has been condemned as being worthless, is so far preferred, that from the time it comes in it commands a price varying from a third to double that which good Black Hamburghs fetch, though the latter, as everyone knows, are better to eat than the variety in question. In the last week of September the retail price in London of English-grown Hamburghs, jet-black and in good condition, was 2s. 6d. per pound, whilst Gros Colmars, no better finished, were 5s. Doubtless there are some who confine the selection of the Grapes and other fruits which they grow to varieties that are best to eat; but it is clear that the majority who use Grapes, yet do not grow them, give preference to appearance rather than quality.

As to Pines, their cultivation by those who grow for sale alone is almost given up, for the obvious reason that the price which they fetch will not pay, and in many private gardens their growth has also been discontinued, and with the majority of those who still continue to cultivate them, the best sorts, viz., The Queen and Black Jamaica, have, to a great extent, given place to the Smooth Cayenne, which, it is needless to say, even in its best form, is a long way behind the other varieties named.

Of Plums there has this season been all but an unprecedented crop, affording plenty of varieties to choose from, all sorts alike appearing to have borne heavily, including the best flavoured kinds that are often more or less shyer bearers than the hardy prolific varieties. In their case the biggest sorts have sold the best. Pond's Seedling, although usually classed as only a cooking variety, has out-sold all others that found their way in quantity to market, including the proverbially unequalled Green Gage. Ordinary kinds, as is well known, have been scarcely worth gathering, yet the fine-looking Pond's Seedling has been selling in the leading West-end shops at 1s. 6d. per basket, containing ten or twelve. Even where this variety has found its way on to the costermongers' barrows in the streets, it has sold for double the price that other sorts equal to it in all but appearance have fetched.

In the case of Strawberries, of which proportionately more people grow their own than of most fruits, there are comparatively few who make flavour the first essential in determining the varieties they cultivate. The old variety Keen's Seedling is rarely met with, yet for flavour it stands a long way ahead of four-fifths of the sorts that find favour with growers, and though the fruit is not so large as that of many of the newer kinds, it makes up in quantity what it lacks in size, so as to nearly equal the larger-fruited varieties in the aggregate weight of crop which it produces.

Some of the very best Pears, unsurpassed for the quality of their flesh and unequalled in flavour, are now generally being displaced by large, coarser kinds, that are inferior in every way except size. The mistaken preference given to fine-looking kinds of Pears before others of better quality is not alone confined to the public who buy them, but a like disposition is as often as otherwise apparent in those who grow their own, as is evidenced by the extent to which the large coarser varieties are planted as compared with the smaller, but better sorts. The inference to be drawn from this state of matters is obvious; those who grow fruit for sale, like the producers of other commodities, find it necessary to meet the tastes and requirements of the consumers; consequently it is tolerably certain that henceforward the market growers will still further direct their attention to the cultivation of kinds that are large and fine-looking, leaving the edible properties as a second consideration. But to adopt this line in private gardens is a mistake, especially in the case of such fruits as Pears or Apples, that require considerable time after the trees are planted before they arrive at a state to give much return. T. B.

COLOUR IN GRAPES.

Allow me to say, in answer to "Hortus" (p. 287), that while admitting several things which he states, and which in no way affects my contention on this subject, I have never found an exception to the rule that "colour is sure to be found in conjunction with high flavour and other good qualities." I can conceive of circumstances in which Red Hamburghs might be better than Black Hamburghs grown on another soil and situation, but what I mean is that under equal conditions the blackest coloured Hamburghs are always the best, provided they are ripe. I have never known an exception to this; has "Hortus?" I remember years ago at one of the Manchester shows there was a dispute amongst the judges as to which of two lots of Black Hamburghs the prize should be awarded to, the contest being between a pair of beautiful Black Hamburghs, good and well coloured, but rather sour, and another pair of equally good bunches that were very red, but ripe and sweet. I forget now how the matter was decided, but I tasted both lots at the request of one of the judges, and there could be no doubt that the blackest coloured were the finest, only they were not ripe. At that time, however, Red *v.* Black Hamburghs was a subject discussed, and the two parties appeared to be more anxious than anything else to give effect to their views on the subject, apart from the actual merits of the case, and so it generally is. I, however, once saw finely coloured Black Hamburghs and very red ones on the same Vine, but on different limbs—one of which had been too heavily cropped—and the red ones were worse in flavour by a great deal than the black ones and not so firm-fleshed. have seen the same or a similar thing often.

If "Hortus" "has eaten green Muscats more richly vinous than golden ones," and if by this expression he simply means better flavoured, then all I have to say is he has had an experience no one else ever had, and when he comes across such a phenomenon again I hope he will let some one else see and taste the Grapes, for I for one decline to believe in anything of the kind without proof. As to people preferring Grizzly Frontignans to Black Hamburghs, that is another matter, and entirely irrelevant here. I prefer Frontignans myself, but my experience is that the Grizzlies that have the deepest colour are always the best flavoured, and I have seen them of all shades from a dirty green to the colour of Red Hamburghs. That your correspondent should cite such an example at all does not say much for his grasp of the subject. The people whom "Hortus" knew who chose watery green Muscats to golden fleshy ones must have had a palate out of its normal condition, like dogs with rabies, that chew anything but their proper food. The idea is too absurd for criticism. As to Melons, Apples, Pears, Plums, Peaches, and Nectarines, I maintain that each in its way is much better when highly coloured, and I deny "Hortus's" assertion that "but little importance" is attached to colour in their case by cultivators. There is just one point on which "Hortus" and I seem agreed, viz., that "wrong-thinking often seems endowed with a vitality equal to right," but it is only seeming; and, so far as I have seen, wrong-thinking is soon discovered wherever any test exists by which to try it, as in the case of green or red *v.* golden or black Grapes, which I venture to say "Hortus" will never be able to show together to prove his case. Chef.

Damsons.—Than these, when true, there are no better Plums for preserving, but three parts of the Plums which are sold in the markets for Damsons are not of that sort. The true Damson is oblong, thick at the point and tapering to the footstalk, and has a delicious flavour peculiarly its own. But the majority of the Damsons of the fruit shops and market stalls are round or nearly so, and have no particular flavour—indeed, either cooked or raw, they are most insipid. We have a few of the true Damson here, but unfortunately they rarely bear a full crop. If I was buying them to preserve I would have a sample submitted for trial, and the round black flavourless specimens would be rejected as useless or nearly so.—J. Muir.

Peaches at Ditton Park.—When I called to see the Peach trees at Ditton Park, Slough, a few days since, I found all the trees cleared of fruit, except those of the Salwey, of which there were three carrying several hundreds of fruits, the best just colouring. Mr. Lindsay said of this late kind, "I have had it really good by the middle of October in some seasons and utterly useless in others. This season, without doubt, most of the fruits will ripen. Of course, the trees are on a south wall and in the best positions. As to the general crop, it has been immense, some 2000 fruits having been disposed of, whilst great quantities have been consumed at home or dispersed abroad as presents. The trees are many, and present a sight rare to witness in these days of indifferent outdoor Peach culture. Apricots also do finely here great trees, twenty years old, covering big wall areas, and perfect throughout. The soil is very good, but not rich, and is seldom fed by strong manures; indeed leaf soil seems to be the chief garden fertiliser. Then there is no considerable cutting and slashing, miscalled pruning; all possible wood is preserved and the best carefully utilised. In planting, the trees receive in each case a bottom of rubble and rough turf for drainage, so that the roots, let the weather be what it may, always rest upon a dry base. Here the trees get practically no protection, for none is at disposal, and in that respect they seem to repay the lack of care much more thoroughly than do myriads of trees coddled up for weeks during

the spring with coverings of the most expensive and elaborate kind. Mr. Lindsay is one of the old school of Peach growers. Perhaps the ways of the old school are largely forgotten, or have not been learned by younger men.—A. D.

WATERING FRUIT TREES IN SEPTEMBER.

Possibly "J. J. H.'s" remarks on this subject (p. 287) were written some weeks before they were printed (September 25), and, if so, they might then have been safe and useful. But so late in the growing season any watering of the roots of wall trees, such, for example, as Peaches or Pears, is not only unnecessary, but likely to prove injurious. Our climate, on the whole, is rather too moist than too dry for such trees, and late watering is likely to foster late growth, one of the greatest enemies to the well-doing of trees in our climate. Nor must the dry state of the roots of our fruit trees in winter be accepted as proof that they have not had sufficient water for their well-being. Possibly, almost certainly, the natural condition of the roots is one of semi-dryness at all periods of the year, and more especially during the resting period. In a thickly-planted artificial or natural forest the soil is so full of roots and so hard as to be well nigh water-proof. The major portion of the rainfall runs off them; and possibly one of the most fruitful causes of failure among our superior fruits is the looseness and permeability to water of the borders in which they are grown. Some of the most fruitful gardens and orchards are posted on the sides of hills; and doubtless these owe much of their fertility to the necessarily dry state of their roots.

"J. G. W." and others disposed to follow his advice would be wise to bear in mind that the soil in our climate is far more likely to be too wet than too dry for the free appropriation of food by the roots. Plant-food is but seldom sealed up from the roots by drought, while it is very often washed out or sealed in by water. Dryness is a relative term, and it has yet to be proved that the deeper roots of our fruit trees are easily robbed of their food, or hindered from appropriating it by the dryness of the earth in our fruit tree borders.

As to watering earlier in the season, much depends on the character of the base of our borders, their depth and composition, as also the rainfall of the district or season and the weight of crop.

But, writing generally, surface mulching is far preferable to watering such fruit trees as Peaches and choice Pears in the open air in our climate. It is certain that quality may often be watered out of wall fruits, and if size is acquired at the expense of quality, the consumer is a heavy loser by it; for he mostly loses twice—thus he gives more labour or money for the large fruit, while, measured by quality, it may not be worth half as much as the smaller. There is also a third loss often due to undue feeding or copious waterings in the open air—the trees are forced into greater grossness, and this results in greater tenderness, shorter life, and more uncertain fruitfulness. D. T. F.

Morello Cherries on north walls.—No kind of stone fruit succeeds so well on a north wall as Morello Cherries. Failure with them on this aspect is almost unknown, owing, doubtless, to their not blooming until the weather has become genial. Apart, too, from their cropping heavily, they also keep well on a north wall. At the present time, September 22, we have still a quantity of Morello Cherries hanging on a north wall tree in good condition; and where a succession of fruit is valued, trees on this aspect form a useful continuation of the crop of Cherries which we commenced to gather early in August from a tree on a west aspect.—J. Muir, *Margam, Port Talbot.*

The Musch-Musch and Kaisha Apricots.—"J. C. C." renders a useful service to cultivators by calling attention in a recent number of The Garden to the merits of the Musch-Musch Apricot. He truly says it is one of the freest bearers and hardiest varieties we have. The quality is also considered by many superior to the Moor Park, the flesh being semi-transparent, rich, and tender. I have not found it proof, however, against that greatest weakness of Apricots—branch perishing. This, however, is an affair of locality more than variety possibly, and it is pleasing to find that the Musch-Musch is free from it under "J. C. C.'s" care. Varieties proof against this evil would be hailed as boons of special value. For quality, however, the Musch-Musch and all other Apricots I know must retire before Kaisha. This is a smallish variety of citron colour and that semi-transparent flesh that almost invariably ensures high quality. In this case the sign is verified by delicious, juicy, aromatic flesh of the richest quality. The fruit is smaller than that of the Musch-Musch, and the tree is most prolific and fairly hardy, though not specially so.—Hortus.

GRAPE CULTURE IN THE RAINFALL.

It is stated in The Garden of Sept. 25 (p. 286) that "in Lancashire and Westmoreland, where the rainfall is heavy, Black Hamburgh Grapes wanting in colour are much less frequently met with than where the rainfall is less," and the conclusion is arrived at "that the roots in the drier districts do not get enough of water in the shape of rain," &c., and this text being satisfactorily accepted by the writer, he goes on supporting it accordingly. Now, it is not the first time the idea has been broached that the best coloured Grapes are produced in the wettest parts of England and Scotland, but I for one do not believe it, and it is to be regretted that any such notion should be taken for granted without sufficient proof of its correctness, because it can only do harm. Neither at shows nor in gardens up and down the country has it been shown that the best coloured Grapes come from districts with the heaviest rainfall; on the contrary, the facts, so far as they have been ascertained, point to the opposite conclusion. There is a very decided difference in the amount of rainfall on the east and west coasts of Great Britain, the east and south-east coasts being much the driest, and it was there the vineyards flourished in England, when there were any, and where the Grape comes to the greatest perfection now. On the Continent also, Grapes of the best quality are said to be produced in shallow soils among the rocks in those countries where the rainfall is less than with us considerably; indeed, it is supposed and said the heavy rainfall of the British Isles is almost the only obstacle to Grape culture out of doors, because it means less sunlight, less heat, and general climatic conditions inimical to Grape culture. These being the climatic conditions of Lancashire and Westmoreland, the statement, therefore, comes with all the force of a revelation to cultivators that these two counties, and, as a matter of course, the whole of the dripping west coast, produce the best coloured Grapes, and not only that, but that they are "much" the best districts for colouring Hamburghs. Good and well-coloured Grapes used to come from Castle Kennedy, where the climate is moist enough; but Mr. Fowler attributed his success not to the wet climate, but to the means taken to counteract its effects by thoroughly aërated borders inside and out that he could keep as dry above and below as he wished. I believe, also, that his pupil, Mr. Johnstone, of Glamis, made his borders in the same way; here the rainfall is not particularly heavy, and the finish of his Grapes has been one of the most notable and constant qualities about them. There is a great difference as regards rainfall between the climate of Glasgow and that of Edinburgh, the first being wet and the other dry, but no one has recorded the fact that west country Grapes are the best coloured; on the contrary, the East Lothian and Midlothian Grapes have, so far as I have seen or heard, always had the best of it, and the same thing applies to England generally. The counties of Durham and East Yorkshire are amongst the driest in England, and their record of Grape culture is amongst the best. I think it probable enough that the great difference between the west and east coast rainfalls will make a difference to Grape culture, but if ever the subject comes to be investigated, I have little doubt that quite the opposite of "T. B.'s" assertion will be proved. At all events, it is safe to say that at present not a scrap of data exists to prove that the Grapes are best coloured in the wettest counties. Of course, every good cultivator advocates sufficient water for the Grape Vine, but that is quite another thing. Colour does not depend on that so much as on judicious cropping and ventilating, so as to keep the Vines in good vigour. S. W.

KITCHEN GARDEN.

KITCHEN GARDEN NOTES.

Harvesting Onions.—The Onion crop is an important one in all gardens, Onions being in daily demand in every kitchen. A supply of them must, therefore, be kept up all the year round, or as nearly so as possible. Where those sown in spring are properly harvested and autumn-sown ones succeed well, Onions may be had every day in the year. Bulbs from spring-sown seed are generally ready for use in July, and they keep up the supply until the following April or May. Tender white kinds will, however, not keep long, and therefore they should be used first, but James's Keeping and Bedfordshire Champion will both remain sound for six months after being stored, and it is varieties of this stamp that should be carefully harvested now. Those with small necks always mature first and are the best bulbs; those that have very thick necks and do not ripen until the stems have been twisted and laid over do not keep well, and should be stored along with those intended for immediate use. When the bulbs are first drawn up they should be left lying on the surface of the soil until they have dried a little, then they should be moved into any open shed or airy place under cover. There they will dry quickly, and in ten days from the time they are taken in they will be ready to clean and store. In cleaning them the greater part of the stem should be twisted off and the loose outer skin rubbed away with the hands; at first they should only be laid out in a single layer, but now they may be put in a heap in any loft or shed, where they will be free from frost or damp. A place where Apples keep well will always be found suitable for Onions, and if a corner of the Apple room can be devoted to them, they will be quite safe. Many take considerable delight in roping their Onions, but this is no advantage as regards their keeping. They are conveniently got at on ropes, and they look well when properly strung, but this is all that can be said in favour of the practice.

Late Potatoes.—The stems of the majority of these have withered, and the tubers are well matured; therefore, wherever this is the case the crop should be taken up at once. One of the greatest advantages in digging Potatoes is good weather, in which to dry the tubers immediately they are dug up, and this we have just now. It is the worst of all practices to attempt to do anything with them when the soil is wet, as it adheres to them, is long in drying, and generally causes many of the tubers to decay which would otherwise remain sound. The difference between a Potato dug in the wet and one dug in dry weather is very great, and there is double the work attached to housing the former that there is in the case of the latter. The best of all conditions for the soil to be in for digging is when it falls freely to pieces and leaves the tubers clean on the surface. It is then an easy matter to distinguish diseased tubers from sound ones, and the latter can be stored very soon after digging without any danger of them failing to keep.

Globe Artichokes.—These were very late in bearing this spring, but they have done well since, and some of them, especially on heavy soil and where not checked by the drought in summer, are still producing fresh heads. Others in drier situations were soon over, but they have begun to grow again freely, and if the whole of the old

stems are cut off and the plants drenched with liquid manure, they will produce a fine crop of useful heads during this and next month.

Preserving vegetables.—Runner Beans, Globe Artichokes, Vegetable Marrows, and many other things should now be preserved for winter use, and doubtless many readers of The Garden would be glad to know the best way of doing this. It is well known that Kidney Beans are excellent in winter when salted down now, but how few know how to do them. If I may be allowed to give one recipe, it is this: Gather the pods when they are quite tender; pack them as close as they can be put into a wide-mouthed jar; fill up with a strong brine, then place a lid that will go in the jar on the top of the Beans; put a weight on the top of this to press them down, and add more Beans as they are compressed. Repeat the pressing until the jar contains a solid mass of pods and brine, then cover them over, and they will keep for twelve months or more. The jar need not be made air-tight, as it will have to be opened frequently during the winter to take Beans out, and if steeped for one or two hours in fresh water before use, they will not readily be distinguished from pods gathered at the present time.

Planting Cabbages.—The early spring Cabbage crop is always an important one, and a good deal of its success depends on the time and manner in which it is planted in autumn. If the plants are raised too early and planted out in August, they are very apt to become too large before November and to suffer severely from severe weather in winter, or to head prematurely. Too late plants, again, also suffer from hard weather and are late in being ready to cut in spring; but if plants about 5 inches in height are put out now, they will, as a rule, succeed admirably and prove remunerative. Many are in the habit of planting their autumn Cabbage on ground from which the Onion crop is cleared, and as the soil in that case is generally very rich, this practice answers well; but maggots are apt to abound in Onion ground, and therefore, before planting it with Cabbages, we always like to fork into the surface a little hot lime. This proves both an insecticide and stimulant.

Autumn-sown Onions.—These are now up and appear to be very promising, but we always find them to do best in very firm soil, and if a little soot is sprinkled along each side of the rows and the soil is trodden down firmly close to the plants it will be found that they will grow more sturdy and winter much better than those allowed to go on in any kind of loose soil. The sooting and treading may be repeated now and then during winter with both immediate and permanent advantage to the crop.

Tomatoes.—The demand for these is constantly on the increase. All market growers who have glasshouses cultivate them both late and early. They are grown extensively in all private gardens of any size, and many small garden owners who have no glass succeed very well with them in the open air. Those planted in the open in May are now ripening quantities of fruit, the quality and flavour of which is remarkably good. The fruits will not ripen everywhere on plants treated as standards or bushes in the open quarters, but if planted against a south wall they will, as a rule, ripen fruit in September and the forepart of October. Many plants in the open have, however, been put into very rich soil, and have made so much wood that they have become a great mass of leaves, and the fruit is hardly visible. Plants of this kind will never be profitable, and it is questionable if they will ever mature a fruit. If, on the other hand, they are confined to one or two stems, and the foliage is well thinned, so as to expose the fruit to sun and air, the fruit will colour beautifully, and will continue to ripen until cut off by frost. Fruit formed now will never gain any size or become useful, and it is harmful to the more advanced fruit to allow the plants to go on upwards, the best plan being to pinch the points off the shoots immediately above the fruit which is most likely to mature by the end of the season. In late districts, Tomatoes against walls may be forwarded and greatly benefited by placing a glass light over them, either in a slanting or upright position. This will concentrate the heat and keep the early frosts off, but care must be taken that they are well supplied with liquid manure at the root. It very often happens that when Tomatoes are planted out in spring some of them are left over, and these are sometimes retained. Should any of this stamp be in existence now, by giving them a shift into larger pots and placing them in a genial atmosphere, they will soon begin to grow and bloom anew, and will bear a good crop of fruit long after those which have been fruiting all summer are consigned to the rubbish heap.

Weeds.—I am often surprised at the large quantities of weeds that may be seen in some kitchen gardens, especially as it is well known that a man with a Dutch hoe would destroy some acres of them on a fine day or two. The practice of allowing a garden to become thoroughly weedy and then giving it what is supposed to be a thorough clean is bad practice, as all weeds seed very quickly both in summer and autumn, and when the seeds fall, crop after crop will follow each other for an astonishing length of time. The better way is to keep the Dutch hoe going as freely as possible during the time the surface of the soil is dry, and when rain comes it will fail to induce crops to come up which disfigure many gardens for the whole winter. There will not be many more chances this season of hoeing to kill weeds on a dry surface, and all kitchen gardens should, therefore, be hoed over from end to end now. J. Muir.

Margam.

Turnips "bolting."—Observing the remarks of "S. W." (p. 314) as to the bolting of early-sown crops, especially Turnips, and his question as to why early-sown Turnips should thus run to seed, I trust I, as an amateur, may be permitted to say that, from experience, the reason seems to me very obvious, viz., that if there is the slightest frost after Turnip seed has chipped, bolting is inevitable. My instructions, therefore, are, with early-sown Turnips when such frost occurs, at once to make a fresh sowing.—E., *Argyllshire.*

Autumn Giant Cauliflower.—Permit me to add my testimony to that of "J. G., Hants," as to the great value, commercial and otherwise, of this magnificent Cauliflower. Since our first cut of London Market we have been cutting it all the season, and have now many hundreds in different stages that will carry us through till the end of the season, supplemented, should the weather in December be open, with late cuttings of Walcheren. It is hardly possible to conceive a good supply of Cauliflowers for private families being kept up now without the substantial aid of this fine variety. It may, without exaggeration, be called the backbone of a continuous supply; whereas in many markets no other is now seen. At present the stalls and street barrows are piled up with this fine Cauliflower of enormous size and literally white as snow. Its quality, too, whether large or small, is of the highest. No doubt to have it of the largest size early sowing and planting are requisite. But it also does well for late work, and comes in quickly after early Potatoes and other crops, producing sweet crowns of from 4 inches to 6 inches across. At the present moment we have whole borders of these coming in on the heels of a large break of very large heads.—Hortus.

Vegetable Marrows still continue to fruit freely, especially where cutting off the fruits before they get large and seedy is strictly attended to. When grown for market they must be allowed to attain a good size, or they do not sell readily; but for private use they are certainly best if cut rather small, and there is not so much loss in this as many might suppose, as a few large fruits swelling off take more strength out of the plants than a number of small ones, and it is quite a matter of exhaustion that causes them to cease bearing. I find it to be a good plan to put in a few plants rather late in May or early in June, specially for a late supply, for when we get mild autumns they are most useful. During the great glut of vegetables that occurred not long since, a good many people allowed their Marrows to become overgrown and seedy. Now Marrows when ripe make a capital winter vegetable; they should be cut and hung up in a dry house or shed; if laid down, they rot. In cooking they require to be peeled and the seeds removed, when the remainder may be treated exactly the same as Turnips; in early winter no vegetable which we cultivate is more appreciated than these overgrown Marrows. During the past season we found the bush Marrow much the hardiest, but in walled-in gardens where handlights are plentiful to shelter the young growth during the cold nights of May, the long white running variety will generally continue to be the greatest favourite.—James Groom, *Gosport.*

Garden Flora.

PLATE 565.*

MARSH MARIGOLDS.

(WITH A FIGURE OF CALTHA LEPTOSEPALA.)

A small genus consisting of only five or six species, and well represented in this country by C. palustris and its many forms; with the exception of these and the American C. leptosepala, no others to our knowledge are in cultivation. In order to grow them well they require a bog or swamp, or to be planted close to the edge of a lake, or indeed, if shallow, in the water altogether. Thus treated their effect in spring is most effective.

C. leptosepala, represented in the annexed plate, is perhaps one of the rarest of the Marsh Marigolds, although probably as easy to manage as its more popular ally. As in the case of the common Caltha, this species revels in swampy places, and has a fine appearance during the early spring months. It seems to vary considerably according to locality. Plants of it from California proper have large leaves, 2 inches or 3 inches across, almost round in shape, with a deep cordate base, and nearly quite entire margins; its sepals are greenish white and long and narrow. In Rocky Mountain specimens the sepals are narrower still, and invariably bluish-tinted, though the leaves are much the same as those shown in the annexed plate, but slightly crenated. One flower to each stem appears to be the normal condition of this sort, but in robust specimens it is often supplemented by a second and smaller one, when it is said to run into biflora, an obscure plant described in De Candolle's "Prodromus," and of which we have not seen living examples. The description given of it differs little from that of leptosepala, except that it always has two flowers; C. leptosepala has large white flowers, as shown in the plate, on stems from 6 inches to 12 inches in height, and overtop the leaves. The latter are all radical and wavy margined; the stalks are channelled and broaden into wings, where they clasp at the base. Swampy places not too wet suits this plant admirably. It produces flowers freely, though never in such abundance as the common one. Its white flowers amongst ordinary plants of this class are, however, unique, and there is no reason whatever why it should not be as much grown as the yellow-flowered sorts. It forms crowns much in the same way, and may be divided and propagated late in autumn to almost any extent. We have never seen it ripen seeds in this country, though it probably produces them in warm seasons. It is found in swamps near the head of King's River, in California, at 8000 feet above the sea, also on alpine stations from New Mexico, and the Rocky Mountains to Alaska, &c.

The common Marsh Marigold (C. palustris), which inhabits moist, swampy meadows and is often found in great abundance by the sides of

* Drawn by the late Mr. Noel Humphreys in Messrs. Backhouse's nursery at York.

streams, is one of the best hardy plants we possess, though not so plentiful in gardens as it should be, seeing that it is handsomer than two-thirds of the plants which they contain. In a dry border it will not, however, yield such an abundance of bloom nor assume so robust a habit as in a wild state. Every garden does not possess a miniature lake or small stream, but even where these are wanting, a shady, damp spot behind a north wall or group of dense-growing shrubs will, with a little attention until established, suit it perfectly. It is, however, only in gardens where there is a

Flower of Marsh Marigold (Caltha palustris).

lake or rivulet that the various forms of Marsh Marigold can be made a feature. In Lapland it is said to be the first flower that blooms in spring, *i.e.*, in May. With us it is much earlier. It generally comes in with the Daffodil in March, but frequently it may be seen early in February and continues more or less in bloom throughout the spring and summer; indeed, so variable has it become under cultivation, that we have plants of it in flower now. Miller asserts that the greater and smaller Marsh Marigolds never vary either in their natural places of growth or when cultivated, but forms of this species have received no fewer than a dozen distinct names since Miller's time. In the "Student's British Flora" all the English forms are ranked under two sub-species, palustris proper, including vulgaris; Guerangeri, which is probably riparia of Don and the origin of the double-flowered Calthas of gardens. C. minor, a pretty little plant, is also included under palustris. C. radicans is by many considered to be a distinct species, not rare in gardens. Of the first of the sections just named there are two or three distinct

Double-flowered Marsh Marigold.

double forms, one belonging to minor, a handsome plant, and another called monstrosa, bearing huge bunches of beautiful golden flowers. A form recently sent out as C. purpurascens is very deceiving if purple flowers are expected, the name alluding only to the stems, which are purplish, surmounted by large, shining, golden blossoms. It is no unusual sight to see dozens of flower-hawkers collecting Marsh Marigolds on the Thames-side above Richmond early in the morning and tying them up in penny bunches. The different forms may be propagated to any extent by division or seed, which ripens in abundance. Some of the names of the synonyms are ficarioides, parnassifolia, flabellifolia, arctica, dentata, integerrima, asarifolia, &c.

THE ALYSSONS.

(WITH A FIGURE OF ALYSSUM MONTANUM.)

The Madworts, or Alyssons, constitute a large genus, numbering about ninety species, which have been at various times distributed over no fewer than ten genera. There are, perhaps, in cultivation at the present time not more than a dozen really useful kinds, and some of these indeed are so nearly allied, that half of them might be dispensed with altogether. There are a few annual species, but the majority are perennial shrubby or half-shrubby plants, procumbent in habit and for the most part evergreen. The flowers, though individually small, are produced in such dense clusters, and the latter in such numbers, as to render this class of plants quite indispensable in spring and early summer, both in the wilderness, the rockery, and the spring garden. They are of comparatively easy culture when properly situated. Propagation is effected by division and cuttings, the latter in the case of the smaller section being much the safer way. Division should only be resorted to in the case of such sorts, as A. saxatile, that are required in quantities for spring bedding; indeed, so uncertain are plants of the spinosum and argenteum set, that it is always advisable to keep young plants of them on hand, old ones often dying off in a most unaccountable way. Others not mentioned in detail are A. alpestre, nearly allied to montanum, spinosum in the way of argenteum, Wierzbecki, and olympicum, &c.

A. ARGENTEUM.—This is a compact-growing shrubby species, seldom more than a foot or so in height. It makes a charming little plant for a rockery, wedged in between boulders or on perpendicular parts, where, however, the roots can get a good depth of soil; the leaves, which are small, are lanceolate, blunt-pointed, and silvery on the under side, the upper surface being dotted with silvery grey hairs. The flowers, which are produced in dense panicles, are of a fine deep yellow, and appear in April and May. It is found on exposed rocky places in Switzerland.

A. CALYCINUM.—This, like the above, is shrubby in habit and useful in similar places. The whole plant is pubescent, being covered with adpressed stellate hairs. It grows from 6 inches to 12 inches in height, and branches from the base. The leaves are small, scattered, and blunt-pointed. The flowers, which are small and yellow, are in short racemes, and pretty in masses. Though not indigenous to this country, it is often found in cultivated fields in Southern Europe.

A. MARITIMUM.—This is the Sweet Alysson of gardens, and though perennial, it appears to be much more satisfactorily treated simply as a hardy annual. The flowers, which are small and white, are by no means showy, and indeed only worth attention on account of their fragrance. It is a good plant for covering bare spaces, banks, or tops of unsightly walls, where it will sow itself from year to year. It may be used also as a carpet plant, but in rich soil it generally grows too robust and crowds its neighbours. It is found in waste places near the seaside, but only as a plant escaped from a garden. It is a native of Southern Europe, &c. It is often called Koniga, Lobularia and Clyce.

A. MONTANUM, represented in the annexed coloured plate, is perhaps the handsomest of dwarf-growing alpine Alyssums. It is shrubby or half-shrubby in habit; the stems are profusely branched from near the base and often tufted; the leaves are ovate or obovate, hoary, and curiously embossed with little prominent points. It flowers freely about the end of April, its branches being covered with a profusion of largish pretty yellow sweet-scented blossoms. It rarely produces seed under cultivation; therefore, the only means of propagating it is by cuttings, which, if taken off early, strike freely in a cold frame. It does best in exposed rocky places in free, well-drained soil,

Yellow Rock Alysson (Alyssum saxatile).

and should be planted where the ground in winter is not too moist. It makes a charming little pot plant for a cool house in early spring. It comes from the mountainous parts of Switzerland and Austria.

A. PODOLICUM.—This charming little rockery plant is best known in gardens under its old name of Schivereckia podolica. It has small much-branched stems and grows only 3 inches or 4 inches high. Its leaves are hoary, and its small white flowers are produced in early summer in abundance. It is quite hardy and does well in a half-shady spot. It is a native of South Russia.

A. SAXATILE (Rock Madwort).—This is well known to be one of the most valuable of spring flowers, and certainly one of the easiest to grow. It is used as a spring bedder in almost every garden in the country, and, in company with Candytufts, Arabis, and Aubrietias, it makes a grand

Sweet Alysson (Alyssum maritimum).

display when few other flowers are open. This class of plant is in large demand for the wild garden, where in large masses it is most effective. We often see this plant in shady places, but in such situations it grows but indifferently. Like most other alpines, it requires a sunny exposed situation, the drier the better, and if properly placed it need not be removed for years. In

heavy, flat ground (although quite hardy when kept dry) it is often severely cut during winter, and indeed in such localities it should be renewed annually from cuttings. Besides flowering in spring, if trimmed back, it not unusually yields a second crop in autumn. It might be used with advantage for bordering shrubberies facing the south. A variety called compactum is dwarfer, neater-habited, and, if anything, a more profuse flowerer. The variety variegata, though more beautiful in foliage, is not so free as the type, which comes from Southern Europe. D.

WORK DONE IN WEEK ENDING OCT. 5.

Sept. 29 to Oct. 5.

Except a thunder-storm on the evening of the 1st inst., when we were favoured with over half an inch of rain, the weather has been fine and summer-like, quite to one's mind, both in respect of the good that a sunny autumn does to trees and vegetation generally, and as regards the great help such weather affords to get houses, pits, and frames in readiness for plant storing, &c. Pruned early Hamburgh and early Muscat Vines. We cut back close, or rather to the prominent bud that is nearest the main stem. Soon as pruned, having plenty of water power, the hose was brought into use to wash the glass, outside and in, as well as the Vines, pipes, walls, and floors. Of course the houses are now thrown wide open, and will remain so night and day, except during heavy rain and in cold, frosty weather, when they will be closed for the benefit of the Chrysanthemums, with which the houses are now being filled, as are, already, the early and second Peach houses with the same kind of plants, which positions are only equivalent to being outside, but with this advantage, that should frost come suddenly upon us, safety as to buds will be assured by closing the ventilators. All bush plants of Chrysanthemums are still in the open, and as they are wanted to flower very late they are being moved to a north aspect, and being sheltered by a high wall the first frost will not be likely to harm them. The buds of these are being thinned a little, from three to five buds being left on the Pompon varieties, and from one to three on the large-flowered kinds. All are in rather small pots, and high feeding is therefore a necessity, so that manure-water is given them daily. Put early batch of Primulas into warmth, and potted later batch, as well as Cinerarias, into their flowering-pots. Tree Carnations and Pelargoniums for winter flowering, that have been grown outside during the summer, have been afforded space in a well-ventilated pit, on to which heat will be turned as the weather gets cold and damp. All stock pots of bedding plants as struck are moved from the plunging bed to this description of pit, to well harden them off for the winter. Calceolarias and Violas are being put into the manure frames that have thus been liberated, and here they will strike and winter, with mats and litter protection in severe weather. Grapes now need looking over twice a week to cut out any bad berries there may be, and all the light and air possible is afforded to the fruit by cutting away all laterals and some of the wood that was allowed to extend during the growing season. Finding that the inside borders of two of our latest houses were drier than was expected, each has been given another and last watering for the season. A mulching of clean straw now covers the borders, and both prevents evaporation and produces a neat and cared-for effect as to the fruit. Apple and Pear gathering goes on daily; the latter needs a lot of attention and experience to house the fruit at the right time, though, as a rule, as soon as it begins to drop it is ready to gather. Pears cannot be gathered too carefully or laid on the shelves too thinly; if possible, in single layers only, which facilitates examination of the fruit as well as the prevention of decay. Except Coe's Golden Drop, all our Plums are over, and the trees have been well washed and watered. Owing to free fruiting, none of the trees have made much wood, and there is nothing to do in the way of autumn pruning in order to expose fruiting buds to the rays of the sun to get them well ripened. Thanks to the long spell of fine weather that enabled us to destroy all weeds, as well as keep pace with earthing up and the like, there has been little else to do in the kitchen garden besides clearing away old Pea haulm and decayed leaves out of the various Cabbage plots, and trenching when the weather has been sufficiently cold to admit of the latter operation being proceeded with. The flower garden, in all its branches, continues very gay, and no pains are spared to keep it in that state by timely removal of decayed flowers and leaves, and safe securing of tall plants against being injured by wind or heavy rains. With regard to the bedded-out garden, though we hope the same may not for some time be required to be put into practice, all our arrangements as to lifting tender plants are completed by putting fresh labels to all that needed it and making note of such as are likely to be required in quantity, so that if needs be all the old plants may be saved. Transplanting and planting of shrubs we have already begun, though the soil is rather dry for it, as we trench some 4 feet deep; the rains that are now due will soon penetrate it, and, meanwhile, the surface-mulching of litter we give will prevent the plants suffering from drought. Hants.

FRUITS UNDER GLASS.

Strawberries.

Pot Strawberries are still growing fast, and show but faint signs of going to rest. The earliest plants having filled their pots with roots will now require very careful watering, as too much will prolong their growth, whilst too little will cause the balls to shrink from the sides of the pots, and the roots, which should never become dry, will suffer. To prevent this and economise labour, those which usually occupy 5-inch pots may be plunged to the rims in a bed of ashes quite out in the open, where they may remain until they are wanted for forcing. Later plants in 7-inch pots must be kept free from weeds and runners, frequently moved to prevent the crock roots from striking into the ground, and sufficiently wide apart to favour a free circulation of air amongst them. Treated in this way and moderately supplied with water, the crowns of all well-advanced plants—for, after all, there is nothing like an early start—will soon begin to ripen, when they can be plunged in the open ground, free from worms, or in cold pits, according to taste, for the winter. If the latter course is pursued, the lights should only be used for protection from incessant rain and heavy falls of snow, as all the hardy varieties resent coddling, and throw up the best bloom after a period of decided rest. Moderate rain in mild weather is beneficial, and dry frost does no harm provided it is not sufficiently severe to swell the balls and burst the pots when it breaks up. In this case the pots suffer more than the plants, as a well-ripened crown will stand any reasonable amount of frost, and the pot can always be preserved by the use of a thin layer of dry Bracken. The only kinds which I find it necessary to protect more from damp than frost are Dr. Hogg and British Queen, and as these are invariably kept back for leading up to early outdoor crops, they are plunged up to the rims in leaves, and kept hardy by full exposure when heavy rain is not falling. If the general stock runs short, a few of these, every alternate row, are drawn from time to time; the others are left to root through into the leaves and ripen fruit where they stand.

Peaches.

While Peaches are still hanging in the latest house, the time again comes round for preparing the trees in the earliest for another year's forcing. Twenty years ago, pruning, cleansing, and painting, like biennial Pine potting, formed quite an event, and all hands down to the night stoker were called in to assist. But Peach forcing, like all other matters horticultural, has undergone a great change, for, what with Amsdens and Alexanders, Hale's, and half a score of other earlies, many people now start a month later and come in a month or two earlier than they used to do. They prune at midsummer, transplant and root-prune while the leaves are fresh upon the trees, and wash the dormant wood twice instead of painting once. Whether the quality of the fruit is better, consumers, who still pay high prices, should be the best judges. In my opinion it is not nearly so good, but so long as a Strawberry in March or a Peach in April and May have fair size and plenty of colour, their flavour is a matter of secondary importance. As yet I have not rooted out my Mignonnes and A Becs, Violette Hâtives and Bellegardes, and given their places to these extra early varieties, as many there are who must and will have the best, and taking time by the forelock enables one to have the best sorts, in quite as early as English grown Peaches are, worth eating. My earliest house was clear of fruit by the end of June, and the trees were at once pruned. The syringe and hose kept the foliage and roots fresh and healthy, and all border work was performed in August. Many of the old leaves are still hanging, and a touch with the old-fashioned switch would lay them low, but so long as they can hold on they must remain, whether or not they are of use to the bright silvery buds now very prominent, but not too forward to swell prematurely. Water, it is hardly necessary to say, has not been withheld, as I can endorse all that Mr. Baines said last week in his excellent article on watering Vine and Peach borders, but whenever the clouds dropped their fatness, portable lights were moved to let this best of all water into the internal borders. When the rain did not suffice the hose was at work, as the scent of a bold and profuse bloom depends entirely upon keeping the forming and maturing buds well supplied by the roots. As we do not commence forcing before November, the trees will be untied, rough cuts will be made smooth, washing and retying will be completed by the end of the present month. Future movements must stand over for another chapter; suffice it to say, the house will have full air and the roots will never feel the want of water.

Midseason houses having been branch and root-pruned, their treatment in no way differs from that accorded to the earliest, an abundance of air and plenty of water being all that they require for the present. Our third house has also been root-pruned, and, judging from the freshness of the large leaves and the bronzed shoots, there exists but little doubt that new roots, spongioles or spongelets, whichever may be proper, have taken hold of the fresh calcareous loam. This is satisfactory, for my

Latest house, which is still in fruit, the remains of a heavy crop, requires immediate attention. Some of the trees having been moved bodily in the autumn of 1884, heavy mulching and watering were all they required last year. This season and this month steel forks will glisten at their work, and fresh loam, only a small quantity, minus manure, will be given to each tree. The hose will then fill a provised basin over the balls, and fresh stable litter, for the roots are outside, will finish the border work for the season. Inside we must be active, for although we never leave a shoot that is not carrying fruit or required for the coming year, some pruning always follows the gathering of the crop. The trees are then well washed, and gentle fires by night and day are kept going until the leaves fall. An abundance of air is given every morning, and the house is closed early with dry sunheat, when that luminary favours us during the months of October and November. My latest Peaches are Walburton Late Admirable, Barrington, Prince of Wales, Gregory's Late, and Sea Eagle. The last keeps a long time in a dry Grape room after being gathered.

Vines.

A slack time in the vineries, but still the energetic gardener finds plenty of work. The renovating and top-dressing of external borders, commenced in August, should be persevered with during the continuance of fine weather, as roots

disturbed or shortened while the leaves are upon the Vines soon take to the new soil and get established by the time the stored-up sap is exhausted in the spring. Late Vines in this respect are most difficult to deal with, as a severe check before the Grapes are quite ripe might prevent them from finishing. If confined to external borders which have fallen into a bad state, the work is best left over until the sap begins to rise in the spring, but where they have a good internal border to sustain the crop, the month of October is perhaps the best for lifting and relaying the outside roots. The mistake which many young beginners make both in planting new and renovating old Vines consists in giving them too much rich compost at the outset. They make their borders too wide and too deep, and, anxious to raise the roots of old ones well up above the ground level, they not unfrequently place too much compost over them. When this happens, the Vines rarely respond to the expectation of the owner, and root-lifting is voted a failure. The theory, however, is right, but the practical part is wrong, and the best way out of the difficulty is careful forking off until the nearest surface roots are met with, when a thorough watering, if at all dry, should precede a thin top-dressing of fresh turfy compost. I lately saw a range of new vineries in which the gardener proposed making the borders 15 feet wide and 3 feet deep to start with, the Vines to be planted in December. Had he given the roots a ridge 5 feet in width and 2 feet 6 inches in depth, and planted as soon as the houses were finished six weeks ago, much expense would have been saved, a season gained, and future piecemeal additions would keep the Vines in the heyday of their vigour for the next twenty years. The veriest tyro in plant culture knows that over-potting is often fatal, and the same rule applies in making Vine borders. Better give a smaller quantity of compost, more drainage, mulching, and water, and we may hear less of imperfect setting, spotting, and shanking.

Autumn vineries.—Houses in which Hamburghs and other thin-skinned Grapes are hanging in a ripe state will now require careful ventilation, and most likely gentle fires to prevent the berries from damping or moulding. Shade, I have often pointed out, is necessary to the preservation as well as the production of that dense colour and bloom which all covet, but do not always attain; but a gradual thinning out of lateral growths must now be followed up until nothing but the main leaves remain. A free circulation of air will thus be secured, and moisture which condenses so rapidly will be prevented from settling on the berries. White Grapes generally keep better than black ones through the most trying months of October and November, simply because all lateral growths are removed early to let light into the bunches; but these as well as Hamburghs should be looked over once or twice a week for decaying berries. Should mould get in, the scissors must, of course, be employed, and a little sulphur thrown about when the pipes are warm will do no harm to the fruit or foliage. It is a good plan, as soon as watering is discontinued, to cover the borders with some dry litter or Fern for keeping down dust and absorbing moisture, also to keep the pipes warm and the houses well ventilated by day; but the heat should be shut off and the ground ventilators closed, or nearly so, when cold damp begins to rise and draw in at night.

Late houses, in which the foliage is now ripening or taking on the autumn tints, may be considered satisfactory, as the fruit in like manner will be well advanced; but where the foliage is fresh and laterals persist in growing, the fire-heat withheld in the spring must now be applied. An immense amount of fire-heat is not absolutely necessary to the colouring of late Grapes, as I have made Gros Colmar jet-black against a stone wall. But bunches intended for hanging until next May must have something more than colour; they must have staying powers, and these can only be secured by the aid of heat steadily and persistently supplied throughout the growing season. Where a given aggregate has not been given, a rush at the end of the summer will not produce the desired effect; neither will the Grapes keep fresh and plump after the leaves fall.

External borders should now be carefully examined, for this has been a season of extremes, and it is just possible the fitful falls of rain may not have reached the lower stratum, and although it is now too late to ply the hose, the usual covering should be delayed until they have become properly moistened. Inside borders, on the other hand, which have been allowed to become too dry may derive great benefit from a moderate surface watering with warm diluted liquid or guano water, but dry covering to prevent the escape of moisture should immediately follow. If laterals have been allowed to run freely, a gradual shortening back, regulated by the condition of the crop, must be followed up until the main foliage only is left, when the buds on young canes and at the base of spur shoots will become prominent, and, under the influence of light and air, form their embryo bunches and ripen properly.

Early vineries intended for starting in November should by this time be fit for pruning if this operation has not already been performed. The present mild weather is not favourable to Vines which, through spider or other causes, lost their foliage early, and some may show signs of breaking prematurely, but this predisposition must not be allowed to interfere, as the breaking of a few terminal buds sometimes sets the sap in motion, whilst bold pruning not unfrequently sets them to rest for the remainder of the season. All border work and top-dressing having been brought to a close, and a good start being half the battle, the annual washing and cleansing of Vines and houses should be efficiently performed. Clean healthy Vines may be washed twice over and slung in a horizontal position as far from the glass as may be convenient. Painting, if a hobby, may also be indulged in, but unless that worst of all pests, mealy bug, has got into the old spurs, strong soapy water should best answer the Grape-grower's purpose.

W. Coleman.

Indoor Garden.

WINTER-FLOWERING PLANTS.

Tea Roses.—Of the value of these for winter flowering there can be no doubt, yet, strange to say, they are by no means so commonly grown as one might be led to believe. Many thousand Tea Roses in pots are annually distributed by nurserymen, who can always sell them, even when other kinds of plants are a drug in the market. But what becomes of them afterwards? Great numbers perish through their owners, or those in charge of them, being under the impression that they are hardy, and will stand all manner of rough usage, this following treatment, perhaps, the very opposite in character, and a break-down is the natural result. In nurseries Tea Roses are grown quickly, as they ought to be, and any which we want to purchase we should prefer having before any severe hardening off is attempted. Our aim would then be to keep them steadily growing under glass, so as to attain a serviceable size before winter sets in; whereas those received late, shifted, and placed in an open spot till cold weather sets in, present a miserable appearance, and seldom do good service. Tea Roses for winter flowering must not be treated as hardy, nor even as greenhouse plants; they require the temperature of a moderately warm stove, or say not lower than 50°, and from 60° to 65° during the daytime. True, under good greenhouse treatment they may yield a few blooms during winter and abundance of fine blooms in spring; but, as a rule, they are much more profitable in heat, small blooms and buds especially being most in demand, and these the forced plants are constantly yielding. Those, therefore, who may have purchased nursery-raised plants, which are usually strongly rooted in 5-inch and 6 inch pots, will do well to give them a fairly liberal shift, using clean, well drained pots and a rather rich loamy compost. Light forcing houses, such as are used during summer for Cucumbers and Melons, will suit them perfectly, but, failing these, they may be set on the front stages in warm plant houses, and even in Pine stoves. They require a light, sunny position and ought not to be crowded amongst other plants. Then, if properly watered and when strongly rooted given frequent supplies of liquid manure, they will grow vigorously, every shoot formed furnishing one or more blooms, and the more these are cut the more quickly are other flowering shoots formed. The bulk of the Teas sold by nurserymen are worked, and consequently any suckers that the stock may throw up are worthless, and should be at once removed. Now, it is the suckers produced by plants on their own roots that give much the best blooms, and also serve to keep the bushes well furnished at the bottom. Hence the advisability of striking cuttings and gradually working up a stock of serviceable sized plants on their own roots, and, seeing how easily this may be accomplished, the wonder is that so few make the attempt. This season we were able to obtain clean, healthy cuttings, and struck nearly the whole that were put in. The best consist of partially matured shoots from which a bud or bloom has been cut; these taken off with a heel, dibbled in singly into 3-inch pots filled with gritty loam, will, if plunged in a gentle bottom heat and kept rather close, strike root quickly. Another plan which we find to answer quite as well is to pack the pots containing the cuttings closely in deep propagating boxes set on a bed or staging in a warm house, and covered closely with squares of glass. No bright sunshine should be allowed to reach the cuttings, nor, on the other hand, should they be shaded more than can be avoided, or the leaves will turn yellow and drop off. Cuttings when rooted must not be allowed to become badly root-bound, nor should they be transferred to a cool house, or they will become stunted and make but poor progress. This season ours were kept growing in a warm house, and were first shifted into 5-inch and 6-inch pots and finally into 8-inch and 9-inch pots, though a few may yet receive another shift. The last shift was given a fortnight ago, and already an improvement has manifested itself; the plants are breaking strongly from the base upwards. Many of them are about 2 feet high and bushy. All buds have been kept closely removed, and will be till near such time as the blooms may be required, and this practice should be observed in the case of both old and young plants all through the summer and early autumn months, as it is very unwise to weaken the plants by the production of blooms that are not needed. Our strong old plants have of necessity to be set out in the open during summer, but they make healthier growth and root more strongly into fresh soil when given a shift if kept in a light greenhouse. All should be housed before heavy or cold rains are encountered. What pruning is needed in order to keep the plants in shape is best done early in the summer, as matured growth is to be preferred for winter flowering. Very old plants, unless they can be induced to push up from the bottom, are not worth keeping; in fact, where there is room to prepare young plants and time to do the work Tea Roses are best treated as annuals. Those forced during the winter need not, however, be thrown away; on the contrary, they may be planted out against warm walls and in other sheltered positions where they will grow and bloom strongly during the same and subsequent seasons. In many forcing houses they might be planted out on old Cucumber or Melon mounds, on which, or in somewhat similar positions, they will flower abundantly without much trouble. It is starvation treatment that has to be avoided in all cases if good results are to be looked for. Green fly and mildew are the greatest enemies to Roses, both being most troublesome when the plants are grown in cold, draughty houses. Tobacco water or a decoction of soft soap and Quassia chips soon destroys the fly, and a solution of lime and flowers of sulphur used in

the syringing water effectually checks the spread of mildew. Red spider will also put in an appearance when the house is kept too dry, but what checks mildew is also destructive to red spider. The varieties which we cultivate and which will suit most places are the following, viz., Anna Ollivier, rose; Catherine Mermet, nearly the same in colour and exceptionally fine; Comtesse de Nadaillac, clear rose; Devoniensis, creamy white; Etoile de Lyon, sulphur-yellow; Grace Darling, creamy white, beautifully tinted with pink; Homer, blush; Isabella Sprunt, sulphur-yellow, very free; Madame Lambard, bright red, very good in the bud state; Marie Van Houtte, yellowish white edged with rose, very good; Niphetos, white, very fine in the bud state; Safrano, apricot, grown for its buds; Souvenir d'Elise, white with a blush centre; Sunset, rich tawny saffron, and very distinct in habit; and Souvenir d'un Ami, deep rose and a vigorous grower.

Heliotropes.—Although the blooms of these are not nearly so durable as those of various other winter-flowering plants, they are, nevertheless, much prized on account of their scent. We are growing a much larger stock of them than usual, *i.e.*, a three-light frameful instead of a one-light frame. The plants were struck at the same time as the last of those used for the flower garden, and were first potted off into 3½-inch pots and then shifted into 5-inch and 6-inch ones, in which size they will flower. They form more sturdy growth in the open than under cover, but we prefer to keep them in cold frames, transferring them from these into a warmer pit about the middle of September. The plants being stopped about three times and the bloom being kept closely pinched off, they grow to a good size; and as plenty of air has been given them, the strong healthy growth which they have made will, when introduced into a warm forcing house, produce abundance of flowering shoots, frequent cutting increasing the supply from back buds. It will thus be seen that we do not treat even these as cool greenhouse plants, nor will they do any good under cool treatment. Our Heliotropes are set on the front stage of some old houses which we have, and there, although the range is all heated to suit Bouvardias, Poinsettias, Begonias, and other heat-loving plants, the fronts are the coolest, and they also receive a fair amount of air or sufficient to check weakly growth. Being well looked after, they continue to flower from the present time till the house is wanted in April for Melons, and, besides the bloom, they will also afford abundance of cuttings. Miss Florence Nightingale is still one of the best for all purposes, but during the winter this, and also President Garfield, more approach lilac than their usual colour. The latter variety is rather more compact than Miss Nightingale, but in other respects it is of doubtful superiority. White Lady we have discarded; it is a very rank grower, and of no service for cutting, owing to the blooms fading quickly. Boule de Neige, an old and a very strong grower, succeeds remarkably well when planted out in a conservatory, or in a Peach house, vinery, or other structure where it can receive a fair amount of light; in fact, it is the only variety with which I am acquainted that blooms continuously in a comparatively cold house.

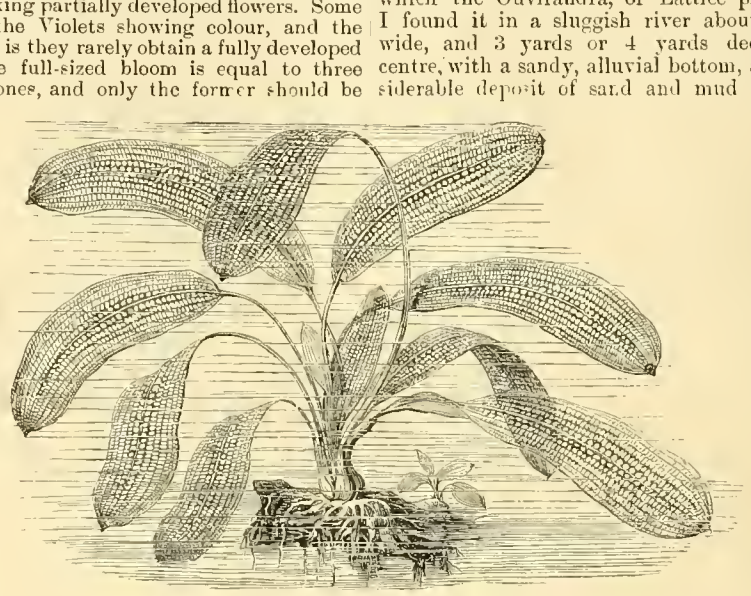
Violets.—These are much better grown without fire-heat than with it, or, if any is given, it should just be sufficient to prevent damping off or loss from severe frosts. At present there is abundance of blooms on The Czar in the open ground, but directly severe frosts occur, the supply will have to be maintained by means of plants in frames, pits, or pots. Marie Louise has become very popular. Only a few years ago Chrichel, in Dorsetshire, had almost a monopoly as regards this variety, long ranges of pits being erected almost purposely for it. Now every large garden grows it extensively, and in nearly every small garden two or more lights are devoted to it during winter. The plants being well prepared in good open ground, are, or ought to be, placed in the frames before severe frosts set in. In some few cases a little bottom-heat is given; but, as a rule, this is not needed; indeed, it may easily be injurious, and the plants are not nearly so continuous blooming under such treatment as when kept cool. The frame or pits should be partially and firmly filled with old hotbed material, on which should be put about a foot of good loamy soil. The plants being lifted with good balls about their roots and cleared of all useless runners, except those, rooted or otherwise, formed close to the parent plant, should be planted firmly and just clear of each other. If planted in loose rich soil, this encourages the production of leaves rather than bloom, while if crowded thickly together they are liable to damp off. They will also damp off badly if slightly damaged by frosts, or if kept too warm and close. They require a light airy position and ought to be near the glass, though it is possible to err in having them too close. Ours are from 6 inches to 9 inches from the glass, and will receive, now they are well established, all the air possible, the lights being drawn off whenever the weather permits. Already there is plenty of blooms, but none will be picked until those outside are crippled, and at all times we endeavour to avoid picking partially developed flowers. Some gather all the Violets showing colour, and the consequence is they rarely obtain a fully developed flower. One full-sized bloom is equal to three half-grown ones, and only the former should be gathered if an even supply is to be expected. Violets in frames, as a rule, do not need much water, but they ought not to be allowed to get very dry at the roots. Whenever severe frosts are imminent the glass ought to be covered with mats, hop-bags, or other available protecting material, and the sides and top further banked up with rough strawy litter. Violets also succeed remarkably well in pots, provided they are kept in a cool house or pit and have light, airy positions. Marie Louise is undoubtedly often confounded with New York, there being many more of the latter in cultivation than is generally supposed. Both do well in frames or pots. Comte de Brazza's White has grown very strongly this season, and we have planted six lights with it in addition to placing a number in pots. It produces fine white blooms, but, beautiful as they are, they are not so popular as the blue and lavender doubles. For wreaths and bouquets, however, the white kind is especially valuable. W. I. M.

Impatiens Sultani.—If the new Balsam (J. Hawkeri) which has such fine and deep-coloured flowers, is as floriferous as Sultani, then must it be a grand greenhouse plant. With me nothing could be more beautiful as pot plants just now than the older form. The plants are from seed sown early in the spring, and are now in 4½-inch pots. Though such ravenous feeders, yet some check to root action of this kind is needful to produce those wondrous heads of bloom now seen. When looked upon from above, the effect is singularly beautiful. As on warm days water must be given frequently, it is just as well to place the pots in saucers. Still further, it is desirable to set the pots into others a size larger, as the plants make so much growth they become top-heavy.—A. D.

THE LATTICE-LEAF PLANT.

(OUVIRANDRA FENESTRALIS.)

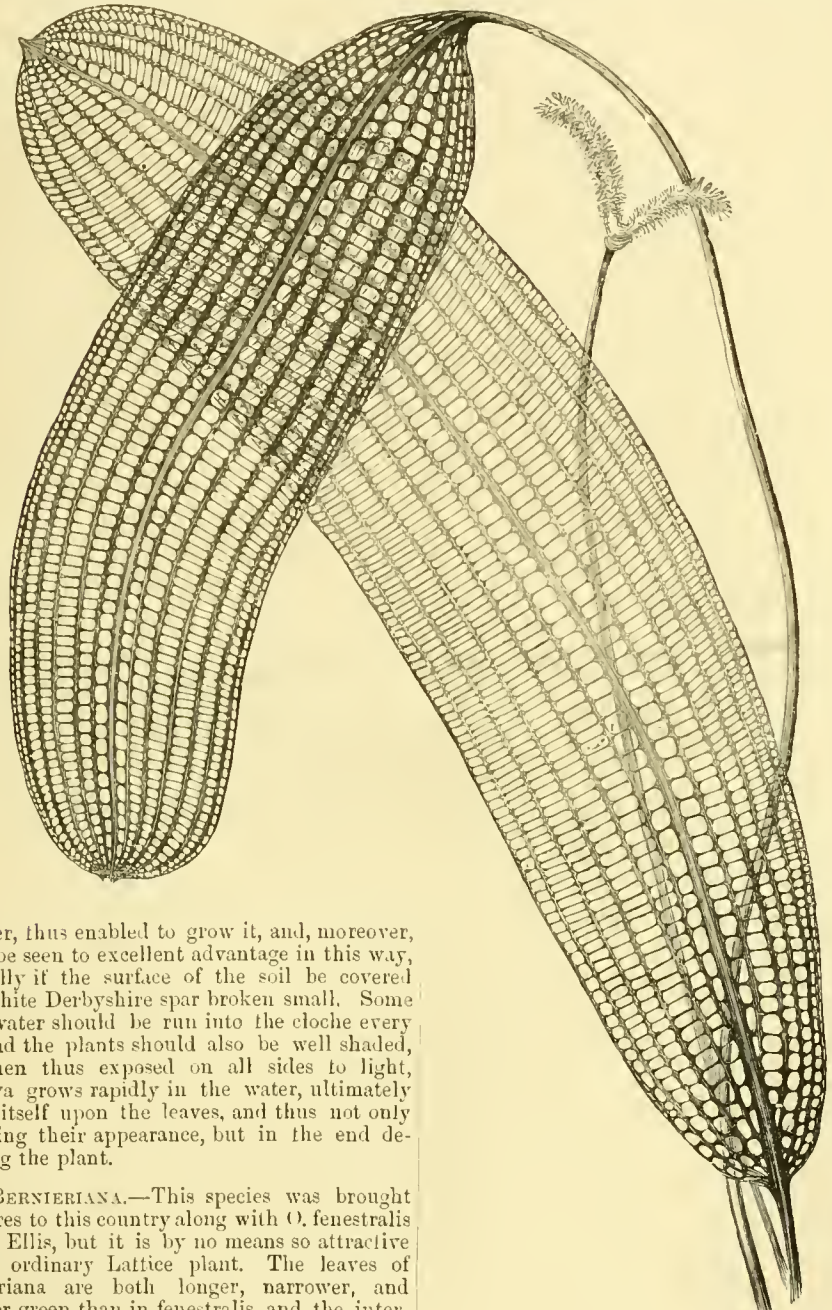
The Lattice-leaf plant, of which the annexed are illustrations, is a native of Madagascar, an island which abounds in unique forms of both vegetable and animal life. The existence of this very remarkable plant was first made known by M. Du Petit-Thouars nearly a century ago, but it was not until 1855 that living plants of it reached this country. These were brought by the late Mr. Ellis, who writes as follows concerning this singular plant in its native home: "Whilst staying at Tamatave I visited a river about eighteen miles distant to see the situation in which the Ouvirandra, or Lattice plant, grew. I found it in a sluggish river about 20 yards wide, and 3 yards or 4 yards deep in the centre, with a sandy, alluvial bottom, and a considerable deposit of sand and mud around the crowns of the plants, indicating that the deposit of soil brought down by the frequent rains from higher parts of the country formed a sort of top-dressing for the plants."



The Lattice-leaf plant as it grows under water.

The Ouvirandra grows in stiff loam or clay—usually near the margin, and about a foot under the surface. It is said to grow in places which at some seasons of the year are dry; when this occurs, the leaves all die, but the roots retain their vitality and rapidly push up new growth with the return of the rains. The native plants, according to Mr. Ellis, measure some 2 feet to 3 feet in diameter; therefore, cultivators at home seem to have been very successful with it, as we have seen plants of it in England upwards of 6 feet in diameter, and bearing hundreds of its curious-looking skeleton leaves, each measuring from 5 inches to 6 inches across. Leaves nearly as large as those just described were received by us the other day from Mr. Whittaker, Crewe Hall, who writes concerning the plant as follows: "We find its cultivation not to be at all difficult, *i.e.*, if potted in good fibry, turfy loam and peat, mixed with sharp sand and placed in a tank of clean, soft, or rain water. We keep it at a temperature of about 85° in summer and 75° in winter. The pan or dish in which it is grown is placed at a foot below the surface, and a portion of fresh water to replace what is used in the

house is added every day. Under this treatment it grows luxuriantly and flowers freely every season." Our own experience has been similar to that just quoted. We have found self-sown seedlings of it to grow very freely. We have also grown this Lattice plant in inverted cloches placed upon a stage in the stove without any bottom-heat, and consequently at a lower temperature than that just named. Under these conditions we have found it to thrive admirably, although it does not grow to so large a size as in heat. People who have no suitable tank are,



Leaves of Lattice leaf plant (half natural size).

however, thus enabled to grow it, and, moreover, it can be seen to excellent advantage in this way, especially if the surface of the soil be covered with white Derbyshire spar broken small. Some fresh water should be run into the cloche every day, and the plants should also be well shaded, for when thus exposed on all sides to light, conferva grows rapidly in the water, ultimately fixing itself upon the leaves, and thus not only impairing their appearance, but in the end destroying the plant.

O. Bernieriana.—This species was brought unawares to this country along with O. fenestralis by Mr. Ellis, but it is by no means so attractive as the ordinary Lattice plant. The leaves of Bernieriana are both longer, narrower, and brighter green than in fenestralis, and the interstices between the ribs are much smaller. It differs from fenestralis, moreover, in producing four spikes of bloom instead of two, and these are rose-coloured instead of greenish white. Judging by the greater length of its peduncles, and by their inflation about the middle, as if to give buoyancy, we should be inclined to believe this species to be a frequenter of deeper water than is usual in the case of fenestralis, notwithstanding its being found accidentally in company with that species. O. Bernieriana first flowered in Messrs. Jackson's nursery at Kingston in 1858. W. H. G.

MARKET-GROWN CHINESE PRIMROSES.

The best Chinese Primroses are generally to be found in our market-growing establishments, where myriads of plants in 4½-inch pots are so even and so admirably grown that they command admiration, and show that specialities, if Chinese Primroses merit such an appellation amongst market plants, always display more of merit than is found amongst plants where many things are attempted. No doubt very much of this perfection in cultivation is due to the fact that the market grower erects only useful houses for his plants and cares nought for appearance. Hence his plants always get plenty of light, are near the glass, and have ample air without being exposed to cold currents. Further, they are always provided with the best available soil to be obtained, and the culture, if somewhat of the high pressure sort, is certainly of the very best. Those privileged to see occasionally the fine breadths of plants found in market-growing establishments can justify this praise of the way in which at such places Chinese Primroses are grown. Of course, the private grower palliates his own lack of good culture by declaring that in all cases these things are the special objects of a market grower's enterprise, and that is quite true. Still it is very obvious that in a much smaller way the market grower's methods and work may be copied. In very many gardens there is a manifest tendency to overpot Primulas. There are few similar plants which need less average pot room than these do, for the roots are exceedingly fine and tender, and are in much danger if in soil that is sodden or sour or too much solidified. It is when these roots, permeating fine, yet free and good, soil, come into free contact with the sides of the pots that real health and strength are evolved. Thus it happens that the market grower from his 4½-inch pots produces such splendid plants full of stout firm foliage, and carrying large heads of bloom of the finest quality. Where thousands of plants are raised successive sowings are needful, not only as a matter of convenience, but also to maintain successional batches of plants over the whole winter season. In private gardens where a few scores of plants suffice for the wants of the winter it is well to sow twice at least, the first sowing being made in gentle heat about the middle of March, and the second sowing from newly-sown seed early in the month of July. The former will give fine plants for early winter and Christmas decoration, whilst the latter sowing gives plants to bloom admirably from January till April.

Of this later batch many of the best flowered plants will well repay for summer keeping after the spring bloom has been removed. If growing in 4½-inch pots they will, about the month of June, stand a shift into 6-inch pots well, or if in 3 inch pots, then into 4½-inch pots. In shifting such stock plants it is well to avoid low potting. Damping-off is not a common evil with yearling plants, but it is often found in plants that are blooming for the second time unless carefully potted. No doubt early potting has considerable value in enabling the plants to become thoroughly established and the pots well filled with roots before the winter sets in. Growing them also during the winter in a gentle heat is helpful in preventing damping, but, with all possible care, it sometimes happens to the best grown plants. It is wise, therefore, in potting to have enough of plants should any of them suffer from a very common complaint. Those preserved plants from the previous winter are most useful for early blooming; indeed, are the best to produce good specimens for the November exhibitions. It is not at all unusual to find these blooming whilst in small pots, and, as it were, prematurely producing comparatively inferior flowers, to show very fine blooms later when repotted, and enabled during the summer and autumn to make full growth. Under ordinary conditions, it is not at all difficult to raise Primula seedlings, for if sown in shallow pans in fine sandy soil, the seed being just buried and then protected by a thin covering of clean Moss or a piece of clouded glass, the seed, if good, will germinate freely in about three weeks. If sown in March, some little artificial heat is desirable, but sowings made in July may be fully trusted to the natural warmth of the season. In most cases more depends upon the quality of the seed than upon methods of raising, for really good seed will germinate under even disadvantageous conditions. As to soil for Primulas, it is generally admitted that it should be good. Composts usually have to be measured for use; hence it becomes a stereotyped method of description to insist upon two-thirds of one and one-third of another item in the compost. The phraseology is useful, inasmuch as it is clear and plainly indicates what is meant. Thus, for Chinese Primulas, a compost of two-thirds sweet turfy loam and one-third of thoroughly decayed manure from a hotbed is the

best, and with all may be mixed a sprinkling of white sharp sand to keep the compost open and light. As to the matter of firm potting or otherwise, no doubt it should be otherwise in the case of seedling plants having their first potting from the seed-pans. But with plants established in the blooming-pots rather more pressure may well be employed, for soil too light and loose soon becomes a mere sponge, through which the water passes as through a sieve. One of the secrets of the success of the market growers in obtaining such remarkable results as they do from 4½-inch pots is found in firm potting; but of course the soil is good, and so composed that it will neither bake hard when dry nor become sodden with moisture.

Although preference is shown for certain colours in Primula flowers, yet all are very pretty and acceptable. The term "washy" as once applied to some of the older hues no longer has force, as we can have plenty of reds and purples, which are not at all washy; whilst in the blush and pink hues the delicacy and beauty found in them must redeem such from a term so depreciatory. The whites are naturally the most popular, because all white flowers are so acceptable during the winter months. We get this tint in very fine form in both pale green and in dark foliage. Perhaps by reason of the contrast, the blooms on the latter always seem the purest; certainly as they age they do not flush with pink, as is so much the case with the others. This latter dark-leaved strain is probably identical with that which gives us flaked or striped flowers, for markings of that kind are found only in plants having dark foliage. The break seems to have come first from the carmine and purple selfs, because we have both these colours in the flakes. Then, in some of the seedlings from the flaked forms there was an entire absence of colouration, the blooms being pure, and this feature has been perpetuated in the strain. Mr. Cannell's Swanley White shows this feature admirably. Next the whites came the lavender-tinted flowers in diverse shades, some bluish, others reddish, but still all of one section. They are, perhaps, too wanting in decisiveness for many growers, but none the less they are exceedingly beautiful; especially so are those flowers which show clear white margins to the petals. Without exception very lovely and refined are the flesh and pink tints. Of these, Prince of Wales, having pale green foliage like the older white forms, and carminata, having reddish green leaf-stalks, are singularly beautiful. Similar sections are probably known under other names, for each seedsman seems to have his own nomenclature, but generally it will be found that they differ only in name. Red or purple shades, meaning thereby the old hue, vary from pale tinted flowers down to deep rosy magenta; really they are neither red nor purple, but contain a combination of both colours more or less. The darker ones, very rich indeed, differ only from the deeper hued Chiswick Red section in the fact that the flowers have a violet tinge, which thus materially changes the hue. The Chiswick Red section so called also gives several shades from carmine to deep, indeed almost blood-red. Really these deeper hued forms are heavy carmines; still they have no special connection with the older carmines, of which we had some beautiful forms years before the Chiswick Red strain was introduced from the Continent. However, this latter strain has done wonders in developing form and colour since it has been with us, and it seems very difficult indeed to excel the very beautiful and richly hued kinds we now have. In some directions size of bloom has been developed in a remarkable degree, but these very large flowers are objectionable to this extent, that the plants are less floriferous than others, and when one or two large flowers fall, a head of bloom is often completely spoiled.

It is worthy of note that some kinds have the green sheath so prominently developed, that they fairly force the blooms from off the truss long before they would otherwise fall; hence we often see what should be fine heads of bloom having a thin, loose appearance. The Fern-leaved section so far has in bloom given nothing which was not previously found on the old or plain-leaved plants. Still the foliage of the Fern form is very pleasing and distinctive, and merits admiration. Few winter-blooming plants are likely to maintain popularity more than Chinese Primroses, and their fairly good seeding propensities render them all the more serviceable. A. D.

WINTER-FLOWERING VIOLETS.

The time has now arrived for moving the tender double-flowered varieties of Violets from their summer quarters to frames. Frames that have been in use for Cucumbers and Melons during the past summer will now be available for Violets. Many growers of these popular flowers plant them in the soil that has been used for the preceding crop, as there is generally a little heat left in it; but I like to have a fresh start with new material, as the beds, if not re-made, get cold just at a time when warmth is most needed to keep the flowers growing; otherwise they remain dormant for a long time just when they are most required, viz, in the short dark days of winter. The frames should be set in a place sheltered from cold winds, but open to the south, so as to husband as much as possible the faint rays of the winter's sun; and with this end in view the frames should always be elevated at the back by means of extra bricks placed under them. The fermenting material in the frames need not be strong, as a violent heat is unnecessary, the main point being to secure a gentle lasting warmth, so that the roots may not get chilled. Although Violets are very hardy, they do not flower freely at mid-winter without a little aid in the way of warmth, and I have found that during severe weather it is a good plan to keep the sides of the frames well protected. Tread the fermenting material in the frames very firmly until within about 1 foot of the glass; then put in a layer of good soil; fresh loam, if possible, is best; then lift the Violets from the open ground with good balls of earth, and set them on the soil as thickly as they will stand, allowing room for the foliage to expand; then fill in with soil, and give a good soaking of water, finishing off with a layer of Cocoa fibre refuse. Keep the lights off, except during exceptionally heavy or cold rains, that might chill the soil too much; but as soon as frost sets in put the lights on the frame and cover up securely at night. Uncover, however, directly the frost is gone, and tilt the lights up at the back. If the plants have been well prepared during summer they will commence to flower in October, and continue to do so throughout the winter. Marie Louise generally flowers early, and is one of the most popular of all Violets, but for early spring the older Neapolitan, with its paler flowers and exquisite scent, is very useful, and the new double white Comte de Brazza is also well worth attention. Its long, stout foot-stalks and large flowers eminently fit it for bouquet making. The common single blue Violet, of which The Czar is still a popular kind, usually flowers very freely during winter, provided new beds of it are made every spring. In this locality they are mostly grown under the partial shade of fruit trees, that keep the sun's rays in summer from drying up the foliage, and break the cold winds of winter, for, in order to insure a supply if frost prevails for any length of time, or snow covers up the plants, it is advisable to have a portion of the stock either covered with movable frames or transferred to cold frames similar to those recommended for the double kinds. In picking Violets only pick fully blown flowers, as it is wasteful to pick half expanded buds, and there is nothing like a Violet's own leaves for garnishing the blooms. The leaves of The Czar variety are large and cup-shaped, and very dark green—just, in fact, what we want in the way of material for garnishing. J. Groom.

Gosport.

Phrynium variegatum and **P. jucundum** are two names for one plant, a very prettily variegated Maranta-like stove plant which is sure to become popular, because it is very free growing, graceful, and highly decorative. The leaves are elevated on almost erect stalks 1 foot long, the blade being about 8 inches by 3 inches wide, bright green, with broad longitudinal streaks and margins of creamy white, and with the excellent habit of drooping just sufficient to display its full beauty. The plant has been introduced and named by two nurserymen at the same time, and we have therefore to decide which of the two names is to stand. Messrs. Linden, of Ghent, published the name P. variegatum along with a figure of the plant in the *Illustration Horticole* at the beginning of this month, and as Mr. N. E. Brown, of Kew, is responsible for the name, we presume this is the one to adopt, notwithstanding that Messrs. Veitch, of Chelsea, exhibited a plant of it under the name of P. jucundum on September 11, and received a first-class certificate for it from the Royal Horticultural Society. Perhaps it is too much to expect that the horticultural committee should have been acquainted with the figure in the *Illustration Horticole* so soon after it was published, and the plant deserved the certificate, no matter what name it bore.

PROPAGATION OF PELARGONIUMS.

Pelargoniums still look well in many flower-beds, and as cuttings taken from them in autumn disfigure or reduce them greatly in many instances, propagation is often left as late in the year as possible. In other cases, and especially in cold backward localities, many Pelargoniums do not make sufficient growth by August to enable anyone to take cuttings from them during that month, and it is frequently near the end of September before the autumn propagation is effected. It is, no doubt, an advantage to do it earlier, and August is a good month for it, but it may also be done successfully now, although it entails a little more work than earlier in the season. In August, for instance, all the cuttings may be freely rooted in the open air, but now they must have the protection of a frame and glass from the first. There is one great advantage, however, secured now, and that is, matured growth. In August the wood is soft and green, and many of the cuttings are apt to decay if not properly managed, but now they are hard, and there is little danger of their damping off; in fact, late propagation has many advantages, especially in the case of those who have glass frames. In beginning to propagate, the first thing to be done is the preparation of the soil. This should be mixed up in one heap, and in sufficient quantity to fill all the pots or boxes that are required. Ordinary garden soil will do where fresh material cannot be had, and two parts of the compost should consist of this, one of light manure or leaf soil, and the other of sand. The latter should be as gritty as possible. Road-scrapings may be mixed with propagating material, but we save all our superfluous potting-shed soil throughout the summer for this purpose, and find it such a good mixture by the end of the season, that it rarely requires any addition. The whole should be well mixed, and then it is ready for use. Either pots or boxes may be employed. Tricolor and variegated Pelargoniums are generally more tender than green-leaved sorts, and it is a good plan to put the former into pots and the latter into boxes. Half-a-dozen cuttings may be inserted in a 3-inch pot, or twelve cuttings may be put in a 6-inch pot. The pots should be carefully drained and filled firmly with the mixture. When the latter is rather dry, it is well to water it thoroughly after putting it into the pots, and then allow the latter to stand for a few hours before putting in the cuttings; water again immediately the cuttings are in. Where boxes are used, a little drainage should be put in the bottom, and over that should be placed some rough pieces of soil, filling up then firmly with the mixture. The boxes may be of any convenient length and width, and about 3 inches deep. The cuttings should be put in 2 inches from each other, and a few boxes about 1 yard in length and 18 inches in width will hold some hundreds of them. I am very much in favour of the box plan, and practise it largely. As soon as the cuttings are all in, they should be placed in a frame where the lights can be put over them at night and during severe or rough weather.

No attempt should be made to shade them, as the sun will harden them, and although they may droop at first, it will do them no harm. Where a frame cannot be devoted to them, place them along the bottom of a wall, and protect them with lights. They do not require very much water at first, and should not be over-watered. They will root in three or four weeks after insertion, and as soon as frost or excessively damp weather sets in, they should have the protection of fire-heat; not, however, with the object of making them grow, but merely to preserve them. CAMBRIAN.

TREES AND SHRUBS.

TREE PLANTING IN PARKS.

SUFFICIENT attention is not directed to park planting, with a view to render the landscape scenery picturesque and varied, when marginal masses, young plantations, clumps, or groups are being formed in new parks; it is also necessary from time to time to fill up blanks in park plantations occasioned by high winds or the decay of trees, if a succession of healthy growing timber be desired throughout the country. Before selecting the subjects to form the principal masses, it is essential to have some knowledge of the trees most suitable to the various conditions of soil, geological formation and climate. As a general rule, it is the safest and perhaps the wisest plan to plant the park belts, marginal masses, and the larger clumps and groups with those trees that are found to thrive best and develop into the finest timber in the locality where the planting is intended to be carried out. Trees suitable for forming the principal masses in the park may be divided into two classes, thus: Oak, Elm, Lime, Horse and Sweet Chestnut trees, for rich loam and clay soils and somewhat sheltered sites; Beech, Sycamore, Norway Maple, and Birch trees for thin poor soils and on exposed sites. Among Conifers (though not strictly park trees) the common and other Silver Firs, the Douglas and Menzies Spruces, and Pinus austriaca, Laricio, Benthamiana, Jeffreyi, ponderosa, macrocarpa, and many other hardy and tall-growing varieties may be planted on the declivities of hills in groups amongst the marginal masses to give variety, contrast, and shelter; they can also be planted in groups to form a background to deciduous trees or prominent hills in the distance to break the hard, level, sky outline. The best and at the same time most pleasing and picturesque effect in park planting is to be produced by grouping with distinct species bold, sweeping masses of different sizes and irregular shapes, to avoid giving similarity in size and form of groups of each distinct kind of park tree, and by planting smaller groups of the newer and more beautiful varieties of each species in front of the common sorts, distributing these latter at wide and irregular distances apart from tree to tree, so as not to add a stiff and clump-like appearance to the larger masses. In a judicious arrangement of groups, ornamental trees, both dwarf and tall, should exhibit a different outline to the eye on every side; and although they should be planted at wide distances apart to allow every tree sufficient room to develop its special features of habit and foliage to the fullest extent, yet still these, when viewed at a distance, should blend into one group. Clumps of park trees are generally round or oval in shape, and mostly planted on prominent knolls. They should be composed of one distinct variety or species. Groups of dwarf trees may be advantageously used to soften down abrupt outlines of clumps. Mixed groups of fine-foliaged and flowering trees, of silvery and dark foliage, of rich autumn-tinted and the more quiet coloured, and the round-headed with the fastigiated forms, the weeping with the irregular or oblong forms, should be tastefully distributed throughout the park, advantage being taken of the undulating surface by planting the groups on the rising ground, leaving the hollows or valleys to form grassy glades. These latter may occasionally be broken when too great a breadth of Grass is visible, by planting groups of dwarf trees in the foreground. Thorns and other dwarf trees should also be planted near carriage drives, and on each side of sharp curves or park roads and drives in scattered groups of various sizes from a triplet to a score or more. These dwarf tree forms, when planted judiciously, give variety without abruptness and a more natural appearance generally to the planting. Single specimen trees of distinct and marked features should be planted on well-chosen spots, but care must be taken not to plant too many, so as to give a speckled or chessboard-like appearance to the park. The leading features to be aimed at in park planting should be variety, with distinctiveness, and a system of arrangement without formality. Conifers are only suited for park adornment at a distance from the mansion, on the sides of hills, or prominent high-lying outskirts; when planted in the foreground or in the low-lying sites of parks, either in clumps, groups, single specimens, or to form avenues, they are altogether out of character with true English park landscape planting. The only exception to this rule is the Cedar of Lebanon, which may be tolerated near a mansion, but even this only when the style of architecture is Elizabethan, Tudor, Jacobean, or of some other allied type. G.

The Sea Buckthorn (Hippophaë rhamnoides).—This forms a large spreading bush or small tree, and does well in loose sandy soil by the seashore, so well, indeed, as to be one of the most valuable of sea-side plants. It also thrives inland in almost any soil and situation. An additional feature is added in the autumn by its bright orange-coloured berries, which are borne in great profusion, and will frequently remain on for months. As seeds are readily obtainable, the Hippophaë is generally propagated in this way, but suckers can often be detached with attendant roots, which quickly form plants.—W. T.

Buerger's Evergreen Oak (Quercus Buergeri).—The list of cultivated kinds of Evergreen Oaks is not large, and this handsome species is such a desirable addition that it well merits a passing note. It forms a tree or large shrub of noble, spreading habit and free growth. The leaves are as large as those of the common Laurel, but of a deeper green, and far more effective. In form they are ovate and pointed, and leathery in texture. It is perfectly hardy, and now forms a fine feature amongst other evergreen trees in the nursery at Coombe Wood.—W.

The Carolina Poplar.—This old acquaintance, and the best of the Poplars for use as a shade tree or for its wood, has been generally known as the Black Italian Poplar—"black," because its foliage is of a deep rich green and dense; and "Italian," because, having been taken to Europe at an early date, and being easily propagated, its peculiar merits for street and road planting caused its extensive use in Italy and Germany. In many places where no fences are used, and the country is nearly bare, the lines of road are, according to the "Cultivator," rendered visible for miles by the double line of these Poplars which grow along their sides. Although the tree is usually grown from cuttings, it does not incline to throw up suckers from the roots, as most Poplars do.

Aucubas from grafts.—This is the method pursued in propagating Aucubas when standards are required. It is, however, more applicable in the case of plants for pot culture than it is for those for outdoor use. Good clean stems of the common sort make the best stocks, and these are mostly selected from the strongest of the seedlings. A. vera is the favourite berry-bearing plant, and, consequently, more of that kind are worked than of any other sort. The operation is done in spring by means of side-grafting in close, gently-heated, and well-shaded pits, and as the scions become united, the ligatures with which they are fastened are undone, and the heads of the stocks are gradually reduced. Grafting the Aucuba is a matter of no great difficulty; therefore, wax of any sort is but seldom used, although a little of it is beneficial as far as excluding wet from the incisions is concerned.

THE WEEPING WILLOW.

THE climate of England appears admirably suited to the Weeping Willow. The noble examples of it which ornament the banks of the Thames are as finely grown as any ever described in its native habitats; and they are also far more numerous than on the banks of the Euphrates, where they are becoming rare. Many of the specimens growing near the course of the Thames have attained from 50 feet to 60 feet in height, and it is said that some, in the broadest extension of the branches, measure fully 80 feet across. That the climate of Scotland is not too cold for it, is proved by the noble tree at Taymouth, in Perthshire, described by Loudon, which, when seen by him, was 70 feet high, though it had only then been planted thirty-six years. With regard to the use of the Weeping Willow in plantations, or as a single ornamental tree, Loudon observes: "The Weeping Willow spoils a landscape when injudiciously planted;" that it is not adapted for sublime effect, but better suited to the character of a pretty sylvan glade, with water; or in a villa garden, drooping over a picturesque rustic bridge. He would not introduce it in close connection with majestic ruins; such offices, he remarks, must be resigned by it in favour of "the Oak, whose dignity can fitly support such contiguity." He is doubtless entirely right in the broad principle; a plantation of Weeping Willows, for instance, would entirely destroy the effects of the glorious ravine of the Tête Noire, and of any scene of that sublime and majestic character. But in the grounds of ordinary residences, at well selected points near our park lakes, and in a hundred other situations connected with home scenery and the general characteristics of landscape gardening, it forms an element of beauty such as no other tree could supply. Even in winter its delicately drooping branchlets form a charming contrast to the more sturdy ramifications of erect-growing trees, and when they are feathered with hoarfrost, the effect is striking in the extreme, drooping as gracefully as the wings of a bird of Paradise. H.

Berberis vulgaris atropurpurea.—This is a handsome variety of the common Barberry, the foliage of which, in spring, is of a deep wine colour, passing gradually into brown, and, in autumn, becomes a purplish green. As the plant is most attractive in a young state, a means has been discovered of perpetuating the charms of its youthful foliage by cutting the stems down close to the ground every second year. This generally prevents the occurrence of flowers or fruit, but as the plant is valuable for the effect of its early foliage only, its flowers and fruit are well sacrificed to obtain it.—T. D.

SHORT NOTES.—TREES AND SHRUBS.

Quercus palustris.—As a coloured tree this Oak possesses great merit. Its young foliage contains many beautiful shades of orange and red, and this quite apart from the very rich tints assumed by it in the autumn.—T. S.

Escallonia revoluta.—This is a beautiful white-flowered shrub, and valuable on account of its blooming at this season of the year. It is one of the hardiest, if not the hardiest, of all Escallonias. In the Cambridge Botanic Garden it forms a fine bush about 7 feet high and dense in habit. The leaves are broadly obovate or nearly round, and the entire plant is hairy except the flowers. These are produced in thyrsoid racemes. It is a native of Chili.

Hardiness of the Oleander.—I believe the Oleander to be hardier than is generally supposed. I had a plant of it in a pot out-of-doors, without any protection whatever, during the winter before last, and though the branches were injured, the lower part was alive the following spring. Last winter it had the benefit of a wall, and is now healthy and has made growths this year nearly 2 feet long. Possibly in mild localities it might be worth growing against a wall.—R. J. L.

PINUS INSIGNIS IN HAMPSHIRE.

I THINK it is agreed that this is the most beautiful of all the Pines; its dense dark foliage reminds us of the plumes in the bonnets of our Scottish regiments. It is not considered by some hardy enough for our climate, and I have seen a statement that some were killed by the winter of 1880-81, and as Mr. Howitz did not include it in his comprehensive list for Ireland, I presume he did not consider it suitable. Before, however, we come to such a conclusion, it would be well to take into consideration the fact that some even of our native trees have been killed by severe winters. Many are the records of Hollies and even Furze that have been killed by severe frost. Gilbert White in his "Natural History of Selborne" in this county says of the winter of 1784: "This frost killed all the Furze and most of the Ivy; the Hollies lost their heads, and scorched alike Laurustines, Bays, Arbutuses, Cypresses, Portugal Laurels, &c." Similar were the effects of the severe winter of 1813-14. Judging from this, it is at least premature to come to a conclusion as to the hardiness of a tree from the severity of one winter. Of course it would be different if we had every year such winters as was experienced in 1854-5, 1860-1, and 1880-1. Another element to be taken into consideration is that a newly introduced plant is generally nursed with care and forced into an unnatural growth, which renders it more unfit to stand an inclement season than if less care were taken of it. As to P. insignis, more is to be feared from a heavy fall of snow than anything else, its dense foliage holding the falling flakes until broken by the weight. One under my own observation suffered severely from this cause in 1881; the leader and higher lateral branches went, and it presented such a figure that it would have been considered well to remove it altogether, so unsightly was it; it, however, made a wonderful recovery in the following year, and in the spring of 1883 it was a cone of dark green, just like a trimmed Yew, and in that year it shot out a leader over 2 feet in length. When I saw it last year another leader was nearly 1 foot long, the two giving it the appearance of a vane, and to complete the illusion, a bird was perched on the top when I looked at it, thus forming the ball; its whole height is a little under 20 feet.

The following are illustrative specimens in this county. No. 1 is at Blackmoor, Selborne, to the east of the mansion; it has a girth of 3 feet; the foliage shows signs of the severe winter of 1880-81. The soil, a moory sand on the Folkestone beds, planted in 1867, measured in 1881. No. 2 is in Woodley Lodge pleasure grounds, near Romsey; it has a girth of 7 feet 5½ inches at 4 feet up, and a sheer estimated height of 50 feet. This is a very fine specimen, in perfect health, and without a tinge of the past severe winters. Soil gravelly, with water at a depth of 4 feet or 5 feet. Subsoil the Bracklesham beds, planted in 1843, measured in 1882. No. 3 stands in front of Upton House, about two miles from Nursley Railway Station; it has a girth of 6 feet 1½ inches, and an actual height of 74 feet, a spread of branches of 22 feet, and contains 50 feet of timber. This is a magnificent tree, in vigorous health, feathered to the ground, and without a flaw in its almost perfect symmetry. The situation is high and much exposed, being only sheltered on the north and north-west by the house and a clump of Wych Elms, in fact, so exposed that a Deodar near has a struggle to maintain a decent appearance, and many other shrubs show the effects of rough winds, while the P. insignis stands unscathed, and apparently has never lost its leader. The soil is a rather peaty vegetable mould on the Bracklesham beds. I could not even guess its age, but it was a considerable tree twenty years ago; measured in May, 1884.

R. S. J.

Spiræa Thunbergi.—This is a favourite shrub with me. Several plants of it I put out in the woods are now from 4 feet to 5 feet high, and form effective bushes. It is altogether a superior deciduous shrub, and I have several plants of it in the nursery as well as those planted out in the woods, and I believe that in a few years they will be from 6 feet to 10 feet high, and as broad as high if allowed their full development. It is a very distinct and pretty Spiræa, one of the earliest to bloom, and not easily mistaken for any other variety; its small lanceolate leaves and slender twigs clothed with white Hawthorn-like flowers at once distinguish it.—G.

NOTES.

FRUITY AUTUMN.—Now and then comes a still soft day in October, when the crisp air is warmed by a genial sun, and, despite the ominous rustle of the dead brown leaves here and there, the drooping Dahlias, and the robin's song, one finds much of freshness and beauty in the garden. The Torch Lilies and Asters, and gold-rayed Lilies are yet most lovely, and Jackman's Clematis and its ruby form hang in festoons among the golden Wistaria leaves. Then, the heavy September rains have started up lots of things. I see the leaves of the Grape Hyacinths, and of the Hooped Petticoat Daffodils, and of some of the Tazetta, or bunch-flowered Narcissus, already peering above the soil. The great flowers of Colchicum speciosum are very beautiful either in the bud stage or as fully open, wine-cup like in the sun. So also the autumn Crocuses, such as C. zonatus, C. pulchellus, C. speciosus, C. Clusii, and C. nudiflorus have never been so rich and satisfying as this season. The Sunflowers and the Golden Rods (Solidago) glow golden here and there, and Gladioli of all shades yield delightful glints of colour among the varied green things among which they grow. Even the Japan Anemones and parti-coloured Gaillardias are yet in bloom along with Dahlias, the blood-coloured Lobelias, and the Phloxes, and Violas of many kinds. The latest Roses, soft flesh-coloured Souvenir de la Malmaison, are now at their best; and the seedling Primroses are beginning to blossom as a foretaste of the spring time to come.

True Egyptian Papyrus. Syrian Papyrus.

CULTIVATION *v.* STARVATION.—One of the best, if not the best, herbaceous borders I ever saw anywhere is not yet a year old from the time when everything in it was replanted. The old soil was taken out to a depth of 2 feet or 3 feet, and new compost (something like what a good gardener would prepare for his Vines or Chrysanthemums) was added, and the results to-day are as I have stated above. The various colours are massed together artistically, that is to say, thoughtfully, in irregular shaped, but perfectly orderly groups. Let us take blue, for example. In the area or space allotted to this colour, no flower of another hue is allowed to intrude, Chionodoxas or Scillas and Irises begin the overture, then Hyacinths and the finest of Bluebells, blue Anemones, or Monkshoods carry on the melody of colour into the rich chords of Iris and Violas, and then the finale is deep and rich-toned, as represented by Agapanthus and autumnal Aconites, with a background of Jackman's Clematis on the wall behind. In a word, from earliest spring to latest autumn, the blue patch is sacred to blue flowers. But this border proves that the old fetish of some gardeners (I mean the words "well established") is only a question of degree, and that it but too often really means well starved. Many plants in the border above alluded to are fully double, often treble, the height that they generally attain when well established. To see hardy flowers at their best, fresh and vigorous, we must replant them often in freshly dug or renewed soils.

THE PAPER REED OF EGYPT.—The question is, are there two species of Papyrus, as Parlatore believed? or are the Syrian, the Palestine, and the African kinds simply geographical forms of the same plant? I prefer to hold to the latter idea; but, be this as it may, the fact remains that if Parlatore's distinction of the plants be correct, then the true Papyrus, formerly grown in the Nile, has never been cultivated in our gardens, the Cyperus syriacus having done duty for it for many years. The main differences are shown in the accompanying woodcut, reproduced from vol. v., p. 504. I am glad that "Narcissa" has drawn attention to there being two forms of Papyrus, and I should like to ask any interested reader to tell us what is intended by the word "byblus" as used by Herodotus. He tells us that it was an annual plant, used in the manufacture of sandals and sails for boats, also the lower portion (? rhizome) as food, and a band of the "byblus" was sealed on the heads of the sacrificial oxen. If the Greek name of "byblos" is the same as that applied to Papyri, we have at least two words in our language derived from this paper-yielding Cyperus. The first is paper itself, from Papyrus, itself a form, original or derivative as the case may be, of the Arabic "babeer;" and secondly, Bible or book, from the Greek name for the plant, or rather its product, Papyri. It is quite possible that the Papyrus of the Nile would attain to its fullest stature in Egypt from seeds sown every year, as is inferred in Isaiah (chap. xix., 7), so that it is doubtful if it was ever really a native of Egypt after all.

GLADIOLUS SAUNDERSI.—Of all the species of Gladiolus which bloom in the autumn I think this one of the best. It is erect in habit, with soft glaucous leaves, and bears nodding flowers of a scarlet colour, having a whitish throat heavily dotted or speckled with red. It is a distinct and showy plant. I used to think the plant very

constant and fixed in its character, but a form imported direct from the Cape to the Botanic Gardens at Edinburgh is different from the original type as distributed by the late Mr. W. Wilson Saunders when at Reigate. This genus offers many attractions to the hybridiser, seeing that the seedlings flower at from twelve to eighteen months after the seed is sown. We have now some very pretty forms of Lemoine's hybrids in flower from seeds sown barely two years ago, and one or other of these Sword flowers may be had in bloom from February, when the forced "brides" come in, until December, when Gloire de Versailles is in flower in a warm greenhouse. I wish some of our plant-collecting friends at the Cape would look up all the beautiful kinds for us. Many were introduced years ago, which bloomed and were figured in the *Botanical Magazine* or other periodicals of the time and then were lost to sight, although they are yet to memory dear. Now that we know all Gladioli may be grown and forced in pots let us hope that these fine old sorts may be re-introduced to our gardens.

The great Apple Rose.—Again the great orange-red or crimson fruits of this old Rose gleam out bright and showy from among the soft glaucous oblong leaves. The tips of the shoots where the leaflets are youngest have quite a fragrant Sweet Brier-like odour, and in all its phases of growth, from earliest leafage and flowering in early summer to the rich fruitage it yields in autumn, the plant is interestingly beautiful. It is a pity that it is now so little grown, but as at least one nurseryman in Ireland has to my knowledge budded it largely on the Brier this season, one may soon see it advertised along with other lovely old single or semi-double kinds, such as Celeste, semi-single and semi-double, and many others not now often seen. The common Sweet Brier, of which a beautiful engraving from a photograph recently appeared in The Garden, is just now again showy, its attraction now being an abundance of bright red hips, which collectively glisten almost as red as a huntsman's coat in the early morning sunshine. But of all the ornamental fruited Roses there are none more distinct than Rosa rugosa, and this great old Apple-fruited Rose of Parkinson with its large soft glaucous Sweet Brier-scented leaves.

Mount Usher.—Deep down by the silvery Vartry River, and embedded among the woods and hills of Wicklow, is one of the prettiest little gardens I know. It is near to Rathnew, and surrounds a pleasant cottage which was in former days an old water mill. At all times the garden around the house is gay with hardy flowers, that is to say, from early spring to latest autumn, and just now roofs and old wall tops are aglow with Virginian Creeper; the porch is a mass of Jackman's Clematis intertwined with a golden green Wistaria which has climbed the gable above in a pretty and natural way. A vigorous mass of a form of Clematis lanuginosa, named C. Henryi, is flowering for the second time this season, and has flowers from 7 inches to 9 inches across, of a soft lavender-purple hue. Tropæolum speciosum, which has been crimson-scarlet on walls and fences alike, now bears its wreaths of berries of the richest turquoise-blue, and the "great Apple Rose" of dear old Parkinson's "Paradisus" bears its big pear-shaped hairy fruits among the soft glaucous leaves. Asters, Veronicas, Tea Roses, and Japanese Anemones are yet beautiful, with many other flowers of beauty which, if once brought hither, are not doomed to neglect nor to remain unseen. Everything beautiful is welcomed, and careful culture and a genial climate have worked wonders in this little world of flowers, many things being hardy in this sheltered spot which are not so elsewhere. Cordyline australis is quite at home in a little enclosure, with its plumy head on a stem 12 feet or more in height. There are other fine specimens; one which was wind-topped has branched out in quite a vigorous way, but the especial interest attached to the larger and older plant consists in its having seeded abundantly, and seedlings from it by the hundred are now strong and healthy plants bearing leaves a foot long or more, although only about a year old. Apart from the cosy beauty of this old mill-house garden, its surroundings are also beautiful. In the adjoining domain yclept "Rosanna," formerly occupied by Mrs. Tighe, the authoress of "Psyche" and other poems, are some fine thick-boled Yews, the fluted or netted stems of which are very characteristic. There is also a variety of Yew tree here with naturally inarched or anastomosed branches, and in the woods beneath fine Beech, Scotch Fir, and Oak; the Cherry Laurel grows 20 feet to 40 feet in height, and the branches are now heavily laden with its red or black-purple fruits. The squirrel (not a native animal) is plentifully naturalised here, and we saw one quite busy stealing Walnuts, unmindful of the dogs and the boys who now and then hunt them from tree to tree. Chestnuts and Limes are also very fine around the old house, part of which dates from the time of good Queen Bess. It is just the place in which to forget the whirl and bustle of the dusty town; one feels buried among lush-meadows through which the river winds, and when at eventide the herons come floating like great bats to fish for their suppers, and the white mists rise and stillness reigns, one feels that there is an arcadia in the world after all.

Michaelmas Daisies.—True to their appointed time, these beautiful flowers are with us once again, and their great trusses or panicles of Daisy flowers form happy hunting-grounds for fly, bee, and butterfly alike. It is nice to see a tall white-flowered kind with stems 7 feet high and as graceful as those of a Bamboo swaying about in the warm breeze and sunshine of an early October day. The robin's song and the rustle of falling leaves seem quite a fitting accompaniment for these flowers and for the patches of rain-beaten or wind-driven Colchicums and Crocuses. Like all other hardy perennials, Asters require good culture, and are never so fine as they are the first and second year after replanting. I wish Mr. W. Dod would give us the names of the twelve best kinds he grows, and I wish others would follow suit, for what is good on one soil may be better in another, and bad in a third. My own plan is to beg a piece of every good Aster I see; and as to their names, they are so intercrossed in gardens, even if not in America, that names do not mean much after all, and are rarely the same in any two gardens. Can anyone tell me how many varieties there are of Erigeron (Stenactis) speciosus? I think I know three or four, and have been told of a snow-white one which I have never seen. Just as I write I am told of a white and crimson Aster in a Dorset garden just like a Cineraria, and I mention it here in case any of our readers may have seen or possess such a variety.

The Japanese Yam.—As a graceful climber in a cool conservatory, or up a pole or stakes out of doors in mild localities on warm soils, this plant is worthy of notice. It has twining stems and glossy heart-shaped leaves, the form being emphasised or strengthened, as it were, by a bit of purple shading between the lobes of the leaf. Once well planted, it comes up year after year, and wreathes an upright stick or a festooned string very prettily. Another good plant of similar habit is the Black Briony (Tamus communis), the slender sprays of which are useful for cutting, and where the female plant is grown it yields a showy crop of glossy red berries. The Yam is, however, a nobler and more solid-looking plant, reminding one of old bronze in its graceful form and purplish green tinting. Its Latin name is Dioscorea japonica. Well planted in deep rich soil it grows to a height of 12 feet to 15 feet in a single season, and remains fresh until cut down by the first sharp frosts. In warm countries the roots are edible, and remind one of a coarse Potato, being a trifle sweeter perhaps in flavour, but yet not so sugary as is the true Sweet Potato (Dioscorea Batatas). Dioscorea japonica, if planted in a deep hole and surrounded with pure sand, is hardy even in cold localities, coming up every year in April or May. Veronica.

Orchids.

ORCHIDS LATE IN AUTUMN.

Now that we are well into October, Orchids need all the sun heat and light that we are likely to get. In the south we use shading where the glass is exposed to the direct rays of the sun up to the end of September, but very seldom indeed in October. Where it is not convenient to use scrim we daub the outer surface of the glass with "Summer Cloud," and when shading is unnecessary the "cloud" is washed off with warm water. Successful culture depends to a great extent upon the moisture maintained in the house. Many have an idea that all they have to do is to keep the paths and stages saturated with water night and day. This answers in summer, but not now. The paths and stages should be sprinkled with water in the morning, and again about four or five in the afternoon, and if the day should happen to be wet, omit the afternoon sprinkling. As the days, too, get shorter, less atmospheric moisture will be required. The cool house requires even less moisture than the warm houses, as there is less evaporation.

The temperature of the East India house should be from 65° to 70° as a minimum. Many of its occupants are in active growth, but some are resting, and it is necessary to give both the treatment which they require. We do not put water into the evaporating troughs either in this or in any of the other houses during winter, but when much artificial heat is required to keep up the temperature, more water must be sprinkled on the paths and stages. The lovely rose-scented Odontoglossum Roezli is now in mid-growth, and must not be checked either by an over-dry atmosphere or a low temperature. Little good is effected when the temperature falls below 60° at night. Saccolabiums in this house should not be encouraged to grow; on the contrary, keep them rather dry at the roots, treatment which also suits Aerides crassifolium. Numbers of Lady's Slippers are grown in the warmest house, and amongst them may be named C. superbiens (Veitchi), C. Stonei, C. Lowi, C. niveum, C. Spicerianum, and C. ciliolare, together with hybrids raised from them. The handsome C. grande we grow in the Cattleya house during summer, and take it into the warm house in winter. Its leaves sometimes become spotted and sickly-looking if the temperature is too low. Oncidium ampliatum majus likes a warm corner in this house now, as it is also making its growth. Slugs are remarkably fond of the embryo flower-spikes, and therefore must be kept in check. Phalænopsids must not now have too much water; spot and other maladies result from giving too much water at this season.

The Cattleya house should now receive its complement of plants. We have taken into it from the cool house Odontoglossum Phalænopsis and vexillarium. The first-named is suspended from the roof in teak baskets, but on the shady side of the house; the others are placed on the stage on the shady side. In a few days various Masdeval-

lias will also be taken into this house, such as M. tovarensis, M. Chimæra, and all that section, and Odontoglossums, such as O. nævium, O. cirrhosum, and a few others. The handsome Vanda cærulea will soon be in blossom; its spikes in the lightest part of the house are making rapid progress. Cattleyas whose pseudo-bulbs have grown to their full size must not have much water, but they must have enough to keep them plump. Some species, such as C. Warneri, need not have any for two or three weeks at a time, while C. Mossiæ may be watered once or twice a week. This species has not such an inveterate tendency to start into late growth as some of the others. Oncidium tigrinum is now throwing up large branching flower-spikes; it is a most useful species—beautiful when in flower, and the flowers are sweetly perfumed. It seems to do best in the cool house in summer and in the Cattleya house in winter. All Orchids in this house that have made up their flowering growths should now be kept comparatively dry at the roots. It is not safe to allow Cattleyas to become over dry; when that happens they flower weakly, and sometimes, as in the case of C. Percivaliana, the flowers do not come up at all. As the various species of Anguloa complete their growth they should likewise be kept dry at the root. Cymbidiums never ought to be quite dry, even at mid-winter. C. Lowianum may now be repotted, *i.e.*, if a shift is required. C. eburneum grows naturally in a ditch, and requires loam to grow in; C. Lowianum succeeds best treated as the others. C. Mastersi is a pretty species and valuable, as it produces flowers at mid-winter. The Cattleya house temperature ought to range from 60° to 65°.

The cool house temperature should be from 50° to 55° as a minimum until cold weather sets in; when the nights are frosty it may fall to 45° and even to 40°, but the lowest temperature is not safe for some classes of plants, although Odontoglossum crispum will do well under it. We begin to find out that many of the best Oncidiums, such as O. Marshallianum and O. macranthum, do better in a cool than in a high temperature, but the plants like to be near the glass, a position which makes all the difference in the case of many cool Orchids. In our house the various forms of Masdevallia Harryana do well on the stage, but one variety will not thrive there; the young growths continue to die off when they have grown 3 inches or 4 inches; while if suspended from the roof this does not happen. The young growths of Odontoglossum nebulosum die off in the same way on the stage, but if the pots are placed in Teak baskets and hung up near the glass, no dying off occurs. I allude, of course, to the winter season; they do not damp off in summer or in autumn. Many of the best Orchid growers repot their Odontoglossums and Masdevallias in September and October, but after the middle of the last-named month I prefer not to disturb them until after Christmas. I have generaliy recommended comparatively small pots for Odontoglossum crispum, but some good growers are now employing much larger ones than those which I have hitherto used. I saw a large house the other day entirely filled with plants of Odontoglossum crispum in large pots, and they looked healthy and well.

Green-fly has been more troublesome than usual this year, and we do not think it desirable to fumigate, as there is always some choice plant or other injured by the Tobacco smoke. The next best way is to dip the plant in soft soapy water to which has been added some Tobacco liquor. Into this we dip the plants, and then lay them on their sides for a quarter of an hour; we then dip them in clear water, or sponge the leaves with it. The right treatment for the cool house is to keep the atmosphere only moderately moist; do not overwater the plants, and admit as much air as possible. It does the plants good to have their leaves moving in the cool autumn air when the temperature outside is over 55°. We very seldom shut the hit-and-miss ventilators fixed in the front wall; they are placed so that the air passing through them comes into immediate contact with the hot-water pipes, and in its warmed state passes up amongst the plants, and as there is usually a small opening at the apex of the roof, there is constant circulation. J. Douglas.

Aerides Lawrenciæ.—We have received from Mr. E. Harvey, Aigburth, Liverpool, a remarkably fine spike of this charming Aerides, undoubtedly the finest of the genus. Individually the blooms were exceptionally fine and the colour bright. The pleasing colour of the flowers of this plant and its delicate fragrance are rendered doubly valuable by its flowering at this season of the year.

Vanda Saunderiana.—This is not only valuable as an autumn flowering Orchid, but specially noticeable for its free-flowering qualities, plants of small dimensions producing fine spikes of large and unique blooms. We have received a spike of bloom of this species from Mr. E. Harvey, Aigburth, Liverpool, bearing eight very large, finely-shaped flowers, considerably over 4 inches in diameter. This is one of the finest forms that have yet come under our notice. The upper sepal and petals are soft mauve, freely spotted at the base with crimson. The lower sepals are very large, tawny orange or nankeen yellow, profusely streaked and tessellated with crimson.

Stenia pallida.—This is a small, Batemannia-like plant, with rather thin lance-shaped leaves, 6 inches long. It has no pseudo-bulbs, and seldom more than three leaves. The flowers are produced at the base of the plant, and are solitary on short decumbent stalks; each flower is 1½ inches across, shaped like a Batemannia, and coloured pale yellow. The lip is saccate, with recurved edges, showing a few red spots. Demerara is the home of this species; we saw a plant of it in flower at Kew a few days ago. It requires tropical treatment. Except where what are called "botanical" Orchids are in favour, we do not suppose this little pale-flowered plant would be grown. S. fimbriata is a second species, with long Flag-like leaves, jointed at the base and sheathed so as to form a stem, as in Pescatorea. The flowers are on erect stalks, and the petals and sepals are reflexed, the lip being spreading, fringed around the margin and red spotted in the centre; they are larger than in S. pallida. Batemannia Beaumonti was once known as a Stenia; it has light green flowers with stripes of olive-brown, the lip being white dotted with purple. —W.

Cycnoches chlorochilum.—This is one of the strangest of a very strange-looking section of the Orchid family, namely, Stanhopiæ, which includes the genus Stanhopea and Coryanthes, Gongora, Catasetum, and Cycnoches. None of these plants are what one could call popular with Orchid growers, although most of them are tractable under cultivation, and almost every one shows a wonderfully interesting structure of flower. In Cycnoches the column is long and gracefully arched, broader at the apex, so as to look like a bird's head, and as this column rises and curves over a broad convex labellum, with wing-like petals at the side, there is in it a singular resemblance to a swan with flapping wings. C. chlorochilum should have a green lip if the name means anything, but in the flower before us the lip is of the clearest cream-yellow. The pseudo-bulbs are fleshy, the leaves ribbed and deciduous, and the flowers are larger than those of Cymbidium giganteum, the sepals being 2½ in. long by three quarters of an inch wide, the petals 3 inches long and 1 inch wide; the lip is 2½ inches by 1¼ inches and shaped exactly like a teaspoon with the concave side downwards, except that in the middle there is a curious bend and beyond this a thickened base to the column, which is 1½ inches long. There is no perceptible fragrance in this flower, which is nevertheless the most interesting Orchid we have seen for some time. It is plentiful in the Orchid market, we believe, having been recently imported in quantity from Demerara.—B.

October Orchids.—The Orchid houses at Selborne, Streatham, are now remarkably gay, especially with Lady's Slippers. Of these the most noteworthy are Cypripedium Spicerianum, the snow-white of the dorsal sepal of which is in this case tinged with violet; C. Harrisianum, in some instances bearing two flowers upon one stem, not a common occurrence; C. Schlimi, and its white variety; C. Godefroyæ, a form with comparatively few spots, which is no improvement, tending, as it does, to bring it nearer to C. concolor; C. Roezli, C. Sedeni, which appears to be almost a perpetual bloomer; and the choice and rare C. vexillarium. Associated with these were also Dendrobium Dearei, a free-blooming species, the white flowers of which are very useful in a cut state, and last long in good condition in water. There are also here charming specimens of the Indian Crocus (Pleione lagenaria) in bloom, though somewhat out of season. The old Butterfly Oncidium (O. Papilio) when well established is nearly always in bloom and always interesting. Other Oncidiums now in flower here are O. crispum and O. incurvum. Cattleya Dormanniana and Lælia præstans were likewise in good condition. Masdevallias were represented by quantities of the snow-white M. tovarensis and of M. macrura (a kind which resembles M. elephanticeps), M. bella and M. Davisi. The old-fashioned genus Stanhopea was likewise well represented by S. Wardi, at once the freest flowerer and best coloured member of its class. The singular Scuticaria Steeli was also in bloom, as were also Zygopetalum maxillare and Z. Mackayi, a very richly coloured form of the true Vanda insignis, and good examples of the blue Vanda (V. cærulea). Amongst blue Vandas was a variety of such immense size, that it certainly deserves a varietal name; the spike was carrying twelve flowers, each bloom measuring 5 inches across; the sepals and petals are large and full, being nearly 2 inches in diameter, and the colour is a good blue, with darker tessellations.—W. H. G.

COOL ORCHIDS.

Stanhopeas.—This family of Orchids received for years a large share of attention from cultivators, but as Orchids became more plentiful, Stanhopeas gradually lost favour, until now they are only to be met with in gardens in which mixed collections of plants are grown. In such gardens their quaint forms have always been appreciated. Some of the reasons assigned by Orchid growers for discarding Stanhopeas were, that they were useless for cutting, the powerful odour of their flowers precluding their admittance to the drawing-room. It was asserted, moreover, that their flowers were so fugacious, that they were useless for exhibition; but the worst fault of all belonging to them was that they were old-fashioned. Stanhopeas are, however, again beginning to find favour with Orchid growers; it has been discovered that all Orchids are not required for exhibition, nor every Orchid flower for indoor decoration, and that the perfume which Stanhopea flowers emit, although unsuited for dwelling-houses, is agreeable enough in a properly ventilated plant house. I have for many years recommended that Stanhopeas should be grown on the cool system, having found them to improve both in health and appearance under such treatment. When grown in a higher temperature, the leaves are liable to be attacked by thrips, which, if not detected early, causes them to speedily turn whitey-brown and become unsightly, but this does not occur under cool treatment. Stanhopeas bloom most freely when a few years old, and when the baskets in which they are grown have become a thorough mass of roots; therefore, I advise the use of open wire baskets for growing them in, as these do not decay so rapidly as those made of wood; hence the plants are undisturbed for a longer period than they otherwise would be, and their floriferousness is increased proportionately. It cannot be denied that the flowers of Stanhopeas are somewhat short-lived, but this a low temperature, such as that in which Odontoglossums grow, tends greatly to obviate, and when well established, flowers are produced in quick and long succession. The different kinds of Stan-

hopea resemble each other greatly in appearance, the chief differences being in their size. They are characterised by somewhat ovate, furrowed pseudo-bulbs, which bear a single (more or less stalked) plaited leaf, leathery in texture and deep green. The flower-scape proceeds from the base of the pseudo-bulb, and pushes downwards through the roots and soil, mostly issuing from the bottom of the basket; hence the necessity for suspension from the roof in the baskets, and also for having the interstices sufficiently wide to enable them to find an easy exit. As to basketing material, it should consist of rough nodules of peat and Sphagnum Moss. They should be grown, as has just been stated, in a low temperature, supplied with abundance of water, and kept well shaded; but after growth has been completed they may be exposed to more light, and during winter no water should be given them, unless they show signs of shrivelling. This, however, under ordinary circumstances in a cool atmosphere is not likely to occur. When in flower great care must be taken to avoid wetting the blooms; carefully keep the syringe from them, but let the baskets in which they are growing be thoroughly soaked a few days before the blossoms begin to open. The following will be found to form a good selection:—

S. Bucephalus.—Racemes bearing from five to six large, fragrant flowers, the ground colour of which is rich tawny-orange, spotted and blotched with blood-red; the column and lip are yellowish white, tinged with green and freckled with crimson. It blooms late in the summer and autumn, and comes from the Andean Mountains, on which it is found at 6000 feet elevation.

S. eburnea.—This is perhaps one of the best species hitherto introduced. It bears flowers which are nearly 6 inches across, spreading, and delicately fragrant. The sepals and petals are pure white; the lip is also white, and dotted and spotted near the base with purple and red. It blooms during the late summer months, and comes from the West Indian Islands.

S. guttulata.—Flowers large and spreading, some four or five being borne on each raceme; their sepals and petals are much reflexed and soft nankeen yellow in colour, over which are irregularly scattered a profusion of rich purple spots and dots; lip nearly the same colour as the other portions of the flower, but unusual in shape. The greater part of the column is round and then it becomes flat. The flowers are produced during early autumn and are very fragrant. It is a native of gloomy forests in Brazil.

S. insignis.—Raceme from six to seven-flowered in the case of vigorous plants; sepals and petals yellowish white, profusely and regularly spotted with reddish purple; lip almost white, freckled with purple, bearing a small black spot on each side near the base; column white, stained with greenish yellow. There are several varieties of this plant which differ more or less in colour; all of them bloom during the late summer and autumn months. It comes from Brazil.

S. Martiana.—This is a superb species, bearing blooms from 6 inches to 7 inches across, but the raceme is somewhat few-flowered. Sepals and petals spreading, but not much reflexed. The former yellowish white in colour, spotted with red; the latter, white, spotted and blotched with crimson. Lip short and broad, deep crimson at the base, white in front; column not stalked, white freckled with red. This is a Mexican species, which blooms during the autumn months.

S. ornatissima.—As its name implies, this species is very beautiful when in bloom. The flowers are fragrant, rich deep orange in colour, spotted with reddish crimson, and having in addition a large blotch of crimson at the base. Lip creamy white, yellow in front, and spotted with rosy crimson. It blooms during the late summer months, and is a native of Mexico.

S. radiosa.—Flowers much reflexed, sepals broad, creamy white, suffused with pale orange, deepest towards the base, and sparingly dotted with reddish orange. Petals deeper in colour and narrower than the sepals. Lip rich deep orange, sparingly dotted with red; column creamy white dotted with rose colour. It blooms during the summer months.

S. oculata.—This is, perhaps, the best known of all Stanhopeas, and is more frequently to be found under cultivation than any other. It is, however, frequently mistaken for S. insignis. The raceme in oculata is many-flowered, the individual blooms being large, reflexed, and emitting a powerful aromatic odour. Sepals and petals pale yellow or lemon colour, profusely spotted and dotted with purple. Lip bearing a deep yellow spot at the base, and two, or more large brownish black spots at the sides, which somewhat resemble "eyes"; hence its name. The variety Barkeriana would appear to be almost mid-way between this species and S. insignis. Its flowers are usually produced in early summer, but sometimes they do not appear until autumn.

S. tricornis.—This is a very distinct form, and one easily distinguished from other kinds, by its peculiarity of having a horn-like projection on the front of the lip, in addition to two side ones, which form so common a feature in members of this genus. The flowers are large, freely produced, very fragrant, and less fugacious than some others. Sepals soft yellow; petals much deeper coloured. Lip rich yellow, bearing on each side near the base an orange-yellow eye-like spot. It blooms during the summer months, and is a native of high mountains of Quito.
